The aminoglycosides streptomycin, amikacin, and kanamycin are used for the treatment of mycobacterial diseases. The MICs for *M. tuberculosis* in Middlebrook broth are 0.25-3.0 mg/L for all three aminoglycosides (Heifets, 1991). For *M. avium* streptomycin and amikacin, MICs are 1-8 mg/L; those of kanamycin are 3-12 mg/L. *M. kansasii* is frequently susceptible to these agents, but other nontuberculous mycobacteria are only occasionally susceptible. The pharmacological properties and therapeutic uses of aminoglycosides are discussed in full in [Chapter 54](#).

**Bacterial Resistance.** Primary resistance to streptomycin is found in 2-3% of *M. tuberculosis* clinical isolates. Streptomycin and the two other aminoglycosides inhibit protein synthesis by binding to the 30S ribosomal subunit and causing misreading of the genetic code during translation. The 30s ribosomal unit is made of the 16S mRNA (encoded by *rpsL*), which binds to the ribosomal protein S12 (encoded by *rrs*) to optimize tRNA binding and mRNA decoding. Mutations in *rpsL* and *rrs* are associated with high-level aminoglycoside resistance in mycobacteria. However, mutations in these genes are only encountered in half of clinical isolates with

aminoglycoside resistance. GidB is an rRNA methyltransferase for 16S rRNA, and mutations in *gidB* gene are associated with low-level streptomycin resistance (Okamoto et al., 2007). The *gidB* mutations lead to high-level streptomycin resistant mutants at a rate 2000 times that in wild type. Mutations in *gidB* are encountered in 33% of streptomycin-resistant clinical isolates of *M. tuberculosis*. Finally, efflux pump-mediated resistance was recently demonstrated in clinical isolates with low-level streptomycin-resistant *M. tuberculosis* and interacted with chromosomal mutations in *gidB* (Spies et al., 2008). Thus resistance to aminoglycosides involves several genetic loci, as well as efflux pumps.

**Therapeutic Uses.** Therapeutic uses of aminoglycosides in treatment of mycobacterial infections are discussed later.

## Clofazimine

Clofazimine (LAMPRENE) is a fat-soluble riminophenazine dye. It was discontinued in 2005 but remains licensed as an orphan drug.

**Mechanism of Action.** The biochemical basis for the antimicrobial actions of clofazimine remains to be established (Anonymous, 2008a). Possible mechanisms of action include:

- membrane disruption
- inhibition of mycobacterial phospholipase A<sub>2</sub>
- inhibition of microbial K<sup>+</sup> transport
- generation of hydrogen peroxide
- interference with the bacterial electron transport chain

However, it is known that clofazimine has both antibacterial activity as well as anti-inflammatory effects via inhibition of macrophages, T cells, neutrophils, and complement.

**Antibacterial Activity.** The MICs for *M. avium* clinical isolates are 1-5 mg/L. The MICs for *M. tuberculosis* are ~1.0 mg/L. The compound also is useful for treatment of chronic skin ulcers (Buruli ulcer) produced by *Mycobacterium ulcerans*. It has activity against many gram-positive bacteria with an MIC  $\leq$ 1.0 mg/L against *S. aureus*, coagulase-negative Staphylococci, *Streptococcus pyogenes*, and *Listeria monocytogenes*. Gram-negative bacteria have MICs  $>$ 32 mg/L.

**Bacterial Resistance.** Mechanisms of resistance are unknown.

**Absorption, Distribution, and Excretion.** Clofazimine's oral bioavailability is highly variable, 45-60%; bioavailability is increased 2-fold by high-fat meals and decreased 30% by antacids (Nix et al., 2004). After a single dose, clofazimine is best modeled using a one-compartment model and has a prolonged absorption phase; after 200 mg of clofazimine, the  $t_{\max}$  is 5.3-7.8 hours. After prolonged repeated dosing, the  $t_{1/2}$  is ~70 days. For PK data, see [Table 56–2](#) and Nix et al. (2004). As a result of the good penetration into many tissues, a reddish black discoloration of skin and body secretions may occur and take a long time to resolve. Crystalline deposits of the drug have been encountered in many tissues at autopsy (Anonymous, 2008a). Clofazimine is metabolized in the liver in four steps: hydrolytic dehalogenation, hydrolytic deamination, glucuronidation, and hydroxylation.

**Dosing.** Clofazimine is administered orally at doses up to 300 mg a day.

**Untoward Effects.** GI problems are encountered in 40-50% of patients and include abdominal pain, diarrhea, nausea, and vomiting. In patients who have died following the abdominal pain, crystal deposition in intestinal mucosa, liver, spleen, and abdominal lymph nodes has been demonstrated (Anonymous, 2008a). Body secretion discoloration, eye discoloration, and skin discoloration occur in most patients and can lead to depression in some patients.

**Drug Interactions.** Anti-Inflammatory effects may be inhibited by dapson.

## Fluoroquinolones

Fluoroquinolones are DNA gyrase inhibitors. Their chemistry, spectrum of activity, pharmacology, and adverse events are discussed in greater detail in [Chapter 52](#). Drugs such as ofloxacin and ciprofloxacin have been second-line anti-TB agents for many years, but they are limited by the rapid development

of resistance. Adding C8 halogen and C8 methoxy groups markedly reduces the propensity for drug resistance. Of the C8 methoxy quinolones, moxifloxacin (approved by the Food and Drug Administration for nontubercular infections) is furthest along in clinical testing as an anti-TB agent. Moxifloxacin is being studied to replace either isoniazid or ethambutol.

**Microbial pharmacokinetics-pharmaco-dynamics Relevant to TB.** Fluoroquinolone microbial kill is best explained by  $AUC_{0-24}/MIC$  ratio. In preclinical models, moxifloxacin  $AUC_{0-24}/MIC$  exposures equivalent to those from the standard 400-mg dose were associated with good microbial kill but amplified the drug-resistant subpopulation, so that resistance emerged in 7-13 days with monotherapy (Gumbo et al., 2004). This time to emergence of resistance harmonizes well with speed of resistance emergence in patients (Ginsburg et al., 2003). Moxifloxacin exposure best associated with minimizing emergence of resistance was an  $AUC_{0-24}/MIC$  of 53. Clinical trial simulations revealed that doses >400 mg a day might better achieve this AUC/MIC, which experiments in mice substantiate (Almeida et al., 2007). Given that rifamycins reduce moxifloxacin AUC, these results point to a potential concern of quinolone resistance. Unfortunately, the safety of moxifloxacin doses >400 mg has not been established.

**Therapeutic Uses in Treatment of TB.** In TB patients, moxifloxacin (400 mg/day) has bactericidal effects similar to that of standard doses of isoniazid (Johnson et al., 2006). When replacing ethambutol in the standard multi-drug regimen, 400 mg/day of moxifloxacin produces faster sputum conversion at 4 weeks than ethambutol (Burman et al., 2006b). In a comparison study of moxifloxacin, gatifloxacin, ofloxacin, and ethambutol as the fourth drug administered concurrently with isoniazid, rifampin, and pyrazinamide (Rustomjee et al., 2008b), moxifloxacin led to faster rates of bacterial kill during the early phases, gatifloxacin was equivalent by the eighth week, and ofloxacin was no better than ethambutol. Moxifloxacin is currently being studied in a phase 3 trial that may eventually lead to 4-month duration of anti-TB therapy compared to the current 6 months.

**Drug Interactions Relevant to TB.** In a study of volunteers treated with rifampin, moxifloxacin, or both drugs, rifampin reduced the moxifloxacin  $AUC_{0-24}$  by 27% via induction of sulfate conjugation (Weiner et al., 2007). In

another study, rifapentine reduced moxifloxacin AUC<sub>0-24</sub> by 17% (Dooley et al., 2008). These studies suggest that the most important cause of pharmacokinetic variability for moxifloxacin is concomitantly administered drugs for tuberculosis.

## TMC-207 (R207910)

TMC-207 is a diarylquinone discovered by Andries et al. in 2005.

**Mechanism of Action.** TMC-207 acts by targeting subunit c of the ATP synthase of *M. tuberculosis*, leading to inhibition of the proton pump activity of the ATP synthase (Andries et al., 2005; Koul et al., 2007). Thus, the compound targets bacillary energy metabolism.

**Antibacterial Activity.** The TMC-207 MIC for *M. tuberculosis* is 0.03-0.12 mg/L. It has good activity against *MAC*, *M. leprae*, *M. bovis*, *M. marinum*, *M. kansasii*, *M. ulcerans*, *M. fortuitum*, *M. szulgai*, and *M. abscessus* (Andries et al., 2005; Huitric et al., 2007).

**Bacterial Resistance.** The proportion of *M. tuberculosis* mutants resistant to four times the MIC is  $5 \times 10^{-7}$  to  $2 \times 10^{-8}$ . Resistance is associated with two point mutations: D32V and A63P. This region of the gene encodes the membrane-spanning domain of the ATP synthase *c* subunit.

**Absorption, Distribution, and Excretion.** After oral ingestion of 400 mg of TMC-207, the  $t_{\max}$  was 4 hours, the  $C_{\max}$  was 5.5 mg/L after 400 mg/day, and the AUC<sub>0-24</sub> was 65 mg·h/L. Based on these data, the CL is ~6.2 L/h, although systemic clearance reportedly is “triexponential.” Population pharmacokinetic studies have not been published.

**Pharmacokinetics, Efficacy, and Therapeutic Use.** The anti-TB activity of TMC-207 is correlated with time above MIC. In murine TB, TMC-207 had superior bactericidal activity compared to isoniazid and rifampin, and accelerated sterilization when combined with rifampin, isoniazid, and

pyrazinamide (Andries et al., 2005). In patients with drug-susceptible TB, the rate of sputum bacillary decline was similar to rifampin and isoniazid (Rustomjee et al., 2008a). A regimen of TMC207 400 mg daily for 2 weeks followed by 200 mg three times day thereafter was added to a background second-line regimen of either kanamycin or amikacin, ofloxacin with or without ethambutol in patients with TB resistant to both isoniazid and rifampin (MDR-TB), and led to an 8-week sputum conversion of ~50% with TMC207 compared to 9% without (Diacon et al., 2009).

**Untoward Effects.** The adverse events encountered with TMC207 are mild and include nausea in 26% of patients and diarrhea in 13% of patients, with others such as arthralgia, pain in extremities, and hyperuricemia in a small proportion of patients (Diacon et al., 2009). However, only a limited number of patients have been exposed to this drug, so that the full side-effect profile is unclear.

## PA-824

PA-824 is a nitroimidazopyran discovered by Stover et al. in 2000.

**Mechanism of Action.** PA-824 inhibits *M. tuberculosis* mycolic acid and protein synthesis at the step between hydroxymycolate and ketomycolate (Stover et al., 2000). Similar to the structurally related metronidazole, PA-824 is a pro-drug that requires activation by the bacteria via a nitro-reduction step that requires, among other factors, a specific glucose-6-phosphate dehydrogenase, FGD1, and the reduced deazaflavin co-factor F<sub>420</sub> (Bashiri et al., 2008). Another mechanism involves generation of reactive nitrogen species such as NO by PA-824's des-nitro metabolite, which then augment the kill of intracellular nonreplicating persistent bacilli by the innate immune system (Singh et al., 2008).

**Antibacterial Activity.** *In vitro*, the drug kills both nonreplicating *M. tuberculosis* that are under anaerobic conditions as well as replicating

bacteria in ambient air. The MICs of PA-824 against *M. tuberculosis* range from 0.015–0.25 mg/L, but the drug lacks activity against other mycobacteria.

**Bacterial Resistance.** The proportion of mutants resistant to 5 mg/L of PA-824 is  $10^{-6}$ . Resistance arises due to changes in structure of FGD, which is due to a variety of point mutations in *fgd* gene. However, resistant isolates have also been identified that lack *fgd* mutations, so that resistance may also be due to other mechanisms (Stover et al., 2000).

**Pharmacokinetics and Efficacy.** In murine and guinea pig TB, PA-824 was equivalent to standard doses of isoniazid (Stover et al., 2000). In a recent murine TB study, 100 mg/kg/day of PA-824 with pyrazinamide and rifampin showed total sterilization at 2 months and no relapse, versus 15% relapse with the standard isoniazid, rifampin, and pyrazinamide regimen (Tasneen et al., 2008). Phase 1 studies have been performed, but the pharmacokinetic data have not been published. Phase 2 studies are in progress.

## Ethionamide

Ethionamide (TRECATOR) is a congener of thioisonicotinamide.

**Mechanism of Action.** Mycobacterial EthaA, an NADPH-specific, FAD-containing monooxygenase, converts ethionamide to a sulfoxide, and then to 2-ethyl-4-aminopyridine (Vannelli et al., 2002). Although these products are not toxic to mycobacteria, it is believed that a closely related and transient intermediate is the active antibiotic. Ethionamide inhibits mycobacterial growth by inhibiting the activity of the *inhA* gene product, the enoyl-ACP reductase of fatty acid synthase II (Larsen et al., 2002). This is the same enzyme that activated isoniazid inhibits. Although the exact mechanisms of inhibition may differ, the results are the same: inhibition of mycolic acid biosynthesis and consequent impairment of cell-wall synthesis.

**Antibacterial Activity.** The multiplication of *M. tuberculosis* is suppressed by concentrations of ethionamide ranging from 0.6-2.5 mg/L. A concentration

of  $\leq 10$  mg/L will inhibit  $\sim 75\%$  of photochromogenic mycobacteria; the scotochromogens are more resistant.

**Bacterial Resistance.** Resistance occurs mainly via changes in the enzyme that activates ethionamide, and mutations are encountered in a transcriptional repressor gene that controls its expression, *etaR*. Mutations in *inhA* gene lead to resistance to both ethionamide and isoniazid.

**Absorption, Distribution, and Excretion.** The oral bioavailability of ethionamide approaches 100%. The pharmacokinetics are adequately explained by a one-compartment model with first-order absorption and elimination (Zhu et al., 2002); see PK values in [Table 56-2](#). After oral administration of 500 mg of ethionamide, a  $C_{\max}$  of 1.4 mg/L is achieved in 2 hours. The  $t_{1/2}$  is  $\sim 2$  hours. The concentrations in the blood and various organs are approximately equal. Ethionamide is cleared by hepatic metabolism; six metabolites have been identified. Metabolites are eliminated in the urine, with  $< 1\%$  of ethionamide excreted in an active form.

**Therapeutic Uses.** Ethionamide is administered only orally. The initial dosage for adults is 250 mg twice daily; it is increased by 125 mg/day every 5 days until a dose of 15-20 mg/kg/day is achieved. The maximal dose is 1 g daily. The drug is best taken with meals in divided doses to minimize gastric irritation. Children should receive 10-20 mg/kg/day in two divided doses, not to exceed 1 g/day.

**Untoward Effects.** Approximately 50% of patients are unable to tolerate a single dose larger than 500 mg because of GI upset. The most common reactions are anorexia, nausea and vomiting, gastric irritation, and a variety of neurologic symptoms. Severe postural hypotension, mental depression, drowsiness, and asthenia are common. Convulsions and peripheral neuropathy are rare. Other reactions referable to the nervous system include olfactory disturbances, blurred vision, diplopia, dizziness, paresthesias, headache, restlessness, and tremors. Pyridoxine (vitamin B<sub>6</sub>) relieves the neurologic symptoms, and its concomitant administration is recommended. Severe allergic skin rashes, purpura, stomatitis, gynecomastia, impotence, menorrhagia, acne, and alopecia have also been observed. A metallic taste also may be noted. Hepatitis has been associated with the use of the ethionamide in  $\sim 5\%$  of cases. Hepatic function should be assessed at regular intervals in patients receiving the drug.

## Para-Aminosalicylic Acid

Para-aminosalicylic acid (PAS), discovered by Lehman in 1943, was the first effective treatment for TB.

**Mechanism of Action.** PAS is a structural analog of *para*-aminobenzoic acid, the substrate of dihydropteroate synthase (*folP1/P2*). As a result, PAS is thought to be a competitive inhibitor *folP1*. However, *in vitro* the inhibitory activity against *folP1* is very poor. However, mutation of the thymidylate synthase gene (*thyA*) results in resistance to PAS, but only 37% of the PAS-resistant clinical isolates or spontaneous mutants encode a mutation in *thyA* gene, or in any genes encoding enzymes in the folate pathway or biosynthesis of thymine nucleotides (Mathys et al., 2009). Unidentified actions of PAS likely play more important roles in its anti-TB effects.

**Antibacterial Activity.** PAS is bacteriostatic. *In vitro*, most strains of *M. tuberculosis* are sensitive to a concentration of 1 mg/L. It has no activity against other bacteria.

**Bacterial Resistance.** Mutations in *thyA* gene lead to drug resistance in a minority of drug-resistant isolates.

**Absorption, Distribution, and Excretion.** PAS oral bioavailability is >90%. PAS pharmacokinetics are described by a one-compartment model (Peloquin et al., 2001); see the PK values in [Table 56–2](#). The  $C_{\max}$  increases 1.5-fold and AUC 1.7-fold with food compared to fasting (Peloquin et al., 2001). These results mean that PAS should be administered with food, which also greatly reduces gastric irritation. Protein binding is 50-60%. PAS is N-acetylated in the liver to N-acetyl PAS, a potential hepatotoxin. Over 80% of the drug is excreted in the urine; >50% is in the form of the acetylated compound. Excretion of PAS acid is reduced by renal dysfunction; thus the dose must be reduced in renal dysfunction.

**Therapeutic Uses.** PAS is administered orally in a daily dose of 12 g. The drug is best administered after meals, with the daily dose divided into three equal portions. Children should receive 150-300 mg/kg/day in 3-4 divided doses.

**Untoward Effects.** The incidence of untoward effects associated with the use of PAS is ~10-30%. GI problems predominate and often limit patient adherence. Hypersensitivity reactions to PAS are seen in 5-10% of patients and manifest as skin eruptions, fever, eosinophilia, and other hematological abnormalities.

## Cycloserine

Cycloserine (SEROMYCIN) is D-4-amino-3-isoxazolidone. It is a broad-spectrum antibiotic produced by *Streptococcus orchidaceus*.

**Mechanism of Action.** Cycloserine and d-alanine are structural analogs; thus cycloserine inhibits alanine racemase which converts L-alanine to d-alanine and d-alanine: d-alanine ligase, stopping reactions in which d-alanine is incorporated into bacterial cell-wall synthesis (Anonymous, 2008b).

**Antibacterial Activity.** Cycloserine is a broad-spectrum antibiotic. It inhibits *M. tuberculosis* at concentrations of 5-20 mg/L. It has good activity against MAC, enterococci, *E. coli*, *S. aureus*, *Nocardia* species, and *Chlamydia*.

**Mechanisms of Resistance.** Mutations involved in cycloserine resistance to pathogenic *Mycobacteria* are currently unknown. However, resistance in clinical isolates of *M. tuberculosis* has been detected in 10-82% of isolates (Anonymous, 2008b).

**Absorption, Distribution, and Excretion.** Oral cycloserine is almost completely absorbed. The population pharmacokinetics are best described using a one-compartment model with first-order absorption and elimination (Zhu et al., 2001). The drug's  $t_{1/2}$  is 9 hours.  $C_{\max}$  in plasma is reached in 45 minutes in fasting subjects, but is delayed for up to 3.5 hours with a high-fat meal. See [Table 56-2](#) for PK values. Cycloserine is well distributed

throughout body. There is no appreciable barrier to CNS entry for cycloserine, and cerebrospinal fluid (CSF) concentrations are approximately the same as those in plasma. About 50% of cycloserine is excreted unchanged in the urine in the first 12 hours; a total of 70% is recoverable in the active form over a period of 24 hours. The drug may accumulate to toxic concentrations in patients with renal failure. About 60% of it is removed by hemodialysis, and the drug must be re-dosed after each hemodialysis session (Malone et al., 1999a).

**Therapeutic Uses.** Cycloserine is available for oral administration. The usual dose for adults is 250-500 mg twice daily.

**Untoward Effects.** Neuropsychiatric symptoms are common and occur in 50% of patients on 1 g/day, so much so that the drug has earned the nickname “psych-serine.” Symptoms range from headache and somnolence to severe psychosis, seizures, and suicidal ideas. Large doses of cycloserine or the concomitant ingestion of alcohol increases the risk of seizures. Cycloserine is contraindicated in individuals with a history of epilepsy and should be used with caution in individuals with a history of depression.

## Capreomycin

**Capreomycin** (CAPASTAT) is an antimycobacterial cyclic peptide. It consists of four active components: capreomycins IA, IB, IIA, and IIB. The agent used clinically contains primarily IA and IB. Antimycobacterial activity is similar to that of aminoglycosides as are adverse effects, and capreomycin should not be administered with other drugs that damage cranial nerve VIII.

Bacterial resistance to capreomycin develops when it is given alone; such microorganisms show cross-resistance with kanamycin and neomycin. The adverse reactions associated with the use of capreomycin are hearing loss, tinnitus, transient proteinuria, cylindruria, and nitrogen retention. Severe renal failure is rare. Eosinophilia is common. Leukocytosis, leukopenia, rashes, and fever have also been observed. Injections of the drug may be painful. Capreomycin is a second-line antituberculosis agent. The recommended daily dose is 1g (no more than 20 mg/kg) per day for 60-120 days, followed by 1 g two to three times a week.

## Macrolides

The pharmacology, bacterial activity, resistance mechanisms of macrolides are discussed in [Chapter 55](#). Azithromycin and clarithromycin are used for the treatment of MAC.

## Dapsone

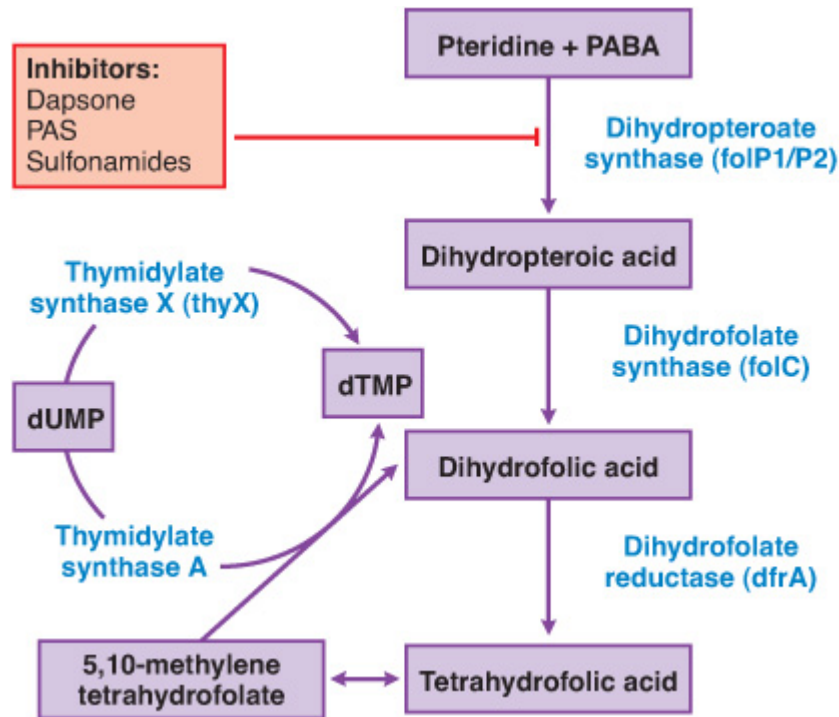

Dapsone (DDS, diamino-diphenylsulfone) or 4'-diaminodiphenylsulfone, was synthesized by Fromm and Wittman in 1908, and its similarity to sulphonamides led to the establishment of anti-streptococcal effects by Buttle et al. and Forneau et al. in 1937.

**Mechanism of Action.** Dapsone is a structural analog of *para*-aminobenzoic acid (PABA) and a competitive inhibitor of dihydropteroate synthase (*fo*/P1/P2) in the folate pathway, shown in [Figure 56–5](#). The effect on this evolutionarily conserved pathway also explains why dapsone is a broad-spectrum agent with antibacterial, anti-protozoal, and antifungal effects.

The anti-Inflammatory effects of dapsone occur via inhibition of tissue damage by neutrophils (summarized by Wolf et al., 2002). First, dapsone inhibits neutrophil myeloperoxidase activity and respiratory burst. Second, it inhibits activity of neutrophil lysosomal enzymes. Third, it may also act as a free radical scavenger, counteracting the effect of free radicals generated by neutrophils. Fourth, dapsone may also inhibit migration of neutrophils to inflammatory lesions (Wolf et al., 2002). Dapsone is extensively used for acne, but this therapy is not recommended.

**Antimicrobial Effects. Antibacterial.** Dapsone is bacteriostatic against *M. leprae* at concentrations of 1-10 mg/L. More than 90% of clinical isolates of MAC and *M. kansasii* have an MIC of  $\leq 8$  mg/L, but the MICs for *M. tuberculosis* isolates are high. It has little activity against other bacteria.

**Figure 56–5.** Effects of antimicrobials on folate metabolism and deoxynucleotide synthesis.

**Anti-parasitic.** Dapsone is also highly effective against *Plasmodium falciparum* with  $IC_{50}$  of 0.006-0.013 mg/mL (0.6-1.3 mg/L) even in sulfadoxine-pyrimethamine-resistant strains. Dapsone has an  $IC_{50}$  of 0.55 mg/L against *Toxoplasma gondii* tachyzoites.

**Antifungal.** Dapsone is effective at concentrations of 0.1/mg/L against the fungus *Pneumocystis jiroveci*.

**Drug Resistance.** Resistance to dapsone in *P. falciparum*, *P. jiroveci*, and *M. leprae* results primarily from mutations in genes encoding dihydropteroate synthase ([Figure 56–5](#)). In *P. falciparum* mutations occur at several positions such as 436, 437, 540, 58, and 613. In *P. jiroveci* isolates, mutations are often amino acid substitutions at positions 55 and 57. In *M. leprae*, mutations are encountered at codons 53 and 55.

**Absorption, Distribution, and Excretion.** After oral administration, absorption is complete; the elimination  $t_{1/2}$  is 20-30 hours. The population pharmacokinetics of dapsone are shown in [Table 56–2](#) (Simpson et al., 2006). CL increases 0.03 L/hour and  $V_d$  0.7 L increases for each 1-kg increase in body weight above 62.3 kg. Dapsone undergoes N-acetylation by

NAT2. N-oxidation to dapsone hydroxylamine is via CYP2E1, and to a lesser extent by CYP2C. Dapsone hydroxylamine enters red blood cells, leading to methemoglobin formation. Sulfones tend to be retained for up to 3 weeks in skin and muscle and especially in liver and kidney. Intestinal reabsorption of sulfones excreted in the bile contributes to long-term retention in the bloodstream; periodic interruption of treatment is advisable for this reason. Epithelial lining fluid to plasma ratio is between 0.76 and 2.91; CSF-to-plasma ratio is 0.21-2.01 (Gatti et al., 1997). Approximately 70-80% of a dose of dapsone is excreted in the urine as an acid-labile mono-*N*-glucuronide and mono-*N*-sulfamate.

**Therapeutic Uses.** Dapsone is administered as an oral agent. Therapeutic uses of dapsone in the treatment of leprosy are described later. Dapsone is combined with chlorproguanil for the treatment of malaria. Dapsone is also used for *P. jiroveci* infection and prophylaxis, and for the prophylaxis for *T. gondii*, as discussed in chapters devoted to these infections. The anti-inflammatory effects are the basis for therapy for pemphigoid, dermatitis herpetiformis, linear IgA bullous disease, relapsing chondritis, and ulcers caused by the brown recluse spider (Wolf et al., 2002).

**Dapsone and Glucose-6-Phosphate Dehydrogenase Deficiency.** Glucose-6-phosphate dehydrogenase (G6PD) protects red cells against oxidative damage. However, G6PD deficiency is encountered in nearly half a billion people worldwide, the most common of 100 variants being G6PD-A<sup>-</sup>. Dapsone, an oxidant, causes severe hemolysis in patients with G6PD deficiency. Thus, G6PD deficiency testing should be performed prior to use of dapsone wherever possible.

**Other Untoward Effects.** Hemolysis develops in almost every individual treated with 200-300 mg of dapsone per day. Doses of  $\leq 100$  mg in healthy persons and  $\leq 50$  mg in healthy individuals with a G6PD deficiency do not cause hemolysis. Methemoglobinemia also is common. A genetic deficiency in the NADH-dependent methemoglobin reductase can result in severe methemoglobinemia after administration of dapsone. Isolated instances of headache, nervousness, insomnia, blurred vision, paresthesias, reversible peripheral neuropathy (thought to be due to axonal degeneration), drug fever, hematuria, pruritus, psychosis, and a variety of skin rashes have been reported. An infectious mononucleosis-like syndrome, which may be fatal, occurs occasionally.

# PRINCIPLES OF ANTITUBERCULOSIS CHEMOTHERAPY

**Evolution and Pharmacology.** *Mycobacterium tuberculosis* is not a single species, but a complex of species with 99.9% similarity at nucleotide level. The complex includes *M. tuberculosis (typus humanus)*, *M. canettii*, *M. africanum*, *M. bovis*, and *M. microti*. They all cause tuberculosis (TB), with *M. microti* responsible for only a handful of human cases.

**Antituberculosis Therapy.** Isoniazid, pyrazinamide, rifampin, ethambutol, and streptomycin are currently considered first-line anti-TB agents. Moxifloxacin is being studied as a first-line agent. First-line agents are more efficacious and better tolerated, relative to second-line agents. Second-line agents are used in case of poor tolerance or resistance to first-line agents. Second-line drugs include ethionamide, PAS, cycloserine, amikacin, kanamycin, and capreomycin.

When anti-TB drug monotherapy was administered to TB patients, resistance emergence terminated the effectiveness of these drugs. The mutation rates to first-line anti-TB drugs are between  $10^{-7}$  and  $10^{-10}$ , so that the likelihood of resistance is high to any single anti-TB drugs in patients with cavitory TB who have  $\sim 10^9$  CFU of bacilli in a 3-cm pulmonary lesion. However, the likelihood that bacilli would develop mutations to two or more different drugs is the product of two mutation rates (between 1 in  $10^{14}$  and 1 in  $10^{20}$ ), which makes the probability of resistance emergence to more than two drugs acceptably small. Thus, only combination therapy anti-TB therapy is currently recommended for treatment of TB. Multidrug therapy has led to a reduction in length of therapy.

## Types of Antituberculosis Therapy

**Prophylaxis.** After infection with *M. tuberculosis*,  $\sim 10\%$  of people will develop active disease over a lifetime. The highest risk of reactivation TB is in patients with Mantoux tuberculin skin test reaction  $\geq 5$  mm who also fall into one of the following categories: recently exposed to TB, have HIV co-infection, have fibrotic changes on chest radiograms, or are immunosuppressed due to HIV infection, post-transplantation, or are taking immunosuppressive medications for any reason. If the tuberculin skin test is

$\geq 10$  mm, high risk of TB is encountered in recent ( $\leq 5$  years) immigrants from areas of high TB prevalence, children  $< 4$  years of age, children exposed to adults with TB, intravenous drug users, as well as residents and employees of high-risk congregate settings. Any person with a skin test  $> 15$  mm is also at high risk of disease. In these patients at high risk of active TB, prophylaxis is recommended to prevent active disease. Prophylaxis consists of oral isoniazid, 300 mg daily or twice weekly, for 6 months in adults. Those who cannot take isoniazid should be given rifampin, 10 mg/kg daily, for 4 months. In children, isoniazid 10-15 mg/kg daily (maximum 300 mg) is administered, or 20-30 mg/kg two times a week directly observed, for 9 months. In children who cannot tolerate isoniazid, rifampin 10-20 mg/kg daily for 6 months is recommended.

**Definitive Therapy.** All active TB cases should be confirmed by culture and have antimicrobial susceptibilities determined. The current standard regimen for drug-susceptible TB consists of isoniazid (5 mg/kg, maximum 300 mg/day), rifampin (10 mg/kg, maximum 600 mg/day), and pyrazinamide (15-30 mg/kg, maximum of 2 g/day) for 2 months, followed by intermittent 10 mg/kg rifampin and 15 mg/kg isoniazid two or three times a week for 4 months. Children should receive 10-20 mg/kg isoniazid per day (300 mg maximum). Rifabutin 5 mg/kg/day can be used for the entire 6 months of therapy in adult HIV-infected patients because rifampin can adversely interact with some antiretroviral agents to reduce their effectiveness. In case there is resistance to isoniazid, initial therapy also may include ethambutol (15-20 mg/kg/day) or streptomycin (1 g/day) until isoniazid susceptibility is documented. Ethambutol doses in children are 15-20 mg/kg/day (maximum 1 g) or 50 mg/kg twice weekly (2.5 g). Because monitoring of visual acuity is difficult in children  $< 5$  years old, caution should be exercised in using ethambutol in these children.

The first 2 months of the four-drug regimen is termed the initial phase of therapy, and the last 4 months the continuation phase of therapy. Rifapentine (10 mg/kg once a week) may be substituted for rifampin in the continuation phase in patients with no evidence of HIV infection or cavitary TB. Pyridoxine, vitamin B<sub>6</sub>, (10-50 mg/day) should be administered with isoniazid to minimize the risks of neurological toxicity in patients predisposed to neuropathy (e.g., the malnourished, elderly, pregnant women, HIV-infected individuals, diabetic patients, alcoholic patients, and uremic

patients). To ensure compliance, therapy is administered as directly observed therapy (DOT). Although DOT is the standard of care, an analysis of a series of 11 randomized clinical trials found no difference in outcome between DOT and self-administered therapy (Volmink and Garner, 2007).

The duration of therapy for drug-susceptible pulmonary TB is 6 months. A 9-month duration should be used for patients with cavitory disease who are still sputum culture positive at 2 months. HIV-infected patients with CD4+ lymphocyte cell counts  $<100/\text{mm}^3$  are at increased risk of developing rifamycin resistance. Therefore, daily therapy is recommended during the continuation phase. Most cases of extrapulmonary TB are treated for 6 months. TB meningitis is an exception that requires a 9- to 12-month duration. In addition, corticosteroids are recommended for TB pericarditis, and results of a meta-analysis suggest they should also be used in TB meningitis (Prasad and Singh, 2008).

**Drug-Resistant TB.** According to the fourth global report of the World Health Organization (WHO), from 2002 to 2006, the proportion of new TB cases resistant to at least one anti-TB drug was 17%; isoniazid resistance was 10%, and MDR (multidrug resistant) was 3%. MDR-TB is said to be present if an isolate is resistant simultaneously to isoniazid and rifampin. According to the CDC, in the U.S., resistance to isoniazid was 8% and MDR was 1%. In previously treated patients, resistance to at least one drug was 35%, isoniazid resistance was 28%, and MDR was 15%; resistance to isoniazid in previously treated cases was 13%, and MDR was 4%; of the MDR, only 3% was extensively drug resistant TB [XDR]. XDR-TB is MDR-TB that is also resistant to fluoroquinolones and at least one of three injectable second-line drugs (i.e., amikacin, kanamycin, or capreomycin).

In documented drug resistance, therapy should be based on evidence of susceptibility and should include:

- at least three drugs to which the pathogen is susceptible, with at least one of the injectable anti-TB agents
- in the case of MDR-TB, use of four to six medications for better outcomes
- at least 18 months of therapy (Blumberg et al., 2003; Orenstein et al., 2009)

The addition to the regimen of a fluoroquinolone and surgical resection of the main lesions have been associated with improved outcome (Chan et al., 2004). There are currently no data to support intermittent therapy.

# PRINCIPLES OF THERAPY AGAINST *MYCOBACTERIUM AVIUM* COMPLEX

The *Mycobacterium avium* complex (MAC) is made up of at least two species: *M. intracellulare* and *M. avium*. *M. intracellulare* causes pulmonary disease often in immunocompetent individuals. *M. avium* is further divided into a number of subspecies: *M. avium* subsp. *hominissuis* causes disseminated disease in immunocompromised patients, *M. avium* subsp. *paratuberculosis* has been implicated in the etiology of Crohn's disease, and *M. avium* subsp. *avium* causes TB of birds. These bacteria are ubiquitous in the environment and can be encountered in water, food, and soil. Therefore, when MAC bacteria are isolated from a nonsterile site in patient's body, one cannot assume they are causing an infection.

## Therapy of MAC Pulmonary Infection

*M. intracellulare* often infects immunocompetent patients. The first decision after isolating MAC from pulmonary specimens is to determine whether disease is actually present or if the organism is merely part of environmental contamination. Criteria in favor of therapy includes bacteriological evidence, which consists of positive cultures from at least two sputums, or one positive culture from bronchoalveolar lavage or pulmonary biopsy with a positive culture or histopathological features, *and* clinical evidence of infection, *and* radiological evidence of infection such as pulmonary cavitation, nodular lesions, and/or bronchiectasis (Griffith et al., 2007).

In newly diagnosed patients with MAC pneumonia, triple drug therapy is recommended. These include a rifamycin, ethambutol, and a macrolide (Griffith et al., 2007; Kasperbauer and Daley, 2008). For the macrolides, either oral clarithromycin or azithromycin may be used. Rifampin is often the rifamycin of choice. Clarithromycin, 1000 mg, or azithromycin, 500 mg, are combined with ethambutol, 25 mg/kg, and rifampin, 600 mg, and administered three times a week for nodular and bronchiectatic disease. Therapy is continued for 12 months after the last negative culture. The same drugs are administered for patients with cavitory disease, but the dosing regimens are azithromycin 250 mg, ethambutol 15 mg/kg, and rifampin 600 mg. Parenteral streptomycin or amikacin at 15 mg/kg are recommended as a fourth drug. The effect of the aminoglycosides on clinical outcomes is

unclear. Duration of therapy is as for nodular disease. In advanced pulmonary disease or during re-treatment, rifabutin 300 mg daily may replace rifampin. Because clarithromycin susceptibility correlates with outcome, risk of failure is high when high clarithromycin MICs are documented. Patients at risk for failure also include those with cavitory disease, presumably due to higher bacillary load. Even with these therapies, long-term success is still fairly limited. Only half of patients have successful outcomes as defined by both culture conversion and clinical outcomes.

## **Therapy for Disseminated *M. Avium* Complex**

Disseminated MAC disease is caused by *M. avium* in 95% of patients. This is a disease of the immunocompromised patient, especially with reduced cell-mediated immunity. MAC usually occurs in patients whose CD4 cell count is  $<50/\text{mm}^3$ . Patients at risk for infection are those who have had other opportunistic infections, are colonized with MAC, or have an HIV RNA burden  $>5 \log \text{ copies}/\text{mm}^3$ .

The symptoms and laboratory findings of disseminated disease are nonspecific and include fever, night sweats, weight loss, elevated serum alkaline phosphates, and anemia at the time of diagnosis. However, when disease occurs in patients already on antiretroviral therapy, it may manifest as a focal disease of the lymph nodes, osteomyelitis, pneumonitis, pericarditis, skin or soft-tissue abscesses, genital ulcers, or CNS infection (DHHS Panel, 2008). In addition to a compatible clinical picture, isolation of MAC from cultures of blood, lymph node, bone marrow, or other normally sterile tissue or body fluids is required for diagnosis.

**Prophylactic Therapy.** The goals of prophylactic therapy are to prevent the development of disease during the time when a patient's CD4 count is low. Monotherapy with either oral azithromycin 1200 mg once a week or clarithromycin 500 mg twice a day is started when patients present with a CD4 count  $<50/\text{mm}^3$  (DHHS Panel, 2008). For patients intolerant to macrolides, rifabutin 300 mg a day is administered. Once the CD4 count is  $>100 \text{ per } \text{mm}^3$  for  $\geq 3$  months, MAC prophylaxis should be discontinued.

**Definitive and Suppressive Therapy.** In patients with disease due to MAC, the goals of therapy include suppression of symptoms and conversion to negative blood cultures. The infection itself is not completely eradicated

until immune reconstitution. Therapy is divided into initial therapy and chronic suppressive therapy. Recommended therapy consists of a combination of clarithromycin 500 mg twice a day with ethambutol 15 mg/kg daily, administered orally (DHHS Panel, 2008). Azithromycin 500-600 mg daily is an acceptable alternative to clarithromycin, especially in those patients in whom clarithromycin would adversely interact with other drugs. The addition of rifabutin 300 mg a day may improve outcomes. Mortality in disseminated MAC is high in patients with either a CD4 cell count  $<50/\text{mm}^3$  or a MAC burden of  $>2 \log_{10} \text{CFU}/\text{mm}^3$  of blood, or in the absence of effective antiretroviral therapy. In these patients, a fourth drug may be added, based on susceptibility testing. Potential fourth agents include amikacin, 10-15 mg/kg intravenously daily; streptomycin, 1 g intravenously or intramuscularly daily; ciprofloxacin, 500-750 mg orally twice daily; levofloxacin, 500 mg orally daily; or moxifloxacin, 400g orally daily. Patients should be continued on suppressive therapy until all three of the following criteria are met:

- therapy duration of at least 12 months
- CD4 count  $>100/\text{mm}^3$  for at least 6 months
- asymptomatic for MAC infection

## **PRINCIPLES OF ANTI-LEPROSY THERAPY**

The global prevalence of leprosy has markedly declined, largely due to the global initiative of the WHO to eliminate leprosy (Hansen's disease) as a public health problem by providing multidrug therapy (rifampin, clofazimine, and dapsone) free of charge. Prevalence of the disease has dropped by ~90% since 1985. Nevertheless, there are pockets of disease around the world, especially in Africa, Asia, and South America. In the U.S.,  $<200$  new cases were reported in 2005, mainly among immigrants.

Four major clinical types of leprosy impact therapy. At one end of the spectrum is *tuberculoid leprosy*, also termed paucibacillary leprosy because the bacterial burden is low and *M. leprae* is rarely found in smears. On the other end of the spectrum is the *lepromatous* form of the disease (Levis and Ernst, 2005). This is characterized by a disseminated infection and a high bacillary burden. Two major intermediate forms of the disease are recognized: borderline (dimorphous) tuberculoid disease, which has features of both tuberculoid and lepromatous leprosy, and indeterminate disease,

which has early hypopigmented lesions without features of the lepromatous and tuberculoid leprosy.

*Mycobacterium leprae* was discovered by Armauer Hansen in 1873. The *M. leprae* genome has undergone reductive evolution and has radically downsized its genome (Cole et al., 2001). As a result, *M. leprae* cannot produce ATP from NADH or utilize acetate or galactose as carbon sources; moreover, it has lost the anaerobic electron transfer system and cannot survive under hypoxic conditions. It has a long doubling time (14 days) and is an obligate intracellular pathogen. As a result, *M. leprae* is difficult to culture on synthetic media, an impediment to basic research on the disease.

## Types of Anti-Leprosy Therapy

Therapy for leprosy is based on multi-drug regimens using rifampin, clofazimine, and dapsone. The reasons for using combinations of agents include reduction in the development of resistance, the need for adequate therapy when primary resistance already exists, and reduction in the duration of therapy. The most bactericidal drug in current regimens is rifampin. Because of high kill rates and massive release of bacterial antigens, rifampin is not often given during a “reversal” reaction (see below) or in patients with erythema nodosum leprosum. Clofazimine is only bacteriostatic against *M. leprae*. However, it also has anti-inflammatory effects and can treat reversal reactions and erythema nodosum leprosum. The third major agent in the regimen is dapsone. The objective of administering these drugs is total cure.

## Definitive Therapy; Standard Therapy

**Pauci-Bacillary Leprosy.** The WHO regimen consists of a single dose of oral rifampin, 600 mg, combined with dapsone, 100 mg, administered under direct supervision once every month for 6 months, and dapsone, 100 mg a day, in between for 6 months. In the U.S., the regimen consists of dapsone, 100 mg, and rifampin, 600 mg, daily for 6 months, followed by dapsone monotherapy for 3-5 years.

**Multibacillary Therapy.** The WHO recommends the same regimen as for paucibacillary leprosy, with two major changes. First, clofazimine, 300 mg a day, is added for the entirety of therapy. Second, the regimen lasts 1 year instead of 6 months. In the U.S., the regimen is also the same as for paucibacillary, but dual therapy continues for 3 years, followed by dapsone

monotherapy for 10 years. Clofazimine (an orphan drug) is added when there is dapsone resistance or chronically reactional patients.

The duration of therapy for multi-bacillary leprosy is a drawback. Studies in murine leprosy, and in patients, have demonstrated that viable bacilli are killed within 3 months of therapy (Ji et al., 1996) suggesting that the length of current therapy for multibacillary leprosy may be unnecessarily long. Recently, the WHO proposed that all forms of leprosy be treated with the same dose as for paucibacillary leprosy; a clinical trial was promising (Kroger et al., 2008). This new shorter regimen promises to reduce duration of therapy radically.

**Treatment of Reactions in Leprosy.** Patients with tuberculoid leprosy may develop “reversal reactions,” manifestations of delayed hypersensitivity to antigens of *M. leprae*. Cutaneous ulcerations and deficits of peripheral nerve function may occur. Early therapy with corticosteroids or clofazimine is effective. Reactions in the lepromatous form of the disease (erythema nodosum leprosum) are characterized by the appearance of raised, tender, intracutaneous nodules, severe constitutional symptoms, and high fever. This reaction may be triggered by several conditions but is often associated with therapy. It is thought to be an Arthus-type reaction related to release of microbial antigens in patients harboring large numbers of bacilli. Treatment with clofazimine or thalidomide is effective.

**Table 56–5 Drugs Used in the Treatment of Mycobacteria Other Than for Tuberculosis, Leprosy, or MAC**

MYCOBACTERIAL SPECIES	FIRST-LINE THERAPY	ALTERNATIVE AGENTS
<i>M. kansasii</i>	Isoniazid + rifampin <sup>a</sup> + ethambutol	Trimethoprim-sulfamethoxazole; ethionamide; cycloserine; clarithromycin; amikacin; streptomycin; moxifloxacin or gatifloxacin
<i>M. fortuitum</i> complex	Amikacin + doxycycline	Cefoxitin; rifampin; a sulfonamide; moxifloxacin or gatifloxacin; clarithromycin; trimethoprim-sulfamethoxazole; imipenem
<i>M. marinum</i>	Rifampin + ethambutol	Trimethoprim-sulfamethoxazole; clarithromycin; minocycline; doxycycline
<i>Mycobacterium ulcerans</i>	Rifampin + streptomycin <sup>c</sup>	Clarithromycin <sup>b</sup> ; rifapentine <sup>b</sup>
<i>M. malmoense</i>	Rifampin + ethambutol ± clarithromycin	Fluoroquinolone
<i>M. haemophilum</i>	Clarithromycin + rifampin + quinolone	-

<sup>a</sup>In HIV-infected patients, the substitution of rifabutin for rifampin minimizes drug interactions with the HIV protease inhibitors and non-nucleoside reverse transcriptase inhibitors. <sup>b</sup>Based on animal models. <sup>c</sup>For *Mycobacterium ulcerans*, surgery is the primary therapy.

## Therapy for Other Nontuberculous Mycobacteria

Mycobacteria other than those already discussed can be recovered from a variety of lesions in humans. Because they frequently are resistant to many of the commonly used agents, they must be examined for sensitivity *in vitro* and drug therapy selected on this basis. Therapy for infections from these organisms is summarized in [Table 56–5](#). In some instances, surgical removal of the infected tissue followed by long-term treatment with effective agents is necessary. *M. kansasii* causes disease similar to that caused by *M. tuberculosis*, but it may be milder. The microorganisms may be resistant to isoniazid. Therapy with isoniazid, rifampin, and ethambutol has been successful.

## CLINICAL SUMMARY

Combination therapy is almost always the desirable approach for mycobacterial disease, to ensure effective eradication and to prevent the emergence of resistance. Isoniazid, rifampin, ethambutol, streptomycin, and pyrazinamide are first-line agents for the treatment of tuberculosis. Moxifloxacin promises to replace either isoniazid or ethambutol and shorten therapy. Antimicrobial agents with excellent activity against *Mycobacterium avium* complex include rifabutin, clarithromycin, azithromycin, and fluoroquinolones. Clinical monitoring of patients with mycobacterial infections is important because drug interactions and adverse drug reactions are common with the multiple-drug regimens used. Considerable progress has been achieved in eliminating leprosy through the use of multiple-drug chemotherapy including dapsone, rifampin, and clofazimine.

# Chapter 57

## Antifungal Agents

John E. Bennett

There are 200,000 known species of fungi, and estimates of the total size of Kingdom Fungi range to well over a million. Residents of the kingdom are quite diverse and include yeasts, molds, mushrooms, smuts, the pathogens *Aspergillus fumigatus* and *Candida albicans*, and the source of penicillin, *Penicillium chrysogenum*. Fortunately, only ~400 fungi cause disease in animals, and even fewer cause significant human disease. However, fungal infections are becoming more common: Patients with AIDS and patients whose immune systems are compromised by drug therapy are especially susceptible to mycotic infections. Fungi are eukaryotes with unique cell walls containing glucans and chitin, and their eradication requires different strategies than those for treatment of bacterial infections. Available agents have effects on the synthesis of membrane and cell-wall components, on membrane permeability, on the synthesis of nucleic acids, and on microtubule/mitotic spindle function ([Figure 57–1](#)).

Antifungal agents described in this chapter are discussed under two major headings, systemic and topical, although this distinction is somewhat arbitrary. The imidazole, triazole, and polyene antifungal agents may be used either systemically or topically, and many superficial mycoses can be treated either systemically or topically.

Although *Pneumocystis jirovecii*, responsible for life-threatening pneumonia in immunocompromised patients, is a fungus and not a protozoan, its treatment is discussed elsewhere because the drugs used are primarily antibacterial or antiprotozoal rather than antifungal.

Major pharmaceutical companies have closed their antifungal development programs, although a few small firms continue to sponsor research in this field. Thus, the near future in this area is likely to be limited to expansion of experience with existing compounds ([Table 57–1](#)). The most recent systemic antifungals to reach clinical development, posaconazole (*NOXAFIL*) and isavuconazole (in phase III trials in the U.S.), are both triazoles.

# SYSTEMIC ANTIFUNGAL AGENTS: SYSTEMIC DRUGS FOR DEEPLY INVASIVE FUNGAL INFECTIONS

## Amphotericin B

**Chemistry.** Amphotericin B is one of a family of some 200 polyene macrolide compounds with antifungal activity. Those studied to date share the characteristics of four to seven conjugated double bonds, an internal cyclic ester, poor aqueous solubility, substantial toxicity on parenteral administration, and a common mechanism of antifungal action. Amphotericin B (see following structure) is a heptaene macrolide containing seven conjugated double bonds in the *trans* position and 3-amino-3,6-dideoxymannose (mycosamine) connected to the main ring by a glycosidic bond. The amphoteric behavior for which the drug is named derives from the presence of a carboxyl group on the main ring and a primary amino group on mycosamine; these groups confer aqueous solubility at extremes of pH. X-ray crystallography has shown the molecule to be rigid and rod-shaped, with the hydrophilic hydroxyl groups of the macrolide ring forming an opposing face to the lipophilic polyenic portion.

**Figure 57–1.** *Sites of action of antifungal drugs.* Amphotericin B and other polyenes, such as nystatin, bind to ergosterol in fungal cell membranes and increase membrane permeability. The imidazoles and triazoles, such as itraconazole and fluconazole, inhibit 14- $\alpha$ -sterol demethylase, prevent ergosterol synthesis, and lead to the accumulation of 14- $\alpha$ -methylsterols. The allylamines, such as naftifine and terbinafine, inhibit squalene epoxidase and prevent ergosterol synthesis. The echinocandins, such as caspofungin, inhibit the formation of glucans in the fungal cell wall.

**Drug Formulations.** There are currently four formulations of amphotericin B commercially available: conventional amphotericin B (C-AMB), liposomal amphotericin B (L-AMB), amphotericin B lipid complex (ABLCL), and amphotericin B colloidal dispersion (ABCD). [Table 57–2](#) summarizes the pharmacokinetic properties of these preparations.

**C-AMB** (Conventional amphotericin B, *FUNGIZONE*). Amphotericin B is insoluble in water but is formulated for intravenous infusion by complexing it with the bile salt deoxycholate. The complex is marketed as a lyophilized powder for injection. C-AMB forms a colloid in water, with particles largely  $<0.4\ \mu\text{m}$  in diameter. Filters in intravenous infusion lines that trap particles  $>0.22\ \mu\text{m}$  in diameter will remove significant amounts of drug. Addition of electrolytes to infusion solutions causes the colloid to aggregate.

**ABCD.** Amphotericin B colloidal dispersion (AMPHOTEC, AMPHOCIL) contains roughly equimolar amounts of amphotericin B and cholesteryl sulfate formulated for injection. Like C-AMB, ABCD forms a colloidal solution when dispersed in aqueous solution. ABCD provides much lower

blood levels than C-AMB in mice and humans. In a study in patients with neutropenic fever comparing daily ABCD (4 mg/kg) with C-AMB (0.8 mg/kg), chills and hypoxia were significantly more common with ABCD than with C-AMB (White et al., 1998). Hypoxia was associated with severe febrile reactions. In a comparison of ABCD (6 mg/kg) and C-AMB (1-1.5 mg/kg) in invasive aspergillosis patients, ABCD was less nephrotoxic than C-AMB (49% vs. 15%) but caused more fever (27% vs. 16%) and chills (53% vs. 30%) (Bowden et al., 2002). Administration of the recommended ABCD dose over 3-4 hours and use of premedication to reduce febrile reactions are advised, particularly with initial infusions. ABCD is approved at a recommended dose of 3-4 mg/kg intravenously daily for patients with invasive aspergillosis who are not responding to or are unable to tolerate C-AMB.

**L-AMB.** Liposomal amphotericin B is a small, unilamellar vesicle formulation of amphotericin B (AMBISOME). The drug is supplied as a lyophilized powder, which is reconstituted with sterile water for injection. Blood levels following intravenous infusion are almost equivalent to those obtained with C-AMB, and because L-AMB can be given at higher doses, blood levels have been achieved that exceed those obtained with C-AMB (Boswell et al., 1998) ([Table 57-2](#)). Amphotericin B accumulation in the liver and spleen is higher with L-AMB than with C-AMB. Adverse effects include nephrotoxicity, hypokalemia, and infusion-related reactions, such as fever, chills, hypoxia, hypotension, and hypertension, but these do not commonly lead to drug discontinuation. Infusion-related pain in the back, abdomen, or chest occurs in occasional patients, usually with the first few doses. Anaphylaxis also has been reported. As empirical therapy or prophylaxis in febrile neutropenic patients, C-AMB and L-AMB are equivalent. As induction therapy of disseminated histoplasmosis in AIDS patients, L-AMB 3 mg/kg was superior to C-AMB 0.7 mg/kg (Johnson, 2002). L-AMB is approved for initial therapy of cryptococcal meningitis of AIDS patients and is listed as an alternative to C-AMB for induction therapy of both disseminated histoplasmosis and cryptococcal meningoencephalitis in AIDS patients (Kaplan et al., 2009). L-AMB is approved for empirical therapy of fever in the neutropenic host not responding to appropriate antibacterial agents, as well as for salvage therapy of aspergillosis and candidiasis. The recommended daily intravenous dose for empirical therapy is 3 mg/kg; for treatment of mycoses, the dosage is 3-5 mg/kg. L-AMB also is

effective in visceral leishmaniasis at doses of 3-4 mg/kg daily. The drug is administered in 5% dextrose in water, with initial doses infused over 2 hours. If well tolerated, infusion duration can be shortened to 1 hour. Doses up to 10 mg/kg have been used but are associated with higher toxicity and, in one randomized trial of aspergillosis, no improvement in efficacy (Cornely, 2007a).

*ABLC* (ABELCET). Amphotericin B lipid complex is a complex of amphotericin B with lipids (dimyristoylphosphatidylcholine and dimyristoylphosphatidylglycerol). ABLC is given in a dose of 5 mg/kg in 5% dextrose in water, infused intravenously once daily over 2 hours. Blood levels of amphotericin B are much lower with ABLC than with the same dose of C-AMB. ABLC is effective in a variety of mycoses, with the possible exception of cryptococcal meningitis. The drug is approved for salvage therapy of deep mycoses.

The three lipid formulations collectively appear to reduce the risk of the patient's serum creatinine doubling during therapy by 58% (Barrett et al., 2003). In patients at high risk for nephrotoxicity, ABLC is more nephrotoxic than L-AMB (Wingard et al., 2000). In some patients, the additive burden of amphotericin B nephrotoxicity can help precipitate advanced renal failure, with attendant morbidity. Infusion-related reactions are not consistently reduced with the use of lipid preparations. ABCD causes more infusion-related reactions than C-AMB. Although L-AMB reportedly causes fewer infusion-related reactions than ABLC during the first dose (Wingard et al., 2000), the difference depends on whether premedication is given and varies considerably between patients. Infusion-related reactions typically decrease with subsequent infusions.

### **Table 57–1 Pharmacotherapy of Mycoses**

DEEP MYCOSES		SUPERFICIAL MYCOSES	
	DRUGS		DRUGS
<b><i>Invasive aspergillosis</i></b>		<b><i>Candidiasis</i></b>	
Immunosuppressed	Voriconazole, amphotericin B	Vulvovaginal	<i>Topical</i> Butoconazole, clotrimazole, miconazole, nystatin, terconazole, tioconazole
Non-immunosuppressed	Voriconazole, amphotericin B, itraconazole		<i>Oral</i> Fluconazole
<b><i>Blastomycosis</i></b>		Oropharyngeal	<i>Topical</i> Clotrimazole, nystatin
Rapidly progressive or CNS	Amphotericin B		<i>Oral (systemic)</i> Fluconazole, itraconazole
Indolent and non-CNS	Itraconazole		Posaconazole
<b><i>Candidiasis</i></b>		Cutaneous	<i>Topical</i> Amphotericin B, clotrimazole, ciclopirox, econazole, ketoconazole, miconazole, nystatin
Deeply invasive	Amphotericin B, fluconazole, voriconazole, caspofungin, micafungin, anidulafungin		
<b><i>Coccidioidomycosis</i></b>		<b><i>Ringworm</i></b>	<i>Topical</i> Butenafine, ciclopirox, clotrimazole, econazole, haloprogin, ketoconazole, miconazole, naftifine, oxiconazole, sertaconazole, sulconazole, terbinafine, tolnaftate, undecylenate
Rapidly progressing	Amphotericin B		<i>Systemic</i> Griseofulvin, itraconazole, terbinafine
Indolent	Itraconazole, fluconazole		
Meningeal	Fluconazole, intrathecal amphotericin B		
<b><i>Cryptococcosis</i></b>			
Non-AIDS and initial AIDS	Amphotericin B, flucytosine		
Maintenance AIDS	Fluconazole		
<b><i>Histoplasmosis</i></b>			
Chronic pulmonary	Itraconazole		
Disseminated			
<i>Rapidly progressing or CNS</i>	Amphotericin B		
<i>Indolent non-CNS</i>	Itraconazole		
<i>Maintenance AIDS</i>	Itraconazole		
<b><i>Mucormycosis</i></b>	Amphotericin B		
<b><i>Pseudallescheriasis</i></b>	Voriconazole, itraconazole		
<b><i>Sporotrichosis</i></b>			
Cutaneous	Itraconazole		
Extracutaneous	Amphotericin B, itraconazole		
<b><i>Prophylaxis in the immunocompromised host</i></b>	Fluconazole		
	Posaconazole		
	Micafungin		
<b><i>Empirical therapy in the immunocompromised host (category not recognized by FDA)</i></b>	Amphotericin B		
	Caspofungin		
	Fluconazole		

The cost of the lipid formulations of amphotericin B greatly exceeds that of C-AMB, making them unavailable in many countries.

**Mechanism of Action.** The antifungal activity of amphotericin B depends principally on its binding to a sterol moiety, primarily ergosterol in the membrane of sensitive fungi. By virtue of their interaction with these sterols, polyenes appear to form pores or channels that increase the permeability of the membrane, allowing leakage of a variety of small molecules ([Figure 57–1](#)).

**Absorption, Distribution, and Excretion.** Gastrointestinal (GI) absorption of all amphotericin B formulations is negligible. Pharmacokinetic properties differ markedly between preparations with L-AMB having the highest plasma concentrations at therapeutic doses ([Table 57–2](#)). C-AMB is released from

its complex with deoxycholate in the bloodstream, and the amphotericin B that remains in plasma is more than 90% bound to proteins, largely  $\beta$ -lipoprotein. Excretion into the urine is negligible with all the formulations. Azotemia, liver failure, or hemodialysis does not have a measurable impact on plasma concentrations. Concentrations of amphotericin B (via C-AMB) in fluids from inflamed pleura, peritoneum, synovium, and aqueous humor are approximately two-thirds of trough concentrations in plasma. Little amphotericin B from any formulation penetrates into cerebrospinal fluid (CSF), vitreous humor, or normal amniotic fluid.

**Table 57–2 Pharmacokinetic Parameters for Amphotericin B Formulations after Multiple Administrations in Humans**

PRODUCT	DOSE (MG/KG)	C <sub>MAX</sub> (μg/mL)	AUC <sub>(1-24hr)</sub> (μg·hr/mL)	V (L/kg)	Cl (mL/hr/kg)
AmBisome (L-AMB)	5	83±35.2	555±311	0.11±0.08	11±6
Amphotec (ABCD)	5	3.1	43	4.3	117
Ablecet (ABLC)	5	1.7±0.8	14±7	131±7.7	426±188.5
Fungizone (C-AMB)	0.6	1.1±0.2	17.1±5	5±2.8	38±15

For details, see Boswell et al. (1998). From Boswell GW, Buell D, Bekersky I. AmBisome (liposomal amphotericin B): A comparative review. *J Clin Pharmacol*, 1998, 38:583–592. ©1998 The American College of Clinical Pharmacology. Reprinted by permission of SAGE Publications.

**Antifungal Activity.** Amphotericin B has useful clinical activity against *Candida* spp., *Cryptococcus neoformans*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*, *Sporothrix schenckii*, *Coccidioides* spp., *Paracoccidioides braziliensis*, *Aspergillus* spp., *Penicillium marneffeii*, and the agents of mucormycosis. Amphotericin B has limited activity against the protozoa *Leishmania* spp. and *Naegleria fowleri*. The drug has no antibacterial activity.

**Fungal Resistance.** Some isolates of *Candida lusitanae* have been relatively resistant to amphotericin B. *Aspergillus terreus* and perhaps *Aspergillus nidulans* may be more resistant to amphotericin B than other *Aspergillus* species (Steinbach et al., 2004). Mutants selected *in vitro* for resistance to nystatin (a polyene antifungal discussed later) or amphotericin B replace ergosterol with certain precursor sterols. The rarity of significant amphotericin B resistance arising during therapy has left it unclear whether ergosterol-deficient mutants retain sufficient pathogenicity to survive in deep tissue.

**Therapeutic Uses.** The recommended doses were given earlier for each formulation. *Candida* esophagitis responds to much lower doses than deeply invasive mycoses. Intrathecal infusion of C-AMB is useful in patients with meningitis caused by *Coccidioides*. Too little is known about intrathecal

administration of lipid formulations to recommend them. C-AMB can be injected into the CSF of the lumbar spine, cisterna magna, or lateral cerebral ventricle. Fever and headache are common reactions that may be decreased by intrathecal administration of 10-15 mg of hydrocortisone. Local injections of amphotericin B into a joint or peritoneal dialysate fluid commonly produce irritation and pain. Intraocular injection following pars plana vitrectomy has been used successfully for fungal endophthalmitis.

Intravenous administration of amphotericin B is the treatment of choice for mucormycosis and is used for initial treatment of cryptococcal meningitis, severe or rapidly progressing histoplasmosis, blastomycosis, coccidioidomycosis, and penicilliosis marneffeii, as well as in patients not responding to azole therapy of invasive aspergillosis, extracutaneous sporotrichosis, fusariosis, alternariosis, and trichosporonosis. Amphotericin B (C-AMB or L-AMB) is often given to selected patients with profound neutropenia who have fever that does not respond to broad-spectrum antibacterial agents over 5-7 days.

**Untoward Effects.** The major acute reactions to intravenous amphotericin B formulations are fever and chills. Infusion-related reactions are worst with ABCD, slightly less with C-C-AMB, even less with ABLC, and least with L-AMB. Tachypnea and respiratory stridor or modest hypotension also may occur, but true bronchospasm or anaphylaxis is rare. Patients with pre-existing cardiac or pulmonary disease may tolerate the metabolic demands of the reaction poorly and develop hypoxia or hypotension. The reaction ends spontaneously in 30-45 minutes; meperidine may shorten it. Pretreatment with oral acetaminophen or use of intravenous hydrocortisone hemisuccinate, 0.7 mg/kg, at the start of the infusion decreases reactions. Febrile reactions abate with subsequent infusions. Infants, children, and patients receiving therapeutic doses of glucocorticoids are less prone to reactions.

Azotemia occurs in 80% of patients who receive C-AMB for deep mycoses (Carlson and Condon, 1994). Lipid formulations are less nephrotoxic, being much less with ABLC, even less with L-AMB, and minimal with ABCD. Toxicity is dose-dependent and usually transient and increased by concurrent therapy with other nephrotoxic agents, such as aminoglycosides or cyclosporine. Although permanent histological changes in renal tubules occur even during short courses of C-AMB, permanent functional impairment is uncommon in adults with normal renal function prior

to treatment unless the cumulative dose exceeds 3-4 g. Renal tubular acidosis and renal wasting of  $K^+$  and  $Mg^{2+}$  also may be seen during and for several weeks after therapy. Supplemental  $K^+$  is required in one-third of patients on prolonged therapy. Saline loading has decreased nephrotoxicity, even in the absence of water or salt deprivation. Administration of 1 L of normal saline intravenously on the day that C-AMB is to be given has been recommended for adults who are able to tolerate the  $Na^+$  load and who are not already receiving that amount in intravenous fluids.

Hypochromic, normocytic anemia commonly occurs during treatment with C-AMB. Anemia is less with lipid formulations and usually not seen over the first 2 weeks. The anemia is most likely due to decreased production of erythropoietin. Patients with low plasma erythropoietin may respond to administration of recombinant erythropoietin. Anemia reverses slowly following cessation of therapy. Headache, nausea, vomiting, malaise, weight loss, and phlebitis at peripheral infusion sites are common. Thrombocytopenia or mild leukopenia is observed rarely. Hepatotoxicity is not firmly established with any amphotericin B formulation. Arachnoiditis has been observed as a complication of injecting C-AMB into the CSF.

## Flucytosine

**Chemistry.** Flucytosine is 5-fluorocytosine, a fluorinated pyrimidine related to fluorouracil and floxuridine.

FLUCYTOSINE

**Mechanism of Action.** All susceptible fungi are capable of deaminating flucytosine to 5-fluorouracil ([Figure 57-2](#)), a potent antimetabolite that is used in cancer chemotherapy ([Chapter 61](#)). Fluorouracil is metabolized first to 5-fluorouracil-ribose monophosphate (5-FUMP) by the enzyme uracil phosphoribosyl transferase (UPRTase; also called uridine monophosphate pyrophosphorylase). As in mammalian cells, 5-FUMP then is either incorporated into RNA (via synthesis of 5-fluorouridine triphosphate) or

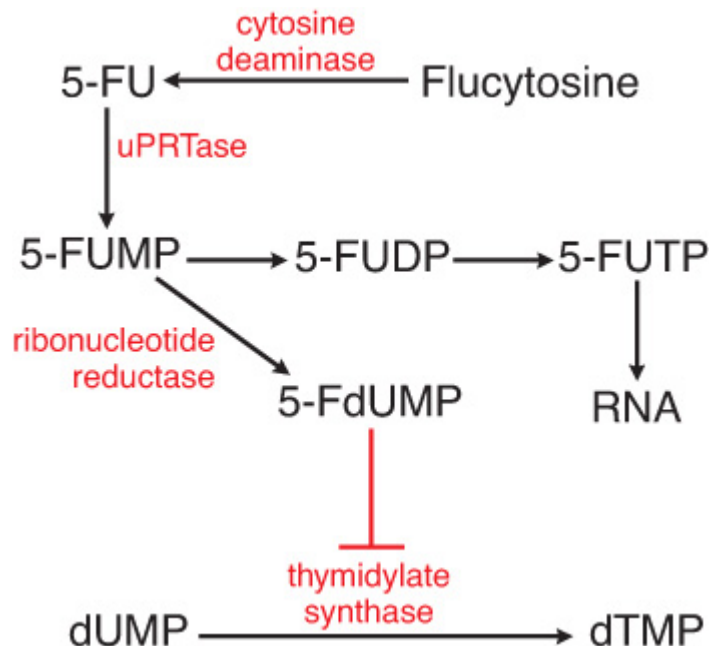

metabolized to 5-fluoro-2'-deoxyuridine-5'-monophosphate (5-FdUMP), a potent inhibitor of thymidylate synthetase. DNA synthesis is impaired as the ultimate result of this latter reaction. The selective action of flucytosine is due to the lack of cytosine deaminase in mammalian cells, which prevents metabolism to fluorouracil.

**Antifungal Activity.** Flucytosine has clinically useful activity against *Cryptococcus neoformans*, *Candida* spp., and the agents of chromoblastomycosis. Within these species, determination of susceptibility *in vitro* has been extremely dependent on the method employed, and susceptibility testing performed on isolates obtained prior to treatment has not correlated with clinical outcome.

**Fungal Resistance.** Drug resistance arising during therapy (secondary resistance) is an important cause of therapeutic failure when flucytosine is used alone for cryptococcosis and candidiasis. In chromoblastomycosis, resurgence of lesions after an initial response has led to the presumption of secondary drug resistance. In isolates of *Cryptococcus* and *Candida* species, secondary drug resistance has been accompanied by a change in the minimal inhibitory concentration from  $<2.5 \mu\text{g/mL}$  to  $>360 \mu\text{g/mL}$ . The mechanism for this resistance can be loss of the permease necessary for cytosine transport or decreased activity of either UPRTase or cytosine deaminase ([Figure 57–2](#)). In *Candida albicans*, substitution of thymidine for cytosine at nucleotide 301 in the gene encoding UPRTase (*FUR1*) causes a cysteine to become an arginine, modestly increasing flucytosine resistance (Dodgson et al., 2004). Flucytosine resistance is further increased if both *FUR1* alleles in the diploid fungus are mutated.

**Absorption, Distribution, and Excretion.** Flucytosine is absorbed rapidly and well from the GI tract. It is widely distributed in the body, with a volume of distribution that approximates total body water, and is minimally bound to plasma proteins. The peak plasma concentration in patients with normal renal function is  $\sim 70\text{--}80 \mu\text{g/mL}$ , achieved 1-2 hours after a dose of 37.5 mg/kg. Approximately 80% of a given dose is excreted unchanged in the urine; concentrations in the urine range from 200-500  $\mu\text{g/mL}$ . The  $t_{1/2}$  of the drug is 3-6 hours in normal individuals. In renal failure, the  $t_{1/2}$  may be as long as 200 hours. The clearance of flucytosine is approximately equivalent to that of creatinine. Reduction of dosage is necessary in patients with decreased renal function, and concentrations of drug in plasma should be measured

periodically. Peak concentrations should range between 50 and 100  $\mu\text{g/mL}$ . Flucytosine is cleared by hemodialysis, and patients undergoing such treatment should receive a single dose of 37.5 mg/kg after dialysis; the drug also is removed by peritoneal dialysis.

**Figure 57–2.** *Action of flucytosine in fungi.* Flucytosine is transported by cytosine permease into the fungal cell, where it is deaminated to 5-fluorouracil (5-FU). The 5-FU is then converted to 5-fluorouracil-ribose monophosphate (5-FUMP) and then is either converted to 5-fluorouridine triphosphate (5-FUTP) and incorporated into RNA or converted by ribonucleotide reductase to 5-fluoro-2'-deoxyuridine-5'-monophosphate (5-FdUMP), which is a potent inhibitor of thymidylate synthase. 5-FUDP, 5-fluorouridine-5'-diphosphate; dUMP, deoxyuridine-5'-monophosphate; dTMP, deoxythymidine-5'-monophosphate.

Flucytosine concentration in CSF is ~65-90% of that found simultaneously in the plasma. The drug also appears to penetrate into the aqueous humor.

**Therapeutic Uses.** Flucytosine (ANCOBON) is given orally at 50-150 mg/kg per day, in four divided doses at 6-hour intervals. Dosage must be adjusted for decreased renal function. Flucytosine is used predominantly in combination with amphotericin B. Flucytosine caused no added toxicity when added to 0.7 mg/kg of amphotericin B for the initial 2 weeks of therapy of cryptococcal meningitis in AIDS patients. Although the CSF colony count diminished more rapidly with combination therapy, there was no apparent

impact on mortality or morbidity (van der Horst et al., 1997). An all-oral regimen of flucytosine plus fluconazole also has been advocated for therapy of AIDS patients with cryptococcosis, but the combination has substantial GI toxicity with no evidence that flucytosine adds benefit (Larsen et al., 1994). In cryptococcal meningitis of non-AIDS patients, the role of flucytosine is more conjectural. The addition of flucytosine to  $\geq 6$  weeks of therapy with C-AMB runs the risk of substantial bone marrow suppression or colitis if the flucytosine dose is not promptly adjusted downward as amphotericin B–induced azotemia occurs. In the 2008 IDSA guidelines for the treatment of cryptococcal meningoencephalitis, addition of flucytosine (100 mg/kg orally in four divided doses) is recommended for the first 2 weeks of treatment with amphotericin B in AIDS patients. A similar practice is often used in HIV-negative patients but the benefit is unknown (Pappas et al., 2001).

***Untoward Effects.*** Flucytosine may depress the bone marrow and lead to leukopenia and thrombocytopenia; patients are more prone to this complication if they have an underlying hematological disorder, are being treated with radiation or drugs that injure the bone marrow, or have a history of treatment with such agents. Other untoward effects—including rash, nausea, vomiting, diarrhea, and severe enterocolitis—have been noted. In  $\sim 5\%$  of patients, plasma levels of hepatic enzymes are elevated, but this effect reverses when therapy is stopped. Toxicity is more frequent in patients with AIDS or azotemia (including those who are receiving amphotericin B concurrently) and when plasma drug concentrations exceed 100  $\mu\text{g/mL}$ . Toxicity may result from conversion of flucytosine to 5-fluorouracil by the microbial flora in the intestinal tract of the host.

## **Imidazoles and Triazoles**

The azole antifungals include two broad classes, imidazoles and triazoles, which share the same antifungal spectrum and mechanism of action. The systemic triazoles are metabolized more slowly and have less effect on human sterol synthesis than the imidazoles. Because of these advantages, new congeners under development are mostly triazoles. Of the drugs now on the market in the U.S., clotrimazole, miconazole, ketoconazole, econazole, butoconazole, oxiconazole, sertaconazole, and sulconazole are imidazoles; terconazole, itraconazole, fluconazole, voriconazole, posaconazole, and isavuconazole (an experimental drug) are triazoles. The topical use of azole

antifungals is described in the second section of this chapter. The basic triazole structure is:

**Mechanism of Action.** At concentrations achieved following systemic administration, the major effect of imidazoles and triazoles on fungi is inhibition of 14- $\alpha$ -sterol demethylase, a microsomal CYP ([Figure 57-1](#)). Imidazoles and triazoles thus impair the biosynthesis of ergosterol for the cytoplasmic membrane and lead to the accumulation of 14- $\alpha$ -methylsterols. These methylsterols may disrupt the close packing of acyl chains of phospholipids, impairing the functions of certain membrane-bound enzyme systems, thus inhibiting growth of the fungi. Some azoles directly increase permeability of the fungal cytoplasmic membrane, but the concentrations required are likely only obtained with topical use.

**Antifungal Activity.** Azoles as a group have clinically useful activity against *Candida albicans*, *Candida tropicalis*, *Candida parapsilosis*, *Candida glabrata*, *Cryptococcus neoformans*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*, *Coccidioides* spp., *Paracoccidioides brasiliensis*, and ringworm fungi (dermatophytes). *Aspergillus* spp., *Scedosporium apiospermum* (*Pseudallescheria boydii*), *Fusarium*, and *Sporothrix schenckii* are intermediate in susceptibility. *Candida krusei* and the agents of mucormycosis are more resistant. Thus, these drugs do not have any useful antibacterial or antiparasitic activity, with the possible exception of antiprotozoal effects against *Leishmania major*. Posaconazole has slightly improved activity *in vitro* against the agents of mucormycosis.

**Resistance.** Azole resistance emerges gradually during prolonged azole therapy, causing clinical failure in patients with far-advanced HIV infection and oropharyngeal or esophageal candidiasis. The primary Mechanisms of Resistance in *C. albicans* is accumulation of mutations in *ERG11*, the gene coding for the 14- $\alpha$ -sterol demethylase. These mutations protect heme in the enzyme pocket from binding to the azole but allow access of the natural substrate for the enzyme lanosterol. Cross-resistance is conferred to all azoles. Increased azole efflux by both ATP-binding cassette (ABC) and major facilitator superfamily transporters can add to fluconazole resistance

in *C. albicans* and *C. glabrata*. Increased production of C14- $\alpha$ -sterol demethylase is another potential cause of resistance. Mutation of the C5,6 sterol reductase gene *ERG3* also can increase azole resistance in some species.

Primary azole resistance has been described in some isolates of *Aspergillus fumigatus* with increased azole transport and decreased ergosterol content, but the clinical significance is unknown. Decreased fluconazole susceptibility has been described in *Cryptococcus neoformans* isolated from AIDS patients failing prolonged therapy.

**Interaction of Azole Anti-Fungals with Other Drugs.** The azoles interact with hepatic CYPs as substrates and inhibitors ([Table 57-3](#)), providing myriad possibilities for the interaction of azoles with many other medications. Thus, azoles can elevate plasma levels of some co-administered drugs ([Table 57-4](#)). Other co-administered drugs can decrease plasma concentrations of azole antifungal agents ([Table 57-5](#)). As a consequence of myriad interactions, combinations of certain drugs with azole antifungal medications may be contraindicated ([Table 57-6](#)).

## Ketoconazole

Ketoconazole, administered orally, has been replaced by itraconazole for the treatment of all mycoses except when the lower cost of ketoconazole outweighs the advantage of itraconazole. Itraconazole lacks ketoconazole's corticosteroid suppression while retaining most of ketoconazole's pharmacological properties and expanding the antifungal spectrum. Ketoconazole sometimes is used to inhibit excessive production of glucocorticoids in patients with Cushing's syndrome ([Chapter 42](#)) and is available for topical use, as described later.

## Itraconazole

This synthetic triazole is an equimolar racemic mixture of four diastereoisomers (two enantiomeric pairs), each possessing three chiral centers. The structure is similar to that of the imidazole ketoconazole.

### **Table 57-3 Interaction of Azole Antifungal Agents with Hepatic CYPs**

FLUCONAZOLE	VORICONAZOLE	ITRACONAZOLE	POSACONAZOLE
CYP3A4 inhibitor CYP2C9 inhibitor CYP2C19 inhibitor	CYP2C9 inhibitor and substrate CYP3A4 inhibitor CYP2C19 inhibitor	CYP3A4 inhibitor	CYP3A4 inhibitor

**Table 57–4 Drugs Exhibiting Elevated Plasma Concentrations When Co-Administered with Azole Anti-Fungal Agents**

Alfentanil	Eplerenone	Losartan	Saquinavir
Alprazolam	Ergot alkaloids	Lovastatin	Sildenafil
Astemizole	Erlotinib	Methadone	Sirolimus
Buspirone	Eszopiclone	Methylprednisolone	Solifenacin
Busulfan	Felodipine	Midazolam	Sunitinib
Carbamazepine	Fexofenadine	Nevirapine	Tacrolimus
Cisapride	Gefitinib	Omeprazole	Triazolam
Cyclosporine	Glimepiride	Phenytoin	Vardenafil
Digoxin	Glipizide	Pimozide	Vinca alkaloids
Docetaxel	Halofantrine	Quinidine	Warfarin
Dofetilide	Haloperidol	Ramelteon	Zidovudine
Efavirenz	Imatinib	Ranolazine	Zolpidem
Eletriptan	Irinotecan	Risperidone	

Mechanism of interaction presumably occurs largely at the level of hepatic CYPs, especially CYPs 3A4, 2C9, and 2D6, but can also involve P-glycoprotein and other mechanisms. Not all drugs listed interact equally with all azoles. For details, see Chapter 6 and Zonios (2008).

**Table 57–5 Some Drugs that Decrease Azole Concentration When Co-Administered**

**Absorption, Distribution, and Excretion.** Itraconazole (SPORANOX, others) is available as a capsule and a solution in hydroxypropyl- $\beta$ -cyclodextrin for oral use. The capsule form of the drug is best absorbed in the fed state, but the oral solution is better absorbed in the fasting state, providing peak plasma concentrations >150% of those obtained with the capsule. Itraconazole is metabolized in the liver. It is both a substrate for and a potent inhibitor of CYP3A4. Itraconazole is present in plasma with an approximately equal concentration of a biologically active metabolite, hydroxy-itraconazole. Bioassays may report up to 3.3 times as much itraconazole in plasma as do physical methods such as high-performance liquid chromatography, depending on the susceptibility of the bioassay organism to hydroxy-itraconazole. The native drug and metabolite are >99% bound to plasma proteins. Neither appears in urine or CSF. The  $t_{1/2}$  of itraconazole at steady state is ~30-40 hours. Steady-state levels of itraconazole are not reached for 4 days and those of hydroxy-itraconazole for 7 days; thus, loading doses are recommended when treating deep mycoses. Severe liver disease will increase itraconazole plasma concentrations, but azotemia and hemodialysis have no effect. Itraconazole is not carcinogenic but is teratogenic in rats and contraindicated for the treatment of

onychomycosis during pregnancy or for women contemplating pregnancy (Category C).

ITRACONAZOLE

**Drug Interactions.** [Tables 57-4](#), [57-5](#), and [57-6](#) list select interactions of azoles with other drugs. Many of the interactions can result in serious toxicity from the companion drug, such as inducing potentially fatal cardiac arrhythmias when used with quinidine, halofantrine (an orphan drug used for malaria), levomethadyl (an orphan drug used for heroin addiction), pimozone (*ORAP*) or cisapride (only available under an investigational limited access program in the U.S.). Other drugs may decrease itraconazole serum levels below therapeutic concentrations ([Table 57-5](#)).

**Therapeutic Uses.** Itraconazole is the drug of choice for patients with indolent, nonmeningeal infections due to *B. dermatitidis*, *H. capsulatum*, *P. brasiliensis*, and *C. immitis*. The drug also is useful in the therapy of indolent invasive aspergillosis outside the CNS, particularly after the infection has been stabilized with amphotericin B. Approximately half the patients with distal subungual onychomycosis respond to itraconazole (Evans and Sigurgeirsson, 1999). Although not an approved use, itraconazole is a reasonable choice for the treatment of pseudallescheriasis, an infection not responding to amphotericin B therapy, as well as cutaneous and extracutaneous sporotrichosis, tinea corporis, and extensive tinea versicolor. HIV-infected patients with disseminated histoplasmosis or *Penicillium marneffe* infections have a decreased incidence of relapse if given prolonged itraconazole “maintenance” therapy. According to the 2008 CDC/IDSA guidelines, discontinuation of itraconazole may be considered in AIDS patients with disseminated histoplasmosis who have completed 1 year of itraconazole, have responded to highly active antiretroviral therapy (HAART) with a CD4 >150/mm<sup>3</sup> for 6 months, have a urine histoplasma antigen <2 units and a negative blood culture for histoplasma (Kaplan et al.,

2009) ([Chapter 59](#)). Itraconazole is not recommended for maintenance therapy of cryptococcal meningitis in HIV-infected patients because of a high incidence of relapse. Long-term therapy has been used in non-HIV-infected patients with allergic bronchopulmonary aspergillosis to decrease the dose of glucocorticoids and reduce attacks of acute bronchospasm (Salez et al., 1999).

Itraconazole solution is effective and approved for use in oropharyngeal and esophageal candidiasis. Because the solution has more GI side effects than fluconazole tablets, itraconazole solution usually is reserved for patients not responding to fluconazole.

**Untoward Effects.** Adverse effects of itraconazole therapy can occur as a result of interactions with many other drugs ([Tables 57–3](#) and [57–4](#)). Serious hepatotoxicity has rarely led to hepatic failure and death. If symptoms of hepatotoxicity occur, the drug should be discontinued and liver function assessed. Intravenous itraconazole causes a dose-dependent inotropic effect that can lead to congestive heart failure in patients with impaired ventricular function. In the absence of interacting drugs, itraconazole capsules and suspension are well tolerated at 200 mg daily. Some patients complain of the taste of the solution, and GI side effects are common, although adherence is generally unimpaired. Diarrhea, abdominal cramps, anorexia, and nausea are more common than with the capsules. In one series of patients receiving 50-400 mg of the capsules per day, nausea and vomiting were recorded in 10%, hypertriglyceridemia in 9%, hypokalemia in 6%, increased serum aminotransferase in 5%, rash in 2%, and at least one side effect in 39%. Occasionally, rash necessitates drug discontinuation, but most adverse effects can be handled with dose reduction. Profound hypokalemia has been seen in patients receiving  $\geq 600$  mg daily and in those who recently have received prolonged amphotericin B therapy. Doses of 300 mg twice daily have led to other side effects, including adrenal insufficiency, lower limb edema, hypertension, and in at least one case, rhabdomyolysis. Doses  $>400$  mg per day are not recommended for long-term use. Anaphylaxis has been observed rarely, as well as severe rash, including Stevens-Johnson syndrome.

**Dosage.** In treating deep (life-threatening) mycoses, a loading dose of 200 mg of itraconazole is administered three times daily for the first 3 days. After the loading doses, two 100-mg capsules are given twice daily with food. The divided doses are alleged to increase the area under the plasma

concentration versus time curve (AUC), even though the  $t_{1/2}$  is  $\sim 30$  hours. For maintenance therapy of HIV-infected patients with disseminated histoplasmosis, 200 mg once daily is used. Onychomycosis can be treated with either 200 mg once daily for 12 weeks or for infections isolated to fingernails, two monthly cycles consisting of 200 mg twice daily for 1 week followed by a 3-week period of no therapy—so-called pulse therapy (Evans and Sigurgeirsson, 1999). Retention of active drug in the nail keratin permits intermittent treatment. Daily therapy is preferred by some authorities for infections likely to be more refractory, but it costs twice as much as pulse therapy. Once-daily terbinafine (250 mg), however, is superior to pulse therapy with itraconazole. For oropharyngeal candidiasis, itraconazole oral solution should be taken fasting in a dose of 100 mg (10 mL) once daily and swished vigorously in the mouth before swallowing to optimize any topical effect. Patients with esophageal thrush unresponsive or refractory to treatment with fluconazole tablets are given 100 mg of the solution twice a day for 2-4 weeks.

## Fluconazole

Fluconazole is a fluorinated bistriazole.

FLUCONAZOLE

**Absorption, Distribution, and Excretion.** Fluconazole is almost completely absorbed from the GI tract. Plasma concentrations are essentially the same whether the drug is given orally or intravenously, and its bioavailability is unaltered by food or gastric acidity. Peak plasma concentrations are 4-8  $\mu\text{g/mL}$  after repetitive doses of 100 mg. Renal excretion accounts for  $>90\%$  of elimination, and the elimination  $t_{1/2}$  is 25-30 hours. Fluconazole diffuses readily into body fluids, including breast milk, sputum, and saliva; concentrations in CSF can reach 50-90% of the simultaneous values in plasma. The dosage interval should be increased from 24-48 hours with a creatinine clearance of 21-40 mL/minute and to 72 hours at 10-20 mL/minute.

A dose of 100-200 mg should be given after each hemodialysis. About 11-12% of drug in the plasma is protein bound.

**Drug Interactions.** Fluconazole is an inhibitor of CYP3A4 and CYP2C9. Fluconazole's drug-drug interactions are shown in [Tables 57-3](#) and [57-4](#). Patients who receive >400 mg daily or azotemic patients who have elevated fluconazole blood levels may experience drug interactions not otherwise seen.

**Therapeutic Uses. Candidiasis.** Fluconazole, 200 mg on the first day and then 100 mg daily for at least 2 weeks, is effective in oropharyngeal candidiasis. Doses of 100-200 mg daily have been used to decrease candiduria in high-risk patients. A single dose of 150 mg is effective in uncomplicated vaginal candidiasis. A dose of 400 mg daily decreases the incidence of deep candidiasis in allogeneic bone marrow transplant recipients and is useful in treating candidemia of nonimmunosuppressed patients. In patients who have not been receiving fluconazole prophylaxis, the drug has been used successfully as empirical treatment of febrile neutropenia in patients not responding to antibacterial agents and who are not judged to be at high risk of mould infections. Although response to *C. glabrata* bloodstream infections in randomized trials using fluconazole has been comparable to that with *C. albicans*, *C. glabrata* becomes resistant upon prolonged exposure to fluconazole. Empirical use of fluconazole for suspected candidemia may not be advisable in patients who have been receiving long-term fluconazole prophylaxis and may be colonized with azole-resistant *C. glabrata*. Based on resistance *in vitro*, *Candida krusei* would not be expected to respond to fluconazole or other azoles.

**Cryptococcosis.** Following IDSA guidelines (Perfect et al., 2010), fluconazole, 400 mg daily, is used for the initial 8 weeks in the treatment of cryptococcal meningitis in patients with AIDS after the patient's clinical condition has been stabilized with at least 2 weeks of intravenous amphotericin B. After 8 weeks in patients no longer symptomatic, the dose is decreased to 200 mg daily and continued indefinitely. If the patient has completed 12 months of treatment for cryptococcosis, responds to HAART, has a CD4 count maintained  $>200/\text{mm}^3$  for at least 6 months, and is asymptomatic from cryptococcal meningitis, it is reasonable to discontinue maintenance fluconazole as long as the CD4 response is maintained. Some would add that an undetectable viral load for 3 months is required.

Fluconazole, 400 mg daily, has been recommended as continuation therapy in non-AIDS patients with cryptococcal meningitis who have responded to an initial course of C-AMB or L-AMB and for patients with pulmonary cryptococcosis.

**Other Mycoses.** Fluconazole is the drug of choice for treatment of coccidioidal meningitis because of good penetration into the CSF and much less morbidity than with intrathecal amphotericin B. In other forms of coccidioidomycosis, fluconazole is comparable to itraconazole. Fluconazole has no useful activity against histoplasmosis, blastomycosis, or sporotrichosis. Fluconazole is not effective in the prevention or treatment of aspergillosis. Fluconazole has some activity in ringworm but is not approved for that indication. As with other azoles, with the possible exception of posaconazole, there is no activity in mucormycosis.

**Untoward Effects.** Side effects in patients receiving >7 days of drug, regardless of dose, include the following: nausea 3.7%, headache 1.9%, skin rash 1.8%, vomiting 1.7%, abdominal pain 1.7%, and diarrhea 1.5%. Use of high doses may be limited by nausea. Reversible alopecia may occur with prolonged therapy at 400 mg daily. Rare cases of deaths due to hepatic failure or Stevens-Johnson syndrome have been reported. Fluconazole is teratogenic in rodents and has been associated with skeletal and cardiac deformities in at least three infants born to two women taking high doses during pregnancy. Fluconazole is a Category C agent that should be avoided during pregnancy unless the potential benefit justifies the possible risk to the fetus.

**Dosage.** Fluconazole (DIFLUCAN, others) is marketed in the U.S. as tablets of 50, 100, 150, and 200 mg for oral administration, powder for oral suspension providing 10 and 40 mg/mL, and intravenous solutions containing 2 mg/mL in saline and in dextrose solution. The daily dose of fluconazole should be based on the infecting organism and the patient's response to therapy. Generally recommended dosages are 50-400 mg once daily for either oral or intravenous administration. A loading dose of twice the daily maintenance dose is generally administered on the first day of therapy. Prolonged maintenance therapy may be required to prevent relapse. Children are treated with 3-12 mg/kg once daily (maximum: 600 mg/day).

## **Voriconazole**

Voriconazole (*VFEND*) is a triazole with a structure similar to fluconazole but with increased activity *in vitro*, an expanded spectrum, and poor aqueous solubility.

VORICONAZOLE

**Absorption, Distribution, and Excretion.** Oral bioavailability is 96% and protein binding 56% (Jeu et al., 2003). Volume of distribution is high (4.6 L/kg), with extensive drug distribution in tissues. Metabolism occurs through CYP2C19 and to a lesser extent CYP2C9; CYP3A4 plays a limited role. Less than 2% of parent drug is recovered from urine, although 80% of the inactive metabolites are excreted in the urine. The oral dose does not have to be adjusted for azotemia or hemodialysis. Peak plasma concentrations after oral doses of 200 mg orally twice daily are  $\sim 3$   $\mu\text{g/mL}$ . CSF concentrations of 1-3  $\mu\text{g/mL}$  have been reported in a patient with fungal meningitis.

Plasma elimination  $t_{1/2}$  is 6 hours. Voriconazole exhibits nonlinear metabolism so that higher doses cause greater-than-linear increases in systemic drug exposure. Genetic polymorphisms in CYP2C19 can cause up to 4-fold differences in drug exposure; 15-20% of Asians are homozygous poor metabolizers, compared with 2% of whites and African Americans. Patients  $>65$  years and patients with mild or moderate hepatic insufficiency have elevated areas under the curve (AUCs). Patients with mild-to-moderate cirrhosis should receive the same loading dose of voriconazole but half the maintenance dose. There are no data to guide dosing in patients with severe hepatic insufficiency.

The intravenous formulation of voriconazole contains sulfobutyl ether  $\beta$ -cyclodextrin (SBECD). When voriconazole is given intravenously, SBECD is excreted completely by the kidney. Significant accumulation of SBECD occurs with a creatinine clearance  $<50$  mL/minute. Because toxicity of

SBECD at high plasma concentrations is unclear, oral voriconazole is preferred in azotemic patients.

**Drug Interactions.** Voriconazole is metabolized by, and inhibits, CYPs 2C19, 2C9, and CYP3A4 (in that order of decreasing potency) The major metabolite of voriconazole, the voriconazole N-oxide, also inhibits these CYPs. Inhibitors or inducers of these CYPs may increase or decrease voriconazole plasma concentrations, respectively. In addition, there is potential for voriconazole and its major metabolite to increase the plasma concentrations of other drugs metabolized by these enzymes ([Tables 57–3, 57–4, and 57–5](#)). Because the sirolimus AUC increases 11-fold when voriconazole is given, co-administration is contraindicated. *When starting voriconazole in a patient receiving  $\geq 40$  mg/day of omeprazole, the dose of omeprazole should be reduced by half.*

**Therapeutic Uses.** In an open randomized trial, voriconazole provided superior efficiency to C-AMB in the primary therapy of invasive aspergillosis (Herbrecht et al., 2002). In a secondary analysis, survival also was superior in the voriconazole arm. Voriconazole was compared to L-AMB in an open randomized trial in the empirical therapy of neutropenic patients whose fever did not respond to >96 hours of antibacterial therapy. Because the 95% confidence interval in this noninferiority trial permitted the possibility that voriconazole might be >10% worse than L-AMB, the Food and Drug Administration did not approve voriconazole for this use (Walsh et al., 2002). However, in a secondary analysis, there were fewer breakthrough infections with voriconazole (1.9%) than with L-AMB (5%). Voriconazole is approved for use in esophageal candidiasis on the basis of a double-blind randomized comparison with fluconazole (Ally et al., 2001). In non-neutropenic patients with candidemia, voriconazole was comparable in efficacy and less toxic than initial C-AMB followed by fluconazole (Kullberg, 2005). Voriconazole is approved for initial treatment of candidemia and invasive aspergillosis, as well as for salvage therapy in patients with *Pseudallescheria boydii* (*Scedosporium apiospermum*) and *Fusarium* infections. Positive response of patients with cerebral fungal suggest that the drug penetrates infected brain.

**Untoward Effects.** Voriconazole is teratogenic in animals and generally contraindicated in pregnancy (Category D). Women of childbearing potential should use effective contraception during treatment. Although voriconazole is

generally well tolerated, occasional cases of hepatotoxicity have been reported, and liver function should be monitored. Voriconazole, like some other azoles, causes a prolongation of the QTc interval, which can become significant in patients with other risk factors for torsades de pointes. Patients must be warned about possible visual effects. Transient visual or auditory hallucinations are frequent after the first dose, usually at night and particularly with intravenous administration. Symptoms diminish with time (Zonios et al., 2008). Patients receiving their first intravenous infusion have had anaphylactoid reactions, with faintness, nausea, flushing, feverishness, and rash. In such patients, the infusion should be stopped. Rash has been reported in 5.8% of patients.

**Dosage.** Voriconazole for intravenous infusion is packaged as 200 mg with 3.2 g SBECD. Treatment is usually initiated with an intravenous infusion of 6 mg/kg every 12 hours for two doses, followed by 3-4 mg/kg every 12 hours. It should be administered no faster than 3 mg/kg/hr (e.g., over 1-2 hours, not as an intravenous bolus). As the patient improves, oral administration is continued as 200 mg every 12 hours. Patients failing to respond may be given 300 mg every 12 hours. Voriconazole is available as 50- or 200-mg tablets or a suspension of 40 mg/mL when hydrated. The tablets, but not the suspension, contain lactose. Because high-fat meals reduce voriconazole bioavailability, oral drug should be given either 1 hour before or 1 hour after meals. Children metabolize voriconazole more rapidly than adults (Walsh, 2004a).

## Posaconazole

Posaconazole (NOXAFIL) is a synthetic structural analog of itraconazole with the same broad antifungal spectrum but with up to 4-fold greater activity *in vitro* against yeasts and filamentous fungi, including the agents of mucormycosis (Guinea et al., 2008; Frampton, 2008). Activity against yeasts *in vitro* is similar to voriconazole. The mechanism of action is the same as other imidazoles, inhibition of sterol 14- $\alpha$  demethylase.

**Absorption, Distribution, and Excretion.** Posaconazole is available as a cherry-flavored suspension containing 40 mg/mL. Bioavailability is significantly enhanced by the presence of food (Courtney et al., 2003; Krieter, 2004). The drug has a long terminal phase  $t_{1/2}$  (25-31 hours), a large volume of distribution (331-1341 L), and extensive binding (>98%) to

protein, predominantly albumin. Systemic exposure is four times higher in homozygous CYP2C19 slow metabolizers than in homozygous wild-type metabolizers. Steady-state concentrations are reached in 7-10 days when dosed four times daily. Saturation of absorption occurs at 800 mg/day (Ezzet et al., 2005; Ullmann et al., 2006). Renal impairment does not alter plasma concentrations; hepatic impairment causes a modest increase (Moton, 2008). With radiolabeled drug given to volunteers, 77% was excreted in the stool, with 66% of the administered dose appearing as unchanged drug. The major metabolic pathway is hepatic UDP glucuronidation (Krieter, 2004). Hemodialysis does not remove detectable amounts of this highly protein-bound drug from the circulation. Gastric acid improves absorption in that an acidic beverage, ginger ale, increased the AUC by 70% in the fasting state (Krishna et al., 2009b). Drugs that reduce gastric acid (e.g., cimetidine and esomeprazole) decreased posaconazole exposure by 32-50% (Frampton and Scott, 2008). Diarrhea reduced the average plasma concentration by 37% (Smith et al., 2009). Plasma concentrations in allogeneic stem cell transplant recipients were 52% lower than in patients not receiving a stem cell transplant (Ullmann et al., 2006). Although monitoring plasma concentrations has been advocated (Smith et al., 2009), the lower limit of therapeutic effect for any indication is unknown.

**Therapeutic Use.** Posaconazole is not inferior to fluconazole for treatment of oropharyngeal candidiasis, although fluconazole is the preferred drug because of safety, cost, and extensive experience. The dose is 100 mg twice daily the first day and once daily thereafter for 13 days. Posaconazole is approved for prophylaxis against candidiasis and aspergillosis in patients >13 years of age who have prolonged neutropenia or severe graft-vs-host disease (GVHD) (Ullmann et al., 2007). Posaconazole and other “azoles” have recently been compared for prophylaxis effect in patients with neutropenia (Cornely et al., 2007b). The broad applicability of posaconazole for prophylaxis of patients with prolonged neutropenia or GVHD remains unsettled, although the drug clearly remains an option for those indications (De Pauw, 2007).

Posaconazole is approved in the E.U. as salvage therapy for aspergillosis and several other infections, as are itraconazole and voriconazole. A number of clinical reports of favorable response to posaconazole as salvage therapy in mucormycosis have appeared in the literature, leaving the issue

unresolved (Dannaoui et al., 2003; Greenberg et al., 2006). Lack of an intravenous formulation continues to limit studies of critically ill patients.

**Drug Interactions.** Posaconazole inhibits CYP3A4. Co-administration with rifabutin or phenytoin increases the plasma concentration of these drugs and decreases posaconazole exposure by 2-fold. The mechanism of induced posaconazole clearance is unknown but may involve hepatic phase 2 glucuronidation, rather than phase 1 oxidative enzymes. Oxidative products have not been recovered in the serum of treated patients. Posaconazole increases the AUC of cyclosporine, tacrolimus (121%), sirolimus (790%), midazolam (83%) and other CYP3A4 substrates ([Table 57–4](#)) (Frampton and Scott, 2008; Krishna et al., 2009a; Moton et al., 2009). Posaconazole is not known to prolong cardiac repolarization, as other azoles may, but posaconazole should not be co-administered with drugs that are CYP3A4 substrates and prolong the QTc interval, such as methadone, haloperidol, pimozide, quinidine, risperidone, sunitinib, tacrolimus, and halofantrine ([Table 57–6](#)).

**Untoward Effects.** The safety profile of posaconazole is good, with nausea, vomiting, diarrhea, abdominal pain, and headache the most commonly reported adverse effects (Smith et al., 2009). Although adverse effects occur in at least a third of patients, discontinuation due to adverse effects in long-term studies has been only 8%. Posaconazole causes fetal bone malformation in pregnant rats and is pregnancy Category C. Safety in children <8 years of age has not been established.

**Dosage.** Dosage for adults and children >8 years of age is 200 mg (5 mL suspension) three times daily for prophylaxis. Treatment of active infection is begun at 200 mg four times daily and changed to 400 mg twice daily once infection has improved. All doses should be taken with a full meal.

## Isavuconazole

Isavuconazole (BAL8557) is an investigational water-soluble pro-drug of the synthetic triazole, BAL4815.

The pro-drug is readily cleaved by esterases in the human body to release the active triazole. *In vitro* activity is comparable to voriconazole (Guinea et al., 2008; Perkhofner et al., 2009).

**Absorption, Distribution, and Excretion.** Oral administration of once-daily doses equivalent to 100 mg BAL4815 for loading followed by 50 mg daily and 200 mg loading followed by 100 mg resulted in peak plasma concentrations at 21 days of 1.37  $\mu\text{g}/\text{mL}$  and 3.5  $\mu\text{g}/\text{mL}$  at 2.25 and 3.5 hours, respectively. The AUCs<sub>0-24h</sub> were 21.6 and 40.3  $\mu\text{g}\cdot\text{h}/\text{mL}$ , respectively (Schmitt-Hoffman et al., 2006). With intravenous administration there was close to a linear dose response, with a 5-fold accumulation over 14 days, a  $t_{1/2}$  of 84.5-117 hours, and a volume of distribution at steady state of 308-542 L. Excretion is by the liver with most drug appearing in feces.

**Therapeutic Use.** Isavuconazole has been found comparable to fluconazole in *Candida* esophagitis with all three isavuconazole regimens tested: loading dose of 200 followed by 50 mg daily, loading dose of 400 mg followed by 100 mg daily, or 400 mg once weekly for 14 days (Odds, 2006). The drug was well tolerated. Phase III trials are enrolling patients with deeply invasive candidiasis and aspergillosis.

## Echinocandins

Screening natural products of fungal fermentation in the 1970s led to the discovery that *echinocandins* had activity against *Candida* and that the biological activity was directed against formation of 1,3- $\beta$ -D-glucans in the fungal cell wall (Wiederhold and Lewis, 2003). The inhibition of glucan synthesis reduces structural integrity of the fungal cell wall ([Figure 57-3](#)), resulting in osmotic instability and cell death. Three echinocandins are approved for clinical use: caspofungin, anidulafungin, and micafungin. All are cyclic lipopeptides with a hexapeptide nucleus. All have the same mechanism of action but differ in pharmacological properties. Susceptible fungi include *Candida* species and *Aspergillus* species (Bennett, 2006).

**General Pharmacological Characteristics.** Echinocandins differ somewhat pharmacokinetically ([Table 57-7](#)) but all share lack of oral bioavailability, extensive protein binding (>97%), inability to penetrate into CSF, lack of renal clearance, and only a slight to modest effect of hepatic insufficiency on plasma drug concentration (Kim et al., 2007; Wagner et al., 2006). Adverse effects are minimal and rarely lead to drug discontinuation (Kim et al., 2007). All three agents are pregnancy Category C. For a review of the basic and clinical pharmacology of the echinocandins, see Wiederhold and Lewis (2007).

The minimum inhibitory concentration (MIC) of *Candida albicans* and several other *Candida* species are in the range of 0.015-0.5 µg/mL, higher for caspofungin than micafungin or anidulafungin. In *Candida* spp., echinocandins cause cell death at concentrations only 2- to 4-fold higher than that needed to inhibit growth. Azole-resistant *Candida* species remain susceptible to echinocandins. MIC of *Candida parapsilosis* and *C. guilliermondii* are consistently higher than other *Candida* spp., usually 2 µg/mL with all three echinocandins. In none of the clinical trials of the three echinocandins has the higher MIC of *C. parapsilosis* been reflected in lower response rates. An unexplained and paradoxical effect of increased growth at concentrations above the MIC has been seen more often in *C. parapsilosis* than with other *Candida* spp. and more commonly with caspofungin than micafungin or anidulafungin (Chamilos et al., 2007). In *Aspergillus*, echinocandins are not cidal but change the shape of hyphae; thus, *in vitro* susceptibility testing is done with a “morphological” end point (change in hyphal shape). Animal models do not suggest activity against dimorphic fungi such as *Histoplasma capsulatum*. Echinocandins have no activity against *Cryptococcus neoformans*, *Trichosporon* spp., or agents of mucormycosis. *In vitro* studies have consistently failed to show synergism or antagonism between echinocandins and amphotericin B. There is no antagonism between echinocandins and azoles; an additive effect has been reported with *Aspergillus* in some *in vitro* systems and animals models. Echinocandin resistance can be selected in *Candida albicans* under drug pressure both *in vitro* and clinically during prolonged echinocandin therapy. Resistance is from mutations in a conserved region of the *FKS1* gene, coding for amino acids Phe<sup>641</sup>-Asp<sup>658</sup> (Park et al., 2005). FKS1p is an essential component of the 1,3-β-D-glucan synthase complex ([Figure 57-3](#)).

**Figure 57–3.** *The fungal cell wall and membrane and the action of echinocandins.* The strength of the fungal cell wall is maintained by fibrillar polysaccharides, largely  $\beta$ -1,3-glucan and chitin, which bind covalently to each other and to proteins. A glucan synthase complex in the plasma membrane catalyzes the synthesis of beta-1,3-glucan; the glucan is extruded into the periplasm and incorporated into the cell wall. Echinocandins inhibit the activity of the glucan synthase complex, resulting in loss of the structural integrity of the cell wall. A subunit of glucan synthase designated Fks1p is thought to be the target of the echinocandin. Mutations in Fks1p, coded for by *FSK1*, cause resistance to echinocandins.

## Caspofungin

Caspofungin acetate (*CANCIDAS*) is a water-soluble, semisynthetic lipopeptide synthesized from the fermentation product of *Glarea lozoyensis* (Johnson and Perfect, 2003; Keating and Figgitt, 2003).

CASPOFUNGIN

**Table 57–7 Pharmacokinetics of Echinocandins in Humans**

DRUG	DOSE (mg)	C <sub>max</sub> (µg/mL)	AUC <sub>0-24h</sub> (mg·h/L)	t <sub>1/2</sub> (h)	Cl (mL/min/kg)	V <sub>d</sub> (L)
Caspofungin	70	12	93.5	10	0.15	9.5
Micafungin	75	7.1	59.9	13	0.16	14
Anidulafungin	200	7.5	104.5	25.6	0.16	33.4

For details, see Wagner et al. (2006).

**Metabolism and Excretion.** Catabolism is largely by hydrolysis and *N*-acetylation, with excretion of the metabolites in the urine and feces. Mild and moderate hepatic insufficiency increases the AUC by 55% and 76%, respectively.

**Drug Interactions.** Caspofungin increase tacrolimus levels by 16%, which should be managed by standard monitoring. Cyclosporine slightly increases caspofungin levels. Rifampin and other drugs activating CYP3A4 can cause a slight reduction in caspofungin levels.

**Therapeutic Use.** Caspofungin is approved for initial therapy of deeply invasive candidiasis and as salvage therapy for patients with invasive aspergillosis who are failing or intolerant of approved drugs, such as amphotericin B formulations or voriconazole. Approval for salvage therapy of aspergillosis was based on a study of 63 patients in a noncomparative salvage trial. Caspofungin is also approved for esophageal candidiasis, based on randomized trials that found noninferiority to fluconazole and C-

AMB (Villanueva et al., 2001). A blinded randomized clinical trial of caspofungin in deeply invasive candidiasis found noninferiority to C-AMB, leading to approval for that indication (Mora-Duarte et al., 2002). Most patients in that multicenter study were not neutropenic and had catheter-acquired candidemia. Efficacy was comparable to that of fluconazole in other studies of the same general patient population. Caspofungin is also approved for the treatment of persistently febrile neutropenic patients with suspected fungal infections, based on noninferiority to L-AMB in a randomized trial (Walsh et al., 2004b).

**Untoward Effects.** Caspofungin has been remarkably well tolerated, with the exception of phlebitis at the infusion site. Histamine-like effects have been reported with rapid infusions. Other symptoms have been equivalent to those observed in patients receiving fluconazole in the comparator arm.

**Dosage.** Caspofungin is administered intravenously once daily over 1 hour. In candidemia and salvage therapy of aspergillosis, the initial dose is 70 mg, followed by 50 mg daily. The dose should be increased to 70 mg daily in patients receiving rifampin as well as in those failing to respond to 50 mg. Esophageal candidiasis is treated with 50 mg daily. In moderate hepatic failure, the dose should be reduced to 35 mg daily.

## Micafungin

Micafungin (*MYCAMINE*) is a water-soluble semisynthetic echinocandin derived from the fungus *Coleophoma empedri*.

**Absorption, Distribution, and Excretion.** Micafungin has linear pharmacokinetics over a large range of doses (1-3 mg/kg) and ages (premature infants to elderly). Feces contain 71% of intravenously administered radiolabeled drug, including both native drug and metabolites (Wiederhold and Lewis, 2007). Small amounts of drug are metabolized in the liver by arylsulfatase and catechol *O*-methyltransferase. Hydroxylation by CYP3A4 is barely detectable. Reduction of dose in moderate hepatic failure is not required. Clearance is more rapid in premature infants and intermediate in children 2-8 years of age, compared to older children and adults.

**Drug Interactions.** In normal volunteers, micafungin appears to be a mild inhibitor of CYP3A4, increasing AUC of nifedipine by 18% and sirolimus by

21%. Micafungin has no effect on tacrolimus clearance.

**Therapeutic Use.** Micafungin is approved for the treatment of deeply invasive candidiasis (Fritz et al., 2008). Doses of 100 mg and 150 mg daily of micafungin were equivalent to caspofungin (Pappas et al., 2007). Micafungin, 100 mg/day, was also not inferior to L-AMB, 3 mg/kg (Kuse et al., 2007). Micafungin is also approved for treatment of esophageal candidiasis and prophylaxis of deeply invasive candidiasis in hematopoietic stem cell transplant recipients.

**Doses.** Micafungin is given intravenously as 100 mg daily over 1 hour for adults, with 50 mg recommended for prophylaxis and 150 mg for esophageal candidiasis. No loading dose is needed.

## Anidulafungin

Anidulafungin (*ERAXIS*) is a water-insoluble semisynthetic compound extracted from the fungus *Aspergillus nidulans*, from which the drug's name derives.

ANIDULAFUNGIN

**Absorption, Distribution and Excretion.** Anidulafungin is cleared from the body by slow chemical degradation, first by opening the hexapeptide ring and then proteolysis of peptide bonds (Vazquez and Sobel, 2006). No metabolism by the liver or renal excretion of active drug occurs. No dose adjustment for hepatic or renal failure is needed. The drug diluent for intravenous infusion contains 3 mg ethanol for every 50 mg anidulafungin, an amount of ethanol insufficient to have a pharmacological effect.

**Drug Interactions.** None are known.

**Therapeutic Use.** In a randomized double-blinded clinical trial, anidulafungin was noninferior to fluconazole in candidemia of non-neutropenic patients (Reboli et al., 2007). Anidulafungin is also approved for the treatment of esophageal candidiasis.

**Dose.** Drug dissolved in the supplied diluent is infused once daily in saline or 5% dextrose in water at a rate not exceeding 1.1 mg/minute. For deeply invasive candidiasis, anidulafungin is given daily as a loading dose of 200 mg followed by 100 mg daily. For esophageal candidiasis, a loading dose of 100 mg is followed by 50 mg daily.

## Griseofulvin

The drug is practically insoluble in water.

**Mechanism of Action.** Griseofulvin inhibits microtubule function and thereby disrupts assembly of the mitotic spindle. Thus, a prominent morphological manifestation of the action of griseofulvin is the production of multinucleate cells as the drug inhibits fungal mitosis. Although the effects of the drug are similar to those of *colchicine* and the vinca alkaloids, griseofulvin's binding sites on the microtubular protein are distinct. In addition to its binding to tubulin, griseofulvin interacts with microtubule-associated protein.

**Absorption, Distribution, and Excretion.** The oral administration of a 0.5 g dose of griseofulvin produces peak plasma concentrations of  $\sim 1 \mu\text{g/mL}$  in  $\sim 4$  hours. Blood levels are quite variable, however. Some studies have shown improved absorption when the drug is taken with a fatty meal. Because the rates of dissolution and disaggregation limit the bioavailability of griseofulvin, micro-sized and ultra-micro-sized powders are now used in preparations (*GRIFULVIN V* and *GRIS-PEG*, respectively). Although the bioavailability of the ultra-microcrystalline preparation is said to be 50% greater than that of the conventional micro-sized powder, this may not always be true. Griseofulvin has a plasma  $t_{1/2}$  of  $\sim 1$  day, and  $\sim 50\%$  of the oral dose can be detected in the urine within 5 days, mostly in the form of metabolites. The primary metabolite is 6-methylgriseofulvin. Barbiturates decrease griseofulvin absorption from the GI tract.

Griseofulvin is deposited in keratin precursor cells; when these cells differentiate, the drug is tightly bound to, and persists in, keratin, providing prolonged resistance to fungal invasion. For this reason, the new growth of hair or nails is the first to become free of disease. As the fungus-containing keratin is shed, it is replaced by normal tissue. Griseofulvin is detectable in the stratum corneum of the skin within 4-8 hours of oral administration. Sweat and transepidermal fluid loss play an important role in the transfer of

the drug in the stratum corneum. Only a very small fraction of a dose of the drug is present in body fluids and tissues.

**Antifungal Activity.** Griseofulvin is fungistatic *in vitro* for various species of the dermatophytes *Microsporum*, *Epidermophyton*, and *Trichophyton*. The drug has no effect on bacteria or on other fungi. Although failure of ringworm lesions to improve is not rare, isolates from these patients usually are still susceptible to griseofulvin *in vitro*.

**Therapeutic Uses.** Mycotic disease of the skin, hair, and nails due to *Microsporum*, *Trichophyton*, or *Epidermophyton* responds to griseofulvin therapy. For tinea capitis in children, griseofulvin remains the drug of choice for efficacy, safety, and availability as an oral suspension; efficacy is best for tinea capitis caused by *Microsporum canis*, *Microsporum audouinii*, *Trichophyton schoenleinii*, and *Trichophyton verrucosum*. Griseofulvin is also effective for ringworm of the glabrous skin; tinea cruris and tinea corporis caused by *M. canis*, *Trichophyton rubrum*, *T. verrucosum*, and *Epidermophyton floccosum*; and tinea of the hands (*T. rubrum* and *T. mentagrophytes*) and beard (*Trichophyton* species). Griseofulvin also is highly effective in tinea pedis, the vesicular form of which is most commonly due to *T. mentagrophytes* and the hyperkeratotic type to *T. rubrum*. Topical therapy is sufficient for most cases of tinea pedis. *T. rubrum* and *T. mentagrophytes* infections may require higher-than-conventional doses of griseofulvin.

**Dosage.** The recommended daily dose of griseofulvin is 2.3 mg/kg (up to 500 mg) for children and 500 mg to 1 g for adults. Doses of 1.5-2 g daily may be used for short periods in severe or extensive infections. Best results are obtained when the daily dose is divided and given at 6-hour intervals, although the drug often is given once or twice per day. Treatment must be continued until infected tissue is replaced by normal hair, skin, or nails, which requires 1 month for scalp and hair ringworm, 6-9 months for fingernails, and at least a year for toenails. Itraconazole or terbinafine is much more effective for onychomycosis.

**Untoward Effects.** The incidence of serious reactions due to griseofulvin is very low. One of the minor effects is headache (incidence as high as 15%), which is sometimes severe and usually disappears as therapy is continued. Other nervous system manifestations include peripheral neuritis, lethargy, mental confusion, impairment of performance of routine tasks, fatigue,

syncope, vertigo, blurred vision, transient macular edema, and augmentation of the effects of alcohol. Among the side effects involving the alimentary tract are nausea, vomiting, diarrhea, heartburn, flatulence, dry mouth, and angular stomatitis. Hepatotoxicity also has been observed. Hematological effects include leukopenia, neutropenia, punctate basophilia, and monocytosis; these often disappear despite continued therapy. Blood studies should be carried out at least once a week during the first month of treatment or longer. Common renal effects include albuminuria and cylindruria without evidence of renal insufficiency. Reactions involving the skin are cold and warm urticaria, photosensitivity, lichen planus, erythema, erythema multiforme-like rashes, and vesicular and morbilliform eruptions. Serum sickness syndromes and severe angioedema develop rarely during treatment with griseofulvin. Estrogen-like effects have been observed in children. A moderate but inconsistent increase of fecal protoporphyrins has been noted with chronic use.

Griseofulvin induces hepatic CYPs, thereby increasing the rate of metabolism of warfarin; adjustment of the dosage of the latter agent may be necessary in some patients. The drug may reduce the efficacy of low-estrogen oral contraceptive agents, probably by a similar mechanism.

## Terbinafine

Terbinafine is a synthetic allylamine, structurally similar to the topical agent naftifine.

TERBINAFINE

Terbinafine is well absorbed, but bioavailability is decreased to ~40% because of first-pass metabolism in the liver. Proteins bind >99% of the drug in plasma. Drug accumulates in skin, nails, and fat. The initial  $t_{1/2}$  is ~12 hours but extends to 200-400 hours at steady state. Terbinafine is not recommended in patients with marked azotemia or hepatic failure because in the latter condition, terbinafine plasma levels are increased by unpredictable

amounts. Rifampin decreases and cimetidine increases plasma terbinafine concentrations. The drug is well tolerated, with a low incidence of GI distress, headache, or rash. Very rarely, fatal hepatotoxicity, severe neutropenia, Stevens-Johnson syndrome, or toxic epidermal necrolysis may occur. The drug is pregnancy Category B and it is recommended that systemic terbinafine therapy for onychomycosis be postponed until after pregnancy is complete. Its mechanism of action is inhibition of fungal squalene epoxidase, blocking ergosterol biosynthesis. Increased intracellular squalene also impairs cell growth.

Terbinafine (LAMISIL, others), given as one 250-mg tablet daily for adults, is somewhat more effective for nail onychomycosis than 200 mg daily of itraconazole, and definitely more effective than pulse itraconazole therapy (Fernandez-Obregon et al., 2007). Duration of treatment varies with the site being treated but typically is 6-12 weeks. Efficacy in onychomycosis can be improved by the simultaneous use of amorolfine 5% nail lacquer (Baran et al., 2007). Terbinafine (250 mg daily) also is effective in tinea capitis and is used off-label for ringworm elsewhere on the body. Oral granules are available for use against tinea capitis, usually a disease of children. The recommended dose is 125-250 mg (depending on weight) daily for 6 weeks. The topical use of terbinafine is discussed later.

## **Topical Antifungal Agents**

Topical treatment is useful in many superficial fungal infections, i.e., those confined to the stratum corneum, squamous mucosa, or cornea. Such diseases include dermatophytosis (ringworm), candidiasis, tinea versicolor, piedra, tinea nigra, and fungal keratitis. Topical administration of antifungal agents usually is not successful for mycoses of the nails (onychomycosis) and hair (tinea capitis) and has no place in the treatment of subcutaneous mycoses, such as sporotrichosis and chromoblastomycosis. The efficacy of topical agents in the treatment of superficial mycoses depends not only on the type of lesion and the mechanism of action of the drug but also on the viscosity, hydrophobicity, and acidity of the formulation. Regardless of formulation, penetration of topical drugs into hyperkeratotic lesions often is poor. Removal of thick, infected keratin is sometimes a useful adjunct to therapy and is the principal mode of action of Whitfield's ointment. Similarly, 40% urea paste can be applied under occlusion to soften infected nails.

Among the topical agents, the preferred formulation for cutaneous application usually is a cream or solution. Ointments are messy and are too occlusive for macerated or fissured intertriginous lesions. The use of powders, whether applied by shake containers or aerosols, is largely confined to the feet and moist lesions of the groin and other intertriginous areas.

The systemic agents used for the treatment of superficial mycoses were discussed earlier. Some of these agents also are administered topically; their uses are described here and also in [Chapter 65](#).

### **Imidazoles and Triazoles for Topical Use.**

These closely related classes of drugs are synthetic antifungal agents that are used both topically and systemically. Indications for their topical use include ringworm, tinea versicolor, and mucocutaneous candidiasis. Resistance to imidazoles or triazoles is very rare among the fungi that cause ringworm. Selection of one of these agents for topical use should be based on cost and availability because testing *in vitro* for fungal susceptibility to these drugs does not predict clinical responses.

**Cutaneous Application.** The preparations for cutaneous use described below are effective for tinea corporis, tinea pedis, tinea cruris, tinea versicolor, and cutaneous candidiasis. They should be applied twice a day for 3-6 weeks. Despite some activity *in vitro* against bacteria, this effect is not clinically useful. The cutaneous formulations are not suitable for oral, vaginal, or ocular use.

**Vaginal Application.** Vaginal creams, suppositories, and tablets for vaginal candidiasis are all used once a day for 1-7 days, preferably at bedtime to facilitate retention. None is useful in trichomoniasis, despite some activity *in vitro*. Most vaginal creams are administered in 5-g amounts. Three vaginal formulations—clotrimazole tablets, miconazole suppositories, and terconazole cream—come in both low- and high-dose preparations. A shorter duration of therapy is recommended for the higher dose of each. These preparations are administered for 3-7 days. Approximately 3-10% of the vaginal dose is absorbed. Although some imidazoles are teratogenic in rodents, no adverse effects on the human fetus have been attributed to the vaginal use of imidazoles or triazoles. The most common side effect is vaginal burning or itching. A male sexual partner may experience mild penile

irritation. Cross-allergenicity among these compounds is assumed to exist, based on their structural similarities.

**Oral Use.** Use of the oral troche of clotrimazole is properly considered as topical therapy. The only indication for this 10-mg troche is oropharyngeal candidiasis. Antifungal activity is due entirely to the local concentration of the drug; there is no systemic effect.

## Clotrimazole

CLOTRIMAZOLE

Absorption of clotrimazole is <0.5% after application to the intact skin; from the vagina, it is 3-10%. Fungicidal concentrations remain in the vagina for as long as 3 days after application of the drug. The small amount absorbed is metabolized in the liver and excreted in bile. In adults, an oral dose of 200 mg/day will give rise initially to plasma concentrations of 0.2-0.35  $\mu\text{g/mL}$ , followed by a progressive decline.

In a small fraction of recipients, clotrimazole on the skin may cause stinging, erythema, edema, vesication, desquamation, pruritus, and urticaria. When it is applied to the vagina, ~1.6% of recipients complain of a mild burning sensation, and rarely of lower abdominal cramps, a slight increase in urinary frequency, or skin rash. Occasionally, the sexual partner may experience penile or urethral irritation. By the oral route, clotrimazole can cause GI irritation. In patients using troches, the incidence of this side effect is ~5%.

**Therapeutic Uses.** Clotrimazole is available as a 1% cream, lotion, powder, aerosol solution, and solution (LOTRIMIN AF, MYCELEX, others), 1% or 2% vaginal cream, or vaginal tablets of 100, 200, or 500 mg (GYNE-LOTRIMIN, others), and 10-mg troches (MYCELEX, others). On the skin, applications are made twice a day. For the vagina, the standard regimens are one 100-mg tablet once a day at bedtime for 7 days, one 200-mg tablet daily for 3 days,

one 500-mg tablet inserted only once, or 5 g of cream once a day for 3 days (2% cream) or 7 days (1% cream). For oropharyngeal candidiasis, troches are to be dissolved slowly in the mouth five times a day for 14 days.

Topical clotrimazole cures dermatophyte infections in 60-100% of cases. The cure rates in cutaneous candidiasis are 80-100%. In vulvovaginal candidiasis, the cure rate is usually >80% when the 7-day regimen is used. A 3-day regimen of 200 mg once a day appears to be similarly effective, as does single-dose treatment (500 mg). Recurrences are common after all regimens. The cure rate with oral troches for oral and pharyngeal candidiasis may be as high as 100% in the immunocompetent host.

## Econazole

Econazole is the deschloro derivative of miconazole. Econazole readily penetrates the stratum corneum and is found in effective concentrations down to the mid-dermis. However, <1% of an applied dose appears to be absorbed into the blood. Approximately 3% of recipients have local erythema, burning, stinging, or itching. Econazole nitrate (SPECTAZOLE, ECOSTATIN, others) is available as a water-miscible cream (1%) to be applied twice a day.

## Miconazole

MICONAZOLE

Miconazole readily penetrates the stratum corneum of the skin and persists there for >4 days after application. Less than 1% is absorbed into the blood. Absorption is no more than 1.3% from the vagina.

Adverse effects from topical application to the vagina include burning, itching, or irritation in ~7% of recipients, and infrequently, pelvic cramps (0.2%), headache, hives, or skin rash. Irritation, burning, and maceration are rare after cutaneous application. Miconazole is considered safe for use

during pregnancy, although some authors avoid its vaginal use during the first trimester.

**Therapeutic Uses.** Miconazole nitrate is available as a 2% cream, ointment, lotion, powder, gel, aerosol powder, and aerosol solution (MICATIN, ZEASORB-AF, others). To avoid maceration, only the lotion should be applied to intertriginous areas. Miconazole is available as a 2% and 4% vaginal cream, and as 100-mg, 200-mg, or 1200-mg vaginal suppositories (MONISTAT 7, MONISTAT 3, MONISTAT 1, others), to be applied high in the vagina at bedtime for 7, 3, or 1 day(s), respectively.

In the treatment of tinea pedis, tinea cruris, and tinea versicolor, the cure rate may be >90%. In the treatment of vulvovaginal candidiasis, the mycologic cure rate at the end of 1 month is ~80-95%. Pruritus sometimes is relieved after a single application. Some vaginal infections caused by *Candida glabrata* also respond.

## **Terconazole and Butoconazole**

Terconazole (TERAZOL, others) is a ketal triazole. The mechanism of action of terconazole is similar to that of the imidazoles. The 80-mg vaginal suppository is inserted at bedtime for 3 days; the 0.4% vaginal cream is used for 7 days and the 0.8% cream for 3 days. Clinical efficacy and patient acceptance of both preparations are at least as good as for clotrimazole in patients with vaginal candidiasis.

Butoconazole is an imidazole that is pharmacologically quite comparable to clotrimazole. Butoconazole nitrate (FEMSTAT 3, others) is available as a 2% vaginal cream; it is used at bedtime in nonpregnant females. Because of the slower response during pregnancy, a 6-day course is recommended (during the second and third trimester).

## **Tioconazole**

Tioconazole (VAGISTAT 1, others) is an imidazole marketed for treatment of *Candida* vulvovaginitis. A single 4.6-g dose of ointment (300 mg) is given at bedtime.

## **Oxiconazole, Sulconazole, and Sertaconazole**

These imidazole derivatives are used for the topical treatment of infections caused by the common pathogenic dermatophytes. Oxiconazole nitrate (OXISTAT) is available as a 1% cream and lotion; sulconazole nitrate (EXELDERM, SULCOSYN) is supplied as a 1% solution and/or cream. Sertaconazole (ERTACZO) is a 2% cream marketed for tinea pedis.

## Ketoconazole

This imidazole is available as a 0.5% cream, foam, gel, and shampoo (NIZORAL, others) for common skin dermatophytes infections, for tinea versicolor, and seborrheic dermatitis.

## Ciclopirox Olamine

CICLOPIROX OLAMINE

*Ciclopirox olamine* (LOPROX, others) has broad-spectrum antifungal activity. It is fungicidal to *C. albicans*, *E. floccosum*, *M. canis*, *T. mentagrophytes*, and *T. rubrum*. It also inhibits the growth of *Malassezia furfur*. After application to the skin, it penetrates through the epidermis into the dermis, but even under occlusion, <1.5% is absorbed into the systemic circulation. Because the  $t_{1/2}$  is 1.7 hours, no systemic accumulation occurs. The drug penetrates into hair follicles and sebaceous glands. It can sometimes cause hypersensitivity. It is available as a 0.77% cream, gel, suspension, and lotion for the treatment of cutaneous candidiasis and for tinea corporis, cruris, pedis, and versicolor. An 8% nail lacquer is available for onychomycosis. Cure rates in the dermatomycoses and candidal infections are 81-94%. No topical toxicity has been noted.

Ciclopirox 0.77% gel and 1% shampoo are also used for the treatment of seborrheic dermatitis of the scalp. An 8% topical solution (PENLAC NAIL LACQUER, others) is an effective treatment for mild to moderate superficial white onychomycosis. An oral agent would be preferred for distal or lateral onychomycosis.

## Haloprogin

*Haloprogin* is a halogenated phenolic ether:

HALOPROGIN

It is fungicidal to various species of *Epidermophyton*, *Pityrosporum*, *Microsporum*, *Trichophyton*, and *Candida*. During treatment with this drug, irritation, pruritus, burning sensations, vesiculation, increased maceration, and “sensitization” (or exacerbation of the lesion) occasionally occur, especially on the foot if occlusive footwear is worn. Haloprogin is poorly absorbed through the skin; it is converted to trichlorophenol in the body. The systemic toxicity from topical application appears to be low.

Haloprogin (HALOTEX) cream or solution is applied twice a day for 2-4 weeks. Its principal use is against tinea pedis, for which the cure rate is ~80%; it is thus approximately equal in efficacy to tolnaftate. It also is used against tinea cruris, tinea corporis, tinea manuum, and tinea versicolor. Haloprogin is no longer available in the U.S.

## Tolnaftate

Tolnaftate is a thiocarbamate with the following structure:

TOLNAFTATE

Tolnaftate is effective in the treatment of most cutaneous mycoses caused by *T. rubrum*, *T. mentagrophytes*, *T. tonsurans*, *E. floccosum*, *M. canis*, *M. audouinii*, *Microsporum gypseum*, and *M. furfur*, but it is ineffective against *Candida*. In tinea pedis, the cure rate is ~80%, compared with ~95% for miconazole. Toxic or allergic reactions to tolnaftate have not been reported.

Tolnaftate (AFTATE, TINACTIN, others) is available in a 1% concentration as a cream, gel, powder, aerosol powder, and topical solution, or as a topical aerosol liquid. The preparations are applied locally twice a day. Pruritus is

usually relieved in 24-72 hours. Involution of interdigital lesions caused by susceptible fungi is very often complete in 7-21 days.

## Naftifine

NAFTIFINE

Naftifine is representative of the allylamine class of synthetic agents that inhibit squalene-2,3-epoxidase and thus inhibit fungal biosynthesis of ergosterol. The drug has broad-spectrum fungicidal activity *in vitro*. Naftifine hydrochloride (*NAFTIN*) is available as a 1% cream or gel. It is effective for the topical treatment of tinea cruris and tinea corporis; twice-daily application is recommended. The drug is well tolerated, although local irritation has been observed in 3% of treated patients. Allergic contact dermatitis also has been reported. Naftifine also may be efficacious for cutaneous candidiasis and tinea versicolor, although the drug is not approved for these uses.

## Terbinafine

Terbinafine 1% cream or spray is applied twice daily and is effective in tinea corporis, tinea cruris, and tinea pedis. Terbinafine is less active against *Candida* species and *Malassezia furfur*, but the cream also can be used in cutaneous candidiasis and tinea versicolor. The systemic use of terbinafine was discussed earlier.

## Butenafine

*Butenafine hydrochloride* (*MENTAX*, *LOTRIMIN ULTRA*) is a benzylamine derivative with a mechanism of action similar to that of terbinafine and naftifine. Its spectrum of antifungal activity and use also are similar to those of the allylamines.

## Polyene Antifungal Antibiotics

**Nystatin.** Nystatin was discovered in the New York State Health Laboratory and was named accordingly; it is a tetraene macrolide produced by *Streptomyces noursei*, is structurally similar to amphotericin B, and has the same mechanism of action. The drug is not absorbed from the GI tract, skin, or vagina. A liposomal formulation (*NYOTRAN*) is in clinical trials for candidemia.

Nystatin (MYCOSTATIN, NILSTAT, others) is useful only for candidiasis and is supplied in preparations intended for cutaneous, vaginal, or oral administration for this purpose. Infections of the nails and hyperkeratinized or crusted skin lesions do not respond. Powders are preferred for moist lesions and are applied two to three times daily. Creams or ointments are used twice daily. Combinations of nystatin with antibacterial agents or corticosteroids also are available. Allergic reactions to nystatin are very uncommon. Although vaginal tablets of nystatin are well tolerated, imidazoles or triazoles are more effective agents than nystatin for vaginal candidiasis.

Nystatin suspension is usually effective for oral candidiasis of the immunocompetent host. Patients should be instructed to swish the drug around in the mouth and then swallow; otherwise, the patient may expectorate the bitter liquid and fail to treat the infected mucosa in the posterior pharynx or esophagus. Other than the bitter taste and occasional complaints of nausea, adverse effects are uncommon.

## **Miscellaneous Antifungal Agents**

**Undecylenic Acid.** Undecylenic acid is 10-undecenoic acid, an 11-carbon unsaturated compound. It is a yellow liquid with a characteristic rancid odor. It is primarily fungistatic, although fungicidal activity may be observed with long exposure to high concentrations of the agent. The drug is active against a variety of fungi, including those that cause ringworm. Undecylenic acid (DESENE, others) is available in a cream, powder, spray powder, soap, and liquid. Zinc undecylenate is marketed in combination with other ingredients. The zinc provides an astringent action that aids in the suppression of inflammation. Compound undecylenic acid ointment contains both undecylenic acid (~5%) and zinc undecylenate (~20%). Calcium undecylenate (CALDESENE, CRUEX) is available as a powder.

Undecylenic acid preparations are used in the treatment of various dermatomycoses, especially tinea pedis. Concentrations of the acid as high as 10%, as well as those of the acid and salt in the compound ointment, may be applied to the skin. The preparations as formulated are usually not irritating to tissue, and sensitization to them is uncommon. It is of undoubted benefit in retarding fungal growth in tinea pedis, but the infection frequently persists despite intensive treatment with preparations of the acid and the zinc salt. At best, the clinical “cure” rate is ~50%, which is much lower than that obtained with the imidazoles, haloprogin, or tolnaftate. Efficacy in the treatment of tinea capitis is marginal, and the drug is no longer used for that purpose. Undecylenic acid preparations also are approved for use in the treatment of diaper rash, tinea cruris, and other minor dermatologic conditions.

***Benzoic Acid and Salicylic Acid.*** An ointment containing benzoic and salicylic acids is known as Whitfield’s ointment. It combines the fungistatic action of benzoate with the keratolytic action of salicylate. It contains benzoic acid and salicylic acid in a ratio of 2:1 (usually 6-3%) and is used mainly in the treatment of tinea pedis. Because benzoic acid is only fungistatic, eradication of the infection occurs only after the infected stratum corneum is shed, and continuous medication is required for several weeks to months. The salicylic acid accelerates the desquamation. The ointment also is sometimes used to treat tinea capitis. Mild irritation may occur at the site of application.

## Chapter 58

# Antiviral Agents (Nonretroviral)

Edward P. Acosta and Charles Flexner

Most antivirals currently available in the U.S. have been developed and approved in the last two decades. This flurry of activity was driven by successes in rational drug design and approval that began with the anti-herpesvirus nucleoside analog acyclovir, whose discovery and development resulted in the awarding of a Nobel Prize to Gertrude Elion and George Hitchings in 1988. Because viruses are obligatory intracellular microorganisms and rely on host biosynthetic machinery to reproduce, there were doubts about the possibility of developing antiviral drugs with selective toxicity, but those doubts have long been erased. Viruses are now obvious targets for effective antimicrobial chemotherapy, and it is certain that the number of available agents in this category will continue to increase.

Viruses are simple microorganisms that consist of either double- or single-stranded DNA or RNA enclosed in a protein coat called a *capsid*. Some viruses also possess a lipid envelope derived from the infected host cell, which, like the capsid, may contain antigenic glycoproteins. There are distinct stages of viral replication and the classes of antiviral agents that can act at each stage ([Table 58–1](#)). Effective antiviral agents inhibit virus-specific replicative events or preferentially inhibit *virus-directed rather than host cell-directed* nucleic acid or protein synthesis. Host cell molecules that are essential to viral replication also offer targets for intervention. Some effective antiviral agents (e.g., interferons; see [Chapter 35](#)) have multiple mechanisms of action that include modulation of host immune responses. [Figure 58–1](#) gives a schematic diagram of the replicative cycle of typical DNA and RNA viruses. DNA viruses (and the diseases they cause) include poxviruses (smallpox), herpesviruses (chickenpox, shingles, oral and genital herpes), adenoviruses (conjunctivitis, sore throat), hepadnaviruses (hepatitis B [HBV]), and papillomaviruses (warts). Most DNA viruses enter the host cell nucleus, where the viral DNA is transcribed into mRNA by host cell polymerase; mRNA is translated in the usual host cell fashion into virus-specific proteins. An exception to this strategy are

poxviruses, which carry their own RNA polymerase and replicate in the host cell cytoplasm.

For RNA viruses, the replication strategy relies either on enzymes in the virion to synthesize mRNA or has the viral RNA serving as its own mRNA. The mRNA is translated into various viral proteins, including RNA polymerase, which directs the synthesis of more viral mRNA and genomic RNA ([Figure 58–1B](#)). Most RNA viruses complete their replication in the cytoplasm, but some, such as influenza, are transcribed in the host cell nucleus. Examples of RNA viruses (and the diseases they cause) include rubella virus (German measles), rhabdoviruses (rabies), picornaviruses (poliomyelitis, meningitis, colds, hepatitis A), arenaviruses (meningitis, Lassa fever), flaviviruses (West Nile meningoencephalitis, yellow fever, hepatitis C), orthomyxoviruses (influenza), paramyxoviruses (measles, mumps), and coronaviruses (colds, severe acute respiratory syndrome [SARS]). Retroviruses are a special group of RNA viruses that include human immunodeficiency virus (HIV); chemotherapy for retroviruses is described in [Chapter 59](#).

[Table 58–2](#) summarizes currently approved drugs for nonretroviral infections. Their pharmacological properties are presented below, class by class, as listed in the table.

## ANTI-HERPESVIRUS AGENTS

Infection with herpes simplex virus type 1 (HSV-1) typically causes diseases of the mouth, face, skin, esophagus, or brain. Herpes simplex virus type 2 (HSV-2) usually causes infections of the genitals, rectum, skin, hands, or meninges. Both cause serious infections in neonates. HSV infection may be a primary one in a naive host, a nonprimary initial one in a host previously infected by other viruses, or the consequence of activation of a latent infection.

**Table 58—1 Stages of Virus Replication and Possible Targets of Action of Antiviral Agents**

STAGE OF REPLICATION	CLASSES OF SELECTIVE INHIBITORS
Cell entry	
Attachment	Soluble receptor decoys, antireceptor antibodies, fusion protein inhibitors
Penetration	
Uncoating	Ion channel blockers, capsid stabilizers
Release of viral genome	
Transcription of viral genome <sup>a</sup>	Inhibitors of viral DNA polymerase, RNA polymerase, reverse transcriptase, helicase, primase, or integrase
Transcription of viral messenger RNA	
Replication of viral genome	
Translation of viral proteins	Interferons, antisense oligonucleotides, ribozymes
Regulatory proteins (early)	Inhibitors of regulatory proteins
Structural proteins (late)	
Post-translational modifications	
Proteolytic cleavage	Protease inhibitors
Myristoylation, glycosylation	
Assembly of virion components	Interferons, assembly protein inhibitors
Release	Neuraminidase inhibitors, antiviral antibodies, cytotoxic lymphocytes
Budding, cell lysis	

<sup>a</sup>Depends on specific replication strategy of virus, but virus-specified enzyme required for part of process.

The first systemically administered anti-herpesvirus agent, vidarabine (no longer marketed in the U.S.), was approved by the FDA in 1977. However, toxicities restricted its use to life- or vision-threatening infections of HSV and varicella-zoster virus (VZV). The discovery and development of acyclovir, approved in 1982, provided the first effective treatment for less severe HSV and VZV infections in ambulatory patients. Intravenous acyclovir is superior to vidarabine in terms of efficacy and toxicity in HSV encephalitis and in VZV infections of immunocompromised patients. Acyclovir is the prototype of a group of antiviral agents that are phosphorylated intracellularly by a viral kinase and subsequently by host cell enzymes to become inhibitors of viral DNA synthesis. Other agents employing this strategy include penciclovir and ganciclovir.

## Acyclovir and Valacyclovir

**Chemistry and Antiviral Activity.** Acyclovir is an acyclic guanine nucleoside analog that lacks a 3'-hydroxyl on the side chain. Valacyclovir is the *L*-valyl ester prodrug of acyclovir. Acyclovir and valacyclovir chemical structures are depicted in [Figure 58–2](#).

Acyclovir's clinically useful antiviral spectrum is limited to herpesviruses. *In vitro*, acyclovir is most active against HSV-1 (0.02-0.9 µg/mL), approximately half as active against HSV-2 (0.03-2.2 µg/mL), a tenth as potent against VZV (0.8-4.0 µg/mL) and Epstein-Barr virus (EBV), and least active against cytomegalovirus (CMV) (generally >20 µg/mL) and human herpesvirus 6 (HHV-6). Uninfected mammalian cell growth generally is unaffected by high acyclovir concentrations (>50 µg/mL).

**Mechanisms of Action and Resistance.** Acyclovir inhibits viral DNA synthesis via a mechanism outlined in [Figure 58-3](#) (Elion, 1986). Its selectivity of action depends on interaction with two distinct viral proteins: HSV thymidine kinase and DNA polymerase. Cellular uptake and initial phosphorylation are facilitated by HSV thymidine kinase. The affinity of acyclovir for HSV thymidine kinase is ~200 times greater than for the mammalian enzyme. Cellular enzymes convert the monophosphate to acyclovir triphosphate, which is present in 40-100-fold higher concentrations in HSV-infected than in uninfected cells and competes for endogenous deoxyguanosine triphosphate (dGTP).

**Figure 58–1.** *Replicative cycles of DNA (A) and RNA (B) viruses.* The replicative cycles of herpesvirus (A) and influenza (B) are examples of DNA-encoded and RNA-encoded viruses, respectively. Sites of action of antiviral agents also are shown. Key: mRNA = messenger RNA; cDNA = complementary DNA; vRNA = viral RNA; DNAp = DNA polymerase; RNAp = RNA polymerase; cRNA = complementary RNA. The symbol  indicates a block to virus growth.

A. Replicative cycles of herpes simplex virus, a DNA virus, and the probable sites of action of antiviral agents. Herpesvirus replication is a regulated multistep process. After infection, a small number of immediate-early genes are transcribed; these genes encode proteins that regulate their own synthesis and are responsible for synthesis of early genes involved in genome replication, such as thymidine kinases, DNA polymerases, etc. After DNA replication, the bulk of the herpesvirus genes (called late genes) are expressed and encode proteins that either are incorporated into or aid in the assembly of progeny virions.

B. Replicative cycles of influenza, an RNA virus, and the loci for effects of antiviral agents. The mammalian cell shown is an airway epithelial cell. The M2 protein of influenza virus allows an influx of hydrogen ions into the virion interior, which in turn promotes dissociation of the RNP (ribonuclear protein) segments and release into the cytoplasm (uncoating). Influenza virus mRNA synthesis requires a primer cleared from cellular mRNA and used by the viral RNAp complex. The neuraminidase inhibitors zanamivir and oseltamivir specifically inhibit release of progeny virus. Small capitals indicate virus proteins.

**Table 58–2 Nomenclature of Antiviral Agents**

GENERIC NAME	OTHER NAMES	TRADE NAMES (U.S.)	DOSAGE FORMS AVAILABLE
<b>Antiherpovirus agents</b>			
Acyclovir	ACV, acycloguanosine	ZOVIRAX, others	IV, O, T, ophth <sup>a</sup>
Cidofovir	HPMPC, CDV	VISTIDE	IV
Famciclovir	FCV	FAMVIR, others	O
Foscarnet	PFA, phosphonoformate	FOSCAVIR, others	IV, O <sup>a</sup>
Fomivirsena	ISIS 2922	VITRAVENE	Intravitreal
Ganciclovir	GCV, DHPG	CYTOVENE, VITRASERT, others	IV, O, intravitreal
Idoxuridine	IDUR	HERPLEX, DENDRID	Ophth
Penciclovir	PCV	DENAVIR	T, IV <sup>a</sup>
Trifluridine	TFT, trifluorothymidine	VIROPTIC, others	Ophth
Valacyclovir		VALTREX, others	O
Valganciclovir		VALCYTE, others	O
<b>Anti-influenza agents</b>			
Amantadine		SYMMETREL, others	O
Oseltamivir	GS4104	TAMIFLU	O
Rimantadine		FLUMADINE, others	O
Zanamivir	GC167	RELENZA	Inhalation
<b>Antih hepatitis agents</b>			
Adefovir dipivoxil	Bis-pom-PMEA	HEPSERA	O
Entecavir		BARACLUDE	O
Interferon alfa-N1		<i>wellferon</i> <sup>a</sup>	Injected
Interferon alfa-N3		ALFERON N	Injected
Interferon alfacon-1		INFERGEN	Injected
Interferon alfa-2B		INTRON A	Injected
Interferon alfa-2A		ROFERON A	Injected
Lamivudine	3TC	EPIVIR, others	O
Peginterferon alfa 2A		PEGASYS	SC
Peginterferon alfa 2B		PEG-INTRON	SC
<b>Other antiviral agents</b>			
Ribavirin		VIRAZOLE, REBETOL, COPEGUS, others	O, inhalation, IV
Telbivudine		TYZEKA	O
Tenofovir disoproxil fumarate	TDF	VIREAD, others	O
Imiquimod		ALDARA	Topical

<sup>a</sup>Not currently approved for use in U.S. ABBREVIATIONS: IV, intravenous; O, oral; T, topical; ophth, ophthalmic.

The immunosuppressive agent mycophenolate mofetil ([Chapter 35](#)) potentiates the anti-herpes activity of acyclovir and related agents by depleting intracellular dGTP pools. Acyclovir triphosphate competitively inhibits viral DNA polymerases and, to a much lesser extent, cellular DNA polymerases. Acyclovir triphosphate also is incorporated into viral DNA, where it acts as a chain terminator because of the lack of a 3'-hydroxyl group. By a mechanism termed *suicide inactivation*, the terminated DNA template containing acyclovir binds the viral DNA polymerase and leads to its irreversible inactivation.

Acyclovir resistance in HSV has been linked to one of three mechanisms: impaired production of viral thymidine kinase, altered thymidine kinase substrate specificity (e.g., phosphorylation of thymidine but not acyclovir), or altered viral DNA polymerase. Alterations in viral enzymes are caused by point mutations and base insertions or deletions in the corresponding genes.

Resistant variants are present in native virus populations and in isolates from treated patients. The most common resistance mechanism in clinical HSV isolates is absent or deficient viral thymidine kinase activity; viral DNA polymerase mutants are rare. Phenotypic resistance typically is defined by *in vitro* inhibitory concentrations of >2-3  $\mu\text{g/mL}$ , which predict failure of therapy in immunocompromised patients.

**Figure 58–2.** Chemical Structures of Anti-Herpes Drugs.

Acyclovir resistance in VZV isolates is caused by mutations in VZV thymidine kinase and less often by mutations in viral DNA polymerase.

**Absorption, Distribution, and Elimination.** The oral bioavailability of acyclovir ranges from 10-30% and decreases with increasing dose (Wagstaff et al., 1994). Peak plasma concentrations average 0.4-0.8  $\mu\text{g/mL}$  after 200-mg doses and 1.6  $\mu\text{g/mL}$  after 800-mg doses. Following intravenous dosing, peak and trough plasma concentrations average 9.8 and 0.7  $\mu\text{g/mL}$  after 5 mg/kg every 8 hours and 20.7 and 2.3  $\mu\text{g/mL}$  after 10 mg/kg every 8 hours, respectively.

Valacyclovir is converted rapidly and virtually completely to acyclovir after oral administration in healthy adults. This conversion is thought to result from first-pass intestinal and hepatic metabolism through enzymatic hydrolysis. Unlike acyclovir, valacyclovir is a substrate for intestinal and renal peptide transporters. The relative oral bioavailability of acyclovir increases 3-5 fold to ~70% following valacyclovir administration (Steingrimsdottir et al., 2000). Peak acyclovir concentrations average 5-6 µg/mL following single 1000-mg doses of oral valacyclovir and occur ~2 hours after dosing. Peak plasma concentrations of valacyclovir are only 4% of acyclovir levels. Less than 1% of an administered dose of valacyclovir is recovered in the urine; most is eliminated as acyclovir.

Acyclovir distributes widely in body fluids, including vesicular fluid, aqueous humor, and cerebrospinal fluid (CSF). Compared with plasma, salivary concentrations are low, and vaginal secretion concentrations vary widely. Acyclovir is concentrated in breast milk, amniotic fluid, and placenta. Newborn plasma levels are similar to maternal ones. Percutaneous absorption of acyclovir after topical administration is low.

The mean plasma elimination  $t_{1/2}$  of acyclovir is ~2.5 hours (range: 1.5-6 hours in adults with normal renal function). The elimination  $t_{1/2}$  of acyclovir is ~4 hours in neonates and increases to 20 hours in anuric patients (Wagstaff et al., 1994). Renal excretion of unmetabolized acyclovir by glomerular filtration and tubular secretion is the principal route of elimination. Less than 15% is excreted as 9-carboxymethoxymethylguanine or minor metabolites. The pharmacokinetics of oral acyclovir and valacyclovir appear to be similar in pregnant and nonpregnant women (Kimberlin et al., 1998).

**Figure 58–3.** *Mechanism of Action of Acyclovir in Cells Infected by Herpes Simplex Virus.* A herpes simplex virion is shown attaching to a susceptible host cell, fusing its envelope with the cell membrane, and releasing naked capsids that deliver viral DNA into the nucleus, where it initiates synthesis of viral DNA. Acyclovir molecules entering the cell are converted to acyclovir monophosphate by virus-induced thymidine kinase. Host-cell enzymes add two more phosphates to form acyclovir triphosphate, which is transported into the nucleus. After the herpes DNA polymerase cleaves pyrophosphate from acyclovir triphosphate (indicated by the red arrow in the inset), viral DNA polymerase inserts acyclovir monophosphate rather than 2'-deoxyguanosine monophosphate into the viral DNA (indicated by black arrows in the inset). Further elongation of the chain is impossible because acyclovir monophosphate lacks the 3' hydroxyl group necessary for the insertion of an additional nucleotide, and the exonuclease associated with the viral DNA polymerase cannot remove the acyclovir moiety. In contrast, ganciclovir and penciclovir have a 3' hydroxyl group; therefore, further synthesis of viral DNA is possible in the presence of these drugs. Foscarnet acts at the pyrophosphate-binding site of viral DNA polymerase and prevents cleavage of the pyrophosphate from nucleoside triphosphates, thus stalling

further primer template extension. The red bands between the viral DNA strands in the inset indicate hydrogen bonding of the base pairs. (Adapted with permission from Balfour HH. Antiviral drugs. *N Engl J Med*, 1999,340:1255–1268. Copyright © 1999. Massachusetts Medical Society. All rights reserved.)

**Untoward Effects.** Acyclovir generally is well tolerated. Topical acyclovir in a polyethylene glycol base may cause mucosal irritation and transient burning when applied to genital lesions.

Oral acyclovir has been associated infrequently with nausea, diarrhea, rash, or headache and very rarely with renal insufficiency or neurotoxicity. Valacyclovir also may be associated with headache, nausea, diarrhea, nephrotoxicity, and central nervous system (CNS) symptoms. High doses of valacyclovir have been associated with confusion and hallucinations, nephrotoxicity, and uncommonly, severe thrombocytopenic syndromes, sometimes fatal, in immunocompromised patients. Acyclovir has been associated with neutropenia in neonates. Chronic acyclovir suppression of genital herpes has been used safely for up to 10 years. No excess frequency of congenital abnormalities has been recognized in infants born to women exposed to acyclovir during pregnancy (Ratanajamit et al., 2003).

The principal dose-limiting toxicities of intravenous acyclovir are renal insufficiency and CNS side effects. Preexisting renal insufficiency, high doses, and high acyclovir plasma levels ( $>25 \mu\text{g/mL}$ ) are risk factors for both. Reversible renal dysfunction occurs in  $\sim 5\%$  of patients, probably related to high urine levels causing crystalline nephropathy. Manifestations include nausea, emesis, flank pain, and increasing azotemia. Rapid infusion, dehydration, and inadequate urine flow increase the risk. Infusions should be given at a constant rate over at least an hour. Nephrotoxicity usually resolves with drug cessation and volume expansion. Neurotoxicity occurs in 1-4% of patients and may be manifested by altered sensorium, tremor, myoclonus, delirium, seizures, or extrapyramidal signs. Phlebitis following extravasation, rash, diaphoresis, nausea, hypotension, and interstitial nephritis also have been described. Hemodialysis may be useful in severe cases.

Severe somnolence and lethargy may occur with combinations of zidovudine and acyclovir. Concomitant cyclosporine and probably other nephrotoxic agents enhance the risk of nephrotoxicity. Probenecid decreases

the acyclovir renal clearance and prolongs the elimination  $t_{1/2}$ . Acyclovir may decrease the renal clearance of other drugs eliminated by active renal secretion, such as methotrexate.

**Therapeutic Uses.** In immunocompetent persons, the clinical benefits of acyclovir and valacyclovir are greater in initial HSV infections than in recurrent ones, which typically are milder in severity. These drugs are particularly useful in immunocompromised patients because these individuals experience both more frequent and more severe HSV and VZV infections. Because VZV is less susceptible than HSV to acyclovir, higher doses must be used for treating varicella-zoster infections than for HSV infections. Oral valacyclovir is as effective as oral acyclovir in HSV infections and more effective for treating herpes zoster.

**Herpes Simplex Virus Infections.** In initial genital HSV infections, oral acyclovir (200 mg five times daily or 400 mg three times daily for 7-10 days) and valacyclovir (1000 mg twice daily for 7-10 days) are associated with significant reductions in virus shedding, symptoms, and time to healing (Kimberlin and Rouse, 2004). Intravenous acyclovir (5 mg/kg every 8 hours) has similar effects in patients hospitalized with severe primary genital HSV infections. Topical acyclovir is much less effective than systemic administration. None of these regimens reproducibly reduces the risk of recurrent genital lesions. Acyclovir (200 mg five times daily or 400 mg three times daily for 5 days or 800 mg three times daily for 2 days) or valacyclovir (500 mg twice daily for 3 or 5 days) shortens the manifestations of recurrent genital HSV episodes by 1-2 days. Frequently recurring genital herpes can be suppressed effectively with chronic oral acyclovir (400 mg twice daily or 200 mg three times daily) or with valacyclovir (500 mg or, for very frequent recurrences, 1000 mg once daily). During use, the rate of clinical recurrences decreases by ~90%, and subclinical shedding is markedly reduced, although not eliminated. Valacyclovir suppression of genital herpes reduces the risk of transmitting infection to a susceptible partner by ~50% over an 8-month period (Corey et al., 2004). Chronic suppression may be useful in those with disabling recurrences of herpetic whitlow or HSV-related erythema multiforme.

Oral acyclovir is effective in primary herpetic gingivostomatitis (600 mg/m<sup>2</sup> four times daily for 10 days in children) but provides only modest clinical benefit in recurrent orolabial herpes. Short-term, high-dose

valacyclovir (2 g twice over 1 day) shortens the duration of recurrent orolabial herpes by ~1 day (Elish et al., 2004). The FDA has approved an acyclovir/hydrocortisone combination (LIPSOVIR) for early treatment of recurrent herpes cold sores. Topical acyclovir cream is modestly effective in recurrent labial (Spruance et al., 2002) and genital herpes simplex virus infections. Preexposure acyclovir prophylaxis (400 mg twice daily for 1 week) reduces the overall risk of recurrence by 73% in those with sun-induced recurrences of HSV infections. Acyclovir during the last month of pregnancy reduces the likelihood of viral shedding and the frequency of cesarean delivery in women with primary or recurrent genital herpes (Corey and Wald, 2009).

In immunocompromised patients with mucocutaneous HSV infection, intravenous acyclovir (250 mg/m<sup>2</sup> every 8 hours for 7 days) shortens healing time, duration of pain, and the period of virus shedding. Oral acyclovir (800 mg five times per day) and valacyclovir (1000 mg twice daily) for 5-10 days are also effective. Recurrences are common after cessation of therapy and may require long-term suppression. In those with very localized labial or facial HSV infections, topical acyclovir may provide some benefit. Intravenous acyclovir may be beneficial in viscerally disseminating HSV in immunocompromised patients and in patients with HSV-infected burn wounds.

Systemic acyclovir prophylaxis is highly effective in preventing mucocutaneous HSV infections in seropositive patients undergoing immunosuppression. Intravenous acyclovir (250 mg/m<sup>2</sup> every 8-12 hours) begun prior to transplantation and continuing for several weeks prevents HSV disease in bone marrow transplant recipients. For patients who can tolerate oral medications, oral acyclovir (400 mg five times daily) is effective, and long-term oral acyclovir (200-400 mg three times daily for 6 months) also reduces the risk of VZV infection (Steer et al., 2000). In HSV encephalitis, acyclovir (10 mg/kg every 8 hours for a minimum of 10 days) reduces mortality by >50% and improves overall neurologic outcome compared with vidarabine. Higher doses (15-20 mg/kg every 8 hours) and prolonged treatment (up to 21 days) are recommended by many experts. Intravenous acyclovir (20 mg/kg every 8 hours for 21 days) is more effective than lower doses in viscerally invasive neonatal HSV infections (Kimberlin et al., 2001). In neonates and immunosuppressed patients and, rarely, in

previously healthy persons, relapses of encephalitis following acyclovir may occur. The value of continuing long-term suppression with valacyclovir after completing intravenous acyclovir is under study.

An ophthalmic formulation of acyclovir (not available in the U.S.) is at least as effective as topical vidarabine or trifluridine in herpetic keratoconjunctivitis.

Infection owing to resistant HSV is rare in immunocompetent persons; however, in immunocompromised hosts, acyclovir-resistant HSV isolates can cause extensive mucocutaneous disease and, rarely, meningoencephalitis, pneumonitis, or visceral disease. Resistant HSV can be recovered from 6-17% of immunocompromised patients receiving acyclovir treatment (Bacon et al., 2003). Recurrences after cessation of acyclovir usually are due to sensitive virus but may be due to acyclovir-resistant virus in AIDS patients. In patients with progressive disease, intravenous foscarnet therapy is effective, but vidarabine is not (Chilukuri and Rosen, 2003).

**Varicella-Zoster Virus Infections.** If begun within 24 hours of rash onset, oral acyclovir has therapeutic effects in varicella of children and adults. In children weighing up to 40 kg, acyclovir (20 mg/kg, up to 800 mg per dose, four times daily for 5 days) reduces fever and new lesion formation by ~1 day. Routine use in uncomplicated pediatric varicella is not recommended but should be considered in those at risk of moderate-to-severe illness (persons >12 years of age, secondary household cases, those with chronic cutaneous or pulmonary disorders, or those receiving corticosteroids or long-term salicylates) (Committee on Infectious Diseases, American Academy of Pediatrics, 2003). In adults treated within 24 hours, oral acyclovir (800 mg five times daily for 7 days) reduces the time to crusting of lesions by ~2 days, the maximum number of lesions by one-half, and the duration of fever. Intravenous acyclovir appears to be effective in varicella pneumonia or encephalitis of previously healthy adults. Oral acyclovir (10 mg/kg four times daily) given between 7 and 14 days after exposure may reduce the risk of varicella.

In older adults with localized herpes zoster, oral acyclovir (800 mg five times daily for 7 days) reduces pain and healing times if treatment can be initiated within 72 hours of rash onset. A reduction in ocular complications, particularly keratitis and anterior uveitis, occurs with treatment of zoster ophthalmicus. Prolonged acyclovir and concurrent prednisone for 21 days

speed zoster healing and improve quality-of-life measures compared with each therapy alone. Valacyclovir (1000 mg three times daily for 7 days) provides more prompt relief of zoster-associated pain than acyclovir in older adults ( $\geq 50$  years) with zoster.

In immunocompromised patients with herpes zoster, intravenous acyclovir (500 mg/m<sup>2</sup> every 8 hours for 7 days) reduces viral shedding, healing time, and the risks of cutaneous dissemination and visceral complications, as well as the length of hospitalization, in disseminating zoster. In immunosuppressed children with varicella, intravenous acyclovir decreases healing time and the risk of visceral complications.

Acyclovir-resistant VZV isolates uncommonly have been recovered from HIV-infected children and adults who may manifest chronic hyperkeratotic or verrucous lesions and sometimes meningoradiculitis. Intravenous foscarnet also appears to be effective for acyclovir-resistant VZV infections.

**Other Viruses.** Acyclovir is ineffective therapeutically in established cytomegalovirus (CMV) infections but ganciclovir is effective for CMV prophylaxis in immunocompromised patients. High-dose intravenous acyclovir (500 mg/m<sup>2</sup> every 8 hours for 1 month) in CMV-seropositive bone marrow transplant recipients is associated with  $\sim 50\%$  lower risk of CMV disease and, when combined with prolonged oral acyclovir (800 mg four times daily through 6 months), improves survival. Following engraftment, valacyclovir (2000 mg four times daily to day 100) appears as effective as intravenous ganciclovir prophylaxis in such patients (Winston et al., 2003). High-dose oral acyclovir or valacyclovir (2000 mg four times daily) suppression for 3 months may reduce the risk of CMV disease and its sequelae in certain solid-organ transplant recipients (Lowance et al., 1999), but oral valganciclovir is the preferred agent for mismatched graft recipients (Pereyra and Rubin, 2004). Compared with acyclovir, high-dose valacyclovir reduces CMV disease in advanced HIV infection but is associated with greater toxicity and possibly shorter survival.

In infectious mononucleosis, acyclovir is associated with transient antiviral effects but no clinical benefits. EBV-related oral hairy leukoplakia may improve with acyclovir. Oral acyclovir in conjunction with systemic corticosteroids appears beneficial in treating Bell's palsy, but valacyclovir is ineffective in acute vestibular neuritis.

# Cidofovir

**Chemistry and Antiviral Activity.** Cidofovir is a cytidine nucleotide analog with inhibitory activity against human herpes, papilloma, polyoma, pox, and adenoviruses (Hitchcock et al., 1996). Its structure is shown in [Figure 58–2](#).

*In vitro* inhibitory concentrations range from >0.2 to 0.7  $\mu\text{g/mL}$  for CMV, 0.4 to 33  $\mu\text{g/mL}$  for HSV, and 0.02–17  $\mu\text{g/mL}$  for adenoviruses. Because cidofovir is a phosphonate that is phosphorylated by cellular but not virus enzymes, it inhibits acyclovir-resistant thymidine kinase (TK)–deficient or TK-altered HSV or VZV strains, ganciclovir-resistant CMV strains with UL97 mutations but not those with DNA polymerase mutations, and some foscarnet-resistant CMV strains. Cidofovir synergistically inhibits CMV replication in combination with ganciclovir or foscarnet.

**Mechanisms of Action and Resistance.** Cidofovir inhibits viral DNA synthesis by slowing and eventually terminating chain elongation. Cidofovir is metabolized to its active diphosphate form by cellular enzymes; the levels of phosphorylated metabolites are similar in infected and uninfected cells. The diphosphate acts as both a competitive inhibitor with respect to dCTP and as an alternative substrate for viral DNA polymerase. The diphosphate has a prolonged intracellular  $t_{1/2}$  and competitively inhibits CMV and HSV DNA polymerases at concentrations one-eighth to one six-hundredth of those required to inhibit human DNA polymerases (Hitchcock et al., 1996). A phosphocholine metabolite also has a long intracellular  $t_{1/2}$  (~87 hours) and may serve as an intracellular reservoir of drug. The prolonged intracellular  $t_{1/2}$  of cidofovir diphosphate allows infrequent dosing regimens, and single doses are effective in experimental HSV, varicella, and poxvirus infections.

Cidofovir resistance in CMV is due to mutations in viral DNA polymerase. Low-level resistance to cidofovir develops in up to ~30% of retinitis patients by 3 months of therapy. Highly ganciclovir-resistant CMV isolates that possess DNA polymerase and UL97 kinase mutations are resistant to cidofovir, and prior ganciclovir therapy may select for cidofovir resistance. Some foscarnet-resistant CMV isolates show cross-resistance to cidofovir, and triple-drug-resistant variants with DNA polymerase mutations occur.

**Absorption, Distribution, and Elimination.** Cidofovir is dianionic at physiological pH and has very low oral bioavailability (Cundy, 1999). The

plasma levels after intravenous dosing decline in a biphasic pattern with a terminal  $t_{1/2}$  that averages 2.6 hours. The volume of distribution approximates total-body water. Penetration into the CNS or eye has not been well characterized, but CSF levels are low. Extemporaneously compounded topical cidofovir gel may result in low plasma concentrations ( $<0.5 \mu\text{g/mL}$ ) in patients with large mucocutaneous lesions.

Cidofovir is cleared by the kidney via glomerular filtration and tubular secretion. Over 90% of the dose is recovered unchanged in the urine without significant metabolism in humans. The probenecid-sensitive organic anion transporter 1 mediates uptake of cidofovir into proximal renal tubular epithelial cells (Ho et al., 2000). High-dose probenecid (2 g three hours before and 1 g two and eight hours after each infusion) blocks tubular transport of cidofovir and reduces renal clearance and associated nephrotoxicity. At cidofovir doses of 5 mg/kg, peak plasma concentrations increase from 11.5-19.6  $\mu\text{g/mL}$  with probenecid, and renal clearance is reduced to the level of glomerular filtration. Elimination relates linearly to creatinine clearance, and the  $t_{1/2}$  increases to 32.5 hours in patients on chronic ambulatory peritoneal dialysis (CAPD). Hemodialysis removes  $>50\%$  of the administered dose (Cundy, 1999).

**Untoward Effects.** Nephrotoxicity is the principal dose-limiting side effect of intravenous cidofovir. Proximal tubular dysfunction includes proteinuria, azotemia, glycosuria, metabolic acidosis, and uncommonly, Fanconi's syndrome. Concomitant oral probenecid and saline prehydration reduce the risk of renal toxicity. On maintenance doses of 5 mg/kg every 2 weeks, up to 50% of patients develop proteinuria, 10-15% show an elevated serum creatinine concentration, and 15-20% develop neutropenia. Anterior uveitis that is responsive to topical corticosteroids and cycloplegia occurs commonly and low intraocular pressure occurs infrequently with intravenous cidofovir. Concurrent probenecid administration is associated with gastrointestinal (GI) upset, constitutional symptoms, and hypersensitivity reactions, including fever, rash, and uncommonly, anaphylactoid manifestations. Administration with food and pretreatment with antiemetics, antihistamines, and/or acetaminophen may improve tolerance.

Probenecid, but not cidofovir, alters zidovudine pharmacokinetics such that zidovudine doses should be reduced when probenecid is present, as should the doses of other drugs whose renal secretion probenecid inhibits

(e.g.,  $\beta$ -lactam antibiotics, nonsteroidal anti-inflammatory drugs [NSAIDs], acyclovir, lorazepam, furosemide, methotrexate, theophylline, and rifampin). Concurrent nephrotoxic agents are contraindicated, and at least 7 days should elapse between the end of aminoglycoside therapy and initiation of cidofovir. The same interval should separate intravenous pentamidine, amphotericin B, foscarnet, NSAID, or contrast dye and cidofovir. Cidofovir and oral ganciclovir are poorly tolerated in combination at full doses.

Topical application of cidofovir is associated with dose-related application-site reactions (e.g., burning, pain, and pruritus) in up to one-third of patients and occasionally ulceration. Intravitreal cidofovir may cause vitritis, hypotony, and visual loss and is contraindicated.

Preclinical studies indicate that cidofovir has mutagenic, gonadotoxic, embryotoxic, and teratogenic effects. Because cidofovir is carcinogenic in rats, it is considered a potential human carcinogen. It may cause infertility and is classified as pregnancy Category C.

**Therapeutic Uses.** Intravenous cidofovir is approved for the treatment of CMV retinitis in HIV-infected patients.

Intravenous cidofovir (5 mg/kg once a week for 2 weeks followed by dosing every 2 weeks) increases the time to progression of CMV retinitis in previously untreated patients and in those failing or intolerant of ganciclovir and foscarnet therapy. CMV viremia may persist during cidofovir administration. Maintenance doses of 5 mg/kg are more effective but less well tolerated than 3 mg/kg doses. Intravenous cidofovir has been used for treating acyclovir-resistant mucocutaneous HSV infection, adenovirus disease in transplant recipients (Ljungman et al., 2003), and extensive molluscum contagiosum in HIV patients. Reduced doses (0.25-1 mg/kg every 2-3 weeks) without probenecid may be beneficial in BK virus nephropathy in renal transplant patients (Vats et al., 2003).

Extemporaneously compounded topical cidofovir gel eliminates virus shedding and lesions in some HIV-infected patients with acyclovir-resistant mucocutaneous HSV infections and has been used in treating anogenital warts and molluscum contagiosum in immunocompromised patients and cervical intraepithelial neoplasia in women. Intralesional cidofovir induces remissions in adults and children with respiratory papillomatosis.

## **Famciclovir and Penciclovir**

**Chemistry and Antiviral Activity.** Famciclovir is the diacetyl ester prodrug of 6-deoxy penciclovir and lacks intrinsic antiviral activity. Penciclovir is an acyclic guanine nucleoside analog. The side chain differs structurally in that the oxygen has been replaced by a carbon, and an additional hydroxymethyl group is present [Figure 58–2](#).

Penciclovir is similar to acyclovir in its spectrum of activity and potency against HSV and VZV. The inhibitory concentrations of penciclovir depend on cell type but are usually within 2-fold of those of acyclovir for HSV and VZV. It also is inhibitory for HBV.

**Mechanisms of Action and Resistance.** Penciclovir is an inhibitor of viral DNA synthesis. In HSV- or VZV-infected cells, penciclovir is phosphorylated initially by viral thymidine kinase. Penciclovir triphosphate serves as a competitive inhibitor of viral DNA polymerase ([Figure 58–3](#)). Although penciclovir triphosphate is approximately one one-hundredth as potent as acyclovir triphosphate in inhibiting viral DNA polymerase, it is present in much higher concentrations and for more prolonged periods in infected cells than acyclovir triphosphate. The prolonged intracellular  $t_{1/2}$  of penciclovir triphosphate, 7-20 hours, is associated with prolonged antiviral effects. Because penciclovir has a 3'-hydroxyl group, it is not an obligate chain terminator but does inhibit DNA elongation.

Resistant variants owing to thymidine kinase or DNA polymerase mutations can be selected by passage *in vitro*, but the occurrence of resistance during clinical use is currently low (Bacon et al., 2003). Thymidine kinase-deficient, acyclovir-resistant herpes viruses are cross-resistant to penciclovir.

**Absorption, Distribution, and Elimination.** Oral penciclovir has low (<5%) bioavailability. In contrast, famciclovir is well absorbed orally (bioavailability ~75%) and is converted rapidly to penciclovir by deacetylation of the side chain and oxidation of the purine ring during and following absorption from the intestine (Gill and Wood, 1996). Thus, the bioavailability of penciclovir is ~75% following oral administration of famciclovir.

Food slows absorption but does not reduce overall bioavailability. After single 250- or 500-mg doses of famciclovir, the peak plasma concentration of penciclovir averages 1.6 and 3.3  $\mu\text{g/mL}$ , respectively. A small quantity of

the 6-deoxy precursor but no famciclovir is detectable in plasma. After intravenous infusion of penciclovir at 10 mg/kg, peak plasma levels average 12 µg/mL. The volume of distribution is about twice the volume of total-body water. The plasma elimination  $t_{1/2}$  of penciclovir averages ~2 hours, and >90% is excreted unchanged in the urine, probably by both filtration and active tubular secretion. Following oral famciclovir administration, nonrenal clearance accounts for ~10% of each dose, primarily through fecal excretion, but penciclovir (60% of dose) and its 6-deoxy precursor (<10% of dose) are eliminated primarily in the urine. The plasma  $t_{1/2}$  averages 9.9 hours in renal insufficiency ( $Cl_{cr} < 30$  mL/minute); hemodialysis efficiently removes penciclovir. Lower peak plasma concentrations of penciclovir, but no reduction in overall bioavailability of famciclovir, occur in compensated chronic hepatic insufficiency (Boike et al., 1994).

**Untoward Effects.** Oral famciclovir is well tolerated but may be associated with headache, diarrhea, and nausea. Urticaria, rash, and hallucinations or confusional states (predominantly in the elderly) have been reported. Topical penciclovir, which is formulated in 40% propylene glycol and a cetomacrogol base, is associated infrequently with application-site reactions (~1%). The short-term tolerance of famciclovir is comparable with that of acyclovir.

Penciclovir is mutagenic at high concentrations *in vitro*. Although studies in laboratory animals indicate that chronic famciclovir administration is tumorigenic and decreases spermatogenesis and fertility in rodents and dogs, long-term administration (1 year) does not affect spermatogenesis in men. No teratogenic effects have been observed in animals, but safety during pregnancy has not been established. No clinically important drug interactions have been identified to date with famciclovir or penciclovir (Gill and Wood, 1996).

**Therapeutic Uses.** Oral famciclovir, topical penciclovir, and intravenous penciclovir are approved for managing HSV and VZV infections (Sacks and Wilson, 1999).

Oral famciclovir (250 mg three times a day for 7-10 days) is as effective as acyclovir in treating first-episode genital herpes (Kimberlin and Rouse, 2004). In patients with recurrent genital HSV, patient-initiated famciclovir treatment (125 or 250 mg twice a day for 5 days) reduces healing time and

symptoms by ~1 day. Famciclovir (250 mg twice a day for up to 1 year) is effective for suppression of recurrent genital HSV, but single daily doses are less effective. Higher doses (500 mg twice a day) reduce HSV recurrences in HIV-infected persons. Intravenous penciclovir (5 mg/kg every 8 or 12 hours for 7 days) (not available in the U.S.) is comparable to intravenous acyclovir for treating mucocutaneous HSV infections in immunocompromised hosts. In immunocompetent persons with recurrent orolabial HSV, topical 1% penciclovir cream (applied every 2 hours while awake for 4 days) shortens healing time and symptoms by ~1 day (Raborn et al., 2002).

In immunocompetent adults with herpes zoster of  $\leq 3$  days' duration, famciclovir (500 mg three times a day for 10 days) is at least as effective as acyclovir (800 mg five times daily) in reducing healing time and zoster-associated pain, particularly in those  $\geq 50$  years of age. Famciclovir is comparable with valacyclovir in treating zoster and reducing associated pain in older adults (Tyring et al., 2000). Famciclovir (500 mg three times a day for 7-10 days) also is comparable with high-dose oral acyclovir in treating zoster in immunocompromised patients and in those with ophthalmic zoster (Tyring et al., 2001).

Famciclovir is associated with dose-related reductions in HBV DNA and transaminase levels in patients with chronic HBV hepatitis but is less effective than lamivudine (Lai et al., 2002). Famciclovir is also ineffective in treating lamivudine-resistant HBV infections owing to emergence of multiply resistant variants.

## **Fomivirsen**

Fomivirsen, a 21-base phosphorothioate oligonucleotide, was the first FDA-approved antisense therapy for viral infections. It is complementary to the messenger RNA sequence for the major immediate-early transcriptional region of CMV and inhibits CMV replication through sequence-specific and nonspecific mechanisms, including inhibition of virus binding to cells. Fomivirsen is active against CMV strains resistant to ganciclovir, foscarnet, and cidofovir. CMV variants with 10-fold reduced susceptibility to fomivirsen have been selected by *in vitro* passage.

Fomivirsen is given by intravitreal injection in the treatment of CMV retinitis for patients intolerant of or unresponsive to other therapies. Following injection, it is cleared slowly from the vitreous ( $t_{1/2}$  ~55 hours)

through distribution to the retina and probable exonuclease digestion (Geary et al., 2002). Local metabolism by exonucleases accounts for elimination. In HIV-infected patients with refractory, sight-threatening CMV retinitis, fomivirsen injections (330  $\mu\text{g}$  weekly for 3 weeks and then every 2 weeks or on days 1 and 15 followed by monthly) significantly delay time to retinitis progression (Vitravene Study Group, 2002). Ocular side effects include iritis in up to one-quarter of patients, which can be managed with topical corticosteroids; vitritis; cataracts; and increases in intraocular pressure in 15-20% of patients. Recent cidofovir use may increase the risk of inflammatory reactions. The drug is no longer available in the U.S.

## Foscarnet

**Chemistry and Antiviral Activity.** Foscarnet (trisodium phosphonoformate; [Figure 58–2](#)) is an inorganic pyrophosphate analog that is inhibitory for all herpesviruses and HIV.

*In vitro* inhibitory concentrations are generally 100-300  $\mu\text{M}$  for CMV and 80-200  $\mu\text{M}$  for other herpesviruses, including most ganciclovir-resistant CMV and acyclovir-resistant HSV and VZV strains. Combinations of foscarnet and ganciclovir synergistically inhibit CMV replication *in vitro*. Concentrations of 500-1000  $\mu\text{M}$  reversibly inhibit the proliferation and DNA synthesis of uninfected cells.

**Mechanisms of Action and Resistance.** Foscarnet inhibits viral nucleic acid synthesis by interacting directly with herpesvirus DNA polymerase or HIV reverse transcriptase ([Figure 58–3](#)). It is taken up slowly by cells and does not undergo significant intracellular metabolism. Foscarnet reversibly blocks the pyrophosphate binding site of the viral polymerase in a noncompetitive manner and inhibits cleavage of pyrophosphate from deoxynucleotide triphosphates. Foscarnet has  $\sim$ 100-fold greater inhibitory effects against herpesvirus DNA polymerases than against cellular DNA polymerase- $\alpha$ . Herpesviruses resistant to foscarnet have point mutations in the viral DNA polymerase and are associated with 3- to 7-fold reductions in foscarnet activity *in vitro*.

**Absorption, Distribution, and Elimination.** Oral bioavailability of foscarnet is low. Following an intravenous infusion of 60 mg/kg every 8 hours, peak and trough plasma concentrations are  $\sim$ 450-575 and 80-150  $\mu\text{M}$ ,

respectively. Vitreous levels approximate those in plasma, and CSF levels average 66% of those in plasma at steady state.

Over 80% of foscarnet is excreted unchanged in the urine by glomerular filtration and probably tubular secretion. Plasma clearance decreases proportionately with creatinine clearance, and dose adjustments are indicated for small decreases in renal function. Plasma elimination is complex, with initial bimodal half-lives totaling 4-8 hours and a prolonged terminal elimination  $t_{1/2}$  averaging 3-4 days. Sequestration in bone with gradual release accounts for the fate of an estimated 10-20% of a given dose. Foscarnet is cleared efficiently by hemodialysis (~50% of a dose).

**Untoward Effects.** Foscarnet's major dose-limiting toxicities are nephrotoxicity and symptomatic hypocalcemia. Increases in serum creatinine occur in up to one-half of patients but are reversible after cessation in most patients. High doses, rapid infusion, dehydration, prior renal insufficiency, and concurrent nephrotoxic drugs are risk factors. Acute tubular necrosis, crystalline glomerulopathy, nephrogenic diabetes insipidus, and interstitial nephritis have been described. Saline loading may reduce the risk of nephrotoxicity.

Foscarnet is highly ionized at physiological pH, and metabolic abnormalities are very common. These include increases or decreases in  $\text{Ca}^{2+}$  and phosphate, hypomagnesemia, and hypokalemia. Decreased serum ionized  $\text{Ca}^{2+}$  may cause paresthesia, arrhythmias, tetany, seizures, and other CNS disturbances. Concomitant intravenous pentamidine administration increases the risk of symptomatic hypocalcemia. Parenteral magnesium sulfate does not alter foscarnet-induced hypocalcemia or symptoms (Huycke et al., 2000).

CNS side effects include headache in ~25% of patients, tremor, irritability, seizures, and hallucinosis. Other reported side effects are generalized rash, fever, nausea or emesis, anemia, leukopenia, abnormal liver function tests, electrocardiographic changes, infusion-related thrombophlebitis, and painful genital ulcerations. Topical foscarnet may cause local irritation and ulceration, and oral foscarnet may cause GI disturbance. Preclinical studies indicate that high foscarnet concentrations are mutagenic and may cause tooth and skeletal abnormalities in developing laboratory animals. Safety in pregnancy or childhood is uncertain.

**Therapeutic Uses.** Intravenous foscarnet is effective for treatment of CMV retinitis, including ganciclovir-resistant infections, other types of CMV infection, and acyclovir-resistant HSV and VZV infections. Foscarnet is poorly soluble in aqueous solutions and requires large volumes for administration.

In CMV retinitis in AIDS patients, foscarnet (60 mg/kg every 8 hours or 90 mg/kg every 12 hours for 14-21 days followed by chronic maintenance at 90 to 120 mg/kg every day in one dose) is associated with clinical stabilization in ~90% of patients. A comparative trial of foscarnet with ganciclovir found comparable control of CMV retinitis in AIDS patients but improved overall survival in the foscarnet-treated group (Studies of Ocular Complications of AIDS, 1992). This improved survival with foscarnet may be related to the drug's intrinsic anti-HIV activity, but patients stop taking foscarnet over three times as often as ganciclovir because of side effects. A combination of foscarnet and ganciclovir is more effective than either drug alone in refractory retinitis; combinations may be useful in treating ganciclovir-resistant CMV infections in solid-organ transplant patients. Foscarnet benefits other CMV syndromes in AIDS or transplant patients but is ineffective as monotherapy in treating CMV pneumonia in bone marrow transplant patients (possibly effective if started early). When used for preemptive therapy of CMV viremia in bone marrow transplant recipients, foscarnet (60 mg/kg every 12 hours for 2 weeks followed by 90 mg/kg daily for 2 weeks) is as effective as intravenous ganciclovir and causes less neutropenia (Reusser et al., 2002). When used for CMV infections, foscarnet may reduce the risk of Kaposi's sarcoma in HIV-infected patients. Intravitreal injections of foscarnet also have been used.

In acyclovir-resistant mucocutaneous HSV infections, lower doses of foscarnet (40 mg/kg every 8 hours for  $\geq 7$  days) are associated with cessation of viral shedding and with complete healing of lesions in about three-quarters of patients. Foscarnet also appears to be effective in acyclovir-resistant VZV infections. Topical foscarnet cream is ineffective in treating recurrent genital HSV in immunocompetent persons but appears to be useful in chronic acyclovir-resistant infections in immunocompromised patients.

Resistant clinical isolates of herpesviruses have emerged during therapeutic use and may be associated with poor clinical response to foscarnet treatment.

## Ganciclovir and Valganciclovir

**Chemistry and Antiviral Activity.** Ganciclovir is an acyclic guanine nucleoside analog that is similar in structure to acyclovir except in having an additional hydroxymethyl group on the acyclic side chain. Valganciclovir is the L-valyl ester prodrug of ganciclovir. Their structures are shown in [Figure 58–2](#).

Ganciclovir has inhibitory activity against all herpesviruses but is especially active against CMV (Noble and Faulds, 1998). Inhibitory concentrations are similar to those of acyclovir for HSV and VZV but 10-100 times lower for human CMV strains (0.2-2.8 µg/mL).

Inhibitory concentrations for human bone marrow progenitor cells are similar to those inhibitory for CMV replication, a finding predictive of ganciclovir's myelotoxicity during clinical use. Inhibition of human lymphocyte blastogenic responses also occurs at clinically achievable concentrations of 1-10 µg/mL.

**Mechanisms of Action and Resistance.** Ganciclovir inhibits viral DNA synthesis. It is monophosphorylated intracellularly by viral thymidine kinase during HSV infection and by a viral phosphotransferase encoded by the UL97 gene during CMV infection. Ganciclovir diphosphate and ganciclovir triphosphate are formed by cellular enzymes. At least 10-fold higher concentrations of ganciclovir triphosphate are present in CMV-infected than in uninfected cells. The triphosphate is a competitive inhibitor of deoxyguanosine triphosphate incorporation into DNA and preferentially inhibits viral rather than host cellular DNA polymerases. Ganciclovir is incorporated into both viral and cellular DNA. Incorporation into viral DNA causes eventual cessation of DNA chain elongation ([Figures 58–1B](#) and [58–3](#)).

Intracellular ganciclovir triphosphate concentrations are 10-fold higher than those of acyclovir triphosphate and decline much more slowly with an intracellular elimination  $t_{1/2}$  >24 hours. These differences may account in part for ganciclovir's greater anti-CMV activity and provide the rationale for single daily doses in suppressing human CMV infections.

CMV can become resistant to ganciclovir by one of two mechanisms: reduced intracellular ganciclovir phosphorylation owing to mutations in the viral phosphotransferase encoded by the UL97 gene and mutations in viral

DNA polymerase (Schreiber et al., 2009). Resistant CMV clinical isolates have from 4- to >20-fold increases in inhibitory concentrations. Resistance has been associated primarily with impaired phosphorylation but sometimes only with DNA polymerase mutations. Highly resistant variants with dual UL97 and polymerase mutations are cross-resistant to cidofovir and variably to foscarnet. Ganciclovir also is much less active against acyclovir-resistant thymidine kinase-deficient HSV strains.

**Absorption, Distribution, and Elimination.** The oral bioavailability of ganciclovir averages 6-9% following ingestion with food. Peak and trough plasma levels are ~0.5-1.2 and 0.2-0.5  $\mu\text{g/mL}$ , respectively, after 1000-mg doses every 8 hours. Oral valganciclovir is well absorbed and hydrolyzed rapidly to ganciclovir; the bioavailability of ganciclovir averages 61% following valganciclovir (Curran and Noble, 2001). Food increases the bioavailability of valganciclovir by ~25%, and peak ganciclovir concentrations average 6.1  $\mu\text{g/mL}$  after 875-mg doses. High oral valganciclovir doses in the fed state provide ganciclovir exposures comparable with intravenous dosing (Brown et al., 1999). Following intravenous administration of 5 mg/kg doses of ganciclovir, peak and trough plasma concentrations average 8-11 and 0.6-1.2  $\mu\text{g/mL}$ , respectively. Following intravenous dosing, vitreous fluid levels are similar to or higher than those in plasma and average ~1  $\mu\text{g/mL}$ . Vitreous levels decline with a  $t_{1/2}$  of 23-26 hours. Intraocular sustained-release ganciclovir implants provide vitreous levels of ~4.1  $\mu\text{g/mL}$ .

The plasma elimination  $t_{1/2}$  is ~2-4 hours in patients with normal renal function. Over 90% of ganciclovir is eliminated unchanged by renal excretion through glomerular filtration and tubular secretion. Consequently, the plasma  $t_{1/2}$  increases almost linearly as creatinine clearance declines and may reach 28-40 hours in patients with severe renal insufficiency.

**Untoward Effects.** Myelosuppression is the principal dose-limiting toxicity of ganciclovir. Neutropenia occurs in ~15-40% of patients and thrombocytopenia in 5-20%. Neutropenia is observed most commonly during the second week of treatment and usually is reversible within 1 week of drug cessation. Persistent fatal neutropenia has occurred. Oral valganciclovir is associated with headache and GI disturbance (i.e., nausea, pain, and diarrhea) in addition to the toxicities associated with intravenous ganciclovir, including neutropenia. Recombinant granulocyte colony-

stimulating factor (G-CSF; filgrastim, lenograstim) may be useful in treating ganciclovir-induced neutropenia ([Chapter 37](#)).

CNS side effects occur in 5-15% of patients and range in severity from headache to behavioral changes to convulsions and coma. About one-third of patients must interrupt or prematurely stop intravenous ganciclovir therapy because of bone marrow or CNS toxicity. Infusion-related phlebitis, azotemia, anemia, rash, fever, liver function test abnormalities, nausea or vomiting, and eosinophilia also have been described.

Teratogenicity, embryotoxicity, irreversible reproductive toxicity, and myelotoxicity have been observed in animals at ganciclovir dosages comparable with those used in humans. Ganciclovir is classified as pregnancy Category C.

Zidovudine and probably other cytotoxic agents increase the risk of myelosuppression, as do nephrotoxic agents that impair ganciclovir excretion. Probenecid and possibly acyclovir reduce renal clearance of ganciclovir. Oral ganciclovir increases the absorption and peak plasma concentrations of didanosine by approximately 2-fold and that of zidovudine by ~20%.

**Therapeutic Uses.** Ganciclovir is effective for treatment and chronic suppression of CMV retinitis in immunocompromised patients and for prevention of CMV disease in transplant patients.

In CMV retinitis, initial induction treatment (5 mg/kg intravenously every 12 hours for 10-21 days) is associated with improvement or stabilization in ~85% of patients (Faulds and Heel, 1990). Reduced viral excretion is usually evident by 1 week, and funduscopy improvement is seen by 2 weeks. Because of the high risk of relapse, AIDS patients with retinitis require suppressive therapy with high doses of ganciclovir (5 mg/kg/day). Oral ganciclovir (1000 mg three times daily) is effective for suppression of retinitis after initial intravenous treatment but has been replaced in practice by oral valganciclovir. Oral valganciclovir (900 mg twice daily for 21 days initial treatment) is comparable with intravenous dosing for initial control and sustained suppression (900 mg daily) of CMV retinitis (Schreiber et al., 2009). Intravitreal ganciclovir injections have been used in some patients, and an intraocular sustained-release ganciclovir implant (VITRASERT) is more effective than systemic dosing in suppressing retinitis progression.

Ganciclovir therapy (5 mg/kg every 12 hours for 14-21 days) may benefit other CMV syndromes in AIDS patients or solid-organ transplant recipients (Infectious Disease Community of Practice et al., 2004). Response rates of  $\geq 67\%$  have been found in combination with a decrease in immunosuppressive therapy. The duration of therapy depends on demonstrating clearance of viremia; early switch from intravenous ganciclovir to oral valganciclovir is feasible. Recurrent CMV disease occurs commonly after initial treatment. In bone marrow transplant recipients with CMV pneumonia, ganciclovir alone appears ineffective. However, ganciclovir combined with intravenous immunoglobulin or CMV immunoglobulin reduces the mortality of CMV pneumonia by about one-half. Ganciclovir treatment improved hearing outcomes in neonates with symptomatic congenital CMV infections involving the CNS (Kimberlin et al, 2003).

Ganciclovir has been used for both prophylaxis and preemptive therapy of CMV infections in transplant recipients (Schreiber et al., 2009). In bone marrow transplant recipients, preemptive ganciclovir treatment (5 mg/kg every 12 hours for 7-14 days followed by 5 mg/kg every day to days 100-120 after transplant) starting when CMV is isolated from bronchoalveolar lavage or from other sites is highly effective in preventing CMV pneumonia and appears to reduce mortality in these patients. Initiation of ganciclovir at the time of engraftment also reduces CMV disease rates but does not improve survival in part because of infections owing to ganciclovir-related neutropenia.

Intravenous ganciclovir, oral ganciclovir, and oral valganciclovir reduce the risk of CMV disease in solid-organ transplant recipients (Infectious Disease Community of Practice et al., 2004). Oral ganciclovir (1000 mg three times daily for 3 months) reduces CMV disease risk in liver transplant recipients, including high-risk patients with primary infection or those receiving antilymphocyte antibodies. Oral valganciclovir prophylaxis generally is more effective than high-dose oral acyclovir. Oral valganciclovir (900 mg once daily) provides somewhat greater antiviral effects and similar reductions in CMV disease as oral ganciclovir in mismatched solid-organ transplant recipients (Schreiber et al., 2009). Valganciclovir has recently been approved for prevention of CMV in pediatric transplant patients.

In advanced HIV disease, oral ganciclovir (1000 mg three times daily) may reduce the risk of CMV disease and possibly mortality in those not receiving didanosine (Brosgart et al., 1998) but has been replaced for prophylaxis by oral valganciclovir. The addition of oral high-dose ganciclovir (1500 mg three times daily) to the intraocular ganciclovir implant further delays the time to retinitis progression and reduces the risk of new CMV disease and possibly the risk of Kaposi's sarcoma.

Ganciclovir resistance emerges in a minority of transplant patients, especially mismatched solid-organ recipients (Limaye et al., 2000), and is associated with poorer prognosis. The use of antithymocyte globulin and prolonged ganciclovir exposure are risk factors. Recovery of ganciclovir-resistant CMV isolates has been associated with progressive CMV disease in AIDS and other immunocompromised patients. Over one-quarter of retinitis patients have resistant isolates by 9 months of therapy, and resistant CMV has been recovered from CSF, vitreous fluid, and visceral sites.

A ganciclovir ophthalmic gel formulation (ZIRGAN) is effective in treating HSV keratitis (Colin et al., 1997). Oral ganciclovir also reduces HBV DNA levels and aminotransferase levels in chronic hepatitis B virus infection (Hadziyannis et al., 1999), but the drug is not approved for this indication.

## **Docosanol**

Docosanol is a long-chain saturated alcohol that is FDA-approved as an over-the-counter 10% cream for the treatment of recurrent orolabial herpes. Docosanol inhibits the *in vitro* replication of many lipid-enveloped viruses, including HSV, at millimolar concentrations. It does not inactivate HSV directly but appears to block fusion between the cellular and viral envelope membranes and inhibits viral entry into the cell. Topical treatment beginning within 12 hours of prodromal symptoms or lesion onset reduces healing time by ~1 day and appears to be well tolerated (Elish et al., 2004). Treatment initiation at papular or later stages provides no benefit.

## **Idoxuridine**

Idoxuridine (5-iodo-2'-deoxyuridine) is an iodinated thymidine analog that inhibits the *in vitro* replication of various DNA viruses, including herpesviruses and poxviruses (Prusoff, 1988).

Inhibitory concentrations of idoxuridine for HSV-1 are 2-10  $\mu\text{g/mL}$ , at least 10-fold higher than those of acyclovir. Idoxuridine lacks selectivity, in that low concentrations inhibit the growth of uninfected cells. The triphosphate inhibits viral DNA synthesis and is incorporated into both viral and cellular DNA. Such altered DNA is more susceptible to breakage and also leads to faulty transcription. Resistance to idoxuridine develops readily in vitro and occurs in viral isolates recovered from idoxuridine-treated patients with HSV keratitis.

In the U.S., idoxuridine is approved only for topical (ophthalmic) treatment of HSV keratitis. Idoxuridine formulated in dimethylsulfoxide is available outside the U.S. for topical treatment of herpes labialis, genitalis, and zoster. In ocular HSV infections, topical idoxuridine is more effective in epithelial infections, especially initial episodes, than in stromal infections. Adverse reactions include pain, pruritus, inflammation, and edema involving the eye or lids; rarely do allergic reactions occur.

## **Trifluridine**

Trifluridine (5-trifluoromethyl-2'-deoxyuridine) is a fluorinated pyrimidine nucleoside that has in vitro inhibitory activity against HSV types 1 and 2, CMV, vaccinia, and to a lesser extent, certain adenoviruses.

Concentrations of trifluridine of 0.2-10  $\mu\text{g/mL}$  inhibit replication of herpesviruses, including acyclovir-resistant strains. Trifluridine also inhibits cellular DNA synthesis at relatively low concentrations.

Trifluridine monophosphate irreversibly inhibits thymidylate synthase, and trifluridine triphosphate is a competitive inhibitor of thymidine triphosphate incorporation into DNA; trifluridine is incorporated into viral and cellular DNA. Trifluridine-resistant HSV with altered thymidine kinase substrate specificity can be selected in vitro, and resistance in clinical isolates has been described.

Trifluridine currently is approved in the U.S. for treatment of primary keratoconjunctivitis and recurrent epithelial keratitis owing to HSV types 1 and 2. Topical trifluridine is more active than idoxuridine and comparable with vidarabine in HSV ocular infections. Adverse reactions include discomfort on instillation and palpebral edema. Hypersensitivity reactions, irritation, and superficial punctate or epithelial keratopathy are uncommon.

Topical trifluridine also appears to be effective in some patients with acyclovir-resistant HSV cutaneous infections.

## **ANTI-INFLUENZA AGENTS**

Four drugs are currently approved for the treatment and prevention of influenza virus infection. Over the past several years, there has been increasing concern about the possibility of new influenza pandemics, stemming from small but severe outbreaks of H5N1 avian influenza and the novel 2009 influenza A H1N1, thought to be of swine origin. This has prompted stockpiling of existing agents and motivated new drug discovery. Regulatory responses include Emergency Use Authorization (EUA) granted by the FDA, Centers for Disease Control and Prevention, and the World Health Organization to allow for treatment and prophylaxis of H1N1 in pediatric patients  $\leq 1$  year of age even though the four available agents were never granted conventional approval for this age group. In addition, peramivir, an investigational neuraminidase inhibitor, was made available for intravenous use via EUA authorization.

In the 2008–2009 influenza season, virtually all strains of influenza A H1N1 were resistant to the neuraminidase inhibitor oseltamivir (Moscona, 2009). This has arisen as a consequence of overuse of these drugs, including in veterinary applications. Fortunately the majority of 2009 H1N1 “swine” viruses were susceptible to oseltamivir; however, sporadic cases of oseltamivir resistance have been detected even with this strain. All such viruses tested to date were resistant to the adamantane antivirals, amantadine and rimantadine. Development of resistance to these drugs, and the spread of resistant viruses, is a major challenge in the chemotherapy and chemoprophylaxis of influenza and is likely to drive future recommendations for use of these drugs in global populations.

### **Amantadine and Rimantadine**

**Chemistry and Antiviral Activity.** Amantadine (1-adamantanamine hydrochloride) and its  $\alpha$ -methyl derivative rimantadine ( $\alpha$ -methyl-1-adamantane methylamine hydrochloride) are uniquely configured tricyclic amines. Their structures are depicted in [Figure 58–4](#).

Low concentrations of either agent specifically inhibit the replication of influenza A viruses (Schmidt, 2004). Depending on the assay method and

strain, inhibitory concentrations of the drugs range from ~0.03-1.0 µg/mL for influenza A viruses. Rimantadine generally is 4-10 times more active than amantadine. Concentrations of ≥10 µg/mL inhibit other enveloped viruses but are not achievable in humans and may be cytotoxic. Rimantadine is inhibitory *in vitro* for *Trypanosoma brucei*, a cause of African sleeping sickness, at concentrations of 1-2.5 µg/mL. These agents do not inhibit hepatitis C virus (HCV) enzymes or internal ribosomal entry site-mediated translation but block the ion channel activity of the HCV p7 protein *in vitro* (Griffin et al., 2003).

**Mechanisms of Action and Resistance.** Amantadine and rimantadine share two mechanisms of antiviral action. They inhibit an early step in viral replication, probably viral uncoating; for some strains, they also have an effect on a late step in viral assembly probably mediated through altering hemagglutinin processing. The primary locus of action is the influenza A virus M2 protein, an integral membrane protein that functions as an ion channel. By interfering with this function of the M2 protein, the drugs inhibit the acid-mediated dissociation of the ribonucleoprotein complex early in replication and potentiate acidic pH-induced conformational changes in the hemagglutinin during its intracellular transport later in replication.

**Absorption, Distribution, and Elimination.** Amantadine and rimantadine are well absorbed after oral administration (Schmidt, 2004) ([Table 58-3](#)). Peak plasma concentrations of amantadine average 0.5-0.8 µg/mL on a 100-mg twice-daily regimen in healthy young adults. Comparable doses of rimantadine give peak and trough plasma concentrations of ~0.4-0.5 and 0.2-0.4 µg/mL, respectively. The elderly require only one-half the weight-adjusted dose of amantadine needed for young adults to achieve equivalent trough plasma levels of 0.3 µg/mL. Both drugs have very large volumes of distribution. Nasal secretion and salivary levels of amantadine approximate those found in the serum. Amantadine is excreted in breast milk. Rimantadine concentrations in nasal mucus average 50% higher than those in plasma.

Amantadine is excreted largely unmetabolized in the urine through glomerular filtration and probably tubular secretion. The plasma  $t_{1/2}$  of elimination is ~12-18 hours in young adults. Because amantadine's elimination is highly dependent on renal function, the elimination  $t_{1/2}$  increases up to 2-fold in the elderly and even more in those with renal impairment. Dose adjustments are advisable in those with mild decrements in

renal function. In contrast, rimantadine is metabolized extensively by hydroxylation, conjugation, and glucuronidation prior to renal excretion. Following oral administration, the elimination  $t_{1/2}$  of rimantadine averages 24-36 hours, and 60-90% is excreted in the urine as metabolites. Renal clearance of unchanged rimantadine is similar to creatinine clearance.

**Figure 58–4.** *Chemical Structures of the Anti-Influenza Drugs.*

**Untoward Effects.** The most common side effects related to amantadine and rimantadine are minor dose-related CNS and gastrointestinal (Schmidt, 2004). These include nervousness, light-headedness, difficulty concentrating, insomnia, and loss of appetite or nausea. CNS side effects occur in 5-33% of patients treated with amantadine at doses of 200 mg/day but are significantly less frequent with rimantadine. The neurotoxic effects of amantadine appear to be increased by concomitant ingestion of antihistamines and psychotropic

or anticholinergic drugs, especially in the elderly. Amantadine dose reductions are required in older adults (100 mg/day) because of decreased renal function, but 20-40% of infirm elderly will experience side effects even at this lower dose. At comparable doses of 100 mg/day, rimantadine is significantly better tolerated in nursing home residents than amantadine (Keyser et al., 2000).

High amantadine plasma concentrations (1.0-5.0  $\mu\text{g/mL}$ ) have been associated with serious neurotoxic reactions, including delirium, hallucinosis, seizures, and coma, and cardiac arrhythmias. Exacerbations of preexisting seizure disorders and psychiatric symptoms may occur with amantadine and possibly with rimantadine. Amantadine is teratogenic in animals. Both drugs are considered pregnancy Category C because safety has not been established in pregnancy.

**Therapeutic Uses.** Seasonal prophylaxis with either amantadine or rimantadine (a total of 200 mg/day in one or two divided doses in young adults) is ~70-90% protective against influenza A illness.

Efficacy has been shown during pandemic influenza, in preventing nosocomial influenza, and in curtailing nosocomial outbreaks. Doses of 100 mg/day are better tolerated and still appear to be protective against influenzal illness. Postexposure prophylaxis with either drug provides protection of exposed family contacts if ill young children are not concurrently treated (Schmidt, 2004).

Seasonal prophylaxis is an alternative in high-risk patients if the influenza vaccine cannot be administered or may be ineffective (i.e., in immunocompromised patients). Prophylaxis should be started as soon as influenza is identified in a community or region and should be continued throughout the period of risk (usually 4-8 weeks) because any protective effects are lost several days after cessation of therapy. Alternatively, the drugs can be started in conjunction with immunization and continued for 2 weeks until protective immune responses develop.

The amantadines are effective against influenza A H1N1 in adults and children if treatment is initiated within 2 days of the onset of symptoms (Schmidt, 2004). Therapy reduces duration of viral excretion, fever, and other systemic complaints, but resistance has become more widespread with use. Duration of illness is shortened by ~1 day. In uncomplicated influenza A illness of adults, early amantadine or rimantadine treatment (200 mg/day for

5 days) reduces the duration of fever and systemic complaints by 1-2 days, speeds functional recovery, and sometimes decreases the duration of virus shedding (Schmidt, 2004). In children, rimantadine treatment may be associated with less illness and lower viral titers during the first 2 days of treatment, but rimantadine-treated children have more prolonged shedding of virus. The usual regimen in children ( $\geq 1$  year of age) is 5 mg/kg/day, up to 150 mg, administered once or twice daily.

Resistant variants have been recovered from  $\sim 30\%$  of treated children or outpatient adults by the fifth day of therapy (Schmidt, 2004). Resistant variants also arise commonly in immunocompromised patients (Englund et al., 1998). Illnesses owing to apparent transmission of resistant virus associated with failure of drug prophylaxis have been documented in contacts of drug-treated ill persons in households and in nursing homes (Schmidt, 2004). Resistant variants appear to be pathogenic and can cause typical disabling influenza.

Although both drugs are useful for the prevention and treatment of infections caused by influenza A virus, vaccination against influenza is a more cost-effective means of reducing disease burden. The utility of the amantadines has been limited by the development of resistance. Amantadine and rimantadine are active only against susceptible influenza A viruses (not influenza B); rimantadine is 4- to 10-fold more active than amantadine. Currently, virtually all H3N2 strains of influenza circulating worldwide are resistant to these drugs. Resistance to these drugs results from a mutation in the RNA sequence encoding for the M2 protein transmembrane domain (Schmidt, 2004), and resistant isolates typically appears in the treated patient within 2-3 days of starting therapy.

## Oseltamivir

**Chemistry and Antiviral Activity.** Oseltamivir carboxylate ([Figure 58-4](#)) is a transition-state analog of sialic acid that is a potent selective inhibitor of influenza A and B virus neuraminidases. Oseltamivir phosphate is an ethyl ester prodrug that lacks antiviral activity.

Oseltamivir carboxylate has an antiviral spectrum and potency similar to that of zanamivir. It inhibits amantadine and rimantadine-resistant influenza A viruses and some zanamivir-resistant variants.

**Mechanisms of Action and Resistance.** Influenza neuraminidase cleaves terminal sialic acid residues and destroys the receptors recognized by viral hemagglutinin, which are present on the cell surface, in progeny virions, and in respiratory secretions (Schirmer and Holodniy, 2009). This enzymatic action is essential for release of virus from infected cells. Interaction of oseltamivir carboxylate with the neuraminidase causes a conformational change within the enzyme's active site and inhibits its activity. Inhibition of neuraminidase activity leads to viral aggregation at the cell surface and reduced virus spread within the respiratory tract.

Influenza variants selected *in vitro* for resistance to oseltamivir carboxylate contain hemagglutinin and/or neuraminidase mutations. The most commonly recognized variants (mutations at positions 292 in N2 and 274 in N1 neuraminidases) have reduced infectivity and virulence in animal models. Outpatient oseltamivir therapy has been associated with recovery of resistant variants in ~0.5% of adults and 5.5% of children; a higher frequency (~18%) occurs in hospitalized children. Seasonal influenza A (H1N1) has become virtually 100% resistant to oseltamivir worldwide (Moscona, 2009; Schirmer and Holodniy, 2009). Importantly, novel H1N1 (nH1N1 or swine influenza) remains susceptible to oseltamivir.

**Absorption, Distribution, and Elimination.** Oral oseltamivir phosphate is absorbed rapidly ([Table 58-3](#)) and cleaved by esterases in the GI tract and liver to the active carboxylate. Low blood levels of the phosphate are detectable, but exposure is only 3-5% of that of the metabolite. The bioavailability of the carboxylate is estimated to be ~80%. The time to maximum plasma concentrations of the carboxylate is ~2.5-5 hours. Food does not decrease bioavailability but reduces the risk of GI intolerance. After 75-mg doses, peak plasma concentrations average 0.07 µg/mL for oseltamivir phosphate and 0.35 µg/mL for the carboxylate. The carboxylate has a volume of distribution similar to extracellular water. Bronchoalveolar lavage levels in animals and middle ear fluid and sinus concentrations in humans are comparable with plasma levels. Following oral administration, the plasma  $t_{1/2}$  of oseltamivir phosphate is 1-3 hours; that of the carboxylate is 6-10 hours. Both the prodrug and active metabolite are eliminated primarily unchanged through the kidney. Probenecid doubles the plasma  $t_{1/2}$  of the carboxylate, which indicates tubular secretion by the anionic pathway.

Children <2 years of age exhibit age-related changes in oseltamivir carboxylate clearance and total drug exposure (Kimberlin et al., 2009).

**Untoward Effects.** Oral oseltamivir is associated with nausea, abdominal discomfort, and, less often, emesis, probably owing to local irritation. GI complaints usually are mild to moderate in intensity, typically resolve in 1-2 days despite continued dosing, and are preventable by administration with food. The frequency of such complaints is ~10-15% when oseltamivir is used for the treatment of influenza illness and <5% when used for prophylaxis. An increased frequency of headache was reported in one prophylaxis study in elderly adults.

Oseltamivir phosphate and the carboxylate do not interact with CYPs *in vitro*. Their binding to protein is low. No clinically significant drug interactions have been recognized to date. Oseltamivir does not appear to impair fertility or to be teratogenic in animal studies, but safety in pregnancy is uncertain (pregnancy Category C). Very high doses have been associated with increased mortality, perhaps related to increased brain concentrations, in unweaned rats.

**Therapeutic Uses.** Oral oseltamivir is effective in the treatment and prevention of influenza A and B virus infections.

Treatment of previously healthy adults (75 mg twice daily for 5 days) or children 1-12 years of age (weight-adjusted dosing) with acute influenza reduces illness duration by ~1-2 days, speeds functional recovery, and reduces the risk of complications leading to antibiotic use by 40-50% (Whitley et al., 2001). Treatment is associated with approximate halving of the risk of subsequent hospitalization in adults (Kaiser et al., 2003). When used for prophylaxis during the typical influenza season, oseltamivir (75 mg once daily) is effective (~70-90%) in reducing the likelihood of influenza illness in both unimmunized working adults and in immunized nursing home residents; short-term use (7-10 days) protects against influenza in household contacts (Schirmer and Holodniy, 2009).

### **Table 58–3 Pharmacological Characteristics of Antivirals for Influenza**

	AMANTADINE	RIMANTADINE	ZANAMIVIR	OSELTAMIVIR
Spectrum (types of influenza)	A	A	A, B	A, B
Route/formulations	Oral (tablet/ capsule/syrup)	Oral (tablet/syrup)	Inhaled (powder) Intravenous <sup>d</sup>	Oral (capsule/ syrup) Intravenous <sup>d</sup>
Oral bioavailability	> 90%	> 90%	< 5% <sup>b</sup>	80% <sup>c</sup>
Effect of meals on AUC	Negligible	Negligible	Not applicable	Negligible
Elimination t <sub>1/2</sub> , h	12-18	24-36	2.5-5	6-10 <sup>c</sup>
Protein binding, %	67%	40%	< 10%	3% <sup>c</sup>
Metabolism, %	< 10%	~75%	Negligible	Negligible
Renal excretion, % (parent drug)	>90%	~25%	100%	95% <sup>c</sup>
Dose adjustments	Cl <sub>cr</sub> ≤ 50 Age ≥ 65 yrs	Cl <sub>cr</sub> ≤ 10 Age ≥ 65 years	None <sup>d</sup>	Cl <sub>cr</sub> ≤ 30

A fifth agent, permavir, is investigational in the U.S. and approved in Japan at a dose of 600 mg intravenously once daily in adults. Its elimination is primarily renal, with dosage adjustment required for renal insufficiency.

<sup>a</sup>Investigational at present. <sup>b</sup>Systemic absorption 4-17% after inhalation. <sup>c</sup>For antivirally active oseltamivir carboxylate. <sup>d</sup>Inhaled formulation only. Cl<sub>cr</sub>, creatinine clearance

Because of the global development of resistance of H1N1 seasonal influenza, treatment recommendations issued by the CDC for the 2008–2009 influenza season required the co-administration of an adamantane and a neuraminidase inhibitor. An intravenous formulation of oseltamivir is being evaluated in adults and children under the 2009 EUA. Until recently, oseltamivir was only licensed for patients >2 years of age; however, with the introduction of 2009 nH1N1, an EUA allows for therapy for all ages (Centers for Disease Control and Prevention, 2009).

## Zanamivir

**Chemistry and Antiviral Activity.** Zanamivir ([Figure 58–4](#)) is a sialic acid analog that potently and specifically inhibits the neuraminidases of influenza A and B viruses.

Depending on the strain, zanamivir competitively inhibits influenza neuraminidase activity at concentrations of ~0.2-3 ng/mL but affects neuraminidases from other pathogens and mammalian sources only at 106-fold higher concentrations. Zanamivir inhibits *in vitro* replication of influenza A and B viruses, including amantadine- and rimantadine-resistant strains and several oseltamivir-resistant variants. It is active after topical administration in animal influenza models.

**Mechanisms of Action and Resistance.** Like oseltamivir, zanamivir inhibits viral neuraminidase and thus causes viral aggregation at the cell surface and reduced spread of virus within the respiratory tract (Eiland and Eiland, 2007).

*In vitro* selection of viruses resistant to zanamivir is associated with mutations in the viral hemagglutinin and/or neuraminidase. Hemagglutinin variants generally have mutations in or near the receptor binding site that make them less dependent on neuraminidase action for release from cells *in vitro*, although they typically retain susceptibility *in vivo*. Hemagglutinin variants are cross-resistant to other neuraminidase inhibitors. Neuraminidase variants contain mutations in the enzyme active site that diminish binding of zanamivir, but the altered enzymes show reduced activity or stability. Zanamivir-resistant variants usually have decreased infectivity in animals. Resistance has not been documented in immunocompetent hosts to date but has been seen rarely in highly immunocompromised patients (Eiland and Eiland, 2007).

**Absorption, Distribution, and Elimination.** The oral bioavailability of zanamivir is low (<5%) ([Table 58–3](#)), and the commercial form is delivered by oral inhalation of dry powder in a lactose carrier. The proprietary inhaler device is breath-actuated and requires a cooperative patient. Following inhalation of the dry powder, ~15% is deposited in the lower respiratory tract and ~80% in the oropharynx. Overall bioavailability is 4-17%, and plasma levels after 10-mg inhaled doses average ~35-100 ng/mL in adults and children. Median zanamivir concentrations in induced sputum samples are 1336 ng/mL at 6 hours and 47 ng/mL at 24 hours after a single 10-mg dose in healthy volunteers. The plasma  $t_{1/2}$  of zanamivir averages 2.5-5 hours after oral inhalation but only 1.7 hours following intravenous dosing. Over 90% is eliminated in the urine as the parent compound (Eiland and Eiland, 2007).

**Untoward Effects.** Orally inhaled zanamivir generally is well tolerated in ambulatory adults and children with influenza. Wheezing and bronchospasm have been reported in some influenza-infected patients without known airway disease, and acute deteriorations in lung function, including fatal outcomes, have occurred in those with underlying asthma or chronic obstructive airway disease. Tolerability in more serious bronchopulmonary disorders or in intubated patients is uncertain. Zanamivir is not generally recommended for treatment of patients with underlying airway disease (e.g., asthma or chronic obstructive pulmonary disease) because of the risk of serious adverse events.

Preclinical studies of zanamivir revealed no evidence of mutagenic, teratogenic, or oncogenic effects (pregnancy Category C). No clinically

significant drug interactions have been recognized to date. Zanamivir does not diminish the immune response to injected influenza vaccine.

**Therapeutic Uses.** Inhaled zanamivir is effective for the prevention and treatment of influenza A and B virus infections.

Early zanamivir treatment (10 mg [two inhalations] twice daily for 5 days) of febrile influenza in ambulatory adults and children  $\geq 5$  years of age shortens the time to illness resolution by 1-3 days (Eiland and Eiland, 2007) and in adults reduces by 40% the risk of lower respiratory tract complications leading to antibiotic use (Kaiser et al., 2000). Once-daily inhaled, but not intranasal, zanamivir is highly protective against community-acquired influenza illness, and when given for 10 days, it protects against household transmission (Eiland and Eiland, 2007). Intravenous zanamivir is protective against experimental human influenza and is being evaluated for the 2009 nH1N1 EUA.

## **ANTI-HEPATITIS VIRUS AGENTS**

A number of agents are available for treatment of hepatitis B virus (HBV) and hepatitis C virus (HCV) infections. Several agents (e.g., interferons, ribavirin, and the nucleoside/nucleotide analogs lamivudine, telbivudine, and tenofovir) have other uses as well ([Chapters 59](#) and [65](#)). Therapeutic strategies for these two chronic viral infections, hepatitis B and C, are very different and are described separately.

### **Drugs Used Mainly for Hepatitis C Virus Infection**

Hepatitis C is one of the most common chronic virus infections in the developed world and is associated with significant morbidity and mortality. Untreated, this virus can cause progressive hepatocellular injury with fibrosis and eventual cirrhosis. Chronic HCV is also a major risk factor for hepatocellular carcinoma.

Although the virus is quite prolific, producing several billion new particles every few days in an infected individual, this RNA virus does not integrate into chromosomal DNA, and it does not establish latency per se. Therefore the infection is, in theory, curable in all affected individuals. The current standard of care for treatment is a combination of peginterferon alfa and ribavirin, which produces a high cure rate in selected virus genotypes

only (McHutchison et al., 2009). Recent advent of highly effective oral agents that are pharmacologically selective for this pathogen, including HCV protease inhibitors and polymerase inhibitors, bring hope for curative combinations of oral agents. It is likely that treatment recommendations for this infection will change radically in the coming decade.

## Interferons

**Classification and Antiviral Activity.** Interferons (IFNs) are potent cytokines that possess antiviral, immunomodulatory, and antiproliferative activities (Biron, 2001; Samuel, 2001) ([Chapter 35](#)). These proteins are synthesized by host cells in response to various inducers and, in turn, cause biochemical changes leading to an antiviral state in cells. Three major classes of human interferons with significant antiviral activity currently are recognized:  $\alpha$  (>18 individual species),  $\beta$ , and  $\gamma$ . Clinically used recombinant  $\alpha$ -IFNs ([Table 58–2](#)) are non-glycosylated proteins of ~19,500 Da, the pegylated forms predominating in the U.S. market.

IFN- $\alpha$  and IFN- $\beta$  may be produced by nearly all cells in response to viral infection and a variety of other stimuli, including double-stranded RNA and certain cytokines (e.g., interleukin 1, interleukin 2, and tumor necrosis factor). IFN- $\gamma$  production is restricted to T-lymphocytes and natural killer cells responding to antigenic stimuli, mitogens, and specific cytokines. IFN- $\alpha$  and IFN- $\beta$  exhibit antiviral and antiproliferative actions; stimulate the cytotoxic activity of lymphocytes, natural killer cells, and macrophages; and upregulate class I major histocompatibility (MHC) antigens and other surface markers. IFN- $\gamma$  has less antiviral activity but more potent immunoregulatory effects, particularly macrophage activation, expression of class II MHC antigens, and mediation of local inflammatory responses. In addition, interferons downregulate production of a number of cellular proteins, which may be an equally important mediator of the pharmacological benefit of these agents.

Most animal viruses are inhibited by IFNs, although many DNA viruses are relatively insensitive. Considerable differences in sensitivity to the effects of IFNs exist among different viruses and assay systems. The biological activity of IFN usually is measured in terms of antiviral effects in cell culture and generally is expressed as international units (IU) relative to reference standards.

**Mechanisms of Action.** Following binding to specific cellular receptors, IFNs activate the JAK-STAT signal-transduction pathway and lead to the nuclear translocation of a cellular protein complex that binds to genes containing an IFN-specific response element. This, in turn, leads to synthesis of over two dozen proteins that contribute to viral resistance mediated at different stages of viral penetration (Samuel, 2001) ([Figure 58–5](#)).

**Figure 58–5. Interferon-Mediated Antiviral Activity Occurs via Multiple Mechanisms.** The binding of IFN to specific cell surface receptor molecules signals the cell to produce a series of antiviral proteins. The stages of viral replication that are inhibited by various IFN-induced antiviral proteins are

shown. Most of these act to inhibit the translation of viral proteins (mechanism 2), but other steps in viral replication also are affected (mechanisms 1, 3, and 4). The roles of these mechanisms in the other actions of IFNs are under study. Key: IFN = interferon; mRNA = messenger RNA; Mx = IFN-induced cellular protein with anti-viral activity; tRNA = transfer RNA; RNase L = latent cellular endoribonuclease; 2'5'A = 2'-5'-oligoadenylates; eIF-2 $\alpha$  = protein synthesis initiation factor. (Modified from Baron et al., 1992, with permission.)

Inhibition of protein synthesis is the major inhibitory effect for many viruses. IFN-induced proteins include 2'-5'-oligoadenylate [2-5(A)] synthetase and a protein kinase, either of which can inhibit protein synthesis in the presence of double-stranded RNA. The 2-5(A) synthetase produces adenylate oligomers that activate a latent cellular endoribonuclease (RNase L) to cleave both cellular and viral single-stranded RNAs. The protein kinase selectively phosphorylates and inactivates a protein involved in protein synthesis, eukaryotic initiation factor 2 (eIF-2). IFN-induced protein kinase also may be an important effector of apoptosis. In addition, IFN induces a phosphodiesterase that cleaves a portion of transfer RNA and thus prevents peptide elongation. A given virus may be inhibited at several steps, and the principal inhibitory effect differs among virus families. Certain viruses are able to counter IFN effects by blocking production or activity of selected IFN-inducible proteins. For example, IFN resistance in hepatitis C virus is attributable to inhibition of the IFN-induced protein kinase, among other mechanisms.

Complex interactions exist between IFNs and other parts of the immune system, so IFNs may ameliorate viral infections by exerting direct antiviral effects and/or by modifying the immune response to infection (Biron, 2001). For example, IFN-induced expression of MHC antigens may contribute to the antiviral actions of IFN by enhancing the lytic effects of cytotoxic T-lymphocytes. Conversely, IFNs may mediate some of the systemic symptoms associated with viral infections and contribute to immunologically mediated tissue damage in certain viral diseases.

**Absorption, Distribution, and Elimination.** Oral administration does not result in detectable IFN levels in serum or increases in 2-5(A) synthetase activity in peripheral blood mononuclear cells (used as a marker of IFN's biologic activity). After intramuscular or subcutaneous injection of IFN- $\alpha$ ,

absorption exceeds 80%. Plasma levels are dose related, peaking at 4-8 hours and returning to baseline by 18-36 hours. Levels of 2-5(A) synthetase in peripheral blood mononuclear cells show increases beginning at 6 hours and lasting through 4 days after a single injection. An antiviral state in peripheral blood mononuclear cells peaks at 24 hours and decreases slowly to baseline by 6 days after injection. Intramuscular or subcutaneous injections of IFN- $\beta$  result in negligible plasma levels, although increases in 2-5(A) synthetase levels may occur. After systemic administration, low levels of IFN are detected in respiratory secretions, CSF, eye, and brain.

Because IFNs induce long-lasting cellular effects, their activities are not easily predictable from usual pharmacokinetic measures. After intravenous dosing, clearance of IFN from plasma occurs in a complex manner (Bocci, 1992). With subcutaneous or intramuscular dosing, the plasma  $t_{1/2}$  of IFN- $\alpha$  ranges is variable, 3-8 hours. Elimination from the blood relates to distribution to the tissues, cellular uptake, and catabolism primarily in the kidney and liver. Negligible amounts are excreted in the urine. Clearance of IFN- $\alpha$ 2B is reduced by ~80% in hemodialysis patients (Uchiharaa et al., 1998).

Attachment of IFN proteins to large inert polyethylene glycol (PEG) molecules (pegylation) slows absorption, decreases clearance, and provides higher and more prolonged serum concentrations that enable once-weekly dosing (Bruno et al., 2004). Two pegylated IFNs are available commercially: peginterferon alfa-2a (PEGASYS) and peginterferon alfa-2B (PEGINTRON). PegIFN alfa-2B has a straight-chain 12,000-Da type of PEG that increases the plasma  $t_{1/2}$  from ~2-3 hours to ~30-54 hours (Glue et al., 2000). PegIFN alfa-2a consists of an ester derivative of a branched-chain 40,000-Da PEG bonded to IFN- $\alpha$ 2A and has a plasma  $t_{1/2}$  averaging ~80-90 hours. PegIFN alfa-2A is more stable and dispensed in solution, whereas pegIFN alfa-2B requires reconstitution prior to use. For pegIFN alfa-2A, peak serum concentrations occur up to 120 hours after dosing and remain detectable throughout the weekly dosing interval (Bruno et al., 2004); steady-state levels occur 5-8 weeks after initiation of weekly dosing (Keating and Curran, 2003). For pegIFN alfa-2A, dose-related maximum plasma concentrations occur at 15-44 hours after dosing and decline by 96-168 hours. These differences in pharmacokinetics may be associated with differences in antiviral effects (Bruno et al., 2004). Increasing PEG size is

associated with longer  $t_{1/2}$  and less renal clearance. About 30% of pegIFN alfa-2B is cleared by the kidneys; pegIFN alfa-2A also is cleared primarily by the liver. Dose reductions in both pegylated IFNs are indicated in end-stage renal disease.

**Untoward Effects.** Injection of recombinant IFN doses of  $\geq 1$  to 2 million units (MU) usually is associated with an acute influenza-like syndrome beginning several hours after injection. Symptoms include fever, chills, headache, myalgia, arthralgia, nausea, vomiting, and diarrhea. Fever usually resolves within 12 hours. Tolerance develops gradually in most patients. Febrile responses can be moderated by pretreatment with antipyretics. Up to one-half of patients receiving intralesional therapy for genital warts experience the influenzal illness initially, as well as discomfort at the injection site, and leukopenia.

The principal dose-limiting toxicities of systemic IFN are depression, myelosuppression with granulocytopenia and thrombocytopenia; neurotoxicity manifested by somnolence, confusion, behavioral disturbance, and rarely, seizures; debilitating neurasthenia and depression; autoimmune disorders including thyroiditis and hypothyroidism; and uncommonly, cardiovascular effects with hypotension and tachycardia. The risk of depression appears to be higher in chronically infected HCV than in HBV patients (Marcellin et al., 2004). Elevations in hepatic enzymes and triglycerides, alopecia, proteinuria and azotemia, interstitial nephritis, autoantibody formation, pneumonia, and hepatotoxicity may occur. Alopecia and personality change are common in IFN-treated children (Sokal et al., 1998). The development of serum neutralizing antibodies to exogenous IFNs may be associated infrequently with loss of clinical responsiveness. IFN may impair fertility, and safety during pregnancy is not established. IFNs can increase the hematological toxicity of drugs such as zidovudine and ribavirin and may increase the neurotoxicity and cardiotoxic effects of other drugs. Thyroid function and hepatic enzymes should be monitored during IFN therapy.

Pegylated IFNs are generally better tolerated than standard IFNs, with discontinuation rates ranging from 2-11%, although the frequencies of fever, nausea, injection-site inflammation, and neutropenia may be somewhat higher. Laboratory abnormalities, including severe neutropenia and the need for dose modifications, are higher in HIV-co-infected persons.

**Therapeutic Uses.** Recombinant, natural, and pegylated IFNs currently are approved in the U.S., depending on the specific IFN type, for treatment of condyloma acuminatum, chronic HCV infection, chronic HBV infection, Kaposi's sarcoma in HIV-infected patients, other malignancies, and multiple sclerosis. In addition, interferons have been granted orphan drug status for a variety of rare disease states including idiopathic pulmonary fibrosis, laryngeal papillomatosis, juvenile rheumatoid arthritis, and infections associated with chronic granulomatous disease.

**Hepatitis B Virus.** In patients with chronic HBV infection, parenteral administration of various IFNs is associated with loss of HBV DNA, loss of HBeAg and development of anti-HBe antibody, and biochemical and histological improvement in ~25-50% of the patients.

Lasting responses require moderately high IFN doses and prolonged administration (typically 5 MU/day or 10 MU in adults and 6 MU/m<sup>2</sup> in children three times per week of IFN $\alpha$ -2B for 4 to 6 weeks) (Sokal et al., 1998). Plasma HBV DNA and polymerase activity decline promptly in most patients, but complete disappearance is sustained in only about one-third of patients or less. Low pretherapy serum HBV DNA levels and high aminotransferase levels are predictors of response. Sustained responses are infrequent in those with vertically acquired infection, anti-HBe positivity, or concurrent immunosuppression owing to HIV. PegIFN alfa-2A appears superior to conventional IFN alfa-2A in HbeAg-positive patients (Cooksley et al., 2003), and treatment (180  $\mu$ g once weekly for 24-48 weeks) is associated with normalization of aminotransferases in ~60% and sustained viral suppression in ~20% of HBeAg-negative patients (Marcellin et al., 2004). Responses with seroconversion to anti-HBe usually are associated with aminotransferase elevations and often a hepatitis-like illness during the second or third month of therapy, likely related to immune clearance of infected hepatocytes. High-dose IFN can cause myelosuppression and clinical deterioration in those with decompensated liver disease.

Remissions in chronic hepatitis B induced by IFN are sustained in >80% of patients treated and frequently are followed by loss of HBV surface antigen (HbsAg), histological improvement or stabilization, and reduced risk of liver-related complications and mortality (Lau et al., 1997). IFN may benefit some patients with nephrotic syndrome and glomerulonephritis owing to chronic HBV infection. Antiviral effects and improvements occur in about

one-half of chronic hepatitis D virus (HDV) infections, but relapse is common unless HbsAg disappears. IFN does not appear to be beneficial in acute HBV or HDV infections.

***Hepatitis C Virus.*** In chronic HCV infection, IFN alfa-2B monotherapy (3 MU three times a week) is associated with an approximate 50-70% rate of aminotransferase normalization and loss of plasma viral RNA, but relapse rates are high, and sustained virologic remission (absence of detectable HCV RNA) is observed in only 10-25% of patients.

Sustained viral responses are associated with long-term histological improvement and probably reduced risk of hepatocellular carcinoma and hepatic failure (Coverdale et al., 2004). Viral genotype and pretreatment RNA level influence response to treatment, but early viral clearance is the best predictor of sustained response. Failure to achieve an early viral response (nondetectable HCV RNA or reduction  $\geq 2 \log_{10}$  units compared with baseline at 12 weeks) predicts lack of sustained viral response with continued treatment (Seeff and Hoofnagle, 2002). Nonresponders generally do not benefit from IFN monotherapy retreatment, but they and patients relapsing after monotherapy often respond to combined pegylated IFN and ribavirin treatment. IFN treatment may benefit HCV-associated cryoglobulinemia and glomerulonephritis. IFN administration during acute HCV infection appears to reduce the risk of chronicity (Alberti et al., 2002).

Pegylated IFNs are superior to conventional thrice-weekly IFN monotherapy in inducing sustained remissions in treatment-naive patients. Monotherapy with pegIFN alfa-2A (180  $\mu\text{g}$  subcutaneously weekly for 48 weeks) or pegIFN alfa-2B (weight-adjusted doses of 1.5  $\mu\text{g}/\text{kg}/\text{week}$  for 1 year) is associated with sustained response in 30-39%, including stable cirrhotic patients (Heathcote et al., 2000), and it is a treatment option in patients unable to take ribavirin. Studies of prolonged (4 years) maintenance monotherapy with pegylated IFNs are in progress for those not responding to IFN-ribavirin combinations. A large randomized comparison of pegIFN alfa-2A versus alfa-2B combined with ribavirin found no difference in response rates (McHutchison et al., 2009).

The efficacy of conventional and pegylated IFNs is enhanced by the addition of ribavirin to the treatment regimens, particularly for genotype 1 infections. Combined therapy with pegIFN alfa-2A (180  $\mu\text{g}$  once weekly for 48 weeks) and ribavirin (1000-1200 mg/day in divided doses) gives higher

sustained viral response rates than IFN-ribavirin combinations in previously untreated patients (Fried et al., 2002). A shorter duration of therapy (24 weeks) and lower ribavirin dose (800 mg/day) are effective in genotype 2 and 3 infections, but prolonged therapy and higher ribavirin doses are needed for genotype 1 and 4 infections (Hadziyannis et al., 2004). Approximately 15-20% of those failing to respond to combined IFN-ribavirin will have sustained responses to combined pegIFN-ribavirin. Histological improvement may occur in patients who do not achieve sustained viral responses. In patients with compensated cirrhosis, treatment may reverse cirrhotic changes and possibly reduce the risk of hepatocellular carcinoma (Poynard et al., 2002).

***Papillomavirus.*** In refractory condylomata acuminata (genital warts), intralesional injection of various natural and recombinant IFNs is associated with complete clearance of injected warts in 36-62% of patients, but other treatments are preferred (Wiley et al., 2002). Relapse occurs in 20-30% of patients. Verruca vulgaris may respond to intralesional IFN- $\alpha$ . Intramuscular or subcutaneous administration is associated with some regression in wart size but greater toxicity. Systemic IFN may provide adjunctive benefit in recurrent juvenile laryngeal papillomatosis and in treating laryngeal disease in older patients.

***Other Viruses.*** IFNs have been shown to have virological and clinical effects in various herpesvirus infections including genital HSV infections, localized herpes-zoster infection of cancer patients or of older adults, and CMV infections of renal transplant patients. However, IFN generally is associated with more side effects and inferior clinical benefits compared with conventional antiviral therapies. Topically applied IFN and trifluridine combinations appear active in acyclovir-resistant mucocutaneous HSV infections.

In HIV-infected persons, IFNs have been associated with antiretroviral effects. In advanced infection, however, the combination of zidovudine and IFN is associated with only transient benefit and excessive hematological toxicity. IFN- $\alpha$  (3 MU three times weekly) is effective for treatment of HIV-related thrombocytopenia resistant to zidovudine therapy.

Except for adenovirus, IFN has broad-spectrum antiviral activity against respiratory viruses *in vitro*. However, prophylactic intranasal IFN- $\alpha$  is protective only against rhinovirus colds, and chronic use is limited by the

occurrence of nasal side effects. Intranasal IFN is therapeutically ineffective in established rhinovirus colds. Systemically administered IFN- $\alpha$  may be beneficial in early treatment of SARS (Loutfy et al., 2003).

## Ribavirin

**Chemistry and Antiviral Activity.** Ribavirin is a purine nucleoside analog with a modified base and D-ribose sugar ([Figure 58–6](#)).

Ribavirin inhibits the replication of a wide range of RNA and DNA viruses, including orthomyxo-, paramyxo-, arena-, bunya-, and flaviviruses *in vitro*. *In vitro* inhibitory concentrations range from 3 to 10  $\mu\text{g/mL}$  for influenza viruses, parainfluenza viruses, and respiratory syncytial viruses (RSV). Similar concentrations may reversibly inhibit macromolecular synthesis and proliferation of uninfected cells, suppress lymphocyte responses, and alter cytokine profiles *in vitro*.

**Mechanisms of Action and Resistance.** The antiviral mechanism of ribavirin is incompletely understood but relates to alteration of cellular nucleotide pools and inhibition of viral messenger RNA synthesis (Tam et al., 2002).

**Figure 58–6.** Chemical Structures of the Anti-Hepatitis Drugs.

Intracellular phosphorylation to the mono-, di-, and triphosphate derivatives is mediated by host cell enzymes. In both uninfected and RSV-infected cells, the predominant derivative (>80%) is the triphosphate, which has an intracellular  $t_{1/2} < 2$  hours.

Ribavirin monophosphate competitively inhibits cellular inosine-5'-phosphate dehydrogenase and interferes with the synthesis of GTP and thus nucleic acid synthesis in general. Ribavirin triphosphate also competitively inhibits the GTP-dependent 5' capping of viral messenger RNA and specifically influenza virus transcriptase activity. Ribavirin appears to have multiple sites of action, and some of these (e.g., inhibition of GTP synthesis) may potentiate others (e.g., inhibition of GTP-dependent enzymes). Ribavirin also may enhance viral mutagenesis to an extent that some viruses may be inhibited from effective replication, so-called lethal mutagenesis (Hong and Cameron, 2002).

Emergence of viral resistance to ribavirin has not been documented in most viruses but has been reported in Sindbis and HCV (Young et al., 2003); it has been possible to select cells that do not phosphorylate ribavirin to its active forms.

**Absorption, Distribution, and Elimination.** Ribavirin is actively taken up by nucleoside transporters in the proximal small bowel; oral bioavailability averages ~50% (Glue, 1999). Extensive accumulation occurs in plasma, and steady state is reached by ~4 weeks. Food increases plasma levels substantially (Glue, 1999). Following single or multiple oral doses of 600 mg, peak plasma concentrations average ~0.8 and 3.7  $\mu\text{g/mL}$ , respectively. After intravenous doses of 1000 and 500 mg, plasma concentrations average ~24 and 17  $\mu\text{g/mL}$ , respectively. With aerosol administration, plasma levels increase with the duration of exposure and range from 0.2 to 1.0  $\mu\text{g/mL}$  after 5 days (Englund et al., 1990). Levels in respiratory secretions are much higher but vary up to 1000-fold.

The apparent volume of distribution for ribavirin is large (~10 L/kg) owing to its cellular uptake. Plasma protein binding is negligible. The elimination of ribavirin is complex. The plasma  $t_{1/2}$  increases to ~200-300 hours at steady state. Erythrocytes concentrate ribavirin triphosphate; the drug exits red cells gradually, with a  $t_{1/2}$  of ~40 days. Hepatic metabolism and renal excretion of ribavirin and its metabolites are the principal routes of

elimination. Hepatic metabolism involves deribosylation and hydrolysis to yield a triazole carboxamide. Ribavirin clearance decreases by two-thirds in those with advanced renal insufficiency ( $Cl_{cr} = 10\text{-}30$  mL/minute); the drug should be used cautiously in patients with creatinine clearances of  $<50$  mL/minute (Glue, 1999).

**Untoward Effects.** Aerosolized ribavirin may cause conjunctival irritation, rash, transient wheezing, and occasional reversible deterioration in pulmonary function. When used in conjunction with mechanical ventilation, equipment modifications and frequent monitoring are required to prevent plugging of ventilator valves and tubing with ribavirin. Techniques to reduce environmental exposure of healthcare workers are recommended.

Systemic ribavirin causes dose-related reversible anemia owing to extravascular hemolysis and suppression of bone marrow. Associated increases occur in reticulocyte counts and in serum bilirubin, iron, and uric acid concentrations. High ribavirin triphosphate levels may cause oxidative damage to membranes, leading to erythrophagocytosis by the reticuloendothelial system. About 20% of chronic HCV infection patients receiving combination IFN-ribavirin therapy discontinue treatment early because of side effects. In addition to IFN toxicities, oral ribavirin increases the risk of fatigue, cough, rash, pruritus, nausea, insomnia, dyspnea, depression, and particularly, anemia. Preclinical studies indicate that ribavirin is teratogenic, embryotoxic, oncogenic, and possibly gonadotoxic. To prevent possible teratogenic effects, up to 6 months is required for washout following cessation of long-term treatment (Glue, 1999). Bolus intravenous infusion may cause rigors.

Pregnant women should not directly care for patients receiving ribavirin aerosol (FDA pregnancy Category X).

Ribavirin inhibits the phosphorylation and antiviral activity of pyrimidine nucleoside HIV reverse-transcriptase inhibitors such as zidovudine and stavudine but increases the activity of purine nucleoside reverse-transcriptase inhibitors (e.g., didanosine) *in vitro*. It appears to increase the risk of mitochondrial toxicity from didanosine ([Chapter 59](#)).

**Therapeutic Uses.** Oral ribavirin in combination with injected pegIFN alfa-2A or -2B has become standard treatment for chronic HCV infection (Reddy et al., 2009; Seeff and Hoofnagle, 2002).

Ribavirin monotherapy for 6-12 months reversibly decreases aminotransferase elevations to normal in ~30% of patients but does not affect HCV RNA levels. Combination therapy with pegIFN alfa-2A and oral ribavirin (500 mg, or 600 mg if weight is >75 kg, twice daily for 24-48 weeks) increases the likelihood of sustained biochemical and virologic responses to ~56% depending on genotype (Fried et al., 2002). The combination is superior to IFN or pegIFN monotherapy and combinations of pegIFN alfa-2 and ribavirin in both treatment-naive patients and those not responding to, or relapsing after, IFN monotherapy. A longer duration of therapy (48 weeks) appears necessary in those with genotype 1 infections, whereas 24 weeks' therapy is adequate in genotype 2 and 3 infections (Hadziyannis et al., 2004). Combined ribavirin and pegIFN alfa-2A or -2B is effective in achieving sustained viral responses in a minority of HCV/HIV co-infected patients (Reddy et al., 2009). Combined therapy has been used in the management of recurrent HCV infection after liver transplantation.

Ribavirin aerosol is approved in the U.S. for treatment of RSV bronchiolitis and pneumonia in hospitalized children. Aerosolized ribavirin (usual dose of 20 mg/mL as the starting solution in the drug reservoir of the small particle aerosol generator unit for 18 hours' exposure per day for 3-7 days) may reduce some illness measures, but its use generally is not recommended (Committee on Infectious Diseases, American Academy of Pediatrics, 2003). No consistent beneficial effects on duration of hospitalization, ventilatory support, mortality, or long-term pulmonary function have been found. High-dose, reduced-duration therapy (60 mg/mL in the drug reservoir of the small particle aerosol generator unit for 2 hours three times daily) has been used. Aerosol ribavirin combined with intravenous immunoglobulin appears to reduce mortality of RSV infection in bone marrow transplant and other highly immunocompromised patients (Ghosh et al., 2000).

Intravenous and/or aerosol ribavirin has been used occasionally in treating severe influenza virus infection and in the treatment of immunosuppressed patients with adenovirus, vaccinia, parainfluenza, or measles virus infections. Aerosolized ribavirin is associated with reduced duration of fever but no other clinical or antiviral effects in influenza infections in hospitalized children. Intravenous ribavirin decreases mortality in Lassa fever and has been used in treating other arenavirus-related hemorrhagic fevers. Intravenous ribavirin is beneficial in hemorrhagic fever with renal

syndrome owing to Hantavirus infection but appears ineffective in hantavirus-associated cardiopulmonary syndrome or SARS. Oral ribavirin has been used for the treatment and prevention of Crimean-Congo hemorrhagic fever and treatment of Nipah virus infections (Mardani et al., 2003). Intravenous ribavirin is investigational in the U.S.

## Drugs for Hepatitis B Virus Infection

Unlike hepatitis C virus, hepatitis B virus is transcribed into DNA that can be integrated into host chromosomal DNA and is capable of establishing lifelong chronic infection in ~10% of patients. Those with chronic HBV may develop active hepatitis that can lead to fibrosis and cirrhosis, but all such individuals have a greatly increased incidence of hepatocellular carcinoma.

Interferon, or a combination of interferon and ribavirin, can cure patients with chronic infection but is associated with a high rate of side effects, often leading to premature treatment discontinuation. Several antiretroviral nucleoside or nucleotide analog polymerase inhibitors, including lamivudine, telbivudine, and tenofovir, have potent anti-HBV activity and have provided a popular alternative therapy: chronic suppressive oral single agent or combination treatment. These regimens are much better tolerated than IFN-containing regimens but are not usually curative.

### Adefovir

**Chemistry and Antiviral Activity.** Adefovir dipivoxil (9-[2-[bis[(pivaloyloxy)methoxy]phosphinyl]methoxyl]ethyl]adenine, bis-POM PMEA) is a diester prodrug of adefovir, an acyclic phosphonate nucleotide analog of adenosine monophosphate ([Figure 58–6](#)).

It is inhibitory *in vitro* against a range of DNA and RNA viruses, but its clinical use is limited to HBV infections (De Clercq, 2003). Inhibitory concentrations for HBV range from 0.2 to 1.2  $\mu\text{M}$  in cell culture, and it is active against lamivudine-resistant HBV strains. Oral adefovir dipivoxil shows dose-dependent inhibition of hepadnavirus replication in animal models. *In vitro* combinations of adefovir and lamivudine or other anti-HBV nucleosides show enhanced antihepadnavirus activity *in vitro* (Delaney et al., 2004), and trials of dual therapy are in progress.

**Mechanisms of Action and Resistance.** Adefovir dipivoxil enters cells and is deesterified to adefovir. Adefovir is converted by cellular enzymes to the diphosphate, which acts as a competitive inhibitor of viral DNA polymerases and reverse transcriptases with respect to deoxyadenosine triphosphate and also serves as a chain terminator of viral DNA synthesis (Cundy, 1999). Its selectivity relates to a higher affinity for HBV DNA polymerase compared with cellular polymerases.

The intracellular  $t_{1/2}$  of the diphosphate is prolonged, ranging from 5 to 18 hours, so once-daily dosing is feasible. Adefovir resistance has been detected in a small proportion (~4%) of chronically infected HBV patients during 3 years of treatment. Such variants have unique point mutations in the HBV polymerase but retain susceptibility to lamivudine. The consequences of the emergence of resistance remain to be determined.

**Absorption, Distribution, and Elimination.** The parent compound has low oral bioavailability (<12%), whereas the dipivoxil prodrug is absorbed rapidly and hydrolyzed by esterases in the intestine and blood to adefovir with liberation of pivalic acid, providing a bioavailability ~30-60%. After 10-mg doses of the pro-drug, peak serum concentrations of adefovir average 0.02  $\mu\text{g/mL}$ , and the pro-drug is not detectable. Food does not affect bioavailability. Adefovir is scantily protein bound (<5%) and has a volume of distribution similar to body water (~0.4 L/kg).

Adefovir is eliminated unchanged by renal excretion through a combination of glomerular filtration and tubular secretion. After oral administration of adefovir dipivoxil, ~30-45% of the dose is recovered within 24 hours; the serum  $t_{1/2}$  of elimination is 5-7.5 hours. Dose reductions are recommended for  $\text{Cl}_{\text{Cr}}$  values <50 mL/minute. Adefovir is removed by hemodialysis, but the effects of peritoneal dialysis or severe hepatic insufficiency on pharmacokinetics are unknown.

Pivalic acid is a product of adefovir dipivoxil metabolism that can cause reduced free carnitine levels. Although *L*-carnitine has been given in some investigational HIV studies of adefovir, supplementation generally is not recommended at the doses used in chronic HBV infection.

**Untoward Effects.** Adefovir dipivoxil causes dose-related nephrotoxicity and tubular dysfunction, manifested by azotemia and hypophosphatemia, acidosis, glycosuria, and proteinuria that usually are reversible months after

discontinuation. The lower dose (10 mg/day) used in chronic HBV infection patients has been associated with few adverse events (e.g., headache, abdominal discomfort, diarrhea, and asthenia) and negligible renal toxicity compared with a 3-fold higher dose (Hadziyannis et al., 2003; Marcellin et al., 2003). Adverse events lead to premature discontinuation in ~2% of patients. After 2 years of dosing, the risk of serum creatinine levels rising above 0.5 mg/dL is ~2% but is higher in those with preexisting renal insufficiency. Acute, sometimes severe exacerbations of hepatitis can occur in patients stopping adefovir or other anti-HBV therapies. Close monitoring is necessary, and resumption of antiviral therapy may be required in some patients.

No clinically important drug interactions have been recognized to date, although drugs that reduce renal function or compete for active tubular secretion could decrease adefovir clearance. Ibuprofen increases adefovir exposure modestly. An increased risk of lactic acidosis and steatosis may exist when adefovir is used in conjunction with nucleoside analogs or other antiretroviral agents. Adefovir is transported efficiently into tubular epithelium by a probenecid-sensitive organic anion transporter (hOAT1).

Adefovir is genotoxic, and high doses cause hepatotoxicity, lymphoid toxicity, and renal tubular nephropathy in animals. The diphosphate's inhibitory effects on renal adenylyl cyclase may contribute to nephrotoxicity. Adefovir dipivoxil is not associated with reproductive toxicity, although high intravenous doses of adefovir cause maternal and embryotoxicity with fetal malformations in rats (pregnancy Category C).

**Therapeutic Uses.** Adefovir dipivoxil is approved for treatment of chronic HBV infections.

In patients with HBV e-antigen (HbeAg)-positive chronic hepatitis B, adefovir dipivoxil (10 mg/day) reduces serum HBV DNA levels by 99% and, in about one-half of patients, improves hepatic histology and normalization of aminotransferase levels by 48 weeks (Marcellin et al., 2003). Continued therapy is associated with increasing frequencies of aminotransferase normalization and HbeAg seroconversion (De Clercq, 2003). In patients with HbeAg-negative chronic HBV, adefovir is associated with similar biochemical and histological benefits (Hadziyannis et al., 2003). Regression of cirrhosis may occur in some patients.

In patients with lamivudine-resistant HBV infections, adefovir dipivoxil monotherapy results in sustained reductions in serum HBV DNA levels, but lamivudine alone or added to adefovir is not beneficial (Peters et al., 2004). In patients with dual HIV and lamivudine-resistant HBV infections, adefovir dipivoxil (10 mg/day) causes significant HBV DNA level reductions (Benhamou et al., 2001), and it also has been used successfully in patients with lamivudine-resistant HBV infections both before and following liver transplantation. The optimal duration of treatment in different populations, possible long-term effects on HBV complications, and combined use with other anti-HBV agents are under study.

## Entecavir

**Chemistry and Antiviral Activity.** Entecavir is a guanosine nucleoside analog with selective activity against HBV polymerase ([Figure 58–6](#)).

**Mechanisms of Action and Resistance.** Entecavir requires intracellular phosphorylation. Entecavir triphosphate competes with endogenous deoxyguanosine triphosphate and inhibits all three activities of the HBV polymerase (reverse transcriptase):

- base priming
- reverse transcription of the negative strand from the pregenomic messenger RNA
- synthesis of the positive strand of HBV DNA

Entecavir triphosphate is a weak inhibitor of cellular DNA polymerases  $\alpha$ ,  $\beta$ , and  $\delta$  and mitochondrial DNA polymerase  $\gamma$ . The inhibitory concentration against HBV is 0.004  $\mu\text{M}$  in transfected cells and ranges from 0.01 to 0.059  $\mu\text{M}$  against lamivudine-resistant (L180M, M204V) HBV. Eight- to 30-fold reductions in entecavir susceptibility were observed for lamivudine-resistant strains in cell-based assays (Scott and Keating, 2009).

Entecavir selected for an M184I substitution in HIV reverse transcriptase at  $\mu\text{M}$  concentrations in cell culture, and HIV variants containing the M184V substitution showed loss of susceptibility to entecavir. In patients, entecavir decreased HIV-1 RNA in three persons with HIV-1 and HBV co-infection and led to HIV-1 variants with the M184V lamivudine-resistant mutation in one subject (McMahon et al., 2007). Lamivudine and telbivudine resistance confers decreased susceptibility to entecavir. In patients with preexisting

lamivudine resistance, entecavir resistance emerged in 7% and 43% after 1 and 4 years, respectively (Dienstag, 2009).

**Absorption, Distribution, and Elimination.** Following multiple daily doses ranging from 0.1 to 1.0 mg,  $C_{\max}$  and area under the concentration-time curve (AUC) at steady-state increased in proportion to dose. Time to peak occurs in 0.5-1.5 hours. Steady-state is reached after 6-10 days of once daily dosing. The tablet and oral solution can be used interchangeably. Administration with food decreases  $C_{\max}$  by 44-46% and AUC by 18-20%; thus entecavir should be administered on an empty stomach.

Entecavir is extensively distributed in tissues and is 13% bound to serum proteins. It is primarily eliminated unchanged in the kidney. Renal clearance is independent of dose and ranges from 360 to 471 mL/minute, suggesting that entecavir undergoes both glomerular filtration and net tubular secretion. Entecavir exhibits biphasic elimination, with a terminal  $t_{1/2}$  of 128-149 hours; the active triphosphate has an elimination  $t_{1/2}$  of 15 hours. Dose reductions are needed for patients with  $Cl_{Cr} < 50$  mL/minute, typically by extension of the dosing interval (Scott and Keating, 2009).

**Untoward Effects.** Severe acute exacerbations of hepatitis B have been reported in patients who have discontinued anti-HBV therapy, including entecavir. Hepatic function should be monitored closely with both clinical and laboratory follow-up for at least several months in patients who discontinue anti-HBV therapy. There is a potential for development of resistance to nucleoside reverse transcriptase inhibitors in HBV/HIV co-infection especially if HIV is not being treated. Lactic acidosis and severe hepatomegaly with steatosis, including fatal cases, have been reported, mostly in women with some antiretroviral nucleoside analogs ([Chapter 59](#)), but not with entecavir. Other common adverse reactions include headache, fatigue, dizziness, and nausea (Scott and Keating, 2009).

**Therapeutic Uses.** Entecavir is indicated for the treatment of chronic HBV infection in adults with active viral replication and either evidence of persistent elevations in serum aminotransferases or histologically active disease.

The recommended dose for nucleoside-treatment-naive adults (>16 years of age) is 0.5 mg once daily. For patients with lamivudine or telbivudine resistance, the dose is 1 mg once daily. Entecavir is superior to lamivudine

in the degree of suppression and associated with a more frequent fall of HBV DNA to undetectable levels (Dienstag, 2009). Durability of HBeAg responses is comparable to other oral agents. Entecavir had negligible resistance ( $\leq 1\%$ ) for up to 4 years and is active against adefovir-resistant HBV.

## Lamivudine

**Chemistry and Antiviral Activity.** Lamivudine, the (–)-enantiomer of 2',3'-dideoxy-3'-thiacytidine, is a nucleoside analog that inhibits HIV reverse transcriptase and HBV DNA polymerase ([Figure 58–6](#)). Its use as an antiretroviral agent is discussed in [Chapter 59](#).

It inhibits HBV replication *in vitro* by 50% at concentrations of 4-7 ng/mL with negligible cellular cytotoxicity. Cellular enzymes convert lamivudine to the triphosphate, which competitively inhibits HBV DNA polymerase and causes chain termination.

**Mechanisms of Action and Resistance.** Lamivudine triphosphate is a potent inhibitor of the DNA polymerase/reverse transcriptase of HBV; the intracellular  $t_{1/2}$  of the triphosphate averages 17-19 hours in HBV-infected cells, so once-daily dosing is possible.

Oral lamivudine is active in animal models of hepadnavirus infection. Lamivudine shows enhanced antiviral activity in combination with adefovir or penciclovir against hepadnaviruses. Point mutations in the *YMDD* motif of HBV DNA polymerase result in a 40- to 104-fold reduction in *in vitro* susceptibility (Ono et al., 2001). Lamivudine resistance confers cross-resistance to related agents such as emtricitabine and the investigational agent, clevudine, and is often associated with an additional non-*YMDD* mutation that confers cross-resistance to famciclovir. Lamivudine-resistant HBV retains susceptibility to adefovir, tenofovir, and partially to entecavir (Ono et al., 2001). Viruses bearing *YMDD* mutations are less replication competent *in vitro* than wild-type HBV. However, lamivudine resistance is associated with elevated HBV DNA levels, decreased likelihood of HbeAg loss or seroconversion, hepatitis exacerbations, and progressive fibrosis and graft loss in transplant recipients (Dienstag et al., 2003; Lai et al., 2002).

**Absorption, Distribution, and Elimination.** The pharmacokinetic properties of lamivudine are described in detail in [Chapter 59](#). In HBV-infected

children, doses of 3 mg/kg/day provide plasma exposure and trough plasma levels comparable with those in adults receiving 100 mg daily (Sokal et al., 2000). Dose reductions are indicated for moderate renal insufficiency (creatinine clearance <50 mL/minute). Trimethoprim decreases the renal clearance of lamivudine.

**Untoward Effects.** At the doses used for chronic HBV infection, lamivudine generally has been well tolerated. Aminotransferase rises after therapy occur more often in lamivudine recipients, and flares in post-treatment aminotransferase elevations (>500 IU/mL) occur in ~15% of patients after cessation.

**Therapeutic Uses.** Lamivudine is approved for the treatment of chronic HBV hepatitis in adults and children.

In adults, doses of 100 mg/day for 1 year cause suppression of HBV DNA levels, normalization of aminotransferase levels in  $\geq 41\%$  of patients, and reductions in hepatic inflammation in >50% of patients (Dienstag et al., 1999; Lai et al., 2002). Seroconversion with antibody to HbeAg occurs in <20% of recipients at 1 year. In children 2-17 years of age, lamivudine (3 mg/kg/day to a maximum of 100 mg/day for 1 year) is associated with normalization of aminotransferase levels in about one-half and seroconversion to anti-Hbe in about one-fifth of cases (Jonas et al., 2002). In those without emergence of resistant variants, prolonged therapy is associated with sustained suppression of HBV DNA, continued histological improvement, and an increased proportion of patients experiencing a virological response (loss of HbeAg and undetectable HBV DNA). Prolonged therapy is associated with an approximate halving of the risk of clinical progression and development of hepatocellular carcinoma in those with advanced fibrosis or cirrhosis (Liaw et al., 2004). However, the frequency of lamivudine-resistant variants increases progressively with continued drug administration, reaching 67% after 4 years of treatment (Liaw et al., 2004). The risk of resistance development is higher after transplantation and in HIV/HBV co-infected patients.

Combined use of IFN or pegIFN alfa-2A with lamivudine has not improved responses in HBeAg-positive patients consistently. The addition of lamivudine to pegINF alfa-2A for 1 year of therapy does not improve post-treatment response rates in HBeAg-negative patients (Marcellin et al., 2004). In HIV and HBV co-infections, higher lamivudine doses are associated with

antiviral effects and uncommonly anti-HBe seroconversion. Administration of lamivudine before and after liver transplantation may suppress recurrent HBV infection.

## Telbivudine

**Chemistry and Antiviral Activity.** Telbivudine ([Figure 58–6](#)) is a synthetic thymidine nucleoside analog with activity against HBV DNA polymerase.

**Mechanisms of Action and Resistance.** Telbivudine is phosphorylated by cellular kinases to the active triphosphate form, which has a  $t_{1/2}$  of 14 hours. Telbivudine 5'-triphosphate inhibits HBV DNA polymerase (reverse transcriptase) by competing with the natural substrate, thymidine 5'-triphosphate. Incorporation of telbivudine 5'-triphosphate into viral DNA causes chain termination. Telbivudine 5'-triphosphate at concentrations up to 100  $\mu\text{M}$  did not inhibit human cellular DNA polymerases  $\alpha$ ,  $\beta$ , or  $\gamma$ .

In cell-based assays, lamivudine-resistant HBV strains expressing either the M204I substitution or the L180M/M204V double substitution had  $\geq 1000$ -fold reduced susceptibility. Telbivudine retained wild-type phenotypic activity against the lamivudine resistance– associated substitution M204V alone. HBV encoding the adefovir mutation A181V showed 3- to 5-fold reduced susceptibility, but N236T remained susceptible. The A181S and A181T substitutions conferred 2.7- and 3.5-fold reductions in susceptibility to telbivudine, respectively. The A181T substitution is associated with decreased clinical response in patients with HBV treated with adefovir and entecavir (Hadziyannis and Vassilopoulos, 2008).

In a cell culture model, the  $\text{EC}_{50}$  for inhibition of viral DNA synthesis by telbivudine was 0.2  $\mu\text{M}$ . The anti-HBV activity of telbivudine is additive with that of adefovir in cell culture, and it is not antagonized by the HIV-1 nucleoside analogs didanosine and stavudine (Hadziyannis and Vassilopoulos, 2008).

**Absorption, Distribution, and Elimination.** At 600 mg once daily, steady-state peak concentrations are  $\sim 3.7 \mu\text{g/mL}$  at a median of 2 hours post-dose. Steady state is achieved after  $\sim 5$ -7 days of once-daily administration with  $\sim 1.5$ -fold accumulation. *In vitro* protein binding is low (3.3%) and telbivudine is widely distributed into tissues. Telbivudine concentrations decline biexponentially with an elimination  $t_{1/2}$  of 40-49 hours. The drug is

eliminated unchanged in the urine.. Patients with moderate-to-severe renal dysfunction and those undergoing hemodialysis require dose adjustments.

**Untoward Effects.** Telbivudine is generally well tolerated and safe. The most common adverse events resulting in telbivudine discontinuation included increased creatine kinase, nausea, diarrhea, fatigue, myalgia, and myopathy. Elevations of creatine kinase activity, mostly asymptomatic grade 3-4, were more common in telbivudine-treated patients after 2 years of therapy than with lamivudine.

**Therapeutic Uses.** Similar to other oral HBV agents, telbivudine is indicated for the treatment of chronic HBV in adult patients with evidence of viral replication and either evidence of persistent elevations in serum aminotransferases (ALT or AST) or histologically active disease.

The recommended dose is 600 mg orally once daily without regard to food. An oral solution is also available. This dose is based on pharmacodynamic analyses showing a relationship between telbivudine dose and changes in HBV DNA from baseline to week 4 (Lai et al., 2004). The dose producing the maximum effect was between 400 and 800 mg/day. The drug has not been studied in patients with HBV/HIV co-infection. Telbivudine resistance is substantial (25%) after 2 years of treatment and higher than observed with other oral anti-HBV agents (Dienstag, 2009; Hadziyannis and Vassilopoulos, 2008). Cross-resistance and treatment-emergent resistance have limited the use of telbivudine for patients with chronic HBV, compared to alternative agents.

## Tenofovir

Tenofovir is a nucleotide analog with activity against both HIV-1 and HBV ([Figure 58–6](#)). It is administered orally as the disoproxil prodrug. *Chemistry, pharmacokinetic properties, untoward effects, precautions, and interactions* for this drug are covered in more detail in [Chapter 59](#).

In *in vitro* cell cultures, the EC<sub>50</sub> for tenofovir against HBV ranged from 0.14 to 1.5 μM, with cytotoxicity concentrations >100 μM. No antagonistic activity was observed when combined with other oral anti-HBV agents. In cell-based assays, mutant HBV (V173L, L180M, and M204I/V) associated with resistance to lamivudine and telbivudine showed a susceptibility to tenofovir of 0.7-3.4 times that of wild-type virus. Overall, tenofovir has a

favorable resistance profile and has been effective in treating lamivudine-resistant HBV (Dienstag, 2009).

**Therapeutic Uses.** Tenofovir is approved for treatment of HBV infection in adults at a dose of 300 mg once daily without regard to food. In HBeAg-negative patients, tenofovir suppressed HBV DNA to <400 copies/mL in 93% of subjects at 48 weeks, compared to 63% for adefovir. Tenofovir resistance was not evident over 48 weeks of treatment. Due to the safety, efficacy, and resistance profile of tenofovir, it will likely supersede most adefovir use for the treatment of chronic HBV infection.

The tenofovir dose should be adjusted for impaired renal function: For  $Cl_{cr}$  of 30-49 mL/minute, 300 mg every 48 hours; 10-29 mL/minute, 300 mg every 72-96 hours. During hemodialysis the dose is 300 mg every 7 days or after 12 hours of dialysis.

## Clevudine

Clevudine is a nucleoside analog with potent activity against HBV. The oral drug is approved for use in South Korea and the Philippines. However the drug caused myopathy in large Phase 3 clinical trials, casting doubt on its future approval in the U.S.

## OTHER AGENTS

### Imiquimod

*Imiquimod* [1-(2-methylpropyl)-1*H*-imidazo[4,5-*c*]quino-lin-4 amine] is a novel immunomodulatory agent that is effective for topical treatment of condylomata acuminata, molluscum contagiosum, and certain other dermatologic conditions associated with DNA virus infections (Skinner, 2003). It lacks direct antiviral or antiproliferative effects *in vitro* but rather induces cytokines and chemokines with antiviral and immunomodulating effects.

Imiquimod shows antiviral activity in animal models after systemic or topical administration. When applied topically as a 5% cream to genital warts in humans, it induces local IFN- $\alpha$ , - $\beta$ , and - $\gamma$  and TNF $\alpha$  responses and causes reductions in viral load and wart size. When applied topically (three times weekly for up to 16 weeks), imiquimod cream is associated with

complete clearance of treated genital and perianal warts in ~50% of patients, with response rates higher in women than in men (Skinner, 2003; Wiley et al., 2002). The median time to clearance is 8-10 weeks; relapses are not uncommon. Application is associated with local erythema in ~20% of patients, excoriation/flaking in 18-26%, itching in 10-20%, burning in 5-12%, and less often, erosions or ulcerations.

## ***Chapter 59***

# **Antiretroviral Agents and Treatment of HIV Infection**

Charles Flexner

## **I. Overview of HIV Infection and its Treatment**

There are currently several million people taking chronic combination antiretroviral therapy to suppress human immunodeficiency virus (HIV) infection, including >3 million in sub-Saharan Africa alone. This is an amazing achievement for a disease that was uniformly fatal and with few treatment options just two decades ago. Combination antiretroviral therapy prolongs life and prevents progression of disease caused by HIV. The pharmacotherapy of HIV infection is a rapidly moving field. In 2009, 24 antiretroviral drugs were available in the U.S. Three-drug combinations are the minimum standard of care for this infection, so current agents constitute several thousand possible regimens. The long-term management of a patient on antiretroviral therapy can be daunting, even for experienced healthcare providers. Knowing the essential features of the pathophysiology of this disease and how chemotherapeutic agents affect the virus and the host is critical in developing a rational approach to therapy. *Unique features of this drug class include the need for lifelong administration to control virus replication and the possibility of rapid emergence of permanent drug resistance if these agents are not used properly.*

Increasingly, the public health impact of this epidemic has shifted to those regions least able to afford treatment. Because combination antiretroviral therapy has the capacity to improve the quality of human health and to produce near-normal life expectancies (Lee et al., 2001), there is a strong impetus to provide these drugs to as many infected individuals as possible. Through a combination of increased foreign aid, access to generic antiretrovirals, and willingness on the part of legacy pharmaceutical companies to allow violation of intellectual property law for this class of drugs, HIV treatment is now a possibility for much of the world. Because the number of effective treatment options is large, emphasis is shifting from

efficacy to long-term convenience, tolerability, and safety. One outcome has been the development of single tablet fixed-dose combinations of drugs that can be taken orally once or twice a day. Because treatment is taken for years if not decades, the potential adverse effects of each drug take on increasing importance.

## PATHOGENESIS OF HIV-RELATED DISEASE

Human immunodeficiency viruses (HIV) are lentiviruses, a family of mammalian retroviruses evolved to establish chronic persistent infection with gradual onset of clinical symptoms. Unlike herpesviruses, replication is constant following infection, and although some infected cells may harbor nonreplicating virus for years, in the absence of treatment there generally is no true period of viral latency following infection (Greene and Peterlin, 2002). Humans and nonhuman primates are the only natural hosts for these viruses.

There are two major families of HIV. Most of the epidemic involves HIV-1; HIV-2 is more closely related to simian immunodeficiency virus (SIV) and is concentrated in western Africa. HIV-1 is genetically diverse, with at least five distinct subfamilies or clades. HIV-1 and HIV-2 have similar *in vitro* sensitivity to most antiretroviral drugs, although the non-nucleoside reverse transcriptase inhibitors (NNRTIs) are HIV-1-specific and have no activity against HIV-2. Within HIV-1 isolates, clade *per se* does not seem to have a major effect on drug sensitivity.

**Virus Structure.** HIV is a typical retrovirus with a small RNA genome of 9300 base pairs. Two copies of the genome are contained in a nucleocapsid core surrounded by a lipid bilayer, or envelope, that is derived from the host cell plasma membrane ([Figure 59–1](#)). The viral genome encodes three major open reading frames: *gag* encodes a polyprotein that is processed to release the major structural proteins of the virus; *pol* overlaps *gag* and encodes three important enzyme activities—an RNA-dependent DNA polymerase or reverse transcriptase with RNAase activity, protease, and the viral integrase; and *env* encodes the large transmembrane envelope protein responsible for cell binding and entry. Several small genes encode regulatory proteins that enhance virion production or combat host defenses. These include *tat*, *rev*, *nef*, and *vpr* (Greene and Peterlin, 2002).

**Virus Life Cycle.** HIV tropism is controlled by the envelope protein gp160 (env) ([Figure 59–1](#)). The major target for env binding is the CD4 receptor present on lymphocytes and macrophages, although cell entry also requires binding to a coreceptor, generally the chemokine receptor CCR5 or CXCR4 (Greene and Peterlin, 2002). CCR5 is present on macrophage lineage cells. Most infected individuals harbor predominantly the CCR5-tropic virus; HIV with this tropism is responsible for nearly all naturally acquired infections. A shift from CCR5 to CXCR4 utilization is associated with advancing disease, and the increased affinity of HIV-1 for CXCR4 allows infection of T-lymphocyte lines (Berger et al., 1999). A phenotypic switch from CCR5 to CXCR4 heralds accelerated loss of CD4<sup>+</sup> helper T cells and increased risk of immunosuppression. Whether coreceptor switch is a cause or a consequence of advancing disease is still unknown, but it is possible to develop clinical AIDS without this switch.

The gp41 domain of env controls the fusion of the virus lipid bilayer with that of the host cell. Following fusion, full-length viral RNA enters the cytoplasm, where it undergoes replication to a short-lived RNA-DNA duplex; the original RNA is degraded by RNase H to allow creation of a full-length double-stranded DNA copy of the virus ([Figure 59–1](#)). Because the HIV reverse transcriptase is error prone and lacks a proofreading function, mutation is quite frequent and estimated to occur at approximately three bases out of every full-length (9300-base-pair) replication (Coffin, 1995). Virus DNA is transported into the nucleus, where it is integrated into a host chromosome by the viral integrase in a random or quasi-random location (Greene and Peterlin, 2002).

**Figure 59–1.** *Replicative cycle of HIV-1 showing the sites of action of available antiretroviral agents.* Available antiretroviral agents are shown in blue. Key: RT, reverse transcriptase; cDNA, complementary DNA; mRNA, messenger RNA; RNase H, ribonuclease H; gp120 + gp41, extracellular and intracellular domains, respectively, of envelope glycoprotein. (Adapted from Hirsch and D’Aquila, 1993.)

Following integration, the virus may remain in a quiescent state, not producing RNA or protein but replicating as the cell divides. When a cell that harbors the virus is activated, viral RNA and proteins are produced. Structural proteins assemble around full-length genomic RNA to form a nucleocapsid ([Figure 59–1](#)). The envelope and structural proteins assemble at the cell surface, concentrated in cholesterol-rich lipid rafts. The nucleocapsid cores are directed to these sites and bud through the cell membrane, creating new enveloped HIV particles containing two complete single-stranded RNA genomes. Reverse transcriptase is incorporated into virus particles so replication can begin immediately after the virus enters a new cell (Greene and Peterlin, 2002).

**How the Virus Causes Disease.** Sexual acquisition of HIV infection is thought to be mediated by one or, at most, a handful of infectious virus particles. Soon after infection, there is a rapid burst of replication peaking at 2-4 weeks, with  $\geq 10^9$  cells becoming infected. This peak is associated with a transient dip in the number of peripheral CD4<sup>+</sup> (helper) T-lymphocytes. As a result of new host immune responses and target cell depletion, the number of

infectious virions as reflected by the plasma HIV RNA concentration (also known as *viral load*) declines to a quasi-steady state. This level of virus activity has been termed the *set point* and reflects the interplay between host immunity and the pathogenicity of the infecting virus (Coffin, 1995). Most viruses are derived from CD4<sup>+</sup> cells that turn over with a  $t_{1/2}$  of 2.2 days (Perelson et al., 1996). Thus, in the average infected individual, several billion infectious virus particles are produced every few days.

Eventually, the host CD4<sup>+</sup> T-lymphocyte count begins a steady decline, accompanied by a rise in the plasma HIV RNA concentration. Once the peripheral CD4 cell count falls below 200 cells/mm<sup>3</sup>, there is an increasing risk of opportunistic diseases and ultimately death. Sexual acquisition of CCR5-tropic HIV-1 is associated with a median time to clinical AIDS of 8-10 years. Some patients, termed *long-term nonprogressors*, can harbor HIV for more than two decades without significant decline in peripheral CD4 cell count or clinical immunosuppression; this may reflect a combination of favorable host immunogenetics and immune responses (Fauci, 1996).

An important question relevant to treatment is whether HIV disease is a consequence of CD4<sup>+</sup> lymphocyte depletion alone. Most natural history data suggest that this is true, although both the amount of virus measurable in the patient's circulation and the CD4 cell count are independent predictors of disease progression (Mellors et al., 1996, 1997). Regardless, successful therapy is based on inhibition of HIV replication; interventions designed specifically to boost the host immune response without exerting a direct antiviral effect have had no reliable clinical benefit.

**History of Antiretroviral Therapy.** The first effective antiretroviral agent, zidovudine, was synthesized by Horwitz in 1964 as a false nucleoside with disappointing anticancer activity. The drug was shown by Osterag in 1972 to inhibit the *in vitro* replication of a murine type D retrovirus (McLeod and Hammer, 1992). Mitsuya and Broder, working in Bethesda in 1985, reported that this drug had potent *in vitro* anti-HIV activity (Mitsuya et al., 1985). Clinical studies of zidovudine began that same year, and by 1987 this drug was approved and marketed for the control of HIV infection based on the results of a small but definitive randomized clinical trial (Fischl et al., 1987). Large numbers of nucleoside analogs already had been synthesized as potential anticancer and immunomodulatory drugs, and this made it possible

for similar nucleoside reverse transcriptase inhibitors (NRTIs) to be tested efficiently and approved.

Selective non-nucleoside reverse transcriptase inhibitors (NNRTIs) were identified by iterative screening using purified viral enzyme (Pauwels et al., 1990). The clinical development of these drugs was hindered by the rapid emergence of drug resistance (Wei et al., 1995). However, three drugs in this category were approved by 1998 ([Table 59–1](#)). HIV protease inhibitors (PIs) were the products of rational drug design, relying on technology developed to identify transition-state peptidomimetic antagonists of proteases in the renin-angiotensin cascade (Flexner, 1998). Highly selective antagonists of the HIV protease were reported as early as 1987. Phase 1 trials of the first of these drugs, saquinavir, began in 1989, and this drug was approved for prescription use in 1995. Two additional protease inhibitors, ritonavir and indinavir, were approved within the next 4 months.

Innovation in drug approval and regulation facilitated the availability of multiple agents capable of fighting this infection. In 1989, the FDA agreed to make promising agents available to patients with advanced disease through an expanded access program. The capacity to measure plasma HIV RNA concentrations and CD4 cell counts, and proof of the predictive value of these surrogate end points (Mellors et al., 1996) made it possible to collapse the time frame for clinical drug development. The most promising drug combinations were identified by their effect on these end points in clinical trials as short as 6 months.

A detailed understanding of the molecular basis of drug resistance guides the search for new agents and informs the selection of combination strategies for existing drugs. The large number of possible drug combinations has given patients more chances at virus control but also complicates the practice of HIV medicine. Current challenges include access to effective long-term treatment in resource-poor countries and the continuing need for identification of new drugs for treatment-experienced patients with resistance to approved drugs (Flexner, 2007).

**Table 59—1 Antiretroviral Agents Approved for Use in the U.S.**

GENERIC NAME [U.S. TRADE NAME]	ABBREVIATION; CHEMICAL NAMES
<b>Nucleoside Reverse Transcriptase Inhibitors</b>	
Zidovudine [RETROVIR, others] <sup>a</sup>	ZDV; azidothymidine (AZT)
Didanosine [VIDEX; VIDEX EC, others]	ddI; dideoxyinosine
Stavudine [ZERIT]	d4T; didehy- drodeoxythymidine
Zalcitabine [HIVID] <sup>c</sup>	DDC; dideoxycytidine
Lamivudine [EPIVIR] <sup>a</sup>	3TC; dideoxythiacytidine
Abacavir [ZIAGEN] <sup>a</sup>	ABC; cyclopropylami- nopurinylcyclopentene
Tenofovir disoproxil [VIREAD] <sup>a</sup>	TDF; phosphinyl- methoxypropyladenine (PMPA)
Emtricitabine [EMTRIVA] <sup>a</sup>	FTC; fluorooxathiolanyl cytosine
<b>Non-nucleoside Reverse Transcriptase Inhibitors</b>	
Nevirapine [VIRAMUNE]	NVP
Efavirenz [SUSTIVA; STOCRIN] <sup>a</sup>	EFV
Delavirdine [RESCRIPTOR]	DLV
Etravirine [INTELENCE]	ETV

### Protease Inhibitors

Saquinavir [INVIRASE]	SQV
Indinavir [CRIXIVAN]	IDV
Ritonavir [NORVIR]	RTV
Nelfinavir [VIRACEPT]	NFV
Amprenavir [AGENERASE; PROZEL] <sup>c</sup>	APV
Lopinavir [KALETRA; ALUVIA] <sup>b</sup>	LPV/r
Atazanavir [REYATAZ; ZRIVADA]	ATV
Fosamprenavir [LEXIVA; TELZIR]	FPV
Tipranavir [APTIVUS]	TPV
Darunavir [PREZISTA]	DRV

### Entry Inhibitors

Enfuvirtide [FUZEON]	T-20
Maraviroc [SELZENTRY; CELSENTRI]	MVC

### Integrase Inhibitor

Raltegravir [ISENTRESS]	RAL
-------------------------	-----

---

<sup>a</sup>A number of fixed-dose co-formulations are available: zidovudine + lamivudine (COMBIVIR); zidovudine + lamivudine + abacavir (TRIZIVIR); abacavir + lamivudine (EPZICOM); tenofovir + emtricitabine (TRUVADA); tenofovir + efavirenz + emtricitabine (ATRIPLA).

<sup>b</sup>Lopinavir is available only as part of a fixed-dose co-formulation with ritonavir (KALETRA/ALUVIA). <sup>c</sup>No longer marketed worldwide.

## PRINCIPLES OF HIV CHEMOTHERAPY

Current treatment assumes that all aspects of disease derive from the direct toxic effects of HIV on host cells, mainly CD4+ T-lymphocytes. All treatment regimens associated with long-term suppression of HIV replication (as measured by decreased plasma HIV RNA) and repletion of peripheral CD4 cells are clinically beneficial (Lee et al., 2001). The goal of therapy is to suppress virus replication as much as possible for as long as possible.

Deciding when to start antiretroviral therapy has been a shifting target during the epidemic. Current guidelines in the U.S. recommend starting therapy in all those with a CD4 count of  $\leq 350$  cells/mm<sup>3</sup> (Department of Health and Human Services, 2010). Treatment is also recommended for HIV-

infected pregnant women, those with HIV nephropathy, and those with concurrent hepatitis B virus infection requiring treatment regardless of CD4 count. Increasing evidence supports the clinical benefit and cost effectiveness of starting treatment at higher CD4 counts. With more active drug combinations, large systematic reviews of observational studies and a few randomized clinical trials suggest measurable clinical benefit the earlier treatment is initiated, beginning at CD4 counts  $\leq 500$  (Kitahata et al., 2009; When to Start Consortium, 2009). In the foreseeable future, treatment may be recommended for all infected adults and children (Flexner, 2007).

Increasing evidence supports the value of antiretroviral therapy in preventing transmission of the virus from person to person. Although most antiretroviral therapy is used in chronic treatment of established infection, these medications are also used in short courses to prevent infection in post-exposure settings and to prevent mother-to-child transmission (Department of Health and Human Services, 2010). Epidemiological modeling suggests that overall transmission rates are likely to fall in endemic areas where antiretroviral therapy is widely used (Granich et al., 2009). The possible value of targeted antiretroviral therapy to reduce new infections, or even to reduce or eliminate epidemic transmission, has not been adequately explored (Dieffenbach and Fauci, 2009).

A number of studies have confirmed the low likelihood that HIV can be eradicated with drug therapy. A reservoir of long-lived quiescent T cells harboring infectious HIV DNA integrated into the host chromosome was identified independently by several groups of investigators (Chun et al., 1998; Finzi et al., 1997). Infectious HIV can be produced by these quiescent cells after chemical activation *ex vivo* (and presumably if the cells are activated by immune stimuli *in vivo*), but the nonreplicating form of the viral genome is not susceptible to antiretroviral drugs. Most estimates suggest that at least some of these cells will survive for decades and probably for the life of the patient (Siliciano et al., 2003) regardless of the type of anti-HIV treatment. Fortunately, in the presence of suppressive combination antiretroviral therapy it appears that residual viremia is the consequence of release of virus from pre-formed latent reservoirs, and the risk of developing drug resistance in such treated patients is negligible (Nettles et al., 2005). Episodic detection of low level plasma HIV RNA in otherwise suppressed individuals (also known as *blips*) almost certainly represents release of previously formed virus from resting cells; intermittent detection of HIV

RNA at a concentrations  $<500$  copies/mL is not associated with increased risk of treatment failure or drug resistance, unless this is accompanied by nonadherence (Kieffer et al., 2004).

Drug resistance is a key problem that must be prevented and circumvented through a combination of regimen selection and patient education. There is a high likelihood that all untreated infected individuals harbor viruses with single-amino-acid mutations conferring some degree of resistance to every known antiretroviral drug because of the high mutation rate of HIV and the tremendous number of infectious virions (Coffin, 1995). Starting treatment with only a single antiretroviral drug inevitably provokes the emergence of drug-resistant virus, in some cases within a few weeks (Wei et al., 1995). Drug therapy does not cause mutation but rather provides the necessary selective pressure to promote growth of drug-resistant viruses that arise naturally (Coffin, 1995). A combination of active agents therefore is required to prevent drug resistance, analogous to strategies employed in the treatment of tuberculosis ([Chapter 56](#)). Intentional drug holidays, also known as *structured treatment interruptions*, allow the virus to replicate anew and increase the risk of drug resistance and disease progression (Lawrence et al., 2003). Recrudescence replication of HIV after stopping therapy is associated with an acute increase in the risk of death, mainly from cardiovascular events (El-Sadr et al., 2006). This may be the consequence of increased immune activation that accompanies replication of the virus; HIV infection is associated with endothelial cell dysfunction, although the absolute increase in cardiovascular risk after controlling for other risk factors is small (Aberg, 2009).

The current standard of care is to use at least three drugs simultaneously for the entire duration of treatment. The expected outcome of initial therapy in a previously untreated patient is an undetectable *viral load* (plasma HIV RNA  $<50$  copies/mL) within 24 weeks of starting treatment (Department of Health and Human Services, 2010). In prospective comparative trials, two-drug regimens were more effective than single-drug regimens (Fischl et al., 1995; Hammer et al., 1996; Saag et al., 1998), and three-drug regimens are more effective still (Collier et al., 1996; Gulick et al., 1997; Hammer et al., 1997). Mathematical models of HIV replication suggested that three is the minimum number of agents required to guarantee effective long-term suppression of HIV replication without resistance (Muller and Bonhoeffer,

2003). However, earlier models may not adequately predict the effects of newer and more potent antiretrovirals.

Randomized controlled trials found that a combination of two potent drugs (e.g., an NNRTI plus a PI) had equivalent virologic efficacy to either agent plus two NRTIs (Riddler et al., 2008). In treatment-naive patients, a regimen containing a non-nucleoside plus two nucleoside reverse transcriptase inhibitors was as effective as a regimen containing an additional nucleoside (Shafer et al., 2003), indicating the equivalence of these three-drug and four-drug regimens. Four or more drugs may be used simultaneously in pretreated patients harboring drug-resistant virus, but the number of agents a patient can take is limited by toxicity and inconvenience. Even for heavily treatment-experienced patients, a three-drug regimen containing at least two potent active agents is often as effective as regimens containing additional active agents (Steigbigel et al., 2008).

Several small studies have now shown that patients who are fully suppressed (HIV plasma RNA <50 copies/mL) for months on a triple drug combination may be switched to a single “boosted” protease inhibitor (e.g., lopinavir/ritonavir or atazanavir/ritonavir) and maintain full suppression of viral replication for years on antiretroviral monotherapy. Such simplification strategies are investigational and should only be used in patients who are known to be highly adherent and are closely monitored, because randomized trials have found higher failure rates in patients maintained on only a single active agent (Wilkin et al., 2009).

Pharmacodynamic synergy is probably not an important consideration in regimen selection, although most prescribers prefer to use drugs that attack at least two different molecular sites. This could include NRTIs that target the active site of the enzyme combined with an NNRTI that binds to a different site on the same enzyme, or an inhibitor of a different enzyme, such as HIV protease or integrase. Regimens containing an NNRTI or PI plus two NRTIs have similar long-term efficacy.

Failure of an antiretroviral regimen is defined as a persistent increase in plasma HIV RNA concentrations in a patient with previously undetectable virus, despite continued treatment with that regimen (Department of Health and Human Services, 2010). This indicates resistance to one or more drugs in the regimen and necessitates a change in treatment. Once resistance occurs, resistant strains remain in cells (mainly T-lymphocytes) indefinitely, even

though the resistant virus may not be detectable in the plasma. For example, women who received a single dose of nevirapine to prevent mother-to-child transmission of HIV (and thus were more likely to harbor nevirapine-resistant virus) had a higher treatment failure rate if initiating therapy with nevirapine within 6 months, compared to treated women who had never received nevirapine (Lockman et al., 2007). The selection of new agents is therefore informed by the patient's treatment history, as well as viral resistance testing, preferably obtained while the patient is still taking a failing regimen to facilitate proper recovery and characterization of the patient's virus (Kuritzkes, 2004). Treatment failure generally requires implementation of a completely new combination of drugs. Adding a single active agent to a failing regimen is functional monotherapy if the patient is resistant to all drugs in the regimen and is likely to produce resistance to the new agent.

Treatment failure is usually the consequence of non-adherence. The risk of failing a regimen depends on the percentage of prescribed doses taken during any given period of treatment, but it also depends on the drugs in the regimen. Efavirenz-based regimens may be more forgiving of occasional skipped doses, and thus more useful because of the long  $t_{1/2}$  of that drug; ritonavir-boosted PI regimens may be relatively more forgiving because of their higher genetic barrier to resistance (Gardner et al., 2009).

As antiretroviral therapy becomes more effective and easier to take, long-term toxicity of these drugs is of greater concern. An important consequence of long-term therapy is the development of a metabolic syndrome characterized by insulin resistance, fat redistribution, and hyperlipidemia and known as the *HIV lipodystrophy syndrome*. Lipodystrophy occurs in 10-40% of treated patients and has been seen with most drug combinations used in clinical trials. Symptomatic manifestations have been most strongly linked to the older generation of NRTIs, especially stavudine, which had more substantial mitochondrial toxicities; these drugs are now less commonly used in the developed world. The pathogenesis is still somewhat mysterious but involves phenotypic and metabolic changes similar to those seen with other human lipodystrophy syndromes (Garg, 2004). Clinical features include peripheral fat wasting (lipoatrophy), central fat accumulation including enlarged breasts and buffalo hump, insulin resistance and hyperglycemia, and elevations in serum cholesterol and triglycerides. Switching from one drug

regimen to another may not reverse the symptoms, emphasizing its ubiquitous nature and possible role of HIV infection *per se*. Treatment is symptom directed and should include management of hyperlipidemias as recommended by the American Heart Association ([Chapter 31](#)). Lipodystrophy has been associated with an increased risk of myocardial infarction in virologically controlled patients, emphasizing the importance of cardiovascular risk factor reduction.

There is evidence that chronic HIV infection *per se* increases long-term cardiovascular risks, but the quantitative contribution of drug therapy to this risk is not well defined. Metabolic abnormalities associated with chronic HIV infection and possibly exacerbated by some drugs include insulin resistance, hyperglycemia, and increased risk of diabetes mellitus, as well as osteopenia and its attendant complications (Calmy et al., 2009).

A potential concern that applies to all protease inhibitors and NNRTIs is clinically significant pharmacokinetic drug interactions (Piscitelli and Gallicano, 2001). All agents in these two drug classes can act as inhibitors and/or inducers of hepatic CYPs and other drug metabolizing enzymes, as well as drug transport proteins. Prescribing practices should be guided by up-to-date knowledge of these potential effects. Internet-based educational resources are updated frequently (see, e.g., Flexner and Pham, 2009) and are an excellent way to track evolving knowledge about the undesired effects of drugs used in combination with antiretrovirals.

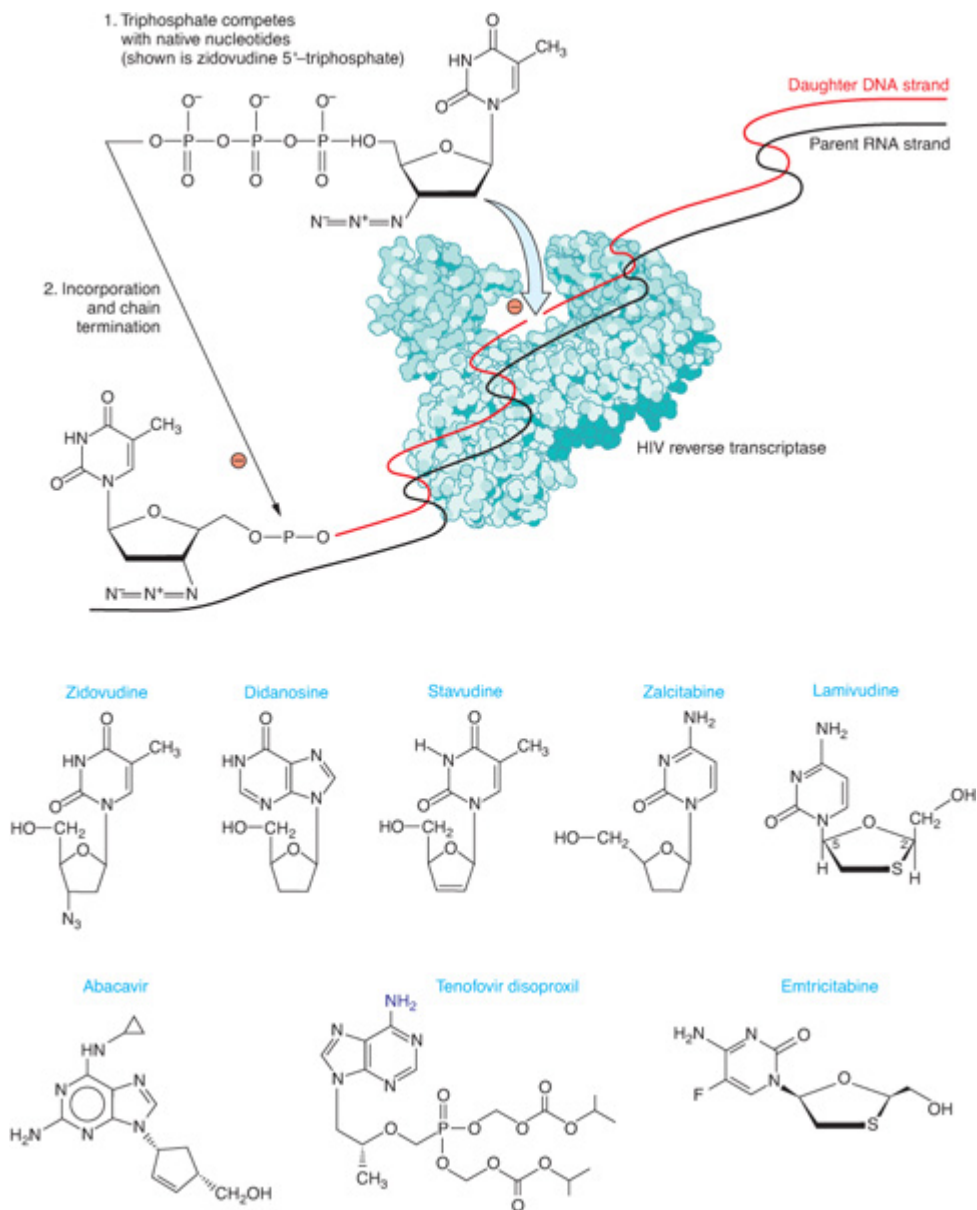

An increasingly recognized complication of initiating antiretroviral therapy is accelerated inflammatory reaction to overt or subclinical opportunistic infections or malignancies. This is thought to reflect reversal of immunodeficiency, resulting in new antimicrobial host defenses. This *immune reconstitution inflammatory syndrome (IRIS)* is most commonly seen when initiating therapy in individuals with low CD4 counts and/or advanced HIV disease, and it is associated with a better virologic response to therapy (Manabe et al., 2007). Not surprisingly, this is now most prevalent in resource-poor countries, where it may occur in >10% of newly treated patients. Infections most commonly associated with IRIS include tuberculosis and other mycobacterial diseases, cryptococcosis, hepatitis virus infections, and Pneumocystis pneumonia. Duration of symptoms ranges from a few days to more than a year. Symptomatic relief can be obtained with anti-

Inflammatory drugs, but systemic corticosteroids do not appear to shorten the course of symptoms (Manabe et al., 2007).

## **II. Drugs Used to Treat HIV Infection**

### **NUCLEOSIDE AND NUCLEOTIDE REVERSE TRANSCRIPTASE INHIBITORS**

The HIV-encoded, RNA-dependent DNA polymerase, also called *reverse transcriptase*, converts viral RNA into proviral DNA that is then incorporated into a host cell chromosome. Available inhibitors of this enzyme are either nucleoside/nucleotide analogs or non-nucleoside inhibitors ([Figure 59–2](#) and [Table 59–2](#)).

**Figure 59–2.** Structures and mechanism of nucleoside and nucleotide reverse transcriptase inhibitors.

**Table 59—2 Pharmacokinetic Properties of Nucleoside Reverse Transcriptase Inhibitors<sup>a</sup>**

PARAMETER	ZIDOVUDINE	LAMIVUDINE	STAVUDINE <sup>b</sup>	DIDANOSINE <sup>c</sup>	ABACAVIR	TENOFOVIR	EMTRICITABINE
Oral bioavailability, %	64	86-87	86	42	83	25	93

<sup>a</sup>Reported mean values in adults with normal renal and hepatic function. <sup>b</sup>Parameters reported for the stavudine capsule formulation. <sup>c</sup>Parameters reported for the didanosine chewable tablet formulation.

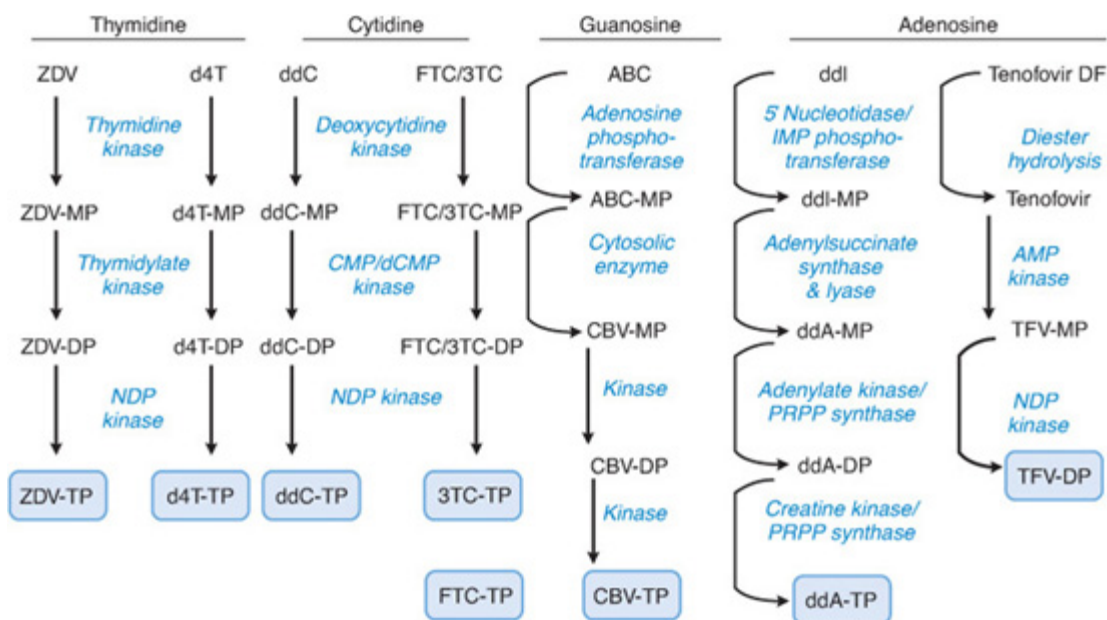

Like all available antiretroviral drugs, nucleoside and nucleotide reverse transcriptase inhibitors prevent infection of susceptible cells but do not eradicate the virus from cells that already harbor integrated proviral DNA. Nucleoside and nucleotide analogs must enter cells and undergo phosphorylation to generate synthetic substrates for the enzyme ([Table 59–2](#)). The fully phosphorylated analogs block replication of the viral genome both by competitively inhibiting incorporation of native nucleotides and by terminating elongation of nascent proviral DNA because they lack a 3'-hydroxyl group (Dudley, 1995).

All but one of the drugs in this class are nucleosides that must be triphosphorylated at the 5'-hydroxyl to exert activity. The sole exception, tenofovir, is a nucleotide monophosphate analog that requires two additional phosphates to acquire full activity. These compounds inhibit both HIV-1 and HIV-2, and several have broad-spectrum activity against other human and animal retroviruses; emtricitabine, lamivudine, and tenofovir are active against hepatitis B virus (HBV), and tenofovir also has activity against herpesviruses ([Chapter 58](#); De Clercq, 2003).

The selective toxicity of these drugs depends on their ability to inhibit the HIV reverse transcriptase without inhibiting host cell DNA polymerases. Although the intracellular triphosphates for all these drugs have low affinity for human DNA polymerase- $\alpha$  and - $\beta$ , some are capable of inhibiting human DNA polymerase- $\gamma$ , which is the mitochondrial enzyme. As a result, the important toxicities common to this class of drugs result in part from the inhibition of mitochondrial DNA synthesis (Lee et al., 2003). These toxicities include anemia, granulocytopenia, myopathy, peripheral neuropathy, and pancreatitis. Lactic acidosis with or without hepatomegaly and hepatic steatosis is a rare but potentially fatal complication seen with stavudine, zidovudine, and didanosine; it is probably not associated

independently with the other drugs (Tripuraneni et al., 2004). Phosphorylated emtricitabine, lamivudine, and tenofovir have low affinity for DNA polymerase- $\gamma$  and are largely devoid of mitochondrial toxicity.

The chemical structures of nucleoside and nucleotide reverse transcriptase inhibitors approved for treating HIV infection are shown in [Figure 59–2](#); their pharmacokinetic properties are summarized in [Table 59–2](#). Phosphorylation pathways for these eight drugs are summarized in [Figure 59–3](#). Most nucleoside and nucleotide reverse transcriptase inhibitors are eliminated from the body primarily by renal excretion. Zidovudine and abacavir, however, are cleared mainly by hepatic glucuronidation. Most of the parent compounds are eliminated rapidly from the plasma, with elimination half-lives of 1-10 hours, with the exception of tenofovir ( $t_{1/2}$  ~14-17 hours) ([Table 59–2](#)). Despite rapid clearance from the plasma, the critical pharmacological pathway for these agents is production and elimination of the intracellular nucleoside triphosphate or nucleotide diphosphate, which is the active anabolite. In general, the phosphorylated anabolites are eliminated from cells much more gradually than the parent drug is eliminated from the plasma. Estimated elimination half-lives for intracellular triphosphates range from 2 to 50 hours ([Table 59–2](#)). This allows for less frequent dosing than would be predicted from plasma half-lives of the parent compounds. All available nucleoside and nucleotide reverse transcriptase inhibitors are dosed once or twice daily.

**Figure 59–3.** *Intracellular activation of nucleoside analog reverse transcriptase inhibitors.* Drugs and phosphorylated anabolites are abbreviated; the enzymes responsible for each conversion are spelled out. The active antiretroviral anabolite for each drug is shown in the blue box. Key: ZDV, zidovudine; d4T, stavudine; ddC, dideoxycytidine; FTC, emtricitabine; 3TC, lamivudine; ABC, abacavir; ddI, didanosine; DF, disoproxil fumarate; MP, monophosphate; DP, diphosphate; TP, triphosphate; AMP, adenosine mono phosphate; CMP, cytidine monophosphate; dCMP, deoxycytidine monophosphate; IMP, inosine 5'-monophosphate; PRPP, phosphoribosyl pyrophosphate; NDP, nucleoside diphosphate. (Adapted with permission from Khoo *et al.*, 2002. Copyright © Elsevier.)

These drugs generally are not involved in clinically significant pharmacokinetic drug interactions because they are not major substrates for hepatic CYPs. Pharmacokinetic drug interactions involving tenofovir and protease inhibitors are likely to be explained by inhibition of OATP drug transporters (Chapman *et al.*, 2003; see [Chapter 5](#)).

High-level resistance to nucleoside/nucleotide reverse transcriptase inhibitors, especially thymidine analogs, occurs slowly by comparison to NNRTIs and first-generation protease inhibitors. For example, zidovudine resistance was noted in only one-third of treated subjects after 1 year of monotherapy (Fischl *et al.*, 1995). High-level resistance can occur rapidly with lamivudine and emtricitabine. In most cases, high-level resistance requires accumulation of a minimum of three to four codon substitutions, although a two-amino-acid insertion is associated with resistance to all drugs in this class (Gallant *et al.*, 2003). Cross-resistance is common but often confined to drugs having similar chemical structures; zidovudine is a thymidine analog, and a zidovudine-resistant isolate is much more likely to be cross-resistant to the thymidine analog stavudine than to the cytidine analog lamivudine.

Nucleoside/nucleotide analogs are generally less active as single agents than other antiretroviral drugs. When used investigationally as monotherapy, most of these drugs produced only a 30-90% mean peak decrease in plasma concentrations of HIV RNA; abacavir monotherapy, however, produced up to a 99% decrease (Hervey and Perry, 2000). CD4 lymphocyte count increases were also modest with nucleoside monotherapy (mean increases of 50-100 cells/mm<sup>3</sup>, depending on disease stage). Nonetheless, these drugs remain a

critical component of therapy, and nearly all patients starting antiretroviral treatment do so with at least one agent from this class. Although modest in their own antiviral potency, several nucleoside analogs have favorable safety and tolerability profiles and are useful in suppressing the emergence of HIV isolates resistant to the more potent drugs in combination regimens.

## Zidovudine

**Chemistry and Antiviral Activity.** Zidovudine (3'-azido-3'-deoxythymidine; AZT) is a synthetic thymidine analog with potent *in vitro* activity against a broad spectrum of retroviruses including HIV-1, HIV-2, and human T-cell lymphotropic viruses (HTLV) I and II (McLeod and Hammer, 1992). Its IC<sub>50</sub> against laboratory and clinical isolates of HIV-1 ranges from 10 to 48 nM.

Zidovudine is active in lymphoblastic and monocytic cell lines but is substantially less active in chronically infected cells (Geleziunas et al., 1993), probably because it has no impact on cells already infected with HIV. Zidovudine appears to be more active in lymphocytes than in monocyte-macrophage cells because of enhanced phosphorylation in the former. For the same reason, the drug is more potent in activated than in resting lymphocytes because the phosphorylating enzyme, thymidine kinase, is S-phase-specific (Gao et al., 1994).

**Mechanisms of Action and Resistance.** Like other nucleoside analogs, intracellular zidovudine is phosphorylated by thymidine kinase to zidovudine 5'-monophosphate, which is then phosphorylated by thymidylate kinase to the diphosphate and by nucleoside diphosphate kinase to zidovudine 5'-triphosphate ([Figure 59-3](#)). Zidovudine 5'-triphosphate terminates the elongation of proviral DNA because it is incorporated by reverse transcriptase into nascent DNA but lacks a 3'-hydroxyl group. The monophosphate competitively inhibits cellular thymidylate kinase, and this may reduce the amount of intracellular thymidine triphosphate. Zidovudine 5'-triphosphate only weakly inhibits cellular DNA polymerase- $\alpha$  but is a more potent inhibitor of mitochondrial polymerase- $\gamma$ .

Because the conversion of zidovudine 5'-monophosphate to diphosphate is very inefficient, high concentrations of the monophosphate accumulate inside cells (Dudley, 1995) and may serve as a precursor depot for formation of triphosphate. As a consequence, there is little correlation between extracellular concentrations of parent drug and intracellular concentrations of

triphosphate, and higher plasma concentrations of zidovudine do not increase intracellular triphosphate concentrations proportionately.

Resistance to zidovudine is associated with mutations at reverse transcriptase codons 41, 44, 67, 70, 210, 215, and 219 (Gallant et al., 2003). These mutations are referred to as *thymidine analog mutations* (TAMs) because of their ability to confer cross-resistance to other thymidine analogs such as stavudine. Two clusters of resistance mutations occur commonly. The pattern of 41L, 210W, and 215Y is associated with high-level resistance to zidovudine, as well as cross-resistance to other drugs in this class, including tenofovir and abacavir. The pattern 67N, 70R, 215F, and 219Q is less common and also associated with lower levels of resistance and cross-resistance. TAMs associated with resistance to zidovudine and stavudine promote excision of the incorporated nucleotide anabolites through pyrophosphorolysis (Naeger et al., 2002). Mutations accumulated gradually when zidovudine was used as the sole antiretroviral agent, and clinical resistance developed in only 31% of patients after 1 year of zidovudine monotherapy (Fischl et al., 1995). Cross-resistance to multiple nucleoside analogs has been reported following prolonged therapy and has been associated with a mutation cluster involving codons 62, 75, 77, 116, and 151. A mutation at codon 69 (typically T69S) followed by a two-amino-acid insertion produces cross-resistance to all available nucleoside and nucleotide analogs (Gallant et al., 2003).

The M184V substitution in the reverse transcriptase gene associated with the use of lamivudine or emtricitabine greatly restores sensitivity to zidovudine (Gallant et al., 2003). The combination of zidovudine and lamivudine produces greater long-term suppression of plasma HIV RNA than does zidovudine alone (Eron et al., 1995). As a result, this agent is usually combined with lamivudine in clinical practice.

**Absorption, Distribution, and Elimination.** Zidovudine is absorbed rapidly and reaches peak plasma concentrations within 1 hour (Dudley, 1995). Like other nucleoside analogs, the elimination  $t_{1/2}$  of the parent compound (~1 hour) is considerably shorter than that of the intracellular triphosphate, which is 3-4 hours ([Table 59–2](#)). Failure to recognize this led to serious overdosing of the drug when it was first approved; the recommended dose was 250 mg every 4 hours in 1987, compared with 300 mg twice a day presently.

Zidovudine undergoes rapid first-pass hepatic metabolism by conversion to 5-glucuronyl zidovudine, which limits systemic bioavailability to ~64%. Food may slow absorption but does not alter the *AUC* (area under the plasma concentration-time curve) ([Table 59-2](#)), and the drug can be administered regardless of food intake (Dudley, 1995). The pharmacokinetic profile of zidovudine is not altered significantly during pregnancy, and drug concentrations in the newborn approach those of the mother. Parent drug crosses the blood-brain barrier relatively well and achieves a cerebrospinal fluid (CSF)-to-plasma ratio of ~0.6. Zidovudine also is detectable in breast milk, semen, and fetal tissue. Zidovudine concentrations are higher in the male genital tract than in the peripheral circulation, suggesting active transport or trapping.

**Untoward Effects.** Patients initiating zidovudine treatment often complain of fatigue, malaise, myalgia, nausea, anorexia, headache, and insomnia. These symptoms usually resolve within the first few weeks of treatment. Bone marrow suppression, mainly anemia and granulocytopenia, occurs most often in individuals with advanced HIV disease and very low CD4 counts and also was more common with the higher doses used when the drug was first approved. Erythrocytic macrocytosis is seen in ~90% of all patients but usually is not associated with anemia.

Chronic zidovudine administration has been associated with nail hyperpigmentation. Skeletal muscle myopathy can occur and is associated with depletion of mitochondrial DNA, most likely as a consequence of inhibition of DNA polymerase- $\gamma$ . Serious hepatic toxicity, with or without steatosis and lactic acidosis, is rare but can be fatal. Risk factors for the lactic acidosis-steatosis syndrome include female sex, obesity, and prolonged exposure to the drug (Tripuraneni et al., 2004).

**Precautions and Interactions.** Zidovudine is not a substrate or inhibitor of CYPs. However, probenecid, fluconazole, atovaquone, and valproic acid may increase plasma concentrations of zidovudine probably through inhibition of glucuronosyl transferase (Dudley, 1995). The clinical significance of these interactions is unknown because intracellular triphosphate levels may be unchanged despite higher plasma concentrations. Zidovudine can cause bone marrow suppression and should be used cautiously in patients with preexisting anemia or granulocytopenia and in those taking other marrow-suppressive drugs. Stavudine and zidovudine

compete for intracellular phosphorylation and should not be used concomitantly. Three clinical trials found a significantly worse virologic outcome in patients taking these two drugs together as compared with either agent used alone (Havlir et al., 2000).

**Therapeutic Use.** Zidovudine is FDA-approved for the treatment of adults and children with HIV infection and for preventing mother-to-child transmission of HIV infection; it is still recommended for post-exposure prophylaxis in HIV-exposed healthcare workers because of the large amount of data supporting its effectiveness in this setting (Centers for Disease Control and Prevention, 2005).

Despite being the oldest antiretroviral drug, zidovudine is still in widespread use, especially in resource-poor settings. This is a consequence of broad experience with the drug and its well-known tolerability, toxicity, and efficacy profiles. Zidovudine (RETROVIR, others) is marketed in oral tablets, capsules, and solution as well as a solution for intravenous injection. Zidovudine is available in coformulated tablets with lamivudine (COMBIVIR) or with lamivudine and abacavir (TRIZIVIR). Zidovudine monotherapy reduced the risk of perinatal transmission of HIV by 67% (Connor et al., 1994), and combining zidovudine with other antiretroviral drugs is even more efficacious in this setting.

## Stavudine

**Chemistry and Antiviral Activity.** Stavudine (2',3'-didehydro-2',3'-dideoxythymidine; d4T) is a synthetic thymidine analog reverse transcriptase inhibitor that is active *in vitro* against HIV-1 and HIV-2. Its IC<sub>50</sub> in lymphoblastoid and monocytic cell lines and in primary mononuclear cells ranges from 0.009 to 4 μM (Hurst and Noble, 1999).

**Mechanisms of Action and Resistance.** Intracellular stavudine is phosphorylated by thymidine kinase to stavudine 5'-monophosphate, which is then phosphorylated by thymidylate kinase to the diphosphate and by nucleoside diphosphate kinase to stavudine 5'-triphosphate (Hurst and Noble, 1999) ([Figure 59-3](#)). Unlike zidovudine monophosphate, stavudine monophosphate does not accumulate in the cell, and the rate-limiting step in activation appears to be generation of the monophosphate. Like zidovudine, stavudine is most potent in activated cells, probably because thymidine kinase is an S-phase-specific enzyme (Gao et al., 1994). Stavudine and

zidovudine are antagonistic *in vitro*, and thymidine kinase has a higher affinity for zidovudine than for stavudine.

Stavudine resistance is seen most frequently with mutations at reverse transcriptase codons 41, 44, 67, 70, 210, 215, and 219 (Gallant et al., 2003), which are the same mutations associated with zidovudine resistance. Clusters of resistance mutations that include M41L, K70R, and T215Y are associated with a lower level of *in vitro* resistance than seen with zidovudine but are found in up to 38% of patients who fail to respond to stavudine. TAMs associated with resistance to zidovudine and stavudine promote excision of the incorporated triphosphate analogs through pyrophosphorolysis (Naeger et al., 2002). As with zidovudine, resistance mutations for stavudine appear to accumulate slowly. Cross-resistance to multiple nucleoside analogs has been reported following prolonged therapy and has been associated with a mutation cluster involving codons 62, 75, 77, 116, and 151. In addition, a mutation at codon 69 (typically T69S) followed by a 2-amino acid insertion produces cross-resistance to all current nucleoside and nucleotide analogs (Gallant et al., 2003).

**Absorption, Distribution, and Elimination.** Stavudine is well absorbed and reaches peak plasma concentrations within 1 hour (Hurst and Noble, 1999). Bioavailability is not affected by food. The drug undergoes active tubular secretion, and renal elimination accounts for ~40% of parent drug.

Stavudine concentrations are higher in patients with low body weight, and the dose should be decreased from 40 to 30 mg twice daily in patients weighing <60 kg, although WHO recommends 30 mg twice daily in all patients. Dose also should be adjusted in patients with renal insufficiency (Jayasekara et al., 1999).

Plasma protein binding is <5%. The drug penetrates well into the CSF, achieving concentrations that are ~40% of those in plasma. Placental concentrations of stavudine are about half those of zidovudine, possibly reflecting stavudine's lower lipid solubility.

**Untoward Effects.** The most common serious toxicity of stavudine is peripheral neuropathy.

Neuropathy occurred in up to 71% of patients in initial monotherapy trials with a dose of 4 mg/kg per day. With the current recommended dose of 40 mg twice daily, the neuropathy incidence is ~12% (Hurst and Noble, 1999).

Although this is thought to reflect mitochondrial toxicity, stavudine is a less potent inhibitor of DNA polymerase- $\gamma$  than either didanosine or zalcitabine, suggesting that other mechanisms may be involved. Peripheral neuropathy is more common with higher doses or concentrations of stavudine and is more prevalent in patients with underlying HIV-related neuropathy or in those receiving other neurotoxic drugs. Stavudine is also associated with a progressive motor neuropathy characterized by weakness and in some cases respiratory failure, similar to Guillain-Barré syndrome (HIV Neuromuscular Syndrome Study Group, 2004).

Lactic acidosis and hepatic steatosis have been associated with stavudine use. This may be more common when stavudine and didanosine are combined. Elevated serum lactate is more common with stavudine than with zidovudine or abacavir (Tripuraneni et al., 2004), but the comparative risk of hepatic steatosis is unknown. Acute pancreatitis is not highly associated with stavudine but is more common when stavudine is combined with didanosine than when didanosine is given alone (Havlir et al., 2001).

Of all nucleoside analogs, stavudine use is associated most strongly with fat wasting, or *lipoatrophy* (Calmy et al., 2009). Whether this is a consequence of the extensive use of this agent combined with its mitochondrial toxicity or reflects a pathogenetic mechanism that has yet to be discovered remains to be determined. Stavudine has fallen out of favor in the developed world largely because of this toxicity. Other reported adverse effects include elevated hepatic transaminases, headache, nausea, and rash; however, these side effects are almost never severe enough to cause discontinuation of the drug.

**Precautions and Interactions.** Stavudine is mainly renally cleared and is not subject to metabolic drug interactions. The incidence and severity of peripheral neuropathy may be increased when stavudine is combined with other neuropathic medications, and therefore drugs such as ethambutol, isoniazid, phenytoin, and vincristine should be avoided.

Combining stavudine with didanosine leads to increased risk and severity of peripheral neuropathy and potentially fatal pancreatitis; therefore, *these two drugs should not be used together* (Havlir et al., 2001). Stavudine and zidovudine compete for intracellular phosphorylation and should not be used concomitantly. Three clinical trials found a significantly worse virologic

outcome in patients taking these two drugs together as compared with either agent used alone (Havlir et al., 2000).

**Therapeutic Use.** Stavudine (ZERIT, others) is approved for use in HIV-infected adults and children, including neonates.

In early monotherapy trials, stavudine reduced plasma HIV RNA by 70-90% and delayed disease progression compared with continued zidovudine therapy. Lamivudine improves the long-term virologic response to stavudine, possibly reflecting the benefits of the M184V mutation (Kuritzkes et al., 1999). Many large prospective clinical trials have demonstrated potent and durable suppression of viremia and sustained increases in CD4+ cell counts when stavudine is combined with other nucleoside analogs plus NNRTIs or protease inhibitors (Hurst and Noble, 1999). Stavudine is no longer a popular drug in the developed world because of toxicity. However, it continues to be widely used in resource-poor settings because of its availability as an inexpensive generic version, often co-formulated with nevirapine and lamivudine.

## Lamivudine

**Chemistry and Antiviral Activity.** Lamivudine [(–)2', 3'-dideoxy, 3'-thiacytidine; 3TC] is a cytidine analog reverse transcriptase inhibitor that is active against HIV-1, HIV-2, and HBV.

The molecule has two chiral centers and is manufactured as the pure 2*R*, *cis*(–)-enantiomer ([Figure 59–2](#)). The racemic mixture from which lamivudine originates has antiretroviral activity but is less potent and substantially more toxic than the pure (–)-enantiomer. Compared with the (+)-enantiomer, the phosphorylated (–)-enantiomer is more resistant to cleavage from nascent RNA/DNA duplexes by cellular 3'-5' exonucleases, which may contribute to its greater potency. The IC<sub>50</sub> of lamivudine against laboratory strains of HIV-1 ranges from 2 to 670 nM, although the IC<sub>50</sub> in primary human peripheral blood mononuclear cells is as high as 15 μM (Perry and Faulds, 1997).

**Mechanisms of Action and Resistance.** Lamivudine enters cells by passive diffusion, is converted to the monophosphate by deoxycytidine kinase, and undergoes further phosphorylation by deoxycytidine monophosphate kinase and nucleoside diphosphate kinase to yield lamivudine 5'-triphosphate,

which is the active anabolite (Perry and Faulds, 1997) ([Figure 59–3](#)). Lamivudine is phosphorylated more efficiently in resting cells, which may explain its reduced potency in primary peripheral blood mononuclear cells as compared with cell lines (Gao et al., 1994). Lamivudine has low affinity for human DNA polymerases, explaining its low toxicity to the host.

High-level resistance to lamivudine occurs with single-amino-acid substitutions, M184V or M184I. These mutations can reduce *in vitro* sensitivity to lamivudine by up to 1000-fold (Perry and Faulds, 1997). The same mutations confer high-level cross-resistance to emtricitabine and a lesser degree of resistance to abacavir (Gallant et al., 2003). The M184V mutation restores zidovudine susceptibility in zidovudine-resistant HIV (Larder et al., 1995) and also partially restores tenofovir susceptibility in tenofovir-resistant HIV harboring the K65R mutation (Wainberg et al., 1999). The same K65R mutation confers resistance to lamivudine, emtricitabine, didanosine, stavudine, and abacavir.

HIV-1 isolates harboring the M184V mutation have increased transcriptional fidelity *in vitro* (Wainberg et al., 1996) and decreased replication capacity (Miller et al., 1999). Variants with the M184I mutation are even more impaired with regard to *in vitro* replication (Larder et al., 1995) and usually are replaced in lamivudine-treated patients by the M184V mutation. The reduced fitness of lamivudine-resistant viruses harboring these mutations, and their ability to prevent or partially reverse the effect of thymidine analog mutations, may contribute to the sustained virologic benefits of zidovudine and lamivudine combination therapy (Eron et al., 1995).

Lamivudine is used to treat HBV infection ([Chapter 58](#)), and some parallels in drug resistance are worth noting. High-level resistance to lamivudine occurs with a single mutation in the HBV DNA polymerase gene; as with HIV, this consists of a methionine-to-valine substitution (M204I) in the enzyme active site. Resistance to lamivudine occurs in up to 90% of HIV/HBV co-infected patients after 4 years of treatment. However, virologic benefits persist in some treated patients harboring lamivudine-resistant HBV possibly because the mutated virus has substantially reduced replicative capacity (Leung et al., 2001).

**Absorption, Distribution, and Elimination.** The oral bioavailability of lamivudine is >80% and is not affected by food. Although lamivudine was

marketed originally with a recommended dose of 150 mg twice daily based on the short plasma  $t_{1/2}$  of the parent compound, the intracellular  $t_{1/2}$  of lamivudine 5'-triphosphate is 12-18 hours, and the drug is now approved for use once daily at 300 mg (Moore et al., 1999).

Lamivudine is excreted primarily unchanged in the urine, and dose adjustment is recommended for patients with a creatinine clearance <50 mL/minute (Jayasekara et al., 1999). Lamivudine does not bind significantly to plasma proteins and freely crosses the placenta into the fetal circulation. Like zidovudine, lamivudine concentrations are higher in the male genital tract than in the peripheral circulation, suggesting active transport or trapping. Penetration to the CNS appears to be moderate, with a CSF-to-plasma concentration ratio of  $\leq 0.15$  (Perry and Faulds, 1997). The clinical significance of the low CSF penetration is unknown.

**Untoward Effects.** Lamivudine is one of the least toxic antiretroviral drugs and has few significant adverse effects.

Neutropenia, headache, and nausea have been reported at higher than recommended doses. Pancreatitis has been reported in pediatric patients, but this has not been confirmed in controlled trials of adults or children. Because lamivudine also has activity against HBV and substantially lowers plasma HBV DNA concentrations, caution is warranted in using this drug in patients co-infected with HBV or in HBV-endemic areas; discontinuation of lamivudine may be associated with a rebound of HBV replication and exacerbation of hepatitis.

**Precautions and Interactions.** Because lamivudine and emtricitabine have nearly identical resistance and activity patterns, there is no rationale for their combined use. Lamivudine is synergistic with most other nucleoside analogs *in vitro* (Perry and Faulds, 1997).

**Therapeutic Use.** Lamivudine (EPIVIR) is approved for HIV in adults and children  $\geq 3$  months of age.

In early monotherapy studies, initial declines in plasma HIV-1 RNA concentrations of up to 90% occurred within 14 days but rebounded rapidly with emergence of lamivudine-resistant HIV (Perry and Faulds, 1997). Patients randomized to the combination of lamivudine plus zidovudine had substantially better mean decreases in plasma HIV-1 RNA at 52 weeks (97% vs. 70% decrease in copies/mL) and increases in CD4+ lymphocyte counts

(+61 versus -53 cells/mm<sup>3</sup>) compared with those receiving zidovudine alone (Eron et al., 1995). In a large randomized double-blind trial, combining lamivudine with zidovudine or stavudine caused ~12-fold further decline in viral load at 24 weeks compared with zidovudine or stavudine monotherapy (Kuritzkes et al., 1999); in the same trial, combining lamivudine with didanosine conferred no additional benefits. Lamivudine has been effective in combination with other antiretroviral drugs in both treatment-naïve and experienced patients (Perry and Faulds, 1997) and is a common component of therapy, given its safety, convenience, and efficacy.

Lamivudine (EPIVIR-HBV) also is approved for treatment of chronic hepatitis B.

## Abacavir

**Chemistry and Antiviral Activity.** Abacavir is a synthetic carbocyclic purine analog ([Figure 59–2](#)).

Carbovir, a related guanine analog, was withdrawn from clinical development owing to poor oral bioavailability (Hervey and Perry, 2000). The IC<sub>50</sub> of abacavir for primary clinical HIV-1 isolates is 0.26 μM, and its IC<sub>50</sub> for laboratory strains ranges from 0.07 to 5.8 μM.

**Mechanisms of Action and Resistance.** Abacavir is the only approved antiretroviral that is active as a guanosine analog. It is initially monophosphorylated by adenosine phosphotransferase. The monophosphate is then converted to (–)-carbovir 3'-monophosphate, which is then phosphorylated to the di- and triphosphates by cellular kinases ([Figure 59–3](#)). Carbovir 5'-triphosphate terminates the elongation of proviral DNA because it is incorporated by reverse transcriptase into nascent DNA but lacks a 3'-hydroxyl group.

Clinical resistance to abacavir is associated with four specific codon substitutions: K65R, L74V, Y115F, and M184V (Gallant et al., 2003). Individually, these substitutions produce only modest (2- to 4-fold) resistance to abacavir, but in combination can reduce susceptibility by up to 10-fold. The Y115F mutation is seen uniquely with abacavir and causes low-level resistance. The L74V mutation is associated with cross-resistance to the purine analog didanosine. K65R confers cross-resistance to all nucleosides except zidovudine. An alternate pathway for abacavir resistance

involves mutations at codons 41, 210, and 215, which have been associated with a reduced likelihood of virologic response. Abacavir sensitivity is greatly reduced by the multinucleoside resistance clusters, including that associated with the Q151M, as well as the 2-amino acid insertion following codon 69 (Gallant et al., 2003).

**Absorption, Distribution, and Elimination.** Abacavir's oral bioavailability is >80% regardless of food intake ([Table 59–2](#)). Abacavir is eliminated by metabolism to the 5'-carboxylic acid derivative catalyzed by alcohol dehydrogenase, and by glucuronidation to the 5'-glucuronide ([Figure 59–3](#)). These metabolites account for 30% and 36% of elimination, respectively (Hervey and Perry, 2000). Abacavir is not a substrate or inhibitor of CYPs. Abacavir is 50% bound to plasma proteins, and the CSF/plasma AUC ratio is ~0.3. Although the introduced dose of abacavir was 300 mg twice daily, carbovir triphosphate accumulates inside the cell and has a reported elimination  $t_{1/2}$  of up to 21 hours (Hervey and Perry, 2000); thus a regimen of 600 mg once daily is approved now.

**Untoward Effects.** The most important adverse effect of abacavir is a unique and potentially fatal hypersensitivity syndrome. This syndrome is characterized by fever, abdominal pain, and other gastrointestinal (GI) complaints; a mild maculopapular rash; and malaise or fatigue. Respiratory complaints (cough, pharyngitis, dyspnea), musculoskeletal complaints, headache, and paresthesias are reported less commonly. Median time to onset of symptoms is 11 days, and 93% of cases occur within 6 weeks of initiating therapy (Hetherington et al., 2002). The presence of concurrent fever, abdominal pain, and rash within 6 weeks of starting abacavir is diagnostic and necessitates immediate discontinuation of the drug. Patients having only one of these symptoms may be observed to see if additional symptoms appear. Unlike many hypersensitivity syndromes, this condition worsens with continued treatment. *Abacavir can never be restarted once discontinued for hypersensitivity because reintroduction of the drug leads to rapid recurrence of severe symptoms, accompanied by hypotension, a shocklike state, and possibly death.* The reported mortality rate of restarting abacavir in sensitive individuals is 4% (Hervey and Perry, 2000).

Abacavir hypersensitivity occurs in 2-9% of patients depending on the population studied. The cause is a genetically mediated immune response linked to both the *HLA-B\*5701* locus and the M493T allele in the heat-shock

locus *Hsp70-Hom* (Mallal et al., 2008). The latter gene is implicated in antigen presentation, and this haplotype is associated with aberrant tumor necrosis factor- $\alpha$  release after exposure of human lymphocytes to abacavir *ex vivo*. This is one of the strongest pharmacogenetic associations ever described. In one white population, the combination of these two markers occurred in 94.4% of cases and <0.5% of controls for a positive predictive value of 93.8% and a negative predictive value of 99.5% (Mallal et al., 2008). *Abacavir should not be given to those with the HLA-B\*5701 genotype*; in all others, the risk of true hypersensitivity is essentially zero (Mallal et al., 2008). Aside from hypersensitivity, abacavir is a well-tolerated drug. Carbovir 5'-triphosphate is a weak inhibitor of human DNA polymerases, including DNA polymerase- $\gamma$  (Hervey and Perry, 2000). Abacavir therefore has not been associated with adverse events thought to be due to mitochondrial toxicity. Epidemiological associations link abacavir use and increased risk of myocardial infarction (D:A:D Study Group et al., 2008).

**Precautions and Interactions.** Abacavir is not associated with any clinically significant pharmacokinetic drug interactions. However, a large dose of ethanol (0.7 g/kg) increased the abacavir plasma AUC by 41% and prolonged the elimination  $t_{1/2}$  by 26% (McDowell et al., 2000) possibly owing to competition for alcohol dehydrogenase.

**Therapeutic Use.** Abacavir (ZIAGEN) is approved for the treatment of HIV-1 infection, in combination with other antiretroviral agents. In initial monotherapy studies, abacavir reduced HIV plasma RNA concentrations up to 300 times more than that seen with other antiretroviral nucleosides, and it increased CD4+ lymphocyte counts by 80-200 cells/mm<sup>3</sup> (Hervey and Perry, 2000). Abacavir is not a more potent inhibitor of HIV replication than other nucleosides *in vitro*, and the mechanism for its more potent *in vivo* monotherapy activity is unexplained.

Abacavir is effective in combination with other nucleoside analogs, NNRTIs, and protease inhibitors. Adding abacavir to zidovudine and lamivudine resulted in a substantially greater decrease in plasma HIV-1 RNA than seen with the two-drug regimen of zidovudine plus lamivudine in adults or children (Hervey and Perry, 2000). Abacavir is available in a co-formulation with zidovudine and lamivudine (TRIZIVIR) for twice-daily dosing. However, the combination of abacavir, zidovudine, and lamivudine

was less effective in a randomized, double-blind, placebo-controlled trial in treatment-naive patients than was the combination of zidovudine, lamivudine, and efavirenz or the four-drug regimen of zidovudine, lamivudine, abacavir, and efavirenz; 79% of patients in the abacavir, zidovudine, lamivudine group had undetectable plasma HIV RNA at 32 weeks as compared with 89% with the other regimens (Gulick et al., 2004).

Abacavir is available in a co-formulation with lamivudine (EPZICOM) for once-daily dosing, which is how it is most commonly used. Abacavir is approved for use in adult and pediatric patients  $\geq 3$  months of age, with dosing in the latter based on body weight.

## Tenofovir

**Chemistry and Antiviral Activity.** Tenofovir disoproxil is a derivative of adenosine 5'-monophosphate lacking a complete ribose ring, and it is the only nucleotide analog currently marketed for the treatment of HIV infection ([Figure 59–2](#)).

Because the parent compound had very poor oral bioavailability, tenofovir is available only as the disoproxil prodrug, which substantially improves oral absorption and cellular penetration. Like lamivudine and emtricitabine, tenofovir is active against HIV-1, HIV-2, and HBV. The  $IC_{50}$  of tenofovir disoproxil against laboratory strains of HIV-1 ranges from 2 to 7 nM, making the prodrug  $\sim 100$ -fold more active *in vitro* than the parent compound (Chapman et al., 2003).

**Mechanisms of Action and Resistance.** Tenofovir disoproxil is hydrolyzed rapidly to tenofovir and then is phosphorylated by cellular kinases to its active metabolite, tenofovir diphosphate (which is actually a triphosphate: the parent drug is a monophosphate) ([Figure 59–3](#)). Tenofovir diphosphate is a competitive inhibitor of viral reverse transcriptases and is incorporated into HIV DNA to cause chain termination because it has an incomplete ribose ring. Although tenofovir diphosphate has broad-spectrum activity against viral DNA polymerases, it has low affinity for human DNA polymerases- $\alpha$ ,  $\beta$ , and  $\gamma$ , which is the basis for its selective toxicity.

Specific resistance occurs with a single substitution at codon 65 of reverse transcriptase (K65R). This mutation reduces *in vitro* sensitivity by only 3- to 4-fold but has been associated with clinical failure of tenofovir-containing

regimens (Chapman et al., 2003). Tenofovir sensitivity and virologic efficacy also are reduced in patients harboring HIV isolates with high-level resistance to zidovudine or stavudine, specifically those having three or more TAMs, including M41L or L120W. However, HIV variants that are resistant to zidovudine show only partial resistance to tenofovir, possibly reflecting less efficient excision of tenofovir diphosphate by pyrophosphorolysis (Naeger et al., 2002). The M184V mutation associated with lamivudine or emtricitabine resistance partially restores susceptibility in tenofovir-resistant HIV harboring the K65R mutation (Wainberg et al., 1999).

The K65R mutation was reported in only 2-3% of tenofovir-treated patients in initial clinical studies, and this mutation usually was not associated with treatment failure. Patients failing most tenofovir-containing regimens are more likely to harbor genotypic resistance to the other drugs in the regimen. Notable exceptions are once-daily combination regimens of three nucleosides, specifically tenofovir plus didanosine and lamivudine and tenofovir plus abacavir and lamivudine. Both of these regimens were associated with very high early rates of virologic failure or nonresponse, and at the time of failure, the K65R mutation was present in 36-64% of virus isolated from patients (Department of Health and Human Services, 2010); these combinations should be avoided.

**Absorption, Distribution, and Elimination.** Tenofovir disoproxil has an oral bioavailability of 25%. A high-fat meal increases the bioavailability to 39%, but the drug can be taken without regard to food (Chapman et al., 2003). Tenofovir is not bound significantly to plasma proteins. The plasma elimination  $t_{1/2}$  ranges from 14 to 17 hours. The reported  $t_{1/2}$  of intracellular tenofovir diphosphate is 11 hours in activated peripheral blood mononuclear cells and  $\geq 49$  hours in resting cells (Chapman et al., 2003). The drug therefore can be dosed once daily. Tenofovir undergoes both glomerular filtration and active tubular secretion. Following an intravenous dose, 70-80% of the drug is recovered unchanged in the urine. Doses should be decreased in those with renal insufficiency (Chapman et al., 2003).

**Untoward Effects.** Tenofovir generally is well tolerated, with few significant adverse effects reported except for flatulence.

In placebo-controlled double-blinded trials, the drug had no other adverse effects reported more frequently than with placebo after treatment for up to 24 weeks. Unlike the antiviral nucleotides adefovir and cidofovir ([Chapter](#)

58), tenofovir is not toxic to human renal tubular cells *in vitro* (Chapman et al., 2003). However, rare episodes of acute renal failure and Fanconi's syndrome have been reported with tenofovir, and this drug should be used with caution in patients with preexisting renal disease. Tenofovir use is associated with small declines in estimated creatinine clearance after months of treatment in some patients (Gallant and Moore, 2009), and because the dose needs to be reduced if renal insufficiency is present, renal function (creatinine and phosphorus) should be monitored regularly in patient taking this drug. Because tenofovir also has activity against HBV and may lower plasma HBV DNA concentrations, caution is warranted in using this drug in patients co-infected with HBV and in regions with high HBV seroprevalence because discontinuation of tenofovir may be associated with a rebound of HBV replication and exacerbation of hepatitis.

**Precautions and Interactions.** Tenofovir is not metabolized to a significant extent by CYPs and is not known to inhibit or induce these enzymes. However, tenofovir has been associated with a few potentially important pharmacokinetic drug interactions.

A 300-mg dose of tenofovir increased the didanosine AUC by 44-60%, probably as a consequence of inhibition of purine nucleoside phosphorylase by both tenofovir and tenofovir monophosphate (Robbins et al., 2003). These two drugs probably should not be used together; if the combination is essential, the dose of didanosine should be reduced from 400 to 250 mg/day (Chapman et al., 2003). Although tenofovir is not known to induce CYPs, it has been reported to reduce the atazanavir AUC by ~26%. In addition, low-dose ritonavir (100 mg twice daily) increases the mean tenofovir AUC by 34%, lopinavir/ritonavir increases the AUC by 32%, and atazanavir increases the tenofovir AUC by 25%. These interactions are most likely mediated by tenofovir's interaction with drug transport proteins.

**Therapeutic Use.** Tenofovir (VIREAD) is FDA approved for treating HIV infection in adults in combination with other antiretroviral agents.

The use of tenofovir in antiretroviral-experienced patients resulted in a further sustained decrease in HIV plasma RNA concentrations of 4.5-7.4-fold relative to placebo after 48 weeks of treatment (Chapman et al., 2003). Several large trials have confirmed the antiretroviral activity of tenofovir in three-drug regimens with other agents, including other nucleoside analogs, protease inhibitors, and/or NNRTIs. In a randomized double-blind

comparison trial in which treatment-naive patients also received lamivudine and efavirenz, tenofovir 300 mg once daily was as effective and less toxic than stavudine 40 mg twice daily (Gallant et al., 2004). Tenofovir is also being investigated as a component of prophylactic regimens, including in the prevention of mother-to-child transmission, and it may have advantages over zidovudine in these settings (Foster et al., 2009).

Tenofovir is also approved for the treatment of chronic hepatitis B in adults.

## Emtricitabine

**Chemistry and Antiviral Activity.** Emtricitabine is a cytidine analog chemically related to lamivudine and shares many of that drug's pharmacodynamic properties.

Like lamivudine, it has two chiral centers and is manufactured as the enantiomerically pure (2*R*,5*S*)-5-fluoro-1-[2-(hydroxymethyl)-1,3-oxathiolan-5-yl]cytosine (FTC) ([Figure 59–2](#)). Emtricitabine is active against HIV-1, HIV-2, and HBV. The IC<sub>50</sub> of emtricitabine against laboratory strains of HIV-1 ranges from 2 to 530 nM, although, on average, the drug is ~10 times more active *in vitro* than lamivudine (Saag, 2006).

**Mechanisms of Action and Resistance.** Emtricitabine enters cells by passive diffusion and is phosphorylated by deoxycytidine kinase and cellular kinases to its active metabolite, emtricitabine 5'-triphosphate ([Figure 59–3](#)). Like lamivudine, emtricitabine has low affinity for human DNA polymerases, explaining its low toxicity to the host.

High-level resistance to emtricitabine occurs with the same mutations affecting lamivudine (mainly the methionine-to-valine substitution at codon 184), although these appear to occur less frequently with emtricitabine. In three studies, M184V/I occurred about half as frequently with emtricitabine-containing regimens as with lamivudine, and patients presenting with virologic failure were two to three times as likely to have wild-type virus at the time of failure as compared with lamivudine (Saag, 2006). The M184V mutation restores zidovudine susceptibility to zidovudine-resistant HIV and also partially restores tenofovir susceptibility to tenofovir-resistant HIV harboring the K65R mutation (Wainberg et al., 1999). The same K65R

mutation confers resistance to emtricitabine and the other cytidine analog lamivudine, as well as didanosine, stavudine, and abacavir.

**Absorption, Distribution, and Elimination.** Emtricitabine is absorbed rapidly and has an oral bioavailability of 93%. Food reduces the  $C_{\max}$  but does not affect the AUC, and the drug can be taken without regard to meals. Emtricitabine is not bound significantly to plasma proteins. Compared with other nucleoside analogs, the drug has a slow systemic clearance and long elimination  $t_{1/2}$  of 8-10 hours (Saag, 2006). In addition, the estimated  $t_{1/2}$  of the intracellular triphosphate is long, possibly up to 39 hours, providing the pharmacokinetic rationale for once-daily dosing. Emtricitabine is excreted primarily unchanged in the urine, undergoing glomerular filtration and active tubular secretion. The dose should be reduced in those with estimated creatinine clearances of  $<50$  mL/minute.

**Untoward Effects.** Emtricitabine is one of the least toxic antiretroviral drugs and, like its chemical relative lamivudine, has few significant adverse effects and no effect on mitochondrial DNA *in vitro* (Saag, 2006).

Prolonged exposure has been associated with hyperpigmentation of the skin, especially in sun-exposed areas. Elevated hepatic transaminases, hepatitis, and pancreatitis have been reported, but these have occurred in association with other drugs known to cause these toxicities. Because emtricitabine also has *in vitro* activity against HBV, caution is warranted in using this drug in patients co-infected with HBV and in regions with high HBV seroprevalence; discontinuation of lamivudine, which is closely related to emtricitabine, has been associated with a rebound of HBV replication and exacerbation of hepatitis.

**Precautions and Interactions.** Emtricitabine is not metabolized to a significant extent by CYPs, and it is not susceptible to any known metabolic drug interactions. The possibility of a pharmacokinetic interaction involving renal tubular secretion, such as that between trimethoprim and lamivudine, has not been investigated for emtricitabine; the drug does not alter the pharmacokinetics of tenofovir.

**Therapeutic Use.** Emtricitabine (EMTRIVA) is FDA-approved for treating HIV infection in adults in combination with other antiretroviral agents. Emtricitabine is available co-formulated with tenofovir  $\pm$  efavirenz.

Two small monotherapy trials showed that the maximal antiviral effect of emtricitabine (mean 1.9 log unit decrease in plasma HIV RNA concentration) was achieved with a dose of 200 mg/day. Several large trials have confirmed the antiretroviral activity of emtricitabine in three-drug regimens with other agents, including nucleoside or nucleotide analogs, protease inhibitors, and/or NNRTIs. In two randomized comparison studies, emtricitabine- and lamivudine-based triple-combination regimens had similar efficacy (Saag, 2006).

## Didanosine

**Chemistry and Antiviral Activity.** Didanosine (2',3'-dideoxyinosine; ddI) is a purine nucleoside analog active against HIV-1, HIV-2, and other retroviruses including HTLV-1 (Perry and Noble, 1999). Its  $IC_{50}$  against HIV-1 ranges from 10 nM in monocytes-macrophage cells, to 10  $\mu$ M in lymphoblast cell lines. Didanosine has been supplanted by less toxic drugs.

**Mechanisms of Action and Resistance.** Didanosine is transported into cells by a nucleobase carrier and undergoes initial phosphorylation by 5'-nucleotidase and inosine 5'-monophosphate phosphotransferase (Dudley, 1995; Khoo et al., 2002). Didanosine 5'-monophosphate is then converted to dideoxyadenosine 5'-monophosphate by adenylosuccinate synthetase and adenylosuccinate lyase ([Figure 59-3](#)). Adenylate kinase and phosphoribosyl pyrophosphate synthetase produce dideoxyadenosine 5'-diphosphate, which is converted to the triphosphate by creatine kinase and phosphoribosyl pyrophosphate synthetase. Dideoxyadenosine 5'-triphosphate is the active anabolite of didanosine, which therefore functions as an antiviral adenosine analog. Dideoxyadenosine 5'-triphosphate terminates the elongation of proviral DNA because it is incorporated by reverse transcriptase into nascent HIV DNA but lacks a 3'-hydroxyl group.

Resistance to didanosine is associated with mutations at reverse transcriptase codons 65 and 74. The L74V substitution, which reduces susceptibility 5- to 26-fold *in vitro*, is seen most commonly in patients failing to respond to didanosine. Other nucleoside analog mutations, including thymidine analog mutations, can contribute to didanosine resistance even though the drug does not appear to select for these mutations *de novo*. The reverse transcriptase insertion mutations at codon 69 produce cross-resistance to all current nucleoside analogs, including didanosine (Gallant et

al., 2003). The M184V mutation seen in response to emtricitabine and lamivudine reduces didanosine susceptibility *in vitro* but probably plays no role in clinical resistance to this drug.

**Absorption, Distribution, and Elimination.** Didanosine is acid labile and is degraded at low gastric pH (Dudley, 1995). An antacid buffer is used in some formulations to improve bioavailability. Chewable tablets contain calcium carbonate and magnesium hydroxide, whereas the powder form contains citrate-phosphate buffer. The pediatric powder formulation lacks buffer and is reconstituted with purified water and mixed with a liquid antacid preparation. Food decreases didanosine bioavailability (AUC) by ~55%, so all formulations of didanosine must be administered at least 30 minutes before or 2 hours after eating (Moreno et al., 2007). This complicates dosing of didanosine in combination with antiretroviral drugs that must be given with food, as is the case for most HIV protease inhibitors. The enzyme purine nucleoside phosphorylase (PNP) probably contributes to the presystemic clearance of didanosine because tenofovir, which inhibits PNP, greatly increases concentrations of orally administered didanosine (Robbins et al., 2003). PNP converts didanosine to hypoxanthine, which is ultimately converted to uric acid.

Peak plasma concentrations of didanosine are seen ~1 hour after oral administration of the chewable tablets or powder formulations and 2 hours after delayed-release capsules. The plasma elimination  $t_{1/2}$  of parent drug is ~1.5 hours, but the estimated intracellular  $t_{1/2}$  of dideoxyadenosine 5'-triphosphate is substantially longer, 25-40 hours (Moreno et al., 2007). As a result, didanosine can be administered once daily. Didanosine is excreted both by glomerular filtration and by tubular secretion and does not undergo metabolism to a significant degree. Drug doses therefore must be adjusted in patients with renal insufficiency or renal failure (Jayasekara et al., 1999). Didanosine is not protein bound to a significant degree. The cerebrospinal penetration of didanosine is less than that of zidovudine, with a CSF-to-plasma ratio of 0.2, but the clinical significance of this is unclear.

**Untoward Effects.** The most serious toxicities associated with didanosine include peripheral neuropathy and pancreatitis, both of which are thought to be a consequence of mitochondrial toxicity. Up to 20% of patients reported peripheral neuropathy in early clinical trials (Moreno et al., 2007). As with other dideoxynucleosides, peripheral neuropathy is more common with

higher doses or concentrations of didanosine and is more prevalent in patients with underlying HIV-related neuropathy, low CD4 count, or in those receiving other neurotoxic drugs. Typically, this is a symmetrical distal sensory neuropathy that begins in the feet and lower extremities but may involve the hands as it progresses (stocking/glove distribution). Patients complain of pain, numbness, and tingling in the affected extremities. If the drug is stopped as soon as symptoms appear, the neuropathy will stabilize and should improve or resolve. However, irreversible neuropathy can occur with continued use. Retinal changes and optic neuritis also have been reported with didanosine, and patients should undergo periodic retinal examinations.

Acute pancreatitis is a rare but potentially fatal complication of didanosine. Acute pancreatitis is associated with higher doses and concentrations of didanosine but has occurred in up to 7% of patients using the recommended dose of 200 mg twice daily (Moreno et al., 2007). Pancreatitis is more common with advanced HIV disease, and other risk factors include a previous history of pancreatitis, alcohol or illicit drug use, and hypertriglyceridemia. Combining didanosine with stavudine, which is also associated with peripheral neuropathy and pancreatitis, increases the risk and severity of both toxicities (Havlir et al., 2001).

As with other dideoxynucleosides and zidovudine, serious hepatic toxicity—with or without steatosis, hepatomegaly, and lactic acidosis—occurs very rarely but can be fatal. Risk factors for the lactic acidosis-steatosis syndrome include female sex, obesity, and prolonged exposure to the drug (Tripuraneni et al., 2004).

Other reported adverse effects include elevated hepatic transaminases, headache, and asymptomatic hyperuricemia and portal hypertension. The impact of didanosine on heart attack risk is under review. Diarrhea is reported more frequently with didanosine than with other nucleoside analogs and has been attributed to the antacid in the buffered oral preparations (Moreno et al., 2007). Didanosine chewable tablets contain 36.5 mg phenylalanine and should be avoided in those with phenylketonuria. Buffered powder for oral solution contains 1.4 g sodium per packet and should be used cautiously in those on sodium-restricted diets.

**Precautions and Interactions.** Buffering agents included in didanosine formulations can interfere with the bioavailability of some co-administered

drugs because of altered pH or chelation with cations in the buffer. For example, the ciprofloxacin AUC is decreased by up to 98% when given with didanosine, and concentrations of ketoconazole and itraconazole, whose absorption is pH dependent, also are diminished (Piscitelli and Gallicano, 2001). A 200-mg dose of buffered didanosine reduced the indinavir AUC by 84%. These interactions generally can be avoided by separating administration of didanosine from that of other agents by at least 2 hours after or 6 hours before the interacting drug. The enteric-coated formulation of didanosine does not alter ciprofloxacin or indinavir absorption.

Didanosine is excreted renally, and shared renal excretory mechanisms provide a basis for drug interactions. Oral ganciclovir can increase plasma didanosine concentrations approximately 2-fold and may be associated with an increase in didanosine toxicity. Allopurinol can increase the didanosine AUC more than 4-fold and is contraindicated. Tenofovir increases the didanosine AUC by 44-60% and also may increase the risk of didanosine toxicity. If these two drugs must be given together, it is recommended to decrease the didanosine dose from 400 to 250 mg once daily for patients >60 kg (Chapman et al., 2003). Methadone decreases the didanosine AUC by 57-63% (Rainey et al., 2000) possibly as a consequence of altered GI motility and delayed absorption, although this has not been associated with a higher risk of failing didanosine treatment.

Didanosine should be avoided in patients with a history of pancreatitis or neuropathy because the risk and severity of both complications increase. Co-administration of other drugs that cause pancreatitis or neuropathy also will increase the risk and severity of these symptoms. Ethambutol, isoniazid, vincristine, cisplatin, and pentamidine also should be avoided.

The combination of didanosine and hydroxyurea was used to exploit a beneficial interaction that creates a favorable intracellular ratio of concentrations of dideoxyadenosine 5'-triphosphate to deoxythymidine 5'-triphosphate (Frank et al., 2004). Although this combination may boost didanosine antiviral activity modestly, it also increases toxicity, producing peripheral neuropathy and fatal pancreatitis, and should be avoided (Havlir et al., 2001).

**Therapeutic Use.** Didanosine (VIDEX, VIDEX EC) is FDA- approved for adults and children with HIV infection in combination with other antiretroviral agents. Didanosine has long-term efficacy when combined with

other nucleoside analogs and HIV protease inhibitors or NNRTIs. Didanosine as a component of combination therapy also has beneficial effects in infants and children (Moreno et al., 2007). However, this drug is no longer widely prescribed in the developed world because of the availability of other agents with less toxicity.

### **Zalcitabine**

Zalcitabine (2',3'-dideoxycytidine; ddC) is a synthetic cytidine analog reverse transcriptase inhibitor that is designated as an orphan drug for the treatment of advanced HIV infection. It is no longer marketed because of toxicity (mainly peripheral neuropathy) and the need for thrice daily dosing. It is active against HIV-1, HIV-2, and hepatitis B virus (HBV). For additional information on this drug, see the 11th edition of this book.

## **NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS**

Non-nucleoside reverse transcriptase inhibitors (NNRTIs) include a variety of chemical substrates that bind to a hydrophobic pocket in the p66 subunit of the HIV-1 reverse transcriptase. The NNRTI-binding pocket is not essential for the function of the enzyme and is distant from the active site. These compounds induce a conformational change in the three-dimensional structure of the enzyme that greatly reduces its activity, and thus they act as noncompetitive inhibitors. Unlike nucleoside and nucleotide reverse transcriptase inhibitors, these compounds do not require intracellular phosphorylation to attain activity. Because the binding site for NNRTIs is virus-strain-specific, the approved agents are active against HIV-1 but not HIV-2 or other retroviruses and should not be used to treat HIV-2 infection (Harris and Montaner, 2000). These compounds also have no activity against host cell DNA polymerases. The two most commonly used agents in this category, efavirenz and nevirapine, are quite potent and transiently decrease plasma HIV RNA concentrations by two orders of magnitude or more when used as sole agents (Havlir et al., 1995; Wei et al., 1995). The chemical structures of the four approved NNRTIs are shown in [Figure 59–4](#), and their pharmacokinetic properties are summarized in [Table 59–3](#).

All approved NNRTIs are eliminated from the body by hepatic metabolism. Nevirapine and delavirdine are primarily substrates for

CYP3A4, whereas efavirenz is a substrate for CYPs 2B6 and 3A4, and etravirine is subject to mixed metabolism. The steady-state elimination half-lives of efavirenz and nevirapine range from 24 to 72 hours, allowing daily dosing. Efavirenz, etravirine, and nevirapine are moderately potent inducers of hepatic drug-metabolizing enzymes including CYP3A4, whereas delavirdine is mainly a CYP3A4 inhibitor. Pharmacokinetic drug interactions are thus an important consideration with this class of compounds and represent a potential toxicity.

All NNRTIs except etravirine are susceptible to high-level drug resistance caused by single-amino-acid changes in the NNRTI-binding pocket (usually in codons 103 or 181). Unlike nucleoside analogs or protease inhibitors, efavirenz or nevirapine can induce resistance and virologic relapse within a few days or weeks if given as monotherapy (Wei et al., 1995). Exposure to even a single dose of nevirapine in the absence of other antiretroviral drugs is associated with resistance mutations in up to one-third of patients (Eshleman et al., 2004). *These agents are potent and highly effective but must be combined with at least two other active agents to avoid resistance.*

The use of efavirenz or nevirapine in combination with other antiretroviral drugs is associated with favorable long-term suppression of viremia and elevation of CD4+ lymphocyte counts (Sheran, 2005). Efavirenz in particular is a common component of first regimens for treatment-naïve patients in recognition of its convenience, tolerability, and potency. Rashes occur frequently with all NNRTIs, usually during the first 4 weeks of therapy. These generally are mild and self-limited, although rare cases of potentially fatal Stevens-Johnson syndrome have been reported with nevirapine, efavirenz, and etravirine. Fat accumulation can be seen after long-term use of NNRTIs (Calmy et al., 2009), and fatal hepatitis has been associated with nevirapine use.

**Figure 59–4.** Structures and mechanism of non-nucleoside reverse transcriptase inhibitors.

**Table 59—3 Pharmacokinetic Properties of Non-nucleoside Reverse Transcriptase Inhibitors<sup>a</sup>**

PARAMETER	NEVIRAPINE <sup>a</sup>	EFAVIRENZ <sup>b</sup>	ETRAVIRINE
Oral bioavailability, %	90-93	50	NR
Effect of meals on AUC	↔	↑17-28%	↑33-102%
Plasma $t_{1/2}$ , elim, h	25-30	40-55	41
Plasma protein binding, %	60	99	99.9
Metabolism	CYP3A4 > CYP2B6	CYP2B6 > CYP3A4	CYP3A4, 2C9, 2C19, UGT
Renal excretion of parent drug, %	<3	<3	1%
Autoinduction of metabolism	Yes	Yes	NR
Inhibition of CYP3A	No	Yes	No

ABBREVIATIONS: AUC, area under plasma concentration–time curve;  $t_{1/2}$ , elim, half-life of elimination; ↑, increase; ↓, decrease; ↔, no effect; NR, not reported; CYP, cytochrome P450; UGT, UDP-glucuronosyltransferase.

<sup>a</sup>Reported mean values in adults with normal renal and hepatic function. <sup>b</sup>Values at steady state after multiple oral doses.

## Nevirapine

**Chemistry and Antiviral Activity.** Nevirapine is a dipyrindiazepinone NNRTI with potent activity against HIV-1 ([Figure 59–4](#)).

The *in vitro* IC<sub>50</sub> of this drug ranges from 10 to 100 nM. Like other compounds in this class, nevirapine does not have significant activity against HIV-2 or other retroviruses (Sheran, 2005).

**Mechanisms of Action and Resistance.** A single mutation at either codon 103 or codon 181 of reverse transcriptase decreases susceptibility by more than two orders of magnitude (Kuritzkes, 2004). Nevirapine resistance is also associated with mutations at codons 100, 106, 108, 188, and 190, but either the K103N or the Y181C mutation is sufficient to produce high-level resistance and clinical treatment failure (Eshleman et al., 2004). *Cross-resistance extends to efavirenz and delavirdine, and any patient who fails treatment with this NNRTI should not be treated with those drugs.*

**Absorption, Distribution, and Elimination.** Nevirapine is well absorbed, and its bioavailability is not altered by food or antacids. The drug readily crosses the placenta and has been found in breast milk, a feature that has encouraged use of nevirapine for prevention of mother-to-child transmission of HIV (Mirochnick et al., 1998).

Nevirapine is eliminated mainly by oxidative metabolism involving CYP3A4 and CYP2B6. Less than 3% of the parent drug is eliminated unchanged in the urine. Nevirapine has a long elimination  $t_{1/2}$  of 25-30 hours at steady state, but  $t_{1/2}$  may be longer in some individuals, especially those of African descent (Sheran, 2005). The drug is a moderate inducer of CYPs, including CYP3A4; thus the drug induces its own metabolism, which decreases the  $t_{1/2}$  from 45 hours following the first dose to 25-30 hours after

2 weeks. To compensate for this, it is recommended that the drug be initiated at a dose of 200 mg once daily for 14 days, with the dose then increased to 200 mg twice daily if no adverse reactions have occurred. Clinical studies of nevirapine have investigated once-daily use, but this dosing regimen is not approved.

**Untoward Effects.** The most frequent adverse event associated with nevirapine is rash, which occurs in ~16% of patients. Mild macular or papular eruptions commonly involve the trunk, face, and extremities and generally occur within the first 6 weeks of therapy. Pruritus is also common. In most patients the rash resolves with continued administration of drug. Up to 7% of patients discontinue therapy owing to rash; administration of glucocorticoids may cause a more severe rash. Life-threatening Stevens-Johnson syndrome is rare but occurs in up to 0.3% of recipients (Sheran, 2005).

Elevated hepatic transaminases occur in up to 14% of patients. Clinical hepatitis occurs in up to 1% of patients. Severe and fatal hepatitis has been associated with nevirapine use, and this may be more common in women with CD4 counts  $>250$  cells/mm<sup>3</sup>, especially during pregnancy (Sheran, 2005). Other reported side effects include fever, fatigue, headache, somnolence, and nausea.

**Precautions and Interactions.** Because nevirapine induces CYP3A4, this drug may lower plasma concentrations of co-administered CYP3A4 substrates. Methadone withdrawal has been reported in patients receiving nevirapine, presumably as a consequence of enhanced methadone clearance. Plasma ethinyl estradiol and norethindrone concentrations decrease by 20% with nevirapine, and alternative methods of birth control are advised.

**Therapeutic Use.** Nevirapine (VIRAMUNE) is FDA approved for the treatment of HIV-1 infection in adults and children in combination with other antiretroviral agents.

In original monotherapy studies, a rapid fall in plasma HIV RNA concentrations of  $\geq 99\%$  was followed by a return toward baseline within 8 weeks because of rapid emergence of resistance (Havlir et al., 1995; Wei et al., 1995). *Nevirapine should never be used as a single agent or as the sole addition to a failing regimen.* Nevirapine is approved for use in infants and children  $\geq 15$  days old, with dosing based on body surface area.

Single-dose nevirapine has been used commonly in pregnant HIV-infected women to prevent mother-to-child transmission. A single oral intrapartum dose of 200 mg nevirapine followed by a single dose given to the newborn reduced neonatal HIV infection to 13% compared with 21.5% infection with a more complicated zidovudine regimen (Sheran, 2005). Although this regimen is very inexpensive and generally well tolerated, the high prevalence of nevirapine resistance following the single oral dose (Eshleman et al., 2004), coupled with the recent recognition of fatal nevirapine hepatitis, has prompted a reexamination of the role this regimen should play in the prevention of vertical transmission (Department of Health and Human Services, 2010).

## Efavirenz

**Chemistry and Antiviral Activity.** Efavirenz is a 1,4-dihydro-2H-3,1-benzoxazin-2-one NNRTI ([Figure 59–4](#)) with potent activity against HIV-1. The *in vitro* IC<sub>50</sub> of this drug ranges from 3 to 9 nM (Sheran, 2005). Like other compounds in this class, efavirenz does not have significant activity against HIV-2 or other retroviruses.

**Mechanisms of Resistance.** The most common efavirenz resistance mutation seen clinically is at codon 103 of reverse transcriptase (K103N), and this decreases susceptibility up to  $\geq 100$ -fold (Kuritzkes, 2004). Additional resistance mutations have been seen at codons 100, 106, 108, 181, 188, 190, and 225, but either the K103N or Y181C mutation is sufficient to produce clinical treatment failure. Cross-resistance extends to nevirapine and delavirdine.

**Absorption, Distribution, and Elimination.** Efavirenz is well absorbed from the GI tract and reaches peak plasma concentrations within 5 hours. There is diminished absorption of the drug with increasing doses. Bioavailability (AUC) is increased by 22% with a high-fat meal.

Efavirenz is >99% bound to plasma proteins and, as a consequence, has a low CSF-to-plasma ratio of 0.01. The clinical significance of this low CNS penetration is unclear, especially because the major toxicities of efavirenz involve the CNS. The drug should be taken initially on an empty stomach at bedtime to reduce side effects (Sheran, 2005).

Efavirenz is cleared *via* oxidative metabolism, mainly by CYP2B6 and to a lesser extent by CYP3A4. The parent drug is not excreted renally to a significant degree. Efavirenz is cleared slowly, with an elimination  $t_{1/2}$  of 40-55 hours at steady state. This safely allows once-daily dosing. Clearance is even slower in recipients with the 516G→T and 983C→T CYP 2B6 genotype (Haas et al., 2009), a common polymorphism in those of Japanese and African ancestry.

**Untoward Effects.** The most important adverse effects of efavirenz involve the CNS. Up to 53% of patients report some CNS or psychiatric side effects, but <5% discontinue the drug for this reason. CNS symptoms may occur with the first dose and last for hours; more severe symptoms may require weeks to resolve. Patients commonly report dizziness, impaired concentration, dysphoria, vivid or disturbing dreams, and insomnia. Episodes of frank psychosis (depression, hallucinations, and/or mania) have been associated with initiating efavirenz. Fortunately, CNS side effects generally become more tolerable and resolve within the first 4 weeks of therapy.

Rash occurs frequently with efavirenz, in up to 27% of adult patients (Sheran, 2005). Rash usually occurs within the first few weeks of treatment but resolves spontaneously and rarely requires drug discontinuation. Life-threatening skin eruptions such as Stevens-Johnson syndrome have been reported during postmarketing experience with efavirenz but are rare.

Other side effects reported with efavirenz include headache, increased hepatic transaminases, and elevated serum cholesterol. False-positive urine screening tests for marijuana metabolites also can occur depending on the assay used (Sheran, 2005).

Efavirenz is the only antiretroviral drug that is unequivocally teratogenic in primates. When efavirenz was administered to pregnant cynomolgus monkeys, 25% of fetuses developed malformations. In 13 known cases where women were exposed to efavirenz during the first trimester of pregnancy, fetuses or infants had significant malformations, mainly of the brain and spinal cord. *Women of childbearing potential therefore should use two methods of birth control and avoid pregnancy while taking efavirenz.*

**Precautions and Interactions.** Efavirenz is a moderate inducer of hepatic enzymes, especially CYP3A4, but also a weak to moderate CYP inhibitor;

because of the drug's long  $t_{1/2}$ , there is no need to alter drug dose during the first few weeks of treatment.

Efavirenz decreases concentrations of phenobarbital, phenytoin, and carbamazepine; the methadone AUC is reduced by 33-66% at steady state. Rifampin concentrations are unchanged by concurrent efavirenz, but rifampin may reduce efavirenz concentrations slightly. Efavirenz reduces the rifabutin AUC by 38% on average. Efavirenz has a variable effect on HIV protease inhibitors. Indinavir, saquinavir, and amprenavir concentrations are reduced, but ritonavir and nelfinavir concentrations are increased. Drugs that induce CYPs 2B6 or 3A4 (e.g., phenobarbital, phenytoin, and carbamazepine) would be expected to increase the clearance of efavirenz and should be avoided (Sheran, 2005).

**Therapeutic Use.** Efavirenz (SUSTIVA) was the first antiretroviral agent approved by the FDA for once-daily administration. Initial short-term monotherapy studies showed substantial decreases in plasma HIV RNA, but the drug should only be used in combination with other effective agents and should not be added as the sole new agent to a failing regimen. Efavirenz has also been effective in patients who have failed previous antiretroviral therapy not containing an NNRTI (Sheran, 2005).

Efavirenz is used widely in the developed world because of its convenience, effectiveness, and long-term tolerability. Especially popular is the once-daily single pill co-formulation of efavirenz, tenofovir, and emtricitabine (ATRIPLA). To date, no antiretroviral regimen has produced better long-term treatment responses than efavirenz-containing regimens in randomized prospective clinical trials. As a result, efavirenz plus two nucleoside reverse transcriptase inhibitors remains a preferred regimen for treatment-naïve patients. Generic versions of efavirenz are increasingly used in treatment regimens in resource-poor countries because of this drug's better toxicity profile compared to nevirapine. Efavirenz can be safely combined with rifampin and is useful in patients also being treated for tuberculosis.

Efavirenz is approved for adult and pediatric patients  $\geq 3$  years of age and weighing at least 10 kg. Efavirenz is only available as tablets and capsules; pediatric dosing is based on weight range.

## **Etravirine**

**Chemistry and Antiviral Activity.** Etravirine is a diarylpyrimidine NNRTI that is active against HIV-1 ([Figure 59–4](#)). The  $IC_{50}$  for HIV-1 in various *in vitro* assays ranges from 1 to 5 nM, but like other NNRTIs, etravirine has no activity against HIV-2 (Deeks and Keating, 2008).

**Mechanisms of Action and Resistance.** Etravirine is unique in its ability to inhibit reverse transcriptase that is resistant to other available NNRTIs. Specifically, activity of the drug is not affected by the K103N, Y181C, or Y188L mutations or the K103N/Y181C double mutations that confer high-level resistance to efavirenz, nevirapine, and delavirdine.

Etravirine appears to have conformational and positional flexibility in the NNRTI binding pocket that allow it to inhibit the function of the HIV-1 reverse transcriptase in the presence of common NNRTI resistance mutations (Deeks and Keating, 2008). Clinically significant drug resistance and treatment failure require the presence of multiple mutations, including V90I, A98G, L100I, K101E/P, V106I, V179D/F, Y181C/I/V, and G190A/S. Best response to an etravirine-containing regimen is seen in patients harboring three or fewer resistance mutations, although likelihood of virologic benefit decreases with each additional mutation. One limitation of etravirine resistance data is that most information comes from patients also receiving darunavir, and few resistance and response data are available for other regimens (Fulco and McNicholl, 2009).

**Absorption, Distribution, and Elimination.** Etravirine is absorbed rapidly after oral administration with peak concentrations occurring 2.5-4 hours after dosing. Food increases the etravirine AUC by 50% (Deeks and Keating, 2008), and it is therefore recommended that the drug be administered with food. Methyl- and dimethyl-hydroxylated metabolites are produced in the liver primarily by CYPs 3A4, 2C9, and 2C19, accounting for most of the elimination of this drug. No unchanged drug is detected in the urine. The terminal elimination  $t_{1/2}$  is ~41 hours; twice-daily dosing of this drug is the historical consequence of enormous pill burdens from older formulations that are no longer in use, and it is likely that the drug could be given once daily (Deeks and Keating, 2008). Etravirine is 99% bound to plasma proteins, mainly to albumin and  $\alpha_1$ -acid glycoprotein.

**Untoward Effects.** In randomized placebo-controlled trials combining etravirine with darunavir in treatment-experienced patients, the only side

effect occurring more commonly with etravirine than with placebo was rash (17% versus 9%), usually occurring within a few weeks of starting therapy and resolving within 1-3 weeks. Overall, 2% of patients in these trials discontinued etravirine because of rash. Severe rash including Stevens-Johnson syndrome and toxic epidermal necrolysis have been reported. Etravirine was not associated with more neuropsychiatric or hepatic adverse effects than placebo (Deeks and Keating, 2008).

**Precautions and Interactions.** Etravirine is an inducer of CYP3A4 and glucuronosyl transferases, and an inhibitor of CYPs 2C9 and 2C19, and can therefore be involved in a number of clinically significant pharmacokinetic drug interactions.

Etravirine can be combined with darunavir/ritonavir, lopinavir/ritonavir, and saquinavir/ritonavir without the need for dose adjustments. The dose of maraviroc should be doubled to 600 mg twice daily when these two drugs are combined. Etravirine should not be administered with tipranavir/ritonavir, fosamprenavir/ritonavir, or atazanavir/ritonavir in the absence of better data to guide dosing. Etravirine should not be combined with efavirenz, nevirapine, or delavirdine. Unlike other NNRTIs, etravirine does not appear to alter the clearance of methadone (Fulco and McNicholl, 2009).

**Therapeutic Use.** Etravirine (INTELENCE) is approved for use only in treatment-experienced HIV-infected adults. NNRTI-experienced patients should not receive etravirine plus NRTIs alone. Etravirine has not yet been approved for pediatric use.

In a pooled analysis of >1200 treatment-experienced patients taking darunavir/ritonavir, 61% of patients randomized to etravirine achieved a plasma HIV RNA <50 copies/mL at 48 weeks compared to 40% on placebo ( $p < 0.0001$ ). Etravirine-treated patients also had a moderately better mean CD4 cell count increase at week 48 (98 vs. 73 cells/mm<sup>3</sup>). Week 48 virologic responses were dependent on the number of baseline etravirine-resistance mutations, with a differential versus placebo of 75% versus 44% if no mutations were present, falling to 25% versus 17% if four or more were present (Fulco and McNicholl, 2009). In small studies, virologic response with etravirine was poor unless the regimen contained at least one other active antiretroviral.

## Delavirdine

Delavirdine is a bisheteroarylpiperazine NNRTI that selectively inhibits HIV-1 ([Figure 59-4](#)). The *in vitro* IC<sub>50</sub> ranges from 6 to 30 nM for laboratory HIV-1 isolates to 1 to 700 nM for clinical isolates (Scott and Perry, 2000). Delavirdine (RESCRIPTOR) is no longer used widely because of its short t<sub>1/2</sub> and requirement for thrice-daily dosing.

Delavirdine does not have significant activity against HIV-2 or other retroviruses. Delavirdine shares resistance mutations with efavirenz and nevirapine, and any patient who fails treatment with this NNRTI should not be treated with those drugs.

Delavirdine is well absorbed, especially at pH<2. Antacids, histamine H<sub>2</sub>-receptor antagonists, proton pump inhibitors, and achlorhydria may decrease its absorption. Standard meals do not alter the delavirdine AUC, and the drug can be administered irrespective of food. The drug may have nonlinear pharmacokinetics because the plasma t<sub>1/2</sub> increases with increasing doses (Scott and Perry, 2000). Delavirdine clearance is primarily through oxidative metabolism by CYP3A4, with <5% of a dose recovered unchanged in the urine. At the recommended dose of 400 mg three times daily, the mean elimination t<sub>1/2</sub> is 5.8 hours (range: 2-11 hours because of the considerable interpatient variability in clearance).

As with all drugs in this class, the most common side effect of delavirdine is rash, which occurs in 18-36% of subjects. Rash usually is seen in the first few weeks of treatment and often resolves despite continued therapy. Severe dermatitis, including erythema multiforme and Stevens-Johnson syndrome, has been reported but is rare. Elevated hepatic transaminases and hepatic failure also have been reported. Neutropenia also may occur rarely (Scott and Perry, 2000).

Delavirdine is both a substrate for and an inhibitor of CYP3A4 and can alter the metabolism of other CYP3A4 substrates. Potent inducers of CYP3A4, such as carbamazepine, phenobarbital, phenytoin, rifabutin, and rifampin, may decrease delavirdine concentrations and should be avoided. Delavirdine increases the plasma concentrations of most HIV protease inhibitors (Scott and Perry, 2000).

Initial monotherapy studies with delavirdine produced only transient decreases in plasma HIV RNA concentrations owing to rapid emergence of resistance. Later studies of delavirdine in combination with nucleoside analogs showed sustained decreases in HIV-1 RNA.

## HIV PROTEASE INHIBITORS

HIV protease inhibitors are peptide-like chemicals that competitively inhibit the action of the virus aspartyl protease ([Figure 59–5](#)). This protease is a homodimer consisting of two 99-amino acid monomers; each monomer contributes an aspartic acid residue that is essential for catalysis (Flexner, 1998). The preferred cleavage site for this enzyme is the N-terminal side of proline residues, especially between phenylalanine and proline. Human aspartyl proteases (i.e., renin, pepsin, gastricsin, and cathepsins D and E) contain only one polypeptide chain and are not significantly inhibited by HIV protease inhibitors.

These drugs prevent proteolytic cleavage of HIV gag and pol precursor polypeptides that include essential structural (p17, p24, p9, and p7) and enzymatic (reverse transcriptase, protease, and integrase) components of the virus. This prevents the metamorphosis of HIV virus particles into their mature infectious form (Flexner, 1998). Infected patients treated with HIV protease inhibitors as sole agents experienced a 100- to 1000-fold mean decrease in plasma HIV RNA concentrations within 12 weeks, an effect similar in magnitude to that produced by NNRTIs (Ho et al., 1995).

The pharmacokinetic properties of HIV protease inhibitors are characterized by high interindividual variability, which may reflect differential activity of intestinal and hepatic CYPs (Flexner, 1998). Clearance is mainly through hepatic oxidative metabolism. All except nelfinavir are metabolized predominantly by CYP3A4 (and nelfinavir's major metabolite is cleared by CYP3A4). Elimination half-lives of the HIV protease inhibitors range from 1.8 to 10 hours ([Table 59–4](#)), and most of these drugs can be dosed once or twice daily. Most HIV protease inhibitors are highly protein bound in plasma, and adding plasma proteins will increase their *in vitro* IC<sub>50</sub> (Molla et al., 1998). Fractional penetration into the CSF is also low for most of these agents, although the clinical significance is unknown.

An important toxicity common to all approved HIV protease inhibitors is the potential for metabolic drug interactions. Most of these drugs inhibit CYP3A4 at clinically achieved concentrations, although the magnitude of inhibition varies greatly, with ritonavir by far the most potent (Piscitelli and Gallicano, 2001). It is now a common practice to combine HIV protease inhibitors with a low dose of ritonavir to take advantage of that drug's remarkable capacity to inhibit CYP3A4 metabolism (Flexner, 2000).

Although the approved dose of ritonavir for antiretroviral treatment is 600 mg twice daily, doses of 100 or 200 mg once or twice daily are sufficient to inhibit CYP3A4 and increase ("boost") the concentrations of most concurrently administered CYP3A4 substrates. Lower doses of ritonavir are much better tolerated. The enhanced pharmacokinetic profile of HIV protease inhibitors administered with ritonavir reflects inhibition of both first-pass and systemic clearance, resulting in improved oral bioavailability and a longer elimination  $t_{1/2}$  of the co-administered drug. This allows a reduction in both drug dose and dosing frequency while increasing systemic concentrations (Flexner, 2000). Combinations of darunavir, lopinavir, fosamprenavir, and atazanavir with ritonavir are approved for once-daily administration.

Most HIV protease inhibitors are substrates for the P-glycoprotein efflux pump (P-gp) ([Chapter 5](#)).

P-gp in capillary endothelial cells of the blood-brain barrier limits the penetration of HIV protease inhibitors into the brain (Kim et al., 1998), although the low CSF-to-plasma drug concentration ratio characteristic of these drugs also may reflect extensive binding to plasma proteins. Most HIV protease inhibitors penetrate less well into semen than do nucleoside reverse transcriptase inhibitors and NNRTIs. Virologic responses in plasma, CSF, and semen usually are concordant (Taylor et al., 1999), and the clinical significance of P-gp and protein-binding effects is unclear.

**Figure 59–5.** Mechanism of action of an HIV protease inhibitor. Shown here is a phenylalanine-proline target peptide sequence (in blue) for the protease enzyme (in golden brown) with chemical structures of the native amino acids (in lower box) to emphasize homology of their structures to that of saquinavir (at top).

**Table 59—4 Pharmacokinetic Properties of HIV-1 Protease Inhibitors<sup>a</sup>**

PARAMETER	SAQUINAVIR <sup>a</sup>	INDINAVIR	RITONAVIR	NELFINAVIR	FOSAMPRENAVIR	LOPINAVIR <sup>c</sup>	ATAZANAVIR	TIPRANAVIR	DARUNAVIR

ABBREVIATIONS: AUC area under plasma concentration-time curve; t<sub>1/2</sub> half-life of elimination; ↑, increase; ↓, decrease; ↔, no effect; CYP, cytochrome P450; ND, not determined; +, weak; ++, moderate; +++, substantial. <sup>a</sup>Reported mean values in adults with normal renal and hepatic function. <sup>b</sup>Parameters reported for the saquinavir soft-gel capsule formulation. <sup>c</sup>Values for lopinavir, tipranavir, and darunavir reflect coadministration with ritonavir.

GI side effects including nausea, vomiting, and diarrhea are common, although symptoms generally resolve within 4 weeks of starting treatment.

The speed with which HIV develops resistance to unboosted protease inhibitors is intermediate between that of nucleoside analogs and NNRTIs. In initial monotherapy studies, the median time to rebound in HIV plasma RNA concentrations of one log or greater was 3-4 months (Flexner, 1998). In contrast to NNRTIs, high-level resistance to these drugs generally requires accumulation of a minimum of four to five codon substitutions, which may take many months.

Initial (primary) resistance mutations in the enzymatic active site confer only a 3- to 5-fold drop in sensitivity to most drugs; these are followed by secondary mutations often distant from the active site that compensate for the reduction in proteolytic efficiency. Accumulation of secondary resistance mutations increases the likelihood of cross-resistance to other PIs (Flexner, 1998; Kuritzkes, 2004). Patients failing boosted PI-based combination regimens are more likely to have resistance mutations to the other drugs in the regimen, especially NRTIs (Kuritzkes, 2004), suggesting a high genetic barrier to resistance.

With potent activity and favorable resistance profiles, these drugs are a common component of regimens for treatment-experienced patients. However, the virologic benefits of these drugs must be balanced against short- and long-term toxicities, including the risk of insulin resistance and lipodystrophy (Garg, 2004). Improvements in pill burden, convenience, and tolerability have greatly improved adherence to drugs in this class (Gardner et al., 2009).

# Saquinavir

**Chemistry and Antiviral Activity.** Saquinavir, the first approved HIV protease inhibitor, is a peptidomimetic hydroxyethylamine ([Figure 59–6](#)). It is a transition-state analog of a phenylalanine-proline cleavage site in one of the native substrate sequences for the HIV aspartyl protease and was the product of a rational drug-design program (Roberts et al., 1990). Saquinavir inhibits both HIV-1 and HIV-2 replication and has an *in vitro* IC<sub>50</sub> in peripheral blood lymphocytes that ranges from 3.5 to 10 nM (Noble and Faulds, 1996).

**Mechanisms of Resistance.** As is typical of HIV protease inhibitors, high-level resistance requires accumulation of multiple resistance mutations.

The primary saquinavir resistance mutation occurs at HIV protease codon 90 (a leucine-to-methionine substitution), although primary resistance also has been reported with a glycine-to-valine substitution at codon 48. Secondary resistance mutations occur at codons 36, 46, 82, 84, and others, and these are associated with clinical saquinavir resistance as well as cross-resistance to most other HIV protease inhibitors (Noble and Faulds, 1996).

**Absorption, Distribution, and Elimination.** Fractional oral bioavailability is low (~4%) owing mainly to extensive first-pass metabolism (Flexner, 1998), and so this drug should always be given in combination with ritonavir. Low doses of ritonavir increase the saquinavir steady-state AUC by 20- to 30-fold (Flexner, 2000), allowing administration once or twice daily.

Substances that inhibit intestinal but not hepatic CYP3A4, such as grapefruit juice, increase the saquinavir AUC by 3-fold at most (Flexner, 2000). Saquinavir is metabolized primarily by intestinal and hepatic CYP3A4 (Fitzsimmons and Collins, 1997); its metabolites are not known to be active against HIV-1. The parent drug and its metabolites are eliminated through the biliary system and feces (>95% of drug), with minimal urinary excretion (<3%).

**Untoward Effects.** The most frequent side effects of saquinavir are GI: nausea, vomiting, diarrhea, and abdominal discomfort. Most side effects of saquinavir are mild and short lived, although long-term use is associated with lipodystrophy.

**Precautions and Interactions.** Saquinavir clearance is increased with CYP3A4 induction; thus, co-administration of inducers of CYP3A4 such as rifampin, phenytoin, or carbamazepine lowers saquinavir concentrations and should be avoided (Flexner, 1998). The effect of nevirapine or efavirenz on saquinavir may be partially or completely reversed with ritonavir. Most drug interactions seen with saquinavir/ritonavir reflect the effect of the boosting agent.

**Therapeutic Use.** Saquinavir is available as a hard-gelatin capsule (INVIRASE). In initial clinical trials, unboosted saquinavir at the approved dose (600 mg three times daily) produced only modest virologic benefit because of its poor oral bioavailability. When combined with ritonavir and nucleoside analogs, saquinavir produces viral load reductions comparable with those of other HIV protease inhibitor regimens (Flexner, 2000). Saquinavir is no longer widely prescribed in the developed world because of its relatively high pill burden, but the drug remains popular as a generic combined with ritonavir in resource-limited settings because of its favorable toxicity and efficacy profile.

## Ritonavir

**Chemistry and Antiviral Activity.** Ritonavir is a peptidomimetic HIV protease inhibitor designed to complement the  $C_2$  axis of symmetry of the enzyme active site (Flexner, 1998) ([Figure 59–5](#)). Ritonavir is active against both HIV-1 and HIV-2, although it may be slightly less active against the latter. Its  $IC_{50}$  for wild-type HIV-1 variants in the absence of human serum ranges from 4 to 150 nM.

**Mechanisms of Resistance.** Ritonavir is mostly used as a pharmacokinetic enhancer (CYP 3A4 inhibitor), and the low doses used for this purpose are not known to induce ritonavir resistance mutations.

**Figure 59–6.** Structure of available HIV protease inhibitors.

The primary ritonavir resistance mutation is usually at protease codon 82 (several possible substitutions for valine) or codon 84 (isoleucine-to-valine substitution). Additional mutations associated with increasing resistance occur at codons 20, 32, 46, 54, 63, 71, 84, and 90. High-level resistance requires accumulation of multiple mutations.

**Absorption, Distribution, and Elimination.** Absorption of ritonavir is rapid and is only slightly affected by food, depending on the formulation. The overall absorption of ritonavir from the capsule formulation increases by 13% when the capsule is taken with meals, but the bioavailability of the oral

solution decreases by 7% (Flexner, 1998). A heat-stable 100-mg tablet formulation is now available. Interindividual variability in pharmacokinetics is high, with a variability exceeding 6-fold in trough concentrations among patients given 600 mg ritonavir every 12 hours as capsules (Hsu et al., 1998).

Ritonavir is metabolized primarily by CYP3A4 and to a lesser extent by CYP2D6. Ritonavir and its metabolites are mainly eliminated in feces (86% of parent drug and metabolites), with only 3% of drug eliminated unchanged in the urine. Ritonavir induces its own metabolism; steady-state concentrations are reached within 2 weeks. Ritonavir is 98-99% bound to plasma proteins, mainly to  $\alpha_1$ -acid glycoprotein. Physiological concentrations of  $\alpha_1$ -acid glycoprotein increase the *in vitro* IC<sub>50</sub> by a factor of 10, whereas albumin increases the IC<sub>50</sub> by a factor of 4 (Molla et al., 1998).

**Untoward Effects.** The major side effects of ritonavir are GI and include dose-dependent nausea, vomiting, diarrhea, anorexia, abdominal pain, and taste perversion. GI toxicity may be reduced if the drug is taken with meals. Peripheral and perioral paresthesias can occur at the therapeutic dose of 600 mg twice daily. These side effects generally abate within a few weeks of starting therapy. Ritonavir also causes dose-dependent elevations in serum total cholesterol and triglycerides, as well as other signs of lipodystrophy, and it could increase the long-term risk of atherosclerosis in some patients.

**Precautions and Interactions.** Ritonavir is one of the most potent known inhibitors of CYP3A4, markedly increasing the plasma concentrations and prolonging the elimination of many drugs. Ritonavir should be used with caution in combination with any CYP3A4 substrate and should not be combined with drugs that have a narrow therapeutic index such as midazolam, triazolam, fentanyl, and ergot derivatives (Flexner, 1998). Ritonavir is a mixed competitive and irreversible inhibitor of CYP 3A4 and its effects can persist for 2-3 days after the drug is discontinued (Washington et al., 2003). Ritonavir is also a weak inhibitor of CYP2D6. Potent inducers of CYP3A4 activity such as rifampin may lower ritonavir concentrations and should be avoided or dosage adjustments considered. The capsule and solution formulations of ritonavir contain alcohol and should not be administered with disulfiram or metronidazole ([Chapter 23](#)).

Ritonavir is also a moderate inducer of CYP3A4, glucuronosyl *S*-transferase, and possibly other hepatic enzymes and drug transport proteins. The concentrations of some drugs therefore will be decreased in the presence of ritonavir. Ritonavir reduces the ethinyl estradiol AUC by 40%, and alternative forms of contraception should be used (Piscitelli and Gallicano, 2001).

**Therapeutic Use.** Among patients with susceptible strains of HIV-1, ritonavir (NORVIR) as a sole agent lowered plasma HIV-1 RNA concentrations by 100- to 1000-fold (Ho et al., 1995). In a trial in patients with advanced HIV disease, the addition of ritonavir to current therapy reduced HIV-related mortality and disease progression by ~50% over a median of 6 months of follow-up (Flexner, 1998). Ritonavir is used infrequently as the sole protease inhibitor in combination regimens because of GI toxicity. However, numerous clinical trials have shown benefit of ritonavir as a pharmacokinetic enhancer in various dual protease inhibitor combinations (Flexner, 2000).

**Use of Ritonavir as a Cyp3A4 Inhibitor.** Ritonavir inhibits the metabolism of all current HIV protease inhibitors and is frequently used in combination with most of these drugs, with the exception of nelfinavir, to enhance their pharmacokinetic profile and allow a reduction in dose and dosing frequency of the co-administered drug (Flexner, 2000). Ritonavir also overcomes the deleterious effect of food on indinavir bioavailability. Under most circumstances, low doses of ritonavir (100 or 200 mg once or twice daily) are just as effective at inhibiting CYP3A4 and are much better tolerated than the 600 mg twice-daily treatment dose.

## Fosamprenavir

**Chemistry and Antiviral Activity.** Fosamprenavir is a phosphonoxy prodrug of amprenavir that has the advantage of greatly increased water solubility and improved oral bioavailability (Arvieux and Tribut, 2005). This allowed reduction in the pill burden from 16 capsules to 4 tablets per day. Fosamprenavir is as effective, more convenient, and generally better tolerated than amprenavir, and as a result, amprenavir is no longer marketed.

Amprenavir is an *N,N*-disubstituted (hydroxyethyl) amino sulfonamide nonpeptide HIV protease inhibitor. Although developed using a sophisticated structure-based drug-design program, the same compound was identified

previously using a more traditional high-throughput screen of an available chemical library (Werth, 1994). Amprenavir contains a sulfonamide moiety, which may play a role in its dermatologic side effects. The drug is active against both HIV-1 and HIV-2, with an  $IC_{90}$  for wild-type HIV-1 of  $\sim 80$  nM.

**Mechanisms of Resistance.** Amprenavir's primary resistance mutation occurs at HIV protease codon 50; this isoleucine-to-valine substitution confers only 2-fold decreased susceptibility *in vitro*. Primary resistance occurs less frequently at codon 84. Secondary resistance mutations occur at codons 10, 32, 46, 47, 54, 73, and 90, which greatly increase resistance and cross-resistance (Arvieux and Tribut, 2005).

**Absorption, Distribution, and Elimination.** Fosamprenavir is dephosphorylated rapidly to amprenavir in the intestinal mucosa. The phosphorylated prodrug is  $\sim 2000$  times more water soluble than amprenavir. Meals have no significant effect on fosamprenavir pharmacokinetics (Arvieux and Tribut, 2005). Amprenavir is 90% bound to plasma proteins, mostly  $\alpha_1$ -acid glycoprotein. This binding is relatively weak, and physiological concentrations of  $\alpha_1$ -acid glycoprotein increase the *in vitro*  $IC_{50}$  only 3- to 5-fold. Amprenavir clearance is mainly by hepatic CYP3A4, and excretion is by the biliary route. Amprenavir is a moderate inhibitor and inducer of CYP3A4. Ritonavir increases amprenavir concentrations by inhibiting CYP3A4, allowing lower fosamprenavir doses. The daily fosamprenavir dose may be reduced from 1400 mg twice daily to 1400 mg plus 200 mg ritonavir when given once daily, or 700 mg (one tablet) plus 100 mg ritonavir twice daily.

**Untoward Effects.** The most common adverse effects associated with fosamprenavir are GI and include diarrhea, nausea, and vomiting. Hyperglycemia, fatigue, paresthesias, and headache also have been reported. Fosamprenavir can produce skin eruptions; moderate to severe rash is reported in up to 8% of recipients, and onset is usually within 2 weeks of starting therapy (Arvieux and Tribut, 2005). Fosamprenavir has fewer effects on plasma lipid profiles than lopinavir-based regimens.

**Precautions and Interactions.** Inducers of hepatic CYP3A4 activity (e.g., rifampin and efavirenz) may lower plasma amprenavir concentrations. Because amprenavir is both a CYP3A4 inhibitor and inducer, pharmacokinetic drug interactions can occur and may be unpredictable. For

example, atorvastatin, ketoconazole, and rifabutin concentrations increase significantly when fosamprenavir is given without ritonavir, whereas methadone concentrations decrease.

**Therapeutic Use.** Clinical trials have demonstrated long-term virologic benefit in treatment-naïve and treatment-experienced patients receiving fosamprenavir (LEXIVA) with or without ritonavir, in combination with nucleoside analogs (Arvieux and Tribut, 2005).

Twice-daily fosamprenavir/ritonavir produces virologic outcomes equivalent to lopinavir/ritonavir in both treatment-naïve and treatment-experienced patients (Arvieux and Tribut, 2005). However, once-daily fosamprenavir/ritonavir is inferior to lopinavir/ritonavir in protease-inhibitor experienced patients, and the drug should only be given twice daily in this patient population. Fosamprenavir is approved for use in treatment-naïve pediatric patients  $\geq 2$  years of age and treatment-experienced patients  $\geq 6$  years of age, at a dose of 30 mg/kg twice daily or 18 mg/kg plus ritonavir 3 mg/kg twice daily.

## Lopinavir

**Chemistry and Antiviral Activity.** Lopinavir is a peptidomimetic HIV protease inhibitor that is structurally similar to ritonavir ([Figure 59–6](#)) but is 3- to 10-fold more potent against HIV-1 *in vitro*. Lopinavir is active against both HIV-1 and HIV-2; its  $IC_{50}$  for wild-type HIV variants in the presence of 50% human serum ranges from 65 to 290 nM. Lopinavir is available only in co-formulation with low doses of ritonavir (KALETRA), which is used to inhibit CYP3A4 metabolism and increase concentrations of lopinavir (Oldfield and Plosker, 2006).

**Mechanisms of Action and Resistance.** Treatment-naïve patients who fail a first regimen containing lopinavir generally do not have HIV protease mutations but may have genetic resistance to the other drugs in the regimen (Oldfield and Plosker, 2006). For treatment-experienced patients, accumulation of four or more HIV protease inhibitor resistance mutations is associated with a reduced likelihood of virus suppression after starting lopinavir (Kuritzkes, 2004).

Mutations most likely to be associated with resistance include I47A/V, V32I, and L76V. Additional mutations associated with lopinavir failure in

treatment-experienced patients include those at HIV protease codons 10, 20, 24, 33, 46, 50, 53, 54, 63, 71, 73, 82, 84, and 90 (Oldfield and Plosker, 2006). There is no evidence that exposure to the low doses of ritonavir in the lopinavir/ritonavir co-formulation selects for ritonavir-specific resistance mutations.

**Absorption, Distribution, and Elimination.** Lopinavir is absorbed rapidly after oral administration. Food has a minimal effect on bioavailability of lopinavir/ritonavir tablets, and the drug can be taken with or without food. Although the tablets contain lopinavir/ritonavir in a fixed 4:1 ratio, the observed plasma concentration ratio for these two drugs following oral administration is nearly 20:1, reflecting the sensitivity of lopinavir to the inhibitory effect of ritonavir on CYP3A4. Lopinavir undergoes extensive hepatic oxidative metabolism by CYP3A4. Approximately 90% of total drug in plasma is the parent compound, and <3% of a dose is eliminated unchanged in the urine. Both lopinavir and ritonavir are highly bound to plasma proteins, mainly to  $\alpha_1$ -acid glycoprotein, and have a low fractional penetration into CSF and semen.

When administered orally without ritonavir, lopinavir plasma concentrations were exceedingly low mainly owing to first-pass metabolism. Both the first-pass metabolism and systemic clearance of lopinavir are very sensitive to inhibition by ritonavir.

A single 50-mg dose of ritonavir increased the lopinavir AUC by 77-fold compared with 400 mg lopinavir alone; 100 mg ritonavir increased the lopinavir AUC by 155-fold. Lopinavir trough concentrations were increased 50- to 100-fold by co-administration of low doses of ritonavir (Oldfield and Plosker, 2006). Multiple-dose pharmacokinetic studies have not been conducted with lopinavir in the absence of ritonavir. Adding 100 mg ritonavir twice daily to the lopinavir/ritonavir co-formulation (a total of 200 mg twice daily of ritonavir) has only a modest further effect on lopinavir concentrations, increasing the mean steady-state AUC by 46%.

**Untoward Effects.** The most common adverse events reported with the lopinavir/ritonavir co-formulation have been GI: loose stools, diarrhea, nausea, and vomiting. These are less frequent and less severe than those reported with the 600 mg twice-daily standard dose of ritonavir but more common compared to those of boosted atazanavir and darunavir. The most common laboratory abnormalities include elevated total cholesterol and

triglycerides. Because the same adverse effects occur with ritonavir, it is unclear whether these side effects are due to ritonavir, lopinavir, or both.

**Precautions and Interactions.** Because lopinavir metabolism is highly dependent on CYP3A4, concomitant administration of agents that induce CYP3A4, such as rifampin, may lower plasma lopinavir concentrations considerably. St. John's wort is a known inducer of CYP3A4, leading to lower concentrations of lopinavir and possible loss of antiviral effectiveness. Co-administration of other antiretrovirals that can induce CYP3A4, including amprenavir, nevirapine or efavirenz, may require increasing the dose of lopinavir (Oldfield and Plosker, 2006).

Although lopinavir is a weak inhibitor of CYP3A4 *in vitro*, the ritonavir in the co-formulated capsule strongly inhibits CYP3A4 activity and probably dwarfs any lopinavir effect. The liquid formulation of lopinavir contains 42% ethanol and should not be administered with disulfiram or metronidazole ([Chapter 23](#)). Ritonavir is also a moderate CYP inducer at the dose employed in the co-formulation and can adversely decrease concentrations of some co-administered drugs (e.g., oral contraceptives). There is no direct proof that lopinavir is a CYP inducer *in vivo*; however, concentrations of some co-administered drugs (e.g., amprenavir and phenytoin) are lower with the lopinavir/ritonavir co-formulation than would have been expected with low-dose ritonavir alone (Oldfield and Plosker, 2006).

**Therapeutic Use.** In comparative clinical trials, lopinavir has antiretroviral activity at least comparable with that of other potent HIV protease inhibitors and better than that of nelfinavir. Lopinavir also has considerable and sustained antiretroviral activity in patients who failed previous HIV protease inhibitor-containing regimens.

In one study, 70 subjects who had failed therapy with one previous HIV protease inhibitor were treated for 2 weeks with lopinavir, followed by the addition of nevirapine. At 48 weeks, 60% of subjects had plasma HIV-1 RNA levels of <50 copies/mL despite substantial phenotypic resistance to other HIV protease inhibitors (Oldfield and Plosker, 2006). Because plasma concentrations of lopinavir generally are much higher than those required to suppress HIV replication *in vitro*, the drug may be capable of suppressing HIV isolates with low-level protease inhibitor resistance.

The adult lopinavir/ritonavir dose is 400/100 mg (two tablets) twice daily, or 800/200 mg (four tablets) once daily, with or without food. Lopinavir/ritonavir should not be dosed once daily in treatment-experienced patients. Lopinavir/ritonavir is approved for use in pediatric patients  $\geq 14$  days, with dosing based on either weight or body surface area. A pediatric tablet formulation is available for use in children  $>6$  months of age.

## Atazanavir

**Chemistry and Antiviral Activity.** Atazanavir is an azapeptide protease inhibitor with a  $C_2$ -symmetrical chemical structure that is active against both HIV-1 and HIV-2 (Croom et al., 2009) ([Figure 59–6](#)). The  $IC_{50}$  for HIV-1 in various *in vitro* assays ranges from 2 to 15 nM. In the presence of 40% human serum, the *in vitro*  $IC_{50}$  is increased 3- to 4-fold (Croom et al., 2009).

**Mechanisms of Resistance.** The primary atazanavir resistance mutation occurs at HIV protease codon 50 and confers about a 9-fold decreased susceptibility. This isoleucine-to-leucine substitution (I50L) is distinct from the isoleucine-to-valine substitution selected by fosamprenavir and darunavir.

This mutation was present in 100% of viruses isolated from patients failing therapy in one clinical trial (Croom et al., 2009). Isolates with only this mutation are still susceptible to inhibition by other protease inhibitors. Sensitivity to atazanavir is affected by various primary and secondary mutations that accumulate in patients who have failed other HIV protease inhibitors, with high-level resistance more likely if five or more additional mutations are present (Croom et al., 2009).

**Absorption, Distribution, and Elimination.** Atazanavir is absorbed rapidly after oral administration, with peak concentrations occurring  $\sim 2$  hours after dosing. Atazanavir absorption is sensitive to food: a light meal increases the AUC by 70%, whereas a high-fat meal increases the AUC by 35% (Croom et al., 2009). It is therefore recommended that the drug be administered with food, which also decreases the interindividual variability in pharmacokinetics, unless given with ritonavir. Absorption is pH dependent, and proton pump inhibitors or other acid-reducing agents substantially reduce atazanavir concentrations after oral dosing; this effect is only partially reversed by concomitant ritonavir.

Atazanavir undergoes oxidative metabolism in the liver primarily by CYP3A4, which accounts for most of the elimination of this drug. Only 7% of the parent drug is excreted unchanged in the urine. The mean elimination  $t_{1/2}$  of atazanavir at the standard 400-mg once-daily dose is ~7 hours; however, the drug has nonlinear pharmacokinetics, and the  $t_{1/2}$  increases to nearly 10 hours at a dose of 600 mg (Croom et al., 2009). Atazanavir is 86% bound to plasma proteins, both to albumin and  $\alpha_1$ -acid glycoprotein. It is present in CSF at <3% of plasma concentrations but has excellent penetration into seminal fluid (Croom et al., 2009).

**Untoward Effects.** Like indinavir, atazanavir frequently causes unconjugated hyperbilirubinemia, although this is mainly a cosmetic side effect and not associated with hepatotoxicity.

Approximately 40% of subjects receiving 400 mg atazanavir once daily in initial clinical trials developed a significant increase in total bilirubin (Croom et al., 2009), although only 5% developed jaundice. This is a consequence of inhibition of UDP-glucuronosyl transferase by atazanavir, and the side effect occurs more prominently in those who are genetically deficient in this enzyme, e.g., patients with Gilbert's syndrome (Rotger et al., 2005). Postmarketing reports include hepatic adverse reactions of cholecystitis, cholelithiasis, cholestasis, and other hepatic function abnormalities.

Other side effects reported with atazanavir include diarrhea and nausea, mainly during the first few weeks of therapy. Overall, 6% of patients discontinued atazanavir because of side effects during 48 weeks of treatment. Patients treated with atazanavir in randomized clinical trials had significantly lower fasting triglyceride and cholesterol concentrations than patients treated with nelfinavir, lopinavir, or efavirenz (Croom et al., 2009), suggesting a reduced propensity to cause these side effects. In addition, atazanavir is not known to cause glucose intolerance or changes in insulin sensitivity.

**Precautions and Interactions.** Because atazanavir is metabolized by CYP3A4, concomitant administration of agents that induce this enzyme (e.g., rifampin) is contraindicated. Efavirenz 600 mg once daily reduced the unboosted atazanavir AUC by 74%. Atazanavir is a moderate inhibitor of CYP3A4 and may alter plasma concentrations of other CYP3A4 substrates. Atazanavir inhibits CYP3A4 less than ritonavir and does not appear to

inhibit other CYP isoforms. Atazanavir is a moderate UGT 1A1 inhibitor, and when given with or without ritonavir increases the raltegravir AUC 41-72% and increases the raltegravir  $C_{12h}$  approximately 2-fold. Atazanavir is not known to induce hepatic drug-metabolizing enzymes.

Ritonavir significantly increases the atazanavir AUC and reduces atazanavir systemic clearance. Ritonavir 100 mg once daily increases the atazanavir 300 mg once-daily steady-state AUC by 2.5-fold and increases the  $C_{min}$  6.5-fold (Croom et al., 2009). Low-dose ritonavir also counters the effect of some inducers, for example efavirenz, on the atazanavir AUC.

Proton pump inhibitors reduce atazanavir concentrations substantially with concomitant administration. These drugs and  $H_2$  blockers should be avoided in patients receiving atazanavir without ritonavir.

**Therapeutic Use.** In treatment-experienced patients, atazanavir (REYATAZ) 400 mg once daily without ritonavir was inferior to the lopinavir/ritonavir co-formulation given twice daily; 81% of lopinavir/ritonavir-treated patients had plasma HIV RNA concentrations <400 copies/mL at week 24 compared with 61% of atazanavir-treated patients. The combination of atazanavir and low-dose ritonavir had a similar viral-load effect as the lopinavir/ritonavir co-formulation in one study (Croom et al., 2009), suggesting that this drug should be combined with ritonavir in treatment-experienced patients—and perhaps in treatment-naïve patients with high baseline viral load—in order to take advantage of the enhanced pharmacokinetic profile.

In addition to its use for treatment-naïve and experienced adults, atazanavir, in combination with ritonavir, is approved for treatment of pediatric patients >6 years of age, with dosing based on weight.

## Darunavir

**Chemistry and Antiviral Activity.** Darunavir is a nonpeptidic protease inhibitor that is active against both HIV-1 and HIV-2 ([Figure 59–6](#)). The  $IC_{50}$  for HIV-1 in various *in vitro* assays ranges from 1 to 5 nM, although human serum and  $\alpha_1$ -acid glycoprotein increase the  $IC_{50}$  by 20-fold (McKeage et al., 2009).

**Mechanisms of Action and Resistance.** Darunavir binds tightly but reversibly to the active site of HIV protease but has also been shown to

prevent protease dimerization.

Clinically significant drug resistance requires accumulation of multiple primary mutations. At least three darunavir-associated resistance mutations are required to confer resistance, and the most commonly seen are V32I, L33F, I47V, I54L and L89V (McKeage et al., 2009). Pretreatment resistance to darunavir is highly unlikely in treatment-naïve patients and occurs in <10% of protease inhibitor-experienced patients.

**Absorption, Distribution, and Elimination.** Darunavir is absorbed rapidly after oral administration with ritonavir, with peak concentrations occurring 2-4 hours after dosing. Ritonavir increases darunavir bioavailability and increases the darunavir AUC by up to 14-fold. The drug should be taken with food because food increases the darunavir AUC by 30% (McKeage et al., 2009).

Darunavir undergoes oxidative metabolism in the liver primarily by CYP3A4, accounting for most of the elimination of this drug. About 8% of the parent drug is excreted unchanged in the urine. When combined with ritonavir, the mean elimination  $t_{1/2}$  of darunavir is ~15 hours. In the presence of ritonavir 100 mg twice daily, the AUC after a 600-mg dose administered twice daily was increased 14-fold (McKeage et al., 2009). Darunavir is 95% bound to plasma proteins, mainly to  $\alpha_1$ -acid glycoprotein.

**Untoward Effects.** Because darunavir must be combined with a low dose of ritonavir, drug administration can be accompanied by all of the side effects caused by ritonavir, including GI complaints in up to 20% of patients. Darunavir, like fosamprenavir, contains a sulfa moiety, and rash has been reported in up to 10% of recipients.

Overall, 3% of patients in randomized clinical trials discontinued darunavir because of side effects during 48 weeks of treatment, compared to 7% of patients treated with lopinavir/ritonavir. Darunavir/ritonavir is associated with increases in plasma triglycerides and cholesterol, although the magnitude of increase is lower than that seen with lopinavir/ritonavir (McKeage et al., 2009). Although causality is not firmly established, darunavir has been associated with episodes of hepatotoxicity.

**Precautions and Interactions.** Because darunavir is metabolized by CYP3A4, concomitant administration of agents that induce this enzyme (e.g.,

rifampin) is contraindicated. The drug interaction profile of darunavir/ritonavir is dominated by those expected with ritonavir.

Efavirenz 600 mg once daily reduced the darunavir AUC by 13% when combined with darunavir/ritonavir 300/100 mg twice daily. Darunavir/ritonavir 600/100 twice daily increased the maraviroc AUC by 344%, and the maraviroc dose should be reduced to 150 mg twice daily when combined with darunavir.

**Therapeutic Use.** Darunavir (PREZISTA) in combination with ritonavir is approved for use in HIV-infected adults.

In treatment-naïve patients receiving tenofovir plus emtricitabine randomized to darunavir/ritonavir 800/100 mg once daily, virologic outcomes after 48 weeks were comparable to those seen with lopinavir/ritonavir 800/200 mg once daily (84% vs. 78%, respectively, achieved plasma HIV RNA <50 copies/mL). In protease inhibitor-experienced patients receiving an optimized background regimen and randomized to darunavir/ritonavir 600/100 mg twice daily, virologic outcomes after 48 weeks were better than those seen with lopinavir/ritonavir 400/100 mg twice daily (71% vs. 60%, respectively, achieving plasma HIV RNA <50 copies/mL) (McKeage et al., 2009).

Darunavir/ritonavir can be used as a once-daily (800/100 mg) or twice-daily (600/100 mg) regimen with nucleosides in treatment-naïve adults and as a twice-daily regimen in treatment-experienced adults, taken with food. Darunavir/ritonavir twice daily is approved for use in pediatric patients >6 years of age, with dosing based on weight.

## Indinavir

**Chemistry and Antiviral Activity.** Indinavir is a peptidomimetic hydroxyethylene HIV protease inhibitor ([Figure 59–6](#)) whose structure was based on a renin inhibitor with some similarity to the phenylalanine-proline cleavage site in the HIV gag polyprotein (Plosker and Noble, 1999), although indinavir is not itself a renin inhibitor. Indinavir is 10-fold more potent against the HIV-1 protease than that of HIV-2, and its 95% inhibitory concentration (IC<sub>95</sub>) for wild-type HIV-1 ranges from 25 to 100 nM.

**Mechanisms of Resistance.** The primary indinavir resistance mutations occur at HIV protease codons 46 (a methionine-to-isoleucine or leucine), 82,

and 84. However, secondary resistance mutations can accumulate at codons 10, 20, 24, 46, 54, 63, 71, 82, 84, and 90, and these are associated with clinical indinavir resistance as well as cross-resistance to other HIV protease inhibitors (Plosker and Noble, 1999).

**Absorption, Distribution, and Elimination.** Indinavir is absorbed rapidly after oral administration, with peak concentrations achieved in ~1 hour. Unlike other drugs in this class, food can adversely affect indinavir bioavailability; a high-calorie, high-fat meal reduces plasma concentrations by 75% (Plosker and Noble, 1999). Therefore, indinavir must be taken with ritonavir or while fasting or with a light low-fat meal.

Indinavir has the lowest protein binding of the HIV protease inhibitors, with only 60% of drug bound to plasma proteins (Plosker and Noble, 1999). As a consequence, indinavir has higher fractional CSF penetration than other drugs in this class, although the clinical significance of this is unknown.

The short  $t_{1/2}$  of indinavir makes thrice-daily (every 8 hours) dosing necessary unless the drug is combined with ritonavir. Indinavir clearance is greatly reduced by low doses of ritonavir, which also overcome the deleterious effects of food on bioavailability (Flexner, 2000). This allows indinavir to be dosed twice daily regardless of meals.

**Untoward Effects.** A unique and common adverse effect of indinavir is crystalluria and nephrolithiasis. This stems from the poor solubility of the drug, which is lower at pH 7.4 than at pH 3.5 (Plosker and Noble, 1999). Precipitation of indinavir and its metabolites in urine can cause renal colic, and nephrolithiasis occurs in ~3% of patients. Patients must drink sufficient fluids to maintain dilute urine and prevent renal complications. Risk of nephrolithiasis is related to higher plasma drug concentrations, which presumably produce higher urine concentrations, regardless of whether or not the drug is combined with ritonavir (Dieleman et al., 1999).

Like atazanavir, indinavir frequently causes unconjugated hyperbilirubinemia, and 10% of patients develop an indirect serum bilirubin concentration >2.5 mg/dL (Plosker and Noble, 1999). This is generally asymptomatic and not associated with serious long-term sequelae. As with other HIV protease inhibitors, prolonged administration of indinavir is associated with the HIV lipodystrophy syndrome, especially fat accumulation. Indinavir has been associated with hyperglycemia and can induce a relative state of insulin resistance in healthy HIV-seronegative

volunteers following a single 800-mg dose (Noor et al., 2002). Dermatologic complications have been reported, including hair loss, dry skin, dry and cracked lips, and ingrown toenails (Plosker and Noble, 1999).

**Precautions and Interactions.** Patients taking indinavir should drink at least 2 L of water daily to prevent renal complications. *This is especially problematic for those who live in warm climates.* Because indinavir solubility decreases at higher pH, antacids or other buffering agents *should not* be taken at the same time. Didanosine formulations containing an antacid buffer should not be taken within 2 hours before or 1 hour after indinavir. Like most other HIV protease inhibitors, indinavir is metabolized by CYP3A4 and is a moderately potent CYP3A4 inhibitor. Indinavir should not be co-administered with other CYP3A4 substrates that have a narrow therapeutic index. Drugs that induce CYP3A4 may lower indinavir concentrations and should be avoided.

**Therapeutic Use.** Indinavir (CRIVAN) is no longer widely prescribed because of problems with nephrolithiasis and other nephrotoxicities, and it lacks significant advantages over other available HIV protease inhibitors. When combined with ritonavir and nucleoside analogs, twice-daily indinavir produces viral load reductions comparable with those of other HIV protease inhibitor regimens (Flexner, 2000).

## **Nelfinavir**

**Chemistry and Antiviral Activity.** Nelfinavir is a nonpeptidic protease inhibitor that is active against both HIV-1 and HIV-2 (Bardsley-Elliot and Plosker, 2000) ([Figure 59–6](#)). The mean IC<sub>95</sub> for HIV-1 in various *in vitro* assays is 59 nM.

**Mechanisms of Action and Resistance.** The primary nelfinavir resistance mutation is unique to this drug and occurs at HIV protease codon 30 (aspartic acid-to-asparagine substitution); this mutation results in a 7-fold decrease in susceptibility. Isolates with only this mutation retain full sensitivity to other HIV protease inhibitors (Bardsley-Elliot and Plosker, 2000). Less commonly, a primary resistance mutation occurs at position 90, which can confer cross-resistance. In addition, secondary resistance mutations can accumulate at codons 35, 36, 46, 71, 77, 88, and 90, and these are associated with further resistance to nelfinavir, as well as cross-resistance to other HIV protease inhibitors.

**Absorption, Distribution, and Elimination.** Nelfinavir absorption is very sensitive to food effects; a moderate-fat meal increases the AUC 2- to 3-fold, and higher concentrations are achieved with high-fat meals (Bardsley-Elliot and Plosker, 2000). Intraindividual and interindividual variabilities in plasma nelfinavir concentrations are large as a consequence of variable absorption. Originally approved at a dose of 750 mg three times daily, nelfinavir is now administered at a dose of 1250 mg twice daily using a reduced-volume 625-mg tablet. Nelfinavir's high dependence on fatty foods for optimal absorption, combined with the fact that nelfinavir is the only HIV protease inhibitor whose pharmacokinetics are not substantially improved with ritonavir, have reduced its popularity.

Nelfinavir undergoes oxidative metabolism primarily by CYP2C19 but also by CYP3A4 and CYP2D6. Its major hydroxy-*t*-butylamide metabolite, M8, is formed by CYP2C19 and has *in vitro* antiretroviral activity similar to that of the parent drug. This is the only known active metabolite of any HIV protease inhibitor. Nelfinavir induces its own metabolism, and average trough concentrations after 1 week of therapy are approximately one-half those at day 2 of therapy (Bardsley-Elliot and Plosker, 2000).

**Untoward Effects.** The most important side effect of nelfinavir is diarrhea or loose stools, which resolve in most patients within the first 4 weeks of therapy. Up to 20% of patients report chronic occasional diarrhea lasting >3 months, although <2% of patients discontinue the drug because of diarrhea. Nelfinavir augments intestinal calcium-dependent chloride channel secretory responses *in vitro*, and electrolyte analysis of stool is most consistent with a secretory diarrhea (Rufo et al., 2004). Otherwise, nelfinavir is generally well tolerated but has been associated with glucose intolerance, elevated cholesterol levels, and elevated triglycerides, like other drugs in this class.

**Precautions and Interactions.** Because nelfinavir is metabolized by CYPs 2C19 and 3A4, concomitant administration of agents that induce these enzymes may be contraindicated (as with rifampin) or may necessitate an increased nelfinavir dose (as with rifabutin). Nelfinavir is a moderate inhibitor of CYP3A4 and may alter plasma concentrations of other CYP3A4 substrates. Nelfinavir inhibits CYP3A4 much less than does ritonavir and does not appear to inhibit other CYP isoforms. Nelfinavir also induces hepatic drug-metabolizing enzymes, reducing the AUC of ethinyl estradiol by 47% and norethindrone by 18% (Flexner, 1998). Combination oral

contraceptives therefore should not be used as the sole form of contraception in patients taking nelfinavir. Nelfinavir reduces the zidovudine AUC by 35%, suggesting induction of glucuronosyl *S*-transferase.

**Therapeutic Use.** Nelfinavir (VIRACEPT) is approved for the treatment of HIV infection in adults and children in combination with other antiretroviral drugs. In large randomized comparative trials, long-term virologic suppression with nelfinavir-based combination regimens is statistically significantly inferior to lopinavir/ritonavir, atazanavir, or efavirenz-based regimens. This possibly reflects the unpredictable nature of nelfinavir absorption but contributes to the decreasing popularity of this drug. Nelfinavir is well tolerated in pregnant HIV-infected women and shows no evidence of teratogenesis (Bardsley-Elliot and Plosker, 2000) but detection of a potentially carcinogenic contaminant in 2007 led to a recommendation that the drug not be used pregnant women.

## Tipranavir

**Chemistry and Antiviral Activity.** Tipranavir is a non-peptidic, dihydropyrone protease inhibitor that is active against both HIV-1 and HIV-2 ([Figure 59–6](#)). The  $IC_{50}$  for HIV-1 *in vitro* ranges from 30 to 70 nM, although human plasma increases the  $IC_{50}$  by 4-fold (Orman and Perry, 2008).

**Mechanisms of Action and Resistance.** Tipranavir binding to the active site of the HIV protease depends less on water-mediated hydrogen bonding than other molecules in this class, which may explain, in part, its unique resistance profile.

Clinically significant drug resistance requires accumulation of multiple mutations. The three mutations most commonly associated with treatment failure were L33F/I/V, V82T/L and I84V, although 21 mutations in 16 amino acids have been associated with reduced susceptibility to this drug. In general, tipranavir-resistant HIV retains sensitivity only to saquinavir and darunavir (Orman and Perry, 2008). Fewer than 3% of patients who have failed other protease inhibitors harbor virus with >10-fold resistance tipranavir. Because most HIV strains sensitive to tipranavir are also sensitive to darunavir, the latter drug is preferred for most treatment-experienced patients because of its better tolerability and toxicity profile.

**Absorption, Distribution, and Elimination.** Tipranavir must be administered with ritonavir because of poor oral bioavailability. The recommended regimen of tipranavir/ritonavir 500/200 mg twice daily includes a ritonavir dose higher than that of other boosted HIV protease inhibitors; lower doses of ritonavir should not be used. Food does not alter pharmacokinetics in the presence of ritonavir but may reduce GI side effects. Tipranavir is 99.9% bound in the presence of plasma proteins (Orman and Perry, 2008). Metabolism is mainly via CYP3A4; mean elimination  $t_{1/2}$  is 5-6 hours in the presence of ritonavir.

**Untoward Effects.** Tipranavir use has been associated with rare fatal hepatotoxicity. Through 48 weeks of treatment, grade 3 or 4 elevation of hepatic transaminases occurred in 20% of treatment-naïve and 10% of treatment-experienced patients. Tipranavir use has been associated with rare intracranial hemorrhage (including fatalities) and bleeding episodes in patients with hemophilia. The drug has anticoagulant properties *in vitro* and in animal models, and these effects are potentiated by vitamin E (Flexner et al., 2005). Tipranavir is more likely to cause elevation in lipids and triglycerides than other boosted PIs, possibly due to the higher dose of ritonavir. Tipranavir contains a sulfa moiety, and ~10% of treated patients report a transient rash. The current formulation contains a high amount of vitamin E, and patients should not take supplements containing this fat-soluble vitamin while taking tipranavir (Orman and Perry, 2008).

**Precautions and Interactions.** Like ritonavir, tipranavir is a substrate, inhibitor, and inducer of CYP enzymes. In combination, these two agents produce a broad array of clinically significant pharmacokinetic drug interactions. Tipranavir/ritonavir reduces the concentrations (AUC) of all co-administered protease inhibitors by 44-76% and should not be administered with any of these agents (Orman and Perry, 2008). This reflects the combined effect of the increased ritonavir dose, as well as tipranavir's unique capacity among PIs to induce expression of the P-glycoprotein drug transporter.

**Therapeutic Use.** Tipranavir (APTIVUS) is approved for use only in treatment-experienced adult and pediatric patients whose HIV is resistant to one or more protease inhibitors. In nearly 1500 patients with at least one major PI resistance mutation randomized to tipranavir/ritonavir or a comparator PI regimen, 34% had at least a one log sustained drop in plasma HIV RNA by week 48 compared to 15% of controls. However, 5.4% of

tipranavir recipients discontinued treatment because of adverse events, compared to 1.6% of controls (Orman and Perry, 2008). Combining tipranavir with at least one other active antiretroviral drug, usually enfuvirtide, greatly improved virologic responses in these studies. Tipranavir/ritonavir is approved for use in adults and pediatric patients >2 years of age, with pediatric dosing based on weight or body surface area.

## ENTRY INHIBITORS

There are two drugs available in this class, enfuvirtide and maraviroc, that have different mechanisms of action ([Figure 59–1](#)). Enfuvirtide inhibits fusion of the viral and cell membranes mediated by gp41 and CD4 interactions. Maraviroc is a chemokine receptor antagonist and binds to the host cell CCR5 receptor to block binding of viral gp120. As such, maraviroc is the only approved antiretroviral drug that targets a host protein. One other CCR5 receptor antagonist, vicriviroc, is in advanced clinical development.

CXCR4, the co-receptor for T-lymphocyte tropic HIV, would seem to be an equally good target for antiretroviral drug development. However, two investigational CXCR4 antagonists produced no substantial drop in plasma HIV RNA in most treated patients, even though they efficiently eliminated CXCR4-tropic virus from the circulation (Stone et al., 2007), suggesting that these drugs cause rapid selection for HIV that is CCR5-tropic. Although these compounds are no longer in development for HIV infection, they do cause an increase in circulating leukocytes, presumably as a direct consequence of CXCR4 blockade. One of these compounds, plerixafor, is now approved as an adjunct to stem cell mobilization after cancer chemotherapy ([Chapter 37](#)).

## Maraviroc

**Chemistry and Mechanisms of Action and Resistance.** Maraviroc blocks the binding of the HIV outer envelope protein gp120 to the CCR5 chemokine receptor ([Figure 59–7](#)). Maraviroc is active only against CCR5-tropic strains of HIV and has no activity against viruses that are CXCR4-tropic or dual-tropic. The reported *in vitro* IC<sub>50</sub> for CCR5-tropic HIV-1 ranges from 0.1 to 4.5 nM depending on the virus strain and testing method employed (MacArthur and Novak, 2008). Maraviroc retains activity against viruses

that have become resistant to antiretroviral agents of other classes because of its unique mechanism of action.

HIV can develop resistance to this drug through two distinct pathways. A patient starting maraviroc therapy with HIV that is predominantly CCR5-tropic may experience a shift in tropism to CXCR4- or dual/mixed-tropism predominance. This is especially likely in patients harboring low-level but undetected CXCR4- or dual/mixed-tropic virus prior to initiation of maraviroc. Alternatively, HIV can retain its CCR5-tropism but gain resistance to the drug through specific mutations in the V3 loop of gp 120 that allow virus binding in the presence of inhibitor (MacArthur and Novak, 2008). This results in both an increase in  $IC_{50}$  and a decrease in maximum percent inhibition of virus replication for such viruses *in vitro*.

**Absorption, Distribution, and Elimination.** The oral bioavailability of maraviroc, 23-33%, is dose dependent. Food decreases bioavailability (AUC) as much as 50%, but there are no food requirements for drug administration because clinical efficacy trials were conducted without food restrictions. Maraviroc is 76% protein bound in human plasma, with a volume of distribution of 194 L. Elimination is mainly via CYP3A4 with an elimination  $t_{1/2}$  of 10.6 hours (MacArthur and Novak, 2008).

**Untoward Effects.** Maraviroc is generally well tolerated, with little significant toxicity.

One case of serious hepatotoxicity with allergic features has been reported, but in controlled trials significant (grade 3 or 4) hepatotoxicity was no more frequent with maraviroc than with placebo. There is a theoretical concern that CCR5 inhibition might interfere with immune function; for example, humans with the  $\Delta$ -32 genetic deletion in CCR5 that prevents HIV-1 entry are also more likely to develop severe West Nile virus encephalopathy (MacArthur and Novak, 2008). However, to date there has been no obvious increase in serious infections or malignancies with maraviroc treatment.

**Precautions and Interactions.** Maraviroc is a CYP3A4 substrate and susceptible to pharmacokinetic drug interactions involving CYP3A4 inhibitors or inducers. Recommended dosing of this drug depends on concomitant medications. Maraviroc is not itself a CYP inhibitor or inducer *in vivo*, although high-dose maraviroc (600 mg daily) increased concentrations of the CYP2D6 substrate debrisoquine.

**Therapeutic Uses.** Maraviroc (SELZENTRY) is approved for use in HIV-infected adults who have baseline evidence of predominantly CCR5-tropic virus. Maraviroc is the only antiretroviral drug approved at three different starting doses, depending on concomitant medications. When combined with most CYP3A inhibitors, the starting dose is 150 mg twice daily; when combined with most CYP3A inducers, the starting dose is 600 mg twice daily; for other concomitant medications, the starting dose is 300 mg twice daily.

In phase 3 clinical trials involving heavily pretreated patients with documented multidrug-resistant HIV-1, the addition of maraviroc to optimized background therapy (OBT) resulted in an undetectable (<50 copies/mL) plasma HIV-1 RNA in 44% of patients after 24 weeks, compared to 17% with OBT alone; maraviroc-treated patients also had higher mean CD4 lymphocyte count increases (120 versus 61 cells/mL). A maraviroc-based regimen was inferior to an efavirenz-based regimen in one clinical trial in treatment-naïve patients (MacArthur and Novak, 2008). Maraviroc has little to no efficacy in patients harboring CXCR4- or dual/mixed-tropic virus at baseline. In addition, the requirement for an expensive baseline phenotype test limits its cost effectiveness.

**Figure 59–7.** Mechanism of action of the HIV entry inhibitor maraviroc.

## Enfuvirtide

**Chemistry and Antiviral Activity.** Enfuvirtide is a 36-amino-acid synthetic peptide whose sequence is derived from a part of the transmembrane gp41 region of HIV-1 that is involved in fusion of the virus membrane lipid bilayer with that of the host cell membrane. Enfuvirtide is not active against HIV-2 but has a broad range of potencies against HIV-1 laboratory and clinical isolates. The reported *in vitro*  $IC_{50}$  ranges from 0.1 nM to 1.7  $\mu$ M depending on the HIV-1 strain and testing method employed (Dando and Perry, 2003).

Enfuvirtide was investigated originally as a possible vaccine component, in part because of a high degree of sequence conservation among HIV-1 strains. This peptide turned out to have potent anti-HIV activity *in vitro*, a property eventually attributed to selective inhibition of HIV-mediated membrane fusion (Jiang et al., 1993; Wild et al., 1994). Enfuvirtide is

expensive to manufacture and must be administered by subcutaneous injection twice daily. Thus cost and route of administration limit its use to those with no other treatment options.

**Mechanisms of Action and Resistance.** Enfuvirtide has a unique mechanism of antiretroviral action. The peptide blocks the interaction between the N36 and C34 sequences of the gp41 glycoprotein by binding to a hydrophobic groove in the N36 coil. This prevents formation of a six-helix bundle critical for membrane fusion and viral entry into the host cell. Enfuvirtide inhibits infection of CD4+ cells by free virus particles, as well as cell-to-cell transmission of HIV *in vitro*. Enfuvirtide retains activity against viruses that have become resistant to antiretroviral agents of other classes because of its unique mechanism of action.

HIV can develop resistance to this drug through specific mutations in the enfuvirtide-binding domain of gp41. Of the patients experiencing virologic failure during enfuvirtide treatment, 94% had virus with mutations in the gp41 region associated with enfuvirtide resistance *in vitro*. The most common mutations involve a V38A or N43D substitution. Single-amino-acid substitutions can confer up to 450-fold resistance *in vitro*, although high-level clinical resistance is usually associated with two or more amino acid changes (Dando and Perry, 2003).

**Absorption, Distribution, and Elimination.** Enfuvirtide is the only approved antiretroviral drug that must be administered parenterally. The bioavailability of subcutaneous enfuvirtide is 84% compared with an intravenous dose (Dando and Perry, 2003). Pharmacokinetics of the subcutaneous drug are not affected by site of injection.

The major route of elimination for enfuvirtide has not been determined; only a deamidated metabolite at the C-terminal phenylalanine has been detected (Dando and Perry, 2003). The mean elimination  $t_{1/2}$  of parenteral drug is 3.8 hours, necessitating twice-daily administration. Enfuvirtide is 98% bound to plasma proteins, mainly albumin.

**Untoward Effects.** The most prominent adverse effects of enfuvirtide are injection-site reactions. About 98% of patients develop local side effects including pain, erythema, and induration at the site of injection; 80% of patients develop nodules or cysts (Dando and Perry, 2003). Between 4% and 5% of patients discontinue treatment because of local reactions. Use of

enfuvirtide has been associated with a higher incidence of lymphadenopathy and pneumonia in at least one study. Whether these are direct drug effects, a secondary consequence of drug-related immune dysfunction, or effects from another mechanism is the subject of investigation. Enfuvirtide suppresses interleukin-12 production *in vitro* by >90% at concentrations equal to or less than those required to inhibit HIV replication (Braun et al., 2001); the role this might play in clinical immunosuppression is unclear.

**Precautions and Interactions.** Enfuvirtide is not metabolized to a significant extent and not known to alter the concentrations of any co-administered drugs. Ritonavir, rifampin, or ritonavir plus saquinavir did not alter enfuvirtide concentrations (Dando and Perry, 2003).

**Therapeutic Use.** Enfuvirtide (FUZEON) is FDA-approved for use only in treatment-experienced adults who have evidence of HIV replication despite ongoing antiretroviral therapy.

In phase 3 clinical trials involving heavily pretreated patients with documented multidrug-resistant HIV-1, inclusion of enfuvirtide (90 mg subcutaneously twice daily) in combination with an optimized background regimen enhanced the fraction of patients with undetectable (<50 copies/mL) plasma HIV-1 RNA concentrations after 24 weeks of treatment (~16% on enfuvirtide versus ~6% without) (Dando and Perry, 2003). Treatment response is more likely in patients with at least two other active drugs in the regimen, based on history and HIV genotype. *Given the cost, inconvenience, and cutaneous toxicity of this drug, enfuvirtide generally is reserved for patients who have failed all other feasible antiretroviral regimens.*

## INTEGRASE INHIBITORS

Chromosomal integration is a defining characteristic of retrovirus life cycles and allows viral DNA to remain in the host cell nucleus for a prolonged period of inactivity or latency ([Figure 59–1](#)). Because human DNA is not known to undergo excision and reintegration, this is an excellent target for antiviral intervention. The first approved HIV integrase inhibitor, raltegravir, was licensed in 2007. It prevents the formation of covalent bonds between host and viral DNA—a process known as *strand transfer*—presumably by interfering with essential divalent cations in the enzyme's catalytic core (Hicks and Gulick, 2009; [Figure 59–8](#)).

# Raltegravir

**Chemistry and Mechanism of Action.** Raltegravir blocks the catalytic activity of the HIV-encoded integrase, thus preventing integration of virus DNA into the host chromosome ([Figure 59–8](#)).

Raltegravir has potent activity against both HIV-1 and HIV-2, with an *in vitro* IC<sub>95</sub> range of 6-30 nM (Hicks and Gulick, 2009). Raltegravir retains activity against viruses that have become resistant to antiretroviral agents of other classes because of its unique mechanism of action.

The two major raltegravir resistance pathways involve primary mutations Q184R/H/K, or N155H in the integrase gene. Either mutation can confer 25- to 50-fold changes in drug sensitivity *in*

**Figure 59–8.** Mechanism of action of the HIV integrase inhibitor raltegravir.

*vitro*. The Y143C/H/R mutation has also been observed. In one phase 3 clinical trial, 64% of patients failing raltegravir combination therapy harbored at least one of these primary resistance mutations (Hicks and Gulick, 2009). Additional secondary mutations can accumulate and cause high-level resistance, including cross-resistance to investigational integrase inhibitors.

**Absorption, Distribution, and Elimination.** Peak concentrations of raltegravir occur ~1-3 hours after oral dosing. Elimination is biphasic, with a  $\beta$ -phase  $t_{1/2}$  of ~1 hour and a terminal  $\beta$ -phase  $t_{1/2}$  of 9 hours. The pharmacokinetics of raltegravir are highly variable. Moderate- and high-fat meals increased raltegravir apparent bioavailability (AUC) by as much as 2-

fold; a low-fat meal decreased AUC modestly (46%). There are no food requirements for raltegravir administration because clinical efficacy trials were conducted without food restrictions and because initial antiviral effects were maximal at all concentrations produced with the 400 mg twice-daily dose in clinical studies. Raltegravir is 83% protein bound in human plasma. Raltegravir is eliminated mainly via glucuronidation by UGT1A1.

**Untoward Effects.** Raltegravir is generally well tolerated, with remarkably little clinical toxicity. In clinical trials, the most common complaints occurring at a frequency higher than in placebo recipients were headache, nausea, asthenia, and fatigue. Creatine kinase elevations, myopathy, and rhabdomyolysis have been reported, although a causal relationship to drug exposure is unproven. Exacerbation of depression has also been reported (Hicks and Gulick, 2009).

**Precautions and Interactions.** As a UGT1A1 substrate, raltegravir is susceptible to pharmacokinetic drug interactions involving inhibitors or inducers of this enzyme. Atazanavir, a moderate UGT1A1 inhibitor, increases the raltegravir AUC 41-72%. Tenofovir increased the raltegravir AUC by 49%, but the mechanism for this interaction is unknown. When raltegravir is combined with the CYP inducer rifampin, the raltegravir dose should be doubled to 800 mg twice daily, although no clinical data on this combination have been published. Raltegravir is not a significant enzyme inhibitor or inducer *in vitro* and has little effect on the pharmacokinetics of co-administered drugs.

**Therapeutic Uses.** Raltegravir (ISENTRESS) is approved for use in HIV-infected adults.

In phase 3 clinical trials involving heavily pretreated patients with documented multidrug-resistant HIV-1, the addition of raltegravir to optimized background therapy (OBT) resulted in an undetectable (<50 copies/mL) plasma HIV-1 RNA in 62% of patients after 48 weeks, compared to 33% with placebo (Hicks and Gulick, 2009). Response rates in this study ranged from 45-77%, depending on the number of additional active drugs in the regimen (0, 1, or 2). Raltegravir-treated patients also had higher mean CD4 lymphocyte count increases (109 versus 45 cells/mL).

Raltegravir has also been studied in treatment-naïve patients and was recently approved for use in patients who have not taken prior antiretroviral therapy. In 10-day monotherapy studies, raltegravir decreased mean HIV-1

RNA by 1.7 log at a dose of 400 mg twice daily. In a prospective randomized comparison, raltegravir was as efficacious as efavirenz when combined with two nucleosides, with 83% and 84% of subjects, respectively, having undetectable HIV-1 RNA (<50 copies/mL) after 96 weeks of treatment. Raltegravir-treated subjects achieve an undetectable plasma HIV RNA faster than efavirenz-treated subjects, although the clinical significance of this effect is unknown (Hicks and Gulick, 2009).

## CLINICAL SUMMARY

Although there has been great progress in the management of HIV and its complications, enormous challenges remain. Whereas a decade ago most treatment took place in developed countries, today most treated patients reside in resource-poor settings. In these locations, decision making is driven by availability of low-cost generic drugs. In addition, concurrent infections such as tuberculosis and hepatitis B virus are common and alter the choice of antiretroviral drugs. Potentially detrimental drug interactions and effects of traditional and herbal medicines are of increasing concern (Dooley et al., 2008). Although co-formulation of antiretroviral agents is a current trend intended to improve convenience and adherence, this can complicate management of those who require dose individualization, e.g., young children or those with hepatic or renal insufficiency.

Several expert panels issue periodic recommendations for use of antiretroviral drugs for treatment-naïve and treatment-experienced adults and children. In the U.S., the Panel on Clinical Practices for Treatment of HIV Infection issues updated guidelines approximately every 6 months; their most recent guidelines can be accessed at <http://www.aidsinfo.nih.gov/Guidelines> (Department of Health and Human Services). These recommendations are based on a consensus assessment of the results of published clinical studies. Practitioners need to be aware that such documents are intended to provide general guidance rather than absolute recommendations and may need to be modified based on intercurrent disease, concurrent medications, and other circumstances. U.S. guidelines sometimes are contradicted by guidelines designed for use in other countries or specific patient populations; these differences may reflect different priorities assigned to drug costs, as well as the relative importance of long-term and short-term toxicities.

Current treatment recommendations center around making two important clinical decisions:

- When to start therapy in treatment-naive individuals
- When to change therapy in individuals who are failing their current regimen

In each of these settings, there is a complex algorithm of possible drug choices depending on patient and viral characteristics. The specific drugs recommended may change from year to year as new choices become available and clinical research data accumulate. Selection of drugs in the developed world will be driven by genotypic and phenotypic resistance testing. However, it is likely that future treatment guidelines will continue to be driven by three principles:

- Use of combination therapy to prevent the emergence of resistant virus;
- Emphasis on regimen convenience, tolerability, and adherence to chronically suppress HIV replication;
- Realization of the need for lifelong treatment under most circumstances.

Treatment guidelines are not sufficient to dictate all aspects of patient management. Prescribers of antiretroviral therapy must maintain a comprehensive and current fund of knowledge regarding this disease and its pharmacotherapy. Because the treatment of HIV infection is a long-lived and complex affair, and because mistakes can have dire and irreversible consequences for the patient, the prescribing of these drugs should be limited to those with specialized training.

# General Principles of Cancer Chemotherapy

Bruce A. Chabner

**Introduction.** The practice of cancer medicine has changed dramatically as curative treatments have been identified for many previously fatal malignancies such as testicular cancer, lymphomas, and leukemia. Adjuvant chemotherapy and hormonal therapy can extend life and prevent disease recurrence following surgical resection of localized breast, colorectal, and lung cancers. Chemotherapy is also employed as part of the multimodal treatment of locally advanced head and neck, breast, lung, and esophageal cancers, soft-tissue sarcomas, and pediatric solid tumors, thereby allowing for more limited surgery and even cure in these formerly incurable cases. Colony-stimulating factors restore bone marrow function and expand the utility of high-dose chemotherapy. Chemotherapeutic drugs are increasingly used in nonmalignant diseases: cytotoxic antitumor agents have become standard in treating autoimmune diseases, including rheumatoid arthritis (methotrexate and cyclophosphamide), Crohn's disease (6-mercaptopurine), organ transplantation (methotrexate and azathioprine), sickle cell anemia (hydroxyurea), and psoriasis (methotrexate). Despite these therapeutic successes, few categories of medication have a narrower therapeutic index and greater potential for causing harmful effects than the cytotoxic antineoplastic drugs. A thorough understanding of their pharmacology, including drug interactions and clinical pharmacokinetics, is essential for their safe and effective use in humans.

The compounds used in the chemotherapy of neoplastic disease are quite varied in structure and mechanism of action, including alkylating agents; antimetabolite analogs of folic acid, pyrimidine, and purine; natural products; hormones and hormone antagonists; and a variety of agents directed at specific molecular targets. [Tables 60-1](#) through [60-5](#) summarize of the main classes and examples of these drugs. [Figure 60-1](#) depicts the cellular targets of chemotherapeutic agents.

The strategy for the discovery of anticancer drugs has undergone a dramatic transformation in the past 15 years, based largely on advances in understanding the molecular basis of malignant transformation. In prior years, cancer drugs were discovered through the large-scale testing of synthetic chemicals and natural products against rapidly proliferating animal tumor systems, primarily murine leukemias (Chabner and Roberts, 2005). Most of the agents discovered in these screens interacted with DNA or its precursors, inhibiting the synthesis of new genetic material and causing broad-based damage to DNA in both normal and malignant cells. The rapidly expanding knowledge of cancer biology has led to the discovery of entirely new and more cancer-specific targets (e.g., growth factor receptors, intracellular signaling pathways, epigenetic processes, tumor vascularity, DNA repair defects, and cell death pathways). For example, in many tumors, proliferation and survival depends on the constitutive activity of a single growth factor pathway, or so-called oncogene addiction (i.e., the “Achilles heel”), and inhibition of that pathway leads to cell death (Weinstein and Joe, 2006). Thus, imatinib (GLEEVEC) attacks the unique and specific *bcr-abl* translocation in chronic myelocytic leukemia. Imatinib also inhibits c-kit and produces extended control of gastrointestinal stromal tumors that express a mutated and constitutively activated form of c-kit. Monoclonal antibodies effectively inhibit tumor-associated antigens such as the amplified her-2/neu receptor in breast cancer cells. These examples emphasize that entirely new strategies for drug discovery and development, and advances in patient care, will result from new knowledge of cancer biology. [Figure 60–1](#) outlines the common targets of cancer chemotherapeutic agents. New clinical trial designs, aimed at determining effects of new drugs at the molecular level, increasingly employ biomarkers derived from samples of biological fluids or tumors to assess the effects of these new agents on signaling pathways, tumor proliferation and cell death, and angiogenesis (Maheswaran et al., 2008). Imaging of molecular, metabolic, and physiological effects of drugs will become increasingly important in establishing that drugs effectively engage their targets.

### **Table 60—1 Alkylating Agents**

TYPE OF AGENT	NONPROPRIETARY NAMES	DISEASE
Nitrogen mustards	Mechlorethamine Cyclophosphamide Ifosfamide	Hodgkin's disease Acute and chronic lymphocytic leukemia; Hodgkin's disease; non-Hodgkin's lymphoma; multiple myeloma; neuroblastoma; breast, ovary, lung cancer; Wilms' tumor; cervix, testis cancer; soft-tissue sarcoma
	Melphalan Chlorambucil Procarbazine ( <i>N</i> -methylhydrazine, MIH)	Multiple myeloma Chronic lymphocytic leukemia; macroglobulinemia Hodgkin's disease
Methylhydrazine derivative	Busulfan	Chronic myelogenous leukemia, bone marrow transplantation
Alkyl sulfonate Nitrosoureas	Carmustine (BCNU) Streptozocin (streptozotocin)	Hodgkin's disease; non-Hodgkin's lymphoma; glioblastoma Malignant pancreatic insulinoma; malignant carcinoid
	Bendamustine	Non-Hodgkin's lymphoma
Triazines	Dacarbazine (DTIC; dimethyltriazenoimidazole carboxamide), Temozolomide	Malignant melanoma; Hodgkin's disease; soft-tissue sarcomas; melanoma
	Platinum coordination complexes	Malignant gliomas Testicular, ovarian, bladder, esophageal, lung, head and neck, colon, breast cancer

**Table 60—2 Antimetabolites**

TYPE OF AGENT	NONPROPRIETARY NAMES	DISEASE
Folic acid analogs	Methotrexate (amethopterin) Pemetrexed	Acute lymphocytic leukemia; choriocarcinoma; breast, head, neck and lung cancers; osteogenic sarcoma; bladder cancer Mesothelioma, lung cancer
	Pyrimidine analogs	Breast, colon, esophageal, stomach, pancreas, head and neck; premalignant skin lesion (topical)
Purine analogs and related inhibitors	Fluorouracil (5-fluorouracil; 5-FU), capecitabine	Acute myelogenous and acute lymphocytic leukemia; non-Hodgkin's lymphoma
	Cytarabine (cytosine arabinoside)	Pancreatic, ovarian, lung cancer
	Gemcitabine	Myelodysplasia
	5-aza-cytidine	"
	Deoxy-5-aza-cytidine	"
	Mercaptopurine (6-mercaptopurine; 6-MP)	Acute lymphocytic and myelogenous leukemia; small cell non-Hodgkin's lymphoma
	Pentostatin (2'-deoxycoformycin)	Hairy cell leukemia; chronic lymphocytic leukemia; small cell non-Hodgkin's lymphoma
	Fludarabine	Chronic lymphocytic leukemia
	Clofarabine	Acute myelogenous leukemia
	Nelarabine	T-cell leukemia, lymphoma

**Table 60—3 Natural Products**

TYPE OF AGENT	NONPROPRIETARY NAMES	DISEASE
Vinca alkaloids	Vinblastine	Hodgkin's disease; non-Hodgkin's lymphoma; testis cancer.
	Vinorelbine	Breast and lung cancer
	Vincristine	Acute lymphocytic leukemia; neuroblastoma; Wilms' tumor;
Taxanes	Paclitaxel, docetaxel	rhabdomyosarcoma; Hodgkin's disease; non-Hodgkin's lymphoma
Epipodophyllotoxins	Etoposide	Ovarian, breast, lung, prostate, bladder, head and neck cancer
		Testis, small cell lung and other lung cancer; breast cancer;
Camptothecins	Teniposide	Hodgkin's disease; non-Hodgkin's lymphomas; acute
	Topotecan	myelogenous leukemia; Kaposi's sarcoma
	irinotecan	Acute lymphoblastic leukemia in children
Antibiotics	Dactinomycin (actinomycin D)	Ovarian cancer; small cell lung cancer
	Daunorubicin (daunomycin, rubidomycin)	Colon cancer
	Doxorubicin	Choriocarcinoma; Wilms' tumor; rhabdomyosarcoma; testis; Kaposi's sarcoma
		Acute myelogenous and acute lymphocytic leukemia
Echinocandins	Yondelis	Soft-tissue, osteogenic, and other sarcoma; Hodgkin's disease; non-Hodgkin's lymphoma; acute leukemia; breast, genitourinary, thyroid, lung, and stomach cancer; neuroblastoma and other childhood and adult sarcomas
Anthracenedione	Mitoxantrone	Soft-tissue sarcomas, ovarian cancer
	Bleomycin	Acute myelogenous leukemia; breast and prostate cancer
Enzymes	Mitomycin C	Testis and cervical cancer; Hodgkin's disease; non-Hodgkin's lymphoma
	L-Asparaginase	Stomach, anal, and lung cancer
		Acute lymphocytic leukemia

Although molecularly targeted drugs have had outstanding successes in selected types of cancer, new therapies are not likely to replace cytotoxics in the foreseeable future. Rather, the targeted drugs and cytotoxics will continue to be used in combination. For instance, monoclonal antibodies or small targeted molecules, used as single agents against solid tumors, produce low response rates and modest benefits; however, in combination with cytotoxics and in early stages of disease, monoclonal antibodies such as trastuzumab (HERCEPTIN) and bevacizumab (AVASTIN) are dramatically effective (Romond et al., 2005; Slamon et al., 2001). At the same time, the toxicities of cytotoxic drugs have become more manageable with the development of better anti-nausea medications (Chapters 13 and 46) and with granulocyte colony-stimulating factor and erythropoietin to restore bone marrow function (Chapters 37 and 62). Finally, targeted drugs are helping to overcome resistance to chemotherapeutic agents by normalizing blood flow, promoting apoptosis, and inhibiting pro-survival signals from growth factor pathways. Tumor angiogenesis leads to increased interstitial pressure and diminishes delivery of drugs to tumor cells; inhibitors of angiogenesis (e.g., bevacizumab) normalize blood flow and interstitial pressure (Batchelor et al., 2007), improve drug delivery, and are thus synergistic with cytotoxic drugs in the treatment of lung, breast, and other cancers.

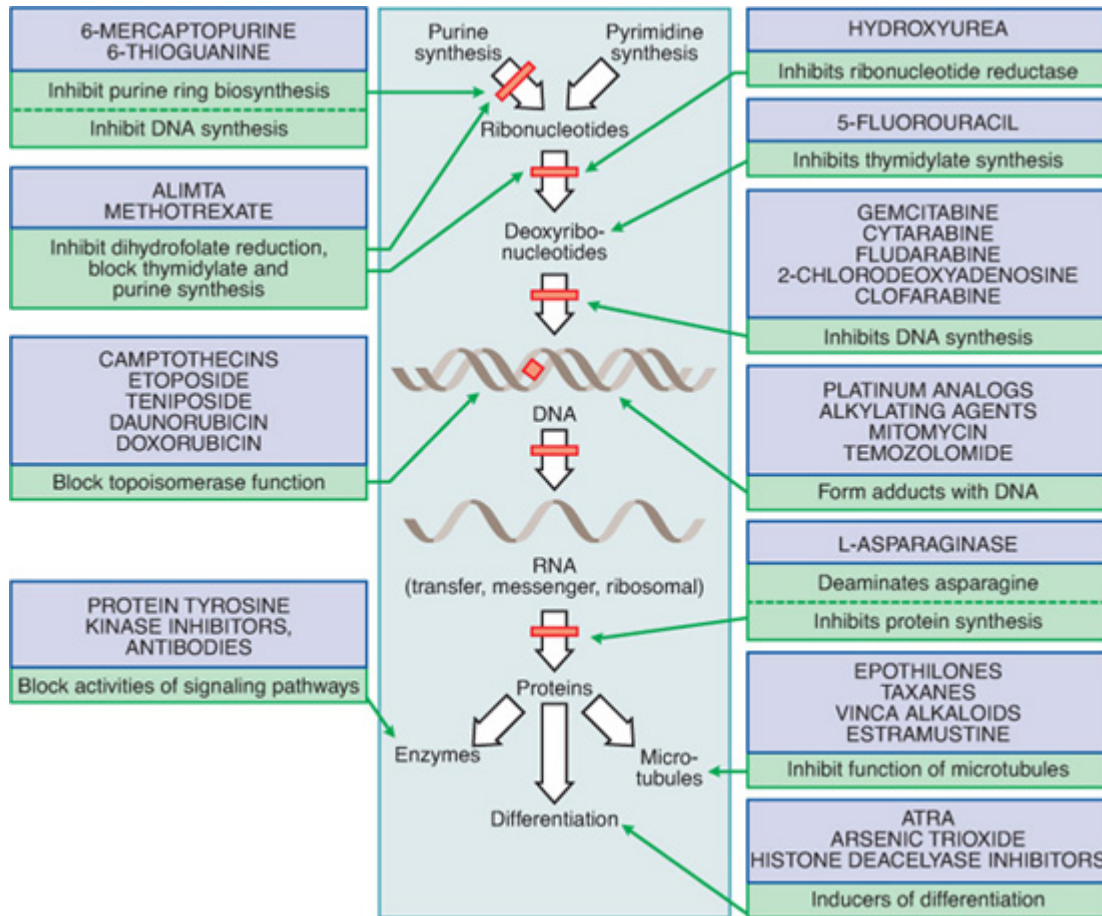

**Table 60—4 Hormones and Antagonists**

TYPE OF AGENT	NONPROPRIETARY NAMES	DISEASE
Adrenocortical suppressants	Mitotane ( <i>o,p'</i> -DDD)	Adrenal cortex cancer
Adrenocortico-steroids	Prednisone (other equivalent preparations available)	Acute and chronic lymphocytic leukemia; non-Hodgkin's lymphoma; Hodgkin's disease; breast cancer, multiple myeloma
Progestins	Hydroxyprogesterone caproate, medroxyprogesterone acetate, megestrol acetate	Endometrial, breast cancer
Estrogens	Diethylstilbestrol, ethinyl estradiol (other preparations available)	Breast, prostate cancer
Anti-estrogens	Tamoxifen, toremifene	Breast cancer
Aromatase inhibitors	Anastrozole, letrozole, exemestane	Breast cancer
Androgens	Testosterone propionate, fluoxymesterone (other preparations available)	Breast cancer
Anti-androgen	Flutamide, casodex	Prostate cancer
GnRH analog	Leuprolide	Prostate cancer

**Table 60—5 Miscellaneous Agents**

TYPE OF AGENT	NONPROPRIETARY NAMES	DISEASE
Substituted urea	Hydroxyurea	Chronic myelogenous leukemia; polycythemia vera; essential thrombocytosis
Differentiating agents	Tretinoin, arsenic trioxide Histone deacetylase inhibitor (vorinostat)	Acute promyelocytic leukemia Cutaneous T-cell lymphoma
Protein tyrosine kinase inhibitors	Imatinib  Dasatinib, nilotinib Gefitinib, erlotinib Sorafenib Sunitinib Lapatinib	Chronic myelogenous leukemia; GI stromal tumors (GIST); hypereosinophilia syndrome Chronic myelogenous leukemia EGFR inhibitors: Non-small cell lung cancer Hepatocellular cancer, renal cancer GIST, renal cancer Breast cancer
Proteasome inhibitor	Bortezomib	Multiple myeloma
Biological response modifiers	Interferon-alfa, interleukin-2	Hairy cell leukemia; Kaposi's sarcoma; melanoma; carcinoid; renal cell; non-Hodgkin's lymphoma; mycosis fungoides; chronic myelogenous leukemia
Immunomodulators	Thalidomide Lenalidomide	Multiple myeloma Myelodysplasia (5q <sup>-</sup> syndrome); multiple myeloma
mTOR Inhibitors	Temsirolimus, everolimus	Renal cancer
Monoclonal antibodies		(see Tables 62-1 and 62-2)

**Figure 60–1.** Summary of the mechanisms and sites of action of some chemotherapeutic agents useful in neoplastic disease.

*Drug resistance* remains a major obstacle to successful cancer treatment. Resistance results from a variety of pharmacokinetic and molecular changes that can defeat the best designed treatments, including poor drug absorption and delivery; genetically determined variability in drug transport, activation, and clearance; and mutations, amplifications, or deletions in drug targets. The resistance process is best understood for targeted agents. Tumors developing resistance to bcr-abl inhibitors and to inhibitors of the epidermal growth factor receptor (EGFR) express mutations in the target enzyme. Cells exhibiting drug-resistant mutations exist in the patient prior to drug treatment and are selected by drug exposure. Resistance to inhibitors of the EGFR may develop through expression of an alternative receptor, c-met, which bypasses EGFR blockade and stimulates proliferation (Engelman et al., 2008). Defects in recognition of DNA breaks and overexpression of specific repair enzymes may also contribute to resistance to cytotoxic drugs (Holleman et al., 2006),

and a loss of apoptotic pathways can lead to resistance to both cytotoxic and targeted agents.

In designing specific clinical regimens, a number of factors must be considered. Drugs in combination can negate the effects of a resistance mechanism specific for a single agent, and they may be synergistic because of their biochemical interactions. Ideally, drug combinations should not overlap in their major toxicities. In general, cytotoxic drugs are used as close as possible to their maximally tolerated individual doses and should be given as frequently as tolerated to discourage tumor regrowth. Because the tumor cell population in patients with clinically detectable disease exceeds  $1 \text{ g}$ , or  $10^9$  cells, and each cycle of therapy kills  $<99\%$  of the cells, it is necessary to repeat treatments in multiple, carefully timed cycles to achieve cure.

**The Cell Cycle.** An understanding of the life cycle of tumors is essential for the rational use of antineoplastic agents ([Figure 60–2](#)). Many cytotoxic agents act by damaging DNA. Their toxicity is greatest during the S, or DNA synthetic, phase of the cell cycle. Others, such as the vinca alkaloids and taxanes, block the formation of a functional mitotic spindle in the M phase. These agents are most effective on cells entering mitosis, the most vulnerable phase of the cell cycle. Accordingly, human neoplasms most susceptible to chemotherapeutic measures, including leukemias and lymphomas, are those having a high percentage of proliferating cells. Normal tissues that proliferate rapidly (bone marrow, hair follicles, and intestinal epithelium) are thus highly susceptible to damage from cytotoxic drugs.

**Figure 60–2.** *Cell cycle specificity of antineoplastic agents.*

Slowly growing tumors with a small growth fraction (e.g., carcinomas of the colon or non-small cell lung cancer) are less responsive to cycle-specific drugs. More effective are agents that inflict high levels of DNA damage (e.g., alkylating agents) or those that remain at high concentrations inside the cell for extended periods of time (e.g., fluoropyrimidines). The results of comparative clinical trials provide evidence for the most effective regimens for specific tumors. The clinical benefit of cytotoxic drugs has primarily been measured by radiological assessment of drug effects on tumor size; newer “targeted” agents, however, may simply slow or halt tumor growth so their effects may best be measured in the assessment of time to disease progression. More recently, there is growing interest in designing drugs that selectively kill the stem cell component of tumors because these cells are believed to be responsible for the continuous proliferation and repopulation of tumors after a toxic exposure to chemotherapy or targeted therapy. For example, bone marrow and epithelial tissues contain a compartment of normal nondividing stem cells that display resistance to cytotoxic drugs and retain the capacity to regenerate the normal cell

population. Tumor stem cells exhibit the same resistance to chemotherapy, radiotherapy, and oxidative insults, and thus they may represent a significant barrier to the cure of neoplasms (Diehn et al., 2009).

Although cells from different tumors display differences in the duration of their transit through the cell cycle, and in the fraction of cells in active proliferation, all cells display a similar pattern of cell cycle progression ([Figure 60-2](#)):

- a phase that precedes DNA synthesis ( $G_1$ )
- a DNA synthetic phase (S)
- an interval following the termination of DNA synthesis ( $G_2$ )
- the mitotic phase (M) in which the cell, containing a double complement of DNA, divides into two daughter  $G_1$  cells
- a probability of moving into a quiescent state ( $G_0$ ) and failing to move forward for long periods of time

At each transition point in the cell cycle, specific proteins such as p53 and chk-1 and 2, monitor the integrity of DNA and, upon detection of DNA damage, may initiate DNA repair processes or, in the presence of massive damage, direct cells down a cell death (apoptosis) pathway. Some cancer chemotherapeutic drugs act at specific phases, in the cell cycle, mainly at the S phase and M phase; other agents are cytotoxic at any point in the cell cycle and are termed cell cycle phase nonspecific agents.

Each transition point in the cell cycle requires the activation of specific cyclin-dependent kinases (CDKs), which, in their active forms, couple with corresponding regulatory proteins called cyclins. The proliferative impact of CDKs is in turn dampened by inhibitory proteins such as p16. Tumor cells often exhibit changes in cell-cycle regulation that lead to relentless proliferation (e.g., mutations or loss of p16 or other inhibitory components of the so-called retinoblastoma pathway, enhanced cyclin or CDK activity). Consequently, CDKs and their effector proteins have become attractive targets for discovery of anti-neoplastic agents.

Because of the central importance of DNA to the identity and functionality of a cell, elaborate mechanisms (“checkpoints”) have evolved to monitor DNA integrity. If a cell possesses normal checkpoint function, drug-induced DNA damage will activate apoptosis when the cell reaches the  $G_1/S$  or  $G_2/M$

boundary. If the p53 gene product or other checkpoint proteins are mutated or absent and the checkpoint function fails, damaged cells will not divert to the apoptotic pathway but will proceed through the S phase and mitosis. The cell progeny will emerge as a mutated and potentially drug-resistant population. Thus, alterations in the regulation of cell-cycle kinetics and checkpoint controls are critical factors in determining sensitivity to cytotoxic drugs and understanding the success or failure of new agents.

**Achieving Therapeutic Integration and Efficacy.** The treatment of cancer patients requires a skillful interdigitation of pharmacotherapy with other modalities of treatment (e.g., surgery and irradiation). Each treatment modality carries its own risks and benefits, with the potential for both antagonistic and synergistic interactions between modalities, particularly between drugs and irradiation. Furthermore, individual patient characteristics determine the choice of modalities. Not all patients can tolerate drugs, and not all drug regimens are appropriate for a given patient. Renal and hepatic function, bone marrow reserve, general performance status, and concurrent medical problems all come into consideration in making a therapeutic plan. Other less quantifiable considerations, such as the natural history of the tumor, the patient's willingness to undergo difficult and potentially dangerous treatments, and the patient's physical and emotional tolerance for side effects, enter the equation, with the goal of balancing the likely long-term gains and risks in the individual patient.

One of the great challenges of therapeutics is to adjust drug regimens to achieve a therapeutic but nontoxic outcome. Although it is customary to base dose on body surface area for individual patients, this practice is not necessarily supported by evidence in the literature (Sawyer and Ratain, 2001). Orally administered drugs are now frequently prescribed using uniform dosing for all adult patients. Dose adjustment based on renal function, on hepatic function, or on pharmacokinetic monitoring does facilitate meeting specific targets such as desired drug concentration in plasma or area under the concentration-time curve (AUC), a measure of the pattern of systemic exposure to the agent in question. Unfortunately, there are few good guidelines for adjusting dose on the basis of obesity or age. Elderly patients, particularly those >70 years of age, exhibit less tolerance for chemotherapy because of decreased renal and hepatic drug clearance, lower protein binding, and less bone marrow reserve, but individuals vary widely. Drug clearance decreases in morbidly obese patients, and dosage should

probably be capped for these patients at no more than 150% of the dosage for patients of average body surface area (1.73 m<sup>2</sup>) (Rodvold et al., 1988), with adjustment upward for tolerance after each subsequent dose.

Even patients with normal renal and hepatic function exhibit significant variability in pharmacokinetics of anticancer drugs that can reduce efficacy or cause excess toxicity. The following examples illustrate the potential of using pharmacokinetic targeting to improve therapy:

1. The thrombocytopenia caused by carboplatin is a direct function of AUC, which in turn is determined by renal clearance of the parent drug. Calvert and Egorin (2002) have devised a formula for targeting a desired AUC based on creatinine clearance.
2. Monitoring of 5-fluorouracil levels in plasma allows dose adjustment to improve response rates in patients with rapid drug clearance, and to avoid toxicity in those with slow drug clearance (Gamelin et al., 2008).
3. High-dose methotrexate therapy requires drug-level monitoring to detect patients at high risk for renal failure and severe myelosuppression. Patients with inappropriately high concentrations of methotrexate at specific time points can be rescued from toxicity by the administration of leucovorin, and in extreme cases, by dialysis or administration of a methotrexate-cleaving enzyme and orphan drug, glucarpidase (VORAXAZE; recombinant carboxypeptidase G2).

**Molecular Testing to Select Patients for Chemotherapy.** Molecular tests are increasingly employed to identify patients likely to benefit from treatment and those at highest risk of toxicity (Roberts and Chabner, 2004). Pretreatment testing has become standard practice to select patients for hormonal therapy of breast cancer and for treatment with antibodies such as trastuzumab (her-2/neu receptor) and rituximab (CD20). The presence of a mutated k-ras gene indicates that a colorectal cancer patient's tumor will not respond to anti-EGFR antibodies (Tol et al., 2009); mutations of EGFR signal a 70% likelihood of response to erlotinib (*TARCEVA*) and gefitinib (*IRESSA*), both inhibitors of this receptor (Sequist and Lynch, 2008). Although *not* yet routinely employed in traditional cytotoxic therapy, molecular testing of tumors could improve outcomes by pairing patients with drugs likely to be effective against mutations that drive tumor proliferation or survival. Mutations of the *b-Raf*, *HER 2/neu*, and *Alk*, which are found in subsets of

solid tumors in human subjects, represent examples of promising targets for solid tumor chemotherapy.

Inherited differences in protein sequence polymorphisms or levels of RNA expression influence toxicity and anti-tumor response. For example, tandem repeats in the promoter region of the gene encoding thymidylate synthase, the target of 5-fluorouracil, determine the level of expression of the enzyme. Increased numbers of repeats are associated with increased gene expression, a lower incidence of toxicity, and a decreased rate of response in patients with colorectal cancer (Pullarkat et al., 2001). Polymorphisms of the dihydropyrimidine dehydrogenase gene, the product of which is responsible for degradation of 5-fluorouracil, are associated with decreased enzyme activity and a significant risk of overwhelming drug toxicity, particularly in the rare individual homozygous for the polymorphic genes (Van Kuilenburg et al., 2002). Other polymorphisms appear to affect the clearance and therapeutic activity of cancer drugs, including tamoxifen (Schroth et al., 2007), methotrexate, irinotecan, and 6-mercaptopurine (Cheok and Evans, 2006).

Other aspects of molecular biology are entering into clinical decision making in oncology. Gene expression profiling, in which the levels of messenger RNA from thousands of genes are randomly surveyed using gene arrays, has revealed tumor profiles that are highly associated with metastasis (Ramaswamy et al., 2003). The expression of the transcription factor HOX B13 correlates with disease recurrence in patients receiving adjuvant hormonal therapy in breast cancer (Ma et al., 2004). Gene expression profiles also predict the benefit of adjuvant chemotherapy for breast cancer patients (Sotiriou and Pusztai, 2009) and the response of ovarian cancer patients to platinum-based therapy (Dressman et al., 2007).

New molecular tests and their more widespread use likely will shorten the time for drug development and approval, realize savings by avoiding the cost and toxicity of ineffective drugs, and ultimately improve patient outcome (Chabner and Roberts, 2005; Roberts and Chabner, 2004). Undoubtedly, molecular testing to select patients for specific treatments will be a cornerstone of cancer chemotherapy for years to come.

**A Cautionary Note.** Although advances in drug discovery and molecular profiling of tumors offer great promise for improving the outcomes of cancer treatment, a final word of caution regarding all treatment regimen deserves

emphasis. *The pharmacokinetics and toxicities of cancer drugs vary among individual patients.* It is imperative to *recognize toxicities early*, to *alter doses or discontinue offending medication* to relieve symptoms and reduce risk, and to *provide vigorous supportive care* (platelet transfusions, antibiotics, and hematopoietic growth factors). Toxicities affecting the heart, lungs, or kidneys may be irreversible if recognized late in their course, leading to permanent organ damage or death. Fortunately, such toxicities can be minimized by early recognition and by adherence to standardized protocols and to the guidelines for drug use.

## **Cytotoxic Agents**

Bruce A. Chabner, Joseph Bertino, James Cleary, Taylor Ortiz, Andrew Lane, Jeffrey G. Supko, and David Ryan

### **I. Alkylating Agents and Platinum Coordination Complexes**

The pervasive toxic effects of sulfur mustard gas were noted as the result of its use in World War I. A potent vesicant, the gas caused a topical burn to skin, eyes, lungs, and mucosa and, after massive exposure, aplasia of the bone marrow and lymphoid tissue and ulceration of the GI tract. Early clinical experiments with topically applied sulfur mustard led to regression of penile tumors. Thereafter, Goodman, Gilman, the originators of this text, working with colleagues at Yale in a consortium organized by the U.S. Department of Defense, confirmed the antineoplastic action of the nitrogen mustards against a murine lymphoma. In 1942, they began clinical studies of intravenous nitrogen mustards in patients with lymphoma, launching the modern era of cancer chemotherapy (Gilman and Philips, 1946).

At present, six major types of alkylating agents are used in the chemotherapy of neoplastic diseases:

- nitrogen mustards
- ethyleneimines
- alkyl sulfonates
- nitrosoureas
- the triazenes
- DNA-methylating drugs, including procarbazine, temozolomide, and dacarbazine

In addition, because of similarities in their mechanisms of action and resistance, platinum complexes are discussed with classical alkylating agents, even though they do not alkylate DNA but instead form covalent metal adducts with DNA. The mechanism of action of alkylating agents is shown in [Figure 61–1](#).

**Chemistry.** The chemotherapeutic alkylating agents have in common the property of forming highly reactive carbonium ion intermediates. These reactive intermediates covalently link to sites of high electron density, such as phosphates, amines, sulfhydryl, and hydroxyl groups. Their chemotherapeutic and cytotoxic effects are directly related to the alkylation of reactive amines, oxygens, or phosphates on DNA. The N7 atom of guanine is particularly susceptible to the formation of a covalent bond with bifunctional alkylating agents and may represent the key target that determines their biological effects. Other atoms in the purine and pyrimidine bases of DNA, including N1 and N3 of the adenine ring, N3 of cytosine, and O6 of guanine, react with these agents, as do the amino and sulfhydryl groups of proteins and the sulfhydryls of glutathione.

The possible actions of alkylating agents on DNA are illustrated in [Figure 61-1](#) with mechlorethamine (nitrogen mustard). First, one 2-chloroethyl side chain undergoes a first-order ( $S_N1$ ) intramolecular cyclization, with release of  $Cl^-$  and formation of a highly reactive ethyleneimine intermediate ([Figure 61-1](#)). The unstable quaternary amine then reacts with a variety of electron-dense sites. This latter reaction proceeds as a second-order ( $S_N2$ ) nucleophilic substitution. Alkylation of the N7 of guanine in DNA, a highly favored reaction, exerts several biologically important effects. Guanine residues in DNA exist predominantly as the keto tautomer and readily make Watson-Crick base pairs by hydrogen bonding with cytosine residues. However, when the N7 of guanine is alkylated (to become a quaternary ammonium nitrogen) the guanine residue is more acidic and the enol tautomer is favored. The modified guanine can mispair with thymine residues during DNA synthesis, leading to the substitution of thymine for cytosine. Second, alkylation of the N7 creates lability in the imidazole ring, leading to opening of the ring and excision of the damaged guanine residue. Mispairing and imidazole ring opening can lead to attempts to repair the damaged stretch of DNA, causing strand breakage. Third, with bifunctional alkylating agents such as nitrogen mustard, the second 2-chloroethyl side chain can undergo a similar cyclization reaction and alkylate a second guanine residue or another nucleophilic moiety, resulting in the cross-linking of two nucleic acid chains or the linking of a nucleic acid to a protein, alterations that would cause a major disruption in nucleic acid function. Any of these effects could contribute to both the mutagenic and cytotoxic effects of alkylating agents.

The extreme cytotoxicity of bifunctional alkylators correlates very closely with interstrand cross-linkage of DNA (Garcia et al., 1988).

**Figure 61–1.** Mechanism of action of alkylating agents. **A.** Activation reaction. **B.** Alkylation of N7 of guanine.

The ultimate cause of cell death related to DNA damage is not known. Specific cellular responses include cell-cycle arrest and attempts to repair DNA. The specific repair enzyme complex utilized will depend on two factors: the chemistry of the adduct formed and the repair capacity of the cell involved. The process of recognizing and repairing DNA generally requires an intact nucleotide excision repair (NER) complex, but, as discussed in the rest of this section, may differ with each drug and with each tumor. Alternatively, recognition of extensively damaged DNA by p53 can trigger apoptosis. Mutations of p53 lead to alkylating agent resistance (Kastan, 1999).

**Structure-Activity Relationships.** Although these alkylating agents share the capacity to alkylate biologically important molecules, modification of the

basic chloroethylamino structure changes reactivity, lipophilicity, active transport across biological membranes, sites of macromolecular attack, and mechanisms of DNA repair, all of which properties determine drug activity *in vivo*. With several of the most valuable agents (e.g., cyclophosphamide, ifosfamide), the active alkylating moieties are generated *in vivo* through hepatic metabolism.

The biological activity of alkylators of the nitrogen mustard type is based on the presence of the *bis*-(2-chloroethyl) group. Although mechlorethamine has been widely used in the past, linkage of the *bis*-(2-chloroethyl) group to electron-rich substitutions such as unsaturated ring systems has yielded more stable drugs with better pharmacodynamic properties and with greater selective killing of tumor cells. *Bis*-(2-chloroethyl) groups linked to amino acids (phenylalanine) and substituted phenyl groups (aminophenol butyric acid, as in chlorambucil) create a more stable and orally available form. The structures of important nitrogen mustards are shown in [Figure 61-2](#).

A classical example of the role of host metabolism in the activation and degradation of an alkylating agent is seen with cyclophosphamide, now the most widely used agent of this class. The drug undergoes metabolic activation (hydroxylation) by CYP2B ([Figure 61-3](#)), with subsequent transport of the activated intermediate to sites of action. The selectivity of cyclophosphamide against certain malignant tissues may result in part from the capacity of normal tissues to degrade the activated intermediates via aldehyde dehydrogenase, glutathione transferase, and other pathways.

Ifosfamide is an oxazaphosphorine, similar to cyclophosphamide. Cyclophosphamide has two chloroethyl groups on the exocyclic nitrogen atom, whereas one of the 2-chloroethyl groups of ifosfamide is on the cyclic phosphoramidate nitrogen of the oxazaphosphorine ring. Ifosfamide is activated in the liver by CYP3A4. The activation of ifosfamide proceeds more slowly, with greater production of dechlorinated metabolites and chloroacetaldehyde. These differences in metabolism likely account for the higher doses of ifosfamide required for equitoxic effects, the greater neurotoxicity of ifosfamide, and the possible differences in antitumor spectrum of the two agents.

**Figure 61–2.** Nitrogen mustards employed in therapy.

**Figure 61–3.** Metabolism of cyclophosphamide.

The newest approved alkylating agent, bendamustine, has the typical chloroethyl reactive groups attached to a benzimidazole backbone.

BENDAMUSTINE

The unique properties and activity of this drug may derive from this purine-like structure; the agent produces slowly repaired DNA cross-links, lacks cross-resistance with other classical alkylators (Leoni et al., 2008), and has significant activity in chronic lymphocytic leukemia (CLL) and large-cell lymphomas refractory to standard alkylators.

A unique class of alkylating agents transfers methyl rather than ethyl groups to DNA. The triazene derivative 5-(3,3-dimethyl-1-triazeno)-imidazole-4-carboxamide, usually referred to as dacarbazine or DTIC, is prototypical of methylating agents.

DACARBAZINE

Dacarbazine requires initial activation by hepatic CYPs through an *N*-demethylation reaction. In the target cell, spontaneous cleavage of the metabolite, methyl-triazeno-imidazole-carboxamide (MTIC), yields an alkylating moiety, a methyl diazonium ion. A related triazene, temozolomide, undergoes spontaneous, nonenzymatic activation to MTIC and has significant activity against gliomas.

TEMOZOLOMIDE

The nitrosoureas, which include compounds such as 1,3-*bis*-(2-chloroethyl)-1-nitrosourea (carmustine; BCNU), 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (lomustine; CCNU), and its methyl derivative (semustine; methyl-CCNU), as well as the antibiotic streptozocin (streptozotocin), exert their cytotoxicity through the spontaneous breakdown to an alkylating intermediate, the 2-chloroethyl diazonium ion.

The 2-chloroethyl diazonium ion, a strong electrophile, can alkylate guanine, cytidine, and adenine bases (Ludlum, 1990). Displacement of the halogen atom can then lead to interstrand or intrastrand cross-linking of DNA. The formation of cross-links after the initial alkylation reaction proceeds relatively slowly and can be reversed by the DNA repair enzyme *O*<sup>6</sup>-alkyl, methyl guanine methyltransferase (MGMT), which displaces the chloroethyl adduct from its binding to guanine in a suicide reaction. The same enzyme, when expressed in human gliomas, produces resistance to nitrosoureas and to other methylating agents, including DTIC, temozolomide, and procarbazine. As with the nitrogen mustards, interstrand cross-linking appears to be the primary lesion responsible for the cytotoxicity of nitrosoureas (Ludlum, 1990). The reactions of the nitrosoureas with macromolecules are shown in [Figure 61-4](#).

**Figure 61-4.** Degradation of carmustine (BCNU) with generation of alkylating and carbamylating intermediates.

Because the formation of the ethyleneimine ion constitutes the initial reaction of the nitrogen mustards, it is not surprising that stable ethyleneimine derivatives have antitumor activity. Several compounds of this type, including triethylenemelamine (TEM) and triethylenethiophosphoramidate (thiotepa), have been used clinically. In standard doses, thiotepa produces little toxicity other than myelosuppression; it also is used for high-dose chemotherapy regimens, in which it causes both mucosal and central nervous system toxicity. Altretamine (hexamethylmelamine; HMM) is mentioned here because of its chemical similarity to TEM. The methylmelamines are *N*-demethylated by hepatic microsomes with the release of formaldehyde, and there is a direct relationship between the degree of the demethylation and their activity against murine tumors.

Esters of alkane sulfonic acids alkylate DNA through the release of methyl radicals. Busulfan is of value in high-dose chemotherapy.

BUSULFAN

## Pharmacological Actions

**Cytotoxic Actions.** The capacity of alkylating agents to interfere with DNA integrity and function and to induce cell death in rapidly proliferating tissues provides the basis for their therapeutic and toxic properties. Acute effects manifest primarily against rapidly proliferating tissues; however, certain alkylating agents may have damaging effects on tissues with normally low mitotic indices (e.g., liver, kidney, and mature lymphocytes), which usually are affected in a delayed time frame. Lethality of DNA alkylation depends on the recognition of the adduct, the creation of DNA strand breaks by repair enzymes, and an intact apoptotic response. The actual mechanism(s) of cell death related to DNA alkylation are not yet well characterized.

In non-dividing cells, DNA damage activates a checkpoint that depends on the presence of a normal p53 gene. Cells thus blocked in the G<sub>1</sub>/S interface either repair DNA alkylation or undergo apoptosis. Malignant cells with mutant or absent p53 fail to suspend cell-cycle progression, do not undergo apoptosis, and exhibit resistance to these drugs.

Although DNA is the ultimate target of all alkylating agents, a crucial distinction must be made between the bifunctional agents, in which cytotoxic effects predominate, and the monofunctional methylating agents (procarbazine, temozolomide), which have greater capacity for mutagenesis and carcinogenesis. This suggests that the cross-linking of DNA strands represents a much greater threat to cellular survival than do other effects, such as single-base alkylation and the resulting depurination and single-chain scission. On the other hand, simple methylation may be bypassed by DNA polymerases, leading to mispairing reactions that permanently modify DNA sequence. These new sequences are transmitted to subsequent generations and may result in mutagenesis or carcinogenesis. Some methylating agents, such as procarbazine, are highly carcinogenic.

DNA repair systems play an important role in removing adducts, and thereby determine the selectivity of action against particular cell types, and acquired resistance to alkylating agents. Alkylation of a single strand of DNA

(mono-adducts) is repaired by the nucleotide excision repair pathway, while the less frequent cross-links require participation of nonhomologous end joining, an error-prone pathway, or the error-free homologous recombination pathway. After drug infusion in humans, mono-adducts appear rapidly and peak within 2 hours of drug exposure, while cross-links peak at 8 hours. The  $t_{1/2}$  for repair of adducts varies among normal tissues and tumors; in peripheral blood mononuclear cells, both mono-adducts and cross-links disappear with a  $t_{1/2}$  of 12-16 hours (Souliotis et al., 1990).

The homologous end-joining pathway has multiple components (Wang et al., 2001):

- sensors of DNA integrity (such as p53)
- activation signals such as the ataxia-telangiectasia-mutated (ATM) and ataxia-telangiectasia and rad-related (ATR) proteins
- the activated repair complex composed of Fanconi anemia proteins and BRCA2, all of which localize at the site of DNA damage and initiate removal of the cross-linked segment of DNA
- homologous recombination, which allows resynthesis of the damaged DNA sequence followed by re-ligation of the repaired sequences

The process depends on the presence and accurate functioning of multiple proteins. Their absence or mutation, as in Fanconi anemia or ataxia telangiectasia, leads to extreme sensitivity to DNA cross-linking agents such as mitomycin, cisplatin, or classical alkylators.

Other repair enzymes are specific for removing methyl and ethyl adducts from the O-6 of guanine (MGMT) and for repair of alkylation of the N-3 of adenine and N-7 of guanine (3-methyladenine-DNA glycosylase) (Matijasevic et al., 1993). High expression of MGMT protects cells from cytotoxic effects of nitrosoureas and methylating agents and confers drug resistance, while methylation and silencing of the gene in brain tumors are associated with clinical response to BCNU and temozolomide (Hegi et al., 2008).

Bendamustine differs from classical chloroethyl alkylators in activating base excision repair, rather than the more complex double-strand break repair or MGMT. It impairs physiological arrest of adduct-containing cells at mitotic checkpoints and leads to mitotic catastrophe rather than apoptosis, and does not require an intact p53 to cause cytotoxicity.

Finally, recognition of DNA adducts is an essential step in promoting attempts at repair and ultimately leading to apoptosis. The Fanconi pathway,

consisting of 12 proteins, recognizes adducts and signals the need for repair of a broad array of DNA-damaging drugs and irradiation (Chen et al., 2007). Absence or inactivation of components of this pathway leads to increased sensitivity to DNA damage. Conversely, for the methylating drugs, nitrosoureas, cisplatin and carboplatin, and thiopurine analogs, the mismatch repair (MMR) pathway is essential for cytotoxicity, causing strand breaks at sites of adduct formation, creating mispairing of thymine residues, and triggering apoptosis.

***Mechanisms of Resistance to Alkylating Agents.*** Resistance to an alkylating agent develops rapidly when it is used as a single agent. Specific biochemical changes implicated in the development of resistance include:

- Decreased permeation of actively transported drugs (mechlorethamine and melphalan).
- Increased intracellular concentrations of nucleophilic substances, principally thiols such as glutathione, which can conjugate with and detoxify electrophilic intermediates.
- Increased activity of DNA repair pathways, which may differ for the various alkylating agents.

Increased activity of the complex NER pathway correlates with resistance to most chloroethyl and platinum adducts. MGMT activity determines response to BCNU and to methylating drugs such as the triazenes, procarbazine, temozolomide, and busulfan. Methylation of the MGMT gene found that pretreatment in 20% of brain tumor patients decreases MGMT expression and strongly correlates with response and survival after BCNU or temozolomide for malignant gliomas. MGMT activity increases with each round of alkylator treatment and with disease progression (Wiewrodt et al., 2008).

- Increased rates of metabolic degradation of the activated forms of cyclophosphamide and ifosfamide to their inactive keto and carboxy metabolites by aldehyde dehydrogenase ([Figure 61–3](#)), and detoxification of most alkylating intermediates by glutathione transferases.
- Loss of ability to recognize adducts formed by nitrosoureas and methylating agents, as the result of defective MMR capability, confers resistance, as does defective checkpoint function for virtually all alkylating drugs.

The MSH6 component of the MMR system seems particularly susceptible to mutation by exposure to alkylating agents; in studies of brain tumor resistance to therapy, loss of MSH6 conferred resistance to temozolomide and related drugs (Cahill et al., 2008).

- Impaired apoptotic pathways, with overexpression of bcl-2 as an example, confer resistance.

To reverse cellular changes that lead to resistance, strategies that are effective in selected experimental tumors have been devised. These include the use of compounds that deplete glutathione, such as l-buthionine-sulfoximine; sulfhydryl compounds such as amifostine (WR-2721) that selectively detoxify alkylating species in normal cells and thereby prevent toxicity; *O*<sup>6</sup>-benzylguanine, which inactivates MGMT; and compounds such as ethacrynic acid, which inhibits glutathione transferases. Although each of these modalities has experimental evidence to support its use, their clinical efficacy has not yet been proven.

## **TOXICITIES OF ALKYLATING AGENTS**

### **Bone Marrow Toxicity**

The alkylating agents differ in their patterns of antitumor activity and in the sites and severity of their side effects. Most cause dose-limiting toxicity to bone marrow elements and, to a lesser extent, intestinal mucosa. Most alkylating agents (i.e., melphalan, chlorambucil, cyclophosphamide, and ifosfamide) cause acute myelosuppression, with a nadir of the peripheral blood granulocyte count at 6-10 days and recovery in 14-21 days.

Cyclophosphamide has lesser effects on peripheral blood platelet counts than do the other agents. Busulfan suppresses all blood elements, particularly stem cells, and may produce a prolonged and cumulative myelosuppression lasting months or even years. For this reason, it is used as a preparative regimen in allogenic bone marrow transplantation. Carmustine and other chloroethylnitrosoureas cause delayed and prolonged suppression of both platelets and granulocytes, reaching a nadir 4-6 weeks after drug administration and reversing slowly thereafter.

Both cellular and humoral immunity are suppressed by alkylating agents, which have been used to treat various auto-immune diseases.

Immunosuppression is reversible at usual doses, but opportunistic infections such as *Pneumocystis jiroveci* pneumonia, or fungal infections, may occur with extended treatment, and reactivation of hepatitis B has been described, prompting some authors to advocate antiviral prophylaxis in hepatitis B carriers undergoing intensive alkylating agent chemotherapy (Grewal et al., 2007).

## Mucosal Toxicity

Alkylating agents are highly toxic to dividing mucosal cells and to hair follicles, leading to oral mucosal ulceration, intestinal denudation, and alopecia.

The mucosal effects are particularly damaging in high-dose chemotherapy protocols associated with bone marrow reconstitution, as they predispose to bacterial sepsis arising from the GI tract. In these protocols, cyclophosphamide, melphalan, and thiotepa have the advantage of causing less mucosal damage than the other agents. In high-dose protocols, however, other toxicities become limiting, as delineated in [Table 61-1](#).

## Neurotoxicity

Nausea and vomiting commonly follow agent administration of nitrogen mustard or BCNU. Ifosfamide is the most neurotoxic agent of this class and may produce altered mental status, coma, generalized seizures, and cerebellar ataxia. These side effects result from the release of chloroacetaldehyde from the phosphate-linked chloroethyl side chain of ifosfamide. High-dose busulfan can cause seizures; in addition, it accelerates the clearance of phenytoin, an anti-seizure medication.

**Other Organ Toxicities.** Although mucosal and bone marrow toxicities occur predictably and acutely with conventional doses of these drugs, other organ toxicities may supervene after prolonged or high-dose use; these effects can appear after months or years and may be irreversible and even lethal. All alkylating agents, including temozolomide, have caused pulmonary fibrosis, usually several months after treatment. In high-dose regimens, particularly those employing busulfan or BCNU, vascular endothelial damage may precipitate veno-occlusive disease (VOD) of the liver, an often fatal side effect that is successfully reversed by the investigational drug defibrotide (Richardson et al., 2003). The nitrosoureas and ifosfamide, after

multiple cycles of therapy, may lead to renal failure. Cyclophosphamide and ifosfamide release a nephrotoxic and urotoxic metabolite, acrolein, which causes a severe hemorrhagic cystitis in high-dose regimens. This adverse effect can be prevented by co-administration of 2-mercaptoethanesulfonate (mesna; *MESNEX*), which conjugates acrolein in urine. Ifosfamide in high doses for transplant causes a chronic, and often irreversible, renal toxicity. Proximal and, less commonly, distal tubules may be affected, leading to defective  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  reabsorption, glycosuria, and renal tubular acidosis. Nephrotoxicity correlates with the total dose of drug received and increases in frequency in children <5 years of age. The syndrome may be due to chloroacetaldehyde and/or acrolein excreted in the urine.

The more unstable alkylating agents (particularly mechlorethamine and the nitrosoureas) have strong vesicant properties, damage veins with repeated use and, if extravasated, produce ulceration.

Finally, all alkylating agents have toxic effects on the male and female reproductive systems, causing an often permanent amenorrhea, particularly in perimenopausal women, and an irreversible azoospermia in men.

**Leukemogenesis.** As a class of drugs, the alkylating agents are highly leukemogenic. Acute nonlymphocytic leukemia, often associated with partial or total deletions of chromosome 5 or 7, peaks in incidence ~4 years after therapy and may affect up to 5% of patients treated on regimens containing alkylating drugs. Leukemia often is preceded by a period of neutropenia or anemia and by bone marrow morphology consistent with myelodysplasia. Melphalan, the nitrosoureas, and the methylating agent procarbazine have the greatest propensity to cause leukemia, while it is less common after cyclophosphamide.

**Table 61—1 Dose-Limiting Extramedullary Toxicities of Single Alkylating Agents**

DRUG	MTD,* mg/m <sup>2</sup>	FOLD INCREASE OVER STANDARD DOSE	MAJOR ORGAN TOXICITIES
Cyclophosphamide	7000	7	Cardiac, hepatic VOD
Ifosfamide	16,000	2.7	Renal, CNS, hepatic VOD
Thiotepa	1000	18	GI, CNS, hepatic VOD
Melphalan	180	5.6	GI, hepatic VOD
Busulfan	640	9	GI, hepatic VOD
Carmustine (BCNU)	1050	5.3	Lung, hepatic VOD
Cisplatin	200	2	PN, renal
Carboplatin	2000	5	Renal, PN, hepatic VOD

\*Maximum tolerated dose (MTD; cumulative) in treatment protocols.

CNS, central nervous system; GI, gastrointestinal; PN, peripheral neuropathy; VOD, veno-occlusive disease.

# CLINICAL PHARMACOLOGY

## Nitrogen Mustards

The chemistry and the pharmacological actions of the alkylating agents as a group, and of the nitrogen mustards, have been presented in the preceding sections. Only the unique pharmacological characteristics of the individual agents are considered in this section.

***Mechlorethamine.*** Mechlorethamine was the first clinically used nitrogen mustard and is the most reactive of the drugs in this class. It rarely is used in current practice.

***Absorption and Fate.*** Severe local reactions of exposed tissues necessitate rapid intravenous injection of mechlorethamine for most clinical uses. In either water or body fluids, at rates affected markedly by pH, mechlorethamine rapidly undergoes chemical degradation as it combines with either water or cellular nucleophiles, and the parent compound disappears from the bloodstream within minutes.

***Therapeutic Uses.*** Mechlorethamine HCl (MUSTARGEN) formerly was used in the combination chemotherapy regimen MOPP (mechlorethamine, vincristine, procarbazine, and prednisone) in patients with Hodgkin's disease. It is given by intravenous bolus administration in doses of 6 mg/m<sup>2</sup> on days 1 and 8 of the 28-day cycles of each course of treatment. It has been largely replaced by cyclophosphamide, melphalan, and other, more stable alkylating agents.

It also is used topically for treatment of cutaneous T-cell lymphoma (CTCL) as a solution that is rapidly mixed and applied to affected areas of the skin.

***Clinical Toxicity.*** The major acute toxic manifestations of mechlorethamine are nausea and vomiting, lacrimation, and myelosuppression. Leukopenia and thrombocytopenia limit the amount of drug that can be given in a single course.

## ***Cyclophosphamide***

***Absorption, Fate, and Excretion.*** Cyclophosphamide is well absorbed orally and is activated to the 4-hydroxy intermediate (Xie et al., 2003)

([Figure 61–3](#)). 4-Hydroxycyclophosphamide exists in equilibrium with the acyclic tautomer aldophosphamide. The rate of metabolic activation of cyclophosphamide exhibits significant interpatient variability and increases with successive doses in high-dose regimens but appears to be saturable at infusion rates of  $>4$  g/90 min and concentrations of the parent compound  $>150$   $\mu$ M (Chen et al., 1995). 4-Hydroxycyclophosphamide may be oxidized further by aldehyde oxidase, either in liver or in tumor tissue, to inactive metabolites. The hydroxyl metabolite of ifosfamide similarly is inactivated by aldehyde dehydrogenase. 4-Hydroxycyclophosphamide and its tautomer, aldophosphamide, travel in the circulation to tumor cells where aldophosphamide cleaves spontaneously, generating stoichiometric amounts of phosphoramidate mustard and acrolein. Phosphoramidate mustard is responsible for antitumor effects, while acrolein causes hemorrhagic cystitis often seen during therapy with cyclophosphamide. Cystitis can be reduced in intensity or prevented by the parenteral co-administration of mesna. Mesna does not negate the systemic antitumor activity of the drug.

Patients should receive vigorous intravenous hydration during high-dose treatment. Brisk hematuria in a patient receiving daily oral therapy should lead to immediate drug discontinuation. Refractory bladder hemorrhage can become life-threatening, and cystectomy may be necessary for control of bleeding.

Inappropriate secretion of antidiuretic hormone has been observed in patients receiving cyclophosphamide, usually at doses  $>50$  mg/kg (see [Chapter 25](#)). It is important to be aware of the possibility of water intoxication, because these patients usually are vigorously hydrated to prevent bladder toxicity.

Pretreatment with CYP inducers such as phenobarbital enhances the rate of activation of the azoxyphosphorenes but does not alter total exposure to active metabolites over time and does not affect toxicity or therapeutic activity in humans. Cyclophosphamide can be used in full doses in patients with renal dysfunction, because it is eliminated by hepatic metabolism. Patients with mild hepatic dysfunction (bilirubin  $<3$  mg/dL) can be treated with full doses of this drug, but those with more significant hepatic dysfunction should receive reduced doses.

Urinary and fecal excretion of unchanged cyclophosphamide is minimal after intravenous administration. Maximal concentrations in plasma are

achieved 1 hour after oral administration, and the  $t_{1/2}$  of parent drug in plasma is ~7 hours.

**Therapeutic Uses.** Cyclophosphamide (LYOPHILIZED CYTOXAN, others) is administered orally or intravenously. Recommended doses vary widely, and standard protocols for determining the schedule and dose of cyclophosphamide in combination with other chemotherapeutic agents should be consulted.

As a single agent, a daily oral dose of 100 mg/m<sup>2</sup> for 14 days has been recommended for patients with lymphomas and CLL. Higher doses of 500 mg/m<sup>2</sup> intravenously every 2-4 weeks are used in combination with other drugs in the treatment of breast cancer and lymphomas. The neutrophil nadir of 500-1000 cells/mm<sup>3</sup> generally serves as a lower limit for dosage adjustments in prolonged therapy. In regimens associated with bone marrow or peripheral stem cell rescue, cyclophosphamide may be given in total doses of 5-7 g/m<sup>2</sup> over a 3- to 5-day period. GI ulceration, cystitis (counteracted by mesna and diuresis), and, less commonly, pulmonary, renal, hepatic, and cardiac toxicities (a hemorrhagic myocardial necrosis) may occur after high-dose therapy with total doses >200 mg/kg.

The clinical spectrum of activity for cyclophosphamide is very broad. It is an essential component of many effective drug combinations for non-Hodgkin's lymphomas, other lymphoid malignancies, breast and ovarian cancers, and solid tumors in children. Complete remissions and presumed cures have been reported when cyclophosphamide was given as a single agent for Burkitt's lymphoma. It frequently is used in combination with doxorubicin and a taxane as adjuvant therapy after surgery for carcinoma of the breast.

Because of its potent immunosuppressive properties, cyclophosphamide has been used to treat auto-immune disorders, including Wegener's granulomatosis, rheumatoid arthritis, and the nephrotic syndrome. Caution is advised when the drug is considered for non-neoplastic conditions, not only because of its acute toxic effects but also because of its potential for inducing sterility, teratogenic effects, and leukemia.

**Ifosfamide.** Ifosfamide (IFEX, others) is an analog of cyclophosphamide. Severe urinary tract and central nervous system (CNS) toxicity limited the use of ifosfamide when it first was introduced in the early 1970s. However,

adequate hydration and co-administration of mesna have reduced its bladder toxicity.

**Therapeutic Uses.** Ifosfamide is approved for treatment of relapsed germ cell testicular cancer and is frequently used for first-time treatment of pediatric and adult sarcomas. It is a common component of high-dose chemotherapy regimens with bone marrow or stem cell rescue; in these regimens, in total doses of 12-14 g/m<sup>2</sup>, it may cause severe neurological toxicity, including hallucinations, coma, and death, with symptoms appearing 12 hours to 7 days after beginning the ifosfamide infusion. This toxicity is thought to result from a metabolite, chloroacetaldehyde. In addition, ifosfamide causes nausea, vomiting, anorexia, leukopenia, nephrotoxicity, and VOD of the liver.

In nonmyeloablative regimens, ifosfamide is infused intravenously over at least 30 minutes at a dose of  $\leq 1.2$  g/m<sup>2</sup>/day for 5 days. Intravenous mesna is given as bolus injections in a dose equal to 20% of the ifosfamide dose concomitantly and an additional 20% again 4 and 8 hours later, for a total mesna dose of 60% of the ifosfamide dose. For ifosfamide doses  $\leq 2$  g/m<sup>2</sup>, oral mesna, at a dose equal to 40% of the ifosfamide dose, can be substituted for the second and third IV mesna doses, given at 2 and 6 hours after each dose of ifosfamide, for a total mesna dose equal to the ifosfamide dose. Alternatively, mesna may be given concomitantly in a single dose equal to the ifosfamide dose. Patients also should receive at least 2 L of oral or intravenous fluid daily. Treatment cycles are repeated every 3-4 weeks after hematological recovery.

**Pharmacokinetics.** The parent compound, ifosfamide, has an elimination t<sub>1/2</sub> in plasma of ~1.5 hours after doses of 3.8-5 g/m<sup>2</sup> and a somewhat shorter t<sub>1/2</sub> at lower doses, although its pharmacokinetics are highly variable from patient to patient due to variable rates of hepatic metabolism. Hydroxylation by CYPs generates an active phosphoramidate mustard.

**Toxicity.** Ifosfamide has virtually the same toxicity profile as cyclophosphamide, although it causes greater platelet suppression, neurotoxicity, nephrotoxicity, and in the absence of mesna, urothelial damage.

**Melphalan.** This alkylating agent primarily is used to treat multiple myeloma and, less commonly, in high-dose chemotherapy with marrow transplantation.

**Pharmacological and Cytotoxic Actions.** The general pharmacological and cytotoxic actions of melphalan are similar to those of other bifunctional alkylators. The drug is not a vesicant.

**Absorption, Fate, and Excretion.** Oral melphalan is absorbed in an inconsistent manner and, for most indications, is given as an intravenous infusion. The drug has a  $t_{1/2}$  in plasma of ~45-90 minutes, and 10-15% of an administered dose is excreted unchanged in the urine. Patients with decreased renal function may develop unexpectedly severe myelosuppression.

**Therapeutic Uses.** Melphalan (ALKERAN) for multiple myeloma is given in doses of 4-10 mg orally for 4-7 days every 28 days, with dexamethasone or thalidomide. Treatment is repeated at 4-week intervals based on response and tolerance. Dosage adjustments should be based on blood cell counts. Melphalan also may be used in myeloablative regimens followed by bone marrow or peripheral blood stem cell reconstitution. For this use, the dose is 180-200 mg/m<sup>2</sup>.

**Clinical Toxicity.** The clinical toxicity of melphalan is mostly hematological and is similar to that of other alkylating agents. Nausea and vomiting are less frequent. The drug causes less alopecia and, rarely, renal or hepatic dysfunction.

**Chlorambucil.** This agent is almost exclusively used in treating CLL, and in this disease has largely been replaced by fludarabine and cyclophosphamide.

**Pharmacological and Cytotoxic Actions.** The cytotoxic effects of chlorambucil on the bone marrow, lymphoid organs, and epithelial tissues are similar to those observed with other nitrogen mustards. As an orally administered agent, chlorambucil is well tolerated in small daily doses and provides flexible titration of blood counts. Nausea and vomiting may result from single oral doses of  $\geq 20$  mg.

**Absorption, Fate, and Excretion.** Oral absorption of chlorambucil is adequate and reliable. The drug has a  $t_{1/2}$  in plasma of ~1.5 hours, and is hydrolyzed to inactive products.

**Therapeutic Uses.** In treating CLL, the standard initial daily dose of chlorambucil (LEUKERAN) is 0.1-0.2 mg/kg, given once daily and continued for 3-6 weeks. With a fall in the peripheral total leukocyte count or clinical

improvement, the dosage is titrated to maintain neutrophils and platelets at acceptable levels. Maintenance therapy (usually 2 mg daily) often is required to maintain clinical response.

***Clinical Toxicity.*** In CLL, chlorambucil treatment may continue for months or years, achieving its effects gradually and often without significant toxicity to a compromised bone marrow.

Although it is possible to induce marked hypoplasia of the bone marrow with excessive doses, its myelosuppressive effects are moderate, gradual, and rapidly reversible. GI discomfort, azoospermia, amenorrhea, pulmonary fibrosis, seizures, dermatitis, and hepatotoxicity rarely may be encountered. A marked increase in the incidence of acute myelocytic leukemia (AML) and other tumors was noted in the treatment of polycythemia vera and in patients with breast cancer receiving chlorambucil as adjuvant chemotherapy (Lerner, 1978).

***Bendamustine.*** This drug is approved for treatment of CLL and non-Hodgkin's lymphoma.

Bendamustine is given as a 30-minute intravenous infusion in dosages of 100 mg/m<sup>2</sup>/day on days 1 and 2 of a 28-day cycle. Lower doses may be indicated in heavily pretreated patients. It is rapidly degraded through sulfhydryl interaction and adduct formation with macromolecules, and <5% of the parent drug is excreted in the urine intact. *N*-demethylation and oxidation produces metabolites that have antitumor activity, but less than that of the parent molecule. The parent drug has a  $t_{1/2}$  in plasma of ~30 minutes (Teichert et al., 2007).

The clinical toxicity pattern of bendamustine is typical of classical alkylators, with a rapidly reversible myelosuppression and mucositis, both generally tolerable in the 28-day regimen.

## **MISCELLANEOUS ALKYLATING DRUGS**

Although nitrogen mustards containing chloroethyl groups constitute the most widely used class of alkylating agents, alternative alkylators with greater chemical stability and well-defined activity in specific types of cancer have value in clinical practice.

### **Ethyleneimines and Methylmelamines**

## **Altretamine**

**Pharmacology and Cytotoxic Effects.** Altretamine (HEXALEN), formerly known as hexamethylmelamine, is structurally similar to triethylenemelamine (tretamine). However, *in vitro* tests for alkylating activity of altretamine and its metabolites have been negative, and the precise mechanism of the cytotoxic action of altretamine is unknown. It is a palliative treatment for persistent or recurrent ovarian cancer following cisplatin-based combination therapy.

The usual dosage of altretamine as a single agent in ovarian cancer is 260 mg/m<sup>2</sup>/day in four divided doses, for 14 or 21 consecutive days out of a 28-day cycle, for up to 12 cycles.

**Absorption, Fate, and Excretion.** Following oral administration, altretamine is well absorbed from the GI tract and undergoes rapid demethylation in the liver. The principal metabolites are pentamethylmelamine and tetramethyl melamine, and the elimination  $t_{1/2}$  is 4-10 hours.

**Clinical Toxicities.** The main toxicities of altretamine are myelosuppression and neurotoxicity. Altretamine causes both peripheral and central neurotoxicity (ataxia, depression, confusion, drowsiness, hallucinations, dizziness, and vertigo). Neurological symptoms abate upon discontinuation of therapy. Peripheral blood counts and a neurological examination should be performed prior to the initiation of each course of therapy. Therapy should be interrupted for at least 14 days and subsequently restarted at a lower dosage of 200 mg/m<sup>2</sup>/day if the white cell count falls to <2000 cells/mm<sup>3</sup> or the platelet count falls to <75,000 cells/mm<sup>3</sup> or if neurotoxic or intolerable GI symptoms occur. If neurological symptoms fail to stabilize on the reduced-dose schedule, altretamine should be discontinued. Nausea and vomiting also are common side effects and may be dose limiting. Renal dysfunction may necessitate discontinuing the drug. Other rare adverse effects include rashes, alopecia, and hepatic toxicity. Severe, life-threatening orthostatic hypotension may develop in patients who receive monoamine oxidase (MAO) inhibitors, amitriptyline, imipramine, or phenelzine concurrently with altretamine.

## **Thiotepa**

**Pharmacological and Cytotoxic Effects.** Thiotepa (THIOPLEX, others) consists of three ethyleneimine groups stabilized by attachment to the nucleophilic thiophosphoryl base. Its current use primarily is for high-dose chemotherapy regimens.

Both thiotepa and its desulfurated primary metabolite, triethylenephosphoramidate (TEPA), to which it is rapidly converted by hepatic CYPs, form DNA cross-links. The aziridine rings open after protonation of the ring-nitrogen, leading to a reactive molecule.

**Absorption, Fate, and Excretion.** TEPA becomes the predominant form of the drug present in plasma within hours of thiotepa administration. The parent compound has a plasma  $t_{1/2}$  of 1.2-2 hours, as compared to a longer  $t_{1/2}$  of 3-24 hours for TEPA. Thiotepa pharmacokinetics essentially are the same in children as in adults at conventional doses ( $\leq 80$  mg/m<sup>2</sup>), and drug and metabolite  $t_{1/2}$  are unchanged in children receiving high-dose therapy of 300 mg/m<sup>2</sup>/day for 3 days. Less than 10% of the administered drug appears in urine as the parent drug or the primary metabolite. Multiple secondary metabolites and chemical degradation products account for the remainder of the administered dose.

**Clinical Toxicities.** The toxicities of thiotepa essentially are the same as those of the other alkylating agents, namely myelosuppression, and to a lesser extent mucositis. Myelosuppression tends to develop somewhat later than with cyclophosphamide, with leukopenic nadirs at 2 weeks and platelet nadirs at 3 weeks. In high-dose regimens, thiotepa may cause neurotoxic symptoms, including coma and seizures.

## Alkyl Sulfonates

**Busulfan.** Busulfan exerts few pharmacological actions other than myelosuppression at conventional doses and, prior to the advent of imatinib mesylate (GLEEVEC), was a standard agent for patients in the chronic phase of myelocytic leukemia and caused a severe and prolonged pancytopenia in some patients. Busulfan now is primarily used in high-dose regimens, in which pulmonary fibrosis, GI mucosal damage, and hepatic veno-occlusive disease (VOD) are important toxicities.

**Absorption, Fate, and Excretion.** Busulfan is well absorbed after oral administration in dosages of 2-6 mg/day and has a plasma  $t_{1/2}$  of 2-3 hours.

The drug is conjugated to GSH by glutathione S-transferase A1A and further metabolized by CYP-dependent pathways; its major urinary metabolite is methane sulfonic acid. In high doses, children <18 years of age clear the drug two to four times faster than adults and tolerate higher doses (Vassal et al., 1993). An intravenous preparation is available for high-dose regimens. With doses of 1 mg/kg every 6 hours for 4 days, peak drug concentrations reach 10  $\mu\text{M}$  in adults but only 1-5  $\mu\text{M}$  in children 1-3 years of age, because of faster clearance. Busulfan clearance varies considerably among patients. VOD is associated with high area under the curve (AUC) (AUC >1500  $\mu\text{M} \times \text{min}$ ) peak drug levels and slow clearance, leading to recommendations for dose adjustment based on drug level monitoring (Grochow, 1993). A target steady-state concentration of 600-900 ng/mL in plasma in adults or AUC <1000  $\mu\text{M} \times \text{min}$  in children achieves an appropriate balance between toxicity and therapeutic benefit (Witherspoon et al., 2001).

***Therapeutic Uses.*** In treating chronic myelogenous leukemia (CML), the initial oral dose of busulfan (MYLERAN, BUSULFEX) varies with the total leukocyte count and the severity of the disease; daily doses of 2-8 mg for adults ( $\sim 60 \mu\text{g}/\text{kg}$  or  $1.8 \text{ mg}/\text{m}^2$  for children) are used to initiate therapy and are adjusted appropriately to subsequent hematological and clinical responses, with the aim of reducing the total leukocyte count to  $\leq 10,000$  cells/ $\text{mm}^3$ . A decrease in the leukocyte count usually is not seen during the first 10-15 days of treatment, and the leukocyte count may actually increase; during this period, an increase in leukocyte count should not be interpreted as drug resistance nor should the dose be increased. Because the leukocyte count may fall for >1 month after discontinuing the drug, it is recommended that busulfan be withdrawn when the total leukocyte count has declined to  $\sim 15,000$  cells/ $\text{mm}^3$ . A normal leukocyte count usually is achieved within 12-20 weeks. During remission, daily treatment resumes when the total leukocyte count reaches  $\sim 50,000$  cells/ $\text{mm}^3$ . Daily maintenance doses are 1-3 mg. In high-dose therapy, doses of 1 mg/kg are given every 6 hours for 4 days, with adjustment based on pharmacokinetics.

In high-dose regimens, busulfan is given at 0.8 mg/kg every 6 hours for 4 days. Anticonvulsants must be used concomitantly to protect against acute CNS toxicities, including tonic-clonic seizures, which may occur several hours after each dose. Busulfan induces the metabolism of phenytoin. In patients requiring anti-seizure medication, non-enzyme-inducing drugs such

as lorazepam are recommended as an alternative to phenytoin. When phenytoin is used concurrently, plasma busulfan levels should be monitored and the busulfan dose adjusted accordingly.

**Clinical Toxicity.** The major toxic effects of busulfan are related to its myelosuppressive properties, and prolonged thrombocytopenia may be a hazard. Occasionally, patients experience nausea, vomiting, and diarrhea. Long-term use leads to impotence, sterility, amenorrhea, and fetal malformation. Rarely, patients develop asthenia and hypotension, a syndrome resembling Addison's disease, but without abnormalities of corticosteroid production.

High-dose busulfan causes VOD of the liver in  $\leq 10\%$  of patients, as well as seizures, hemorrhagic cystitis, permanent alopecia, and cataracts. The coincidence of VOD and hepatotoxicity is increased by its co-administration with drugs that inhibit CYPs, including imidazoles and metronidazole, possibly through inhibition of the clearance of busulfan and/or its toxic metabolites (Nilsson et al., 2003).

## Nitrosoureas

The nitrosoureas have an important role in the treatment of brain tumors and find occasional use in treating lymphomas and in high-dose regimens with bone marrow reconstitution. They function as bifunctional alkylating agents but differ from conventional nitrogen mustards in both pharmacological and toxicological properties.

Carmustine (BCNU) and lomustine (CCNU) are highly lipophilic and thus readily cross the blood-brain barrier, an important property in the treatment of brain tumors. Unfortunately, with the exception of streptozocin, nitrosoureas cause profound and delayed myelosuppression with recovery 4-6 weeks after a single dose. Long-term treatment with the nitrosoureas, especially semustine (methyl-CCNU), has resulted in renal failure. As with other alkylating agents, the nitrosoureas are highly carcinogenic and mutagenic. They generate both alkylating and carbamylating moieties as illustrated in [Figure 61-4](#).

**Carmustine (BCNU).** Carmustine's major action is its alkylation of DNA at the  $O^6$ -guanine position, an adduct repaired by MGMT. Methylation of the MGMT promoter inhibits its expression in  $\sim 30\%$  of primary gliomas and is

associated with sensitivity to nitrosoureas. In high doses with bone marrow rescue, it produces hepatic VOD, pulmonary fibrosis, renal failure, and secondary leukemia (Tew et al., 2001).

**Absorption, Fate, and Excretion.** Carmustine is unstable in aqueous solution and in body fluids. After intravenous infusion, it disappears from the plasma with a highly variable  $t_{1/2}$  of  $\geq 15$ -90 minutes. Approximately 30-80% of the drug appears in the urine within 24 hours as degradation products. The alkylating metabolites enter rapidly into the cerebrospinal fluid (CSF), and their concentrations in the CSF reach 15-30% of the concurrent plasma values.

**Therapeutic Uses.** When used alone, carmustine (BICNU) is administered intravenously at doses of 150-200 mg/m<sup>2</sup>, given by infusion over 1-2 hours and repeated every 6 weeks.

Because of its ability to cross the blood-brain barrier, carmustine has been used in the treatment of malignant gliomas but has been increasingly replaced by temozolomide. An implantable carmustine wafer (GLIADEL) is available for use as an adjunct to surgery and radiation in newly diagnosed high-grade malignant glioma patients and as an adjunct to surgery for recurrent glioblastoma multiforme.

**Streptozocin.** This antibiotic has a methylnitrosourea (MNU) moiety attached to the 2-carbon of glucose. It has a high affinity for cells of the islets of Langerhans and causes diabetes in experimental animals.

**Absorption, Fate, and Excretion.** Streptozocin is rapidly degraded following intravenous administration. The  $t_{1/2}$  of the drug is ~15 minutes. Only 10-20% of a dose is recovered intact in the urine.

**Therapeutic Uses.** Streptozocin (ZANOSAR) is used exclusively in the treatment of human pancreatic islet cell carcinoma and malignant carcinoid tumors. It is administered intravenously, 500 mg/m<sup>2</sup> once daily for 5 days; this course is repeated every 6 weeks. Alternatively, 1000 mg/m<sup>2</sup> can be given weekly for 2 weeks, and the weekly dose then can be increased to a maximum of 1500 mg/m<sup>2</sup>, depending on tolerance and response.

**Clinical Toxicity.** Nausea is frequent. Mild, reversible renal or hepatic toxicity occurs in approximately two-thirds of cases; in <10% of patients, renal toxicity may be cumulative with each dose and may lead to irreversible

renal failure. Proteinuria is an early sign of tubular damage and impending renal failure. Streptozocin should not be given with other nephrotoxic drugs. Hematological toxicity—anemia, leukopenia, or thrombocytopenia—occurs in 20% of patients.

## Triazines

**Dacarbazine (DTIC).** Dacarbazine functions as a methylating agent after metabolic activation to the monomethyl triazeno metabolite, MTIC. It kills cells in all phases of the cell cycle. Resistance has been ascribed to the removal of methyl groups from the  $O^6$ -guanine bases in DNA by MGMT.

**Absorption, Fate, and Excretion.** Dacarbazine is administered intravenously. After an initial rapid phase of disappearance ( $t_{1/2}$  of ~20 minutes), dacarbazine is cleared from plasma with a terminal  $t_{1/2}$  of ~5 hours. The  $t_{1/2}$  is prolonged in the presence of hepatic or renal disease. Almost 50% of the compound is excreted intact in the urine by tubular secretion. Elevated urinary concentrations of 5-aminoimidazole-4-carboxamide reflect from the catabolism of dacarbazine, rather than inhibition of *de novo* purine biosynthesis.

**Therapeutic Uses.** Dacarbazine (DTIC-DOME) for malignant melanoma is given intravenously in dosages of 2-4.5 mg/kg/day for a 10-day period, repeated every 28 days. Alternatively, 250 mg/m<sup>2</sup> can be given daily for 5 days and repeated every 3 weeks. Extravasation of the drug may cause tissue damage and severe pain. In combination with other drugs for Hodgkin's disease, dacarbazine is given in dosages of 150 mg/m<sup>2</sup>/day for 5 days, repeated every 4 weeks, or a single dose of 375 mg/m<sup>2</sup> is given and repeated every 15 days.

At present, the primary clinical indication for dacarbazine is in the combination chemotherapy of Hodgkin's disease. It is modestly effective against malignant melanoma and adult sarcomas.

**Clinical Toxicity.** DTIC induces nausea and vomiting in >90% of patients; vomiting usually develops 1-3 hours after treatment and may last up to 12 hours. Myelosuppression, with both leukopenia and thrombocytopenia, is mild and readily reversible within 1-2 weeks. A flulike syndrome consisting of chills, fever, malaise, and myalgias may occur during treatment with

DTIC. Hepatotoxicity, alopecia, facial flushing, neurotoxicity, and dermatological reactions are less common adverse effects.

**Temozolomide.** Temozolomide (TEMODAR) is the standard agent in combination with radiation therapy for patients with malignant glioma and for astrocytoma. Temozolomide, like dacarbazine, forms the methylating metabolite MTIC and kills cells in all phases of the cell cycle. Resistance arises by any of the common mechanisms attributed to other alkylating agents, but particularly the *loss* of MLH6, a component of MMR.

**Absorption, Fate, and Excretion.** Temozolomide is administered orally in dosages of ~200 mg/day; it has a bioavailability approaching 100%. Maximum drug concentration reaches 5  $\mu\text{g/mL}$ , or ~10  $\mu\text{M}$  in plasma, ~1 hour after administration of a dose of 200 mg and declines with an elimination  $t_{1/2}$  of 1-2 hours. The primary active metabolite MTIC reaches a maximum plasma concentration of 150 ng/mL 90 minutes after a dose and declines with a  $t_{1/2}$  of 2 hours. Little intact drug is recovered in the urine, the primary urinary metabolite being the inactive imidazole carboxamide (Baker et al., 1999).

**Clinical Toxicity.** Temozolomide is available for oral and intravenous administration. It is administered cyclically, and hematological monitoring is necessary to guide dosing adjustments. The toxicities of temozolomide mirror those of DTIC.

## Methylhydrazines

**Procarbazine.** The methylhydrazine derivatives were synthesized in a search for inhibitors of monoamine neurotransmitters. Several compounds in this series had anticancer activity, but only procarbazine (*N*-isopropyl- $\alpha$ -(2-methylhydrazino)-*p*-toluamide), an agent formerly useful in Hodgkin's disease and currently employed for second-line therapy in malignant brain tumors, has a role in clinical chemotherapy.

**Cytotoxic Action.** The antineoplastic activity of procarbazine results from its conversion by CYP-mediated hepatic oxidative metabolism to highly

reactive alkylating species, which methylate DNA. The activation pathways are complex and not fully understood; free-radical intermediates may be cytotoxic. Activated procarbazine can produce chromosomal damage, including chromatid breaks and translocations, consistent with its mutagenic and carcinogenic actions. Resistance to procarbazine develops rapidly when it is used as a single agent. One mechanism results from the increased expression of MGMT, which repairs methylation of guanine.

***Absorption, Fate, and Excretion.*** The pharmacokinetic behavior of procarbazine has not yet been thoroughly defined. The drug is extensively metabolized by CYP isoenzymes to azo, methylazoxy, and benzylazoxy intermediates, which are found in the plasma and yield the alkylating metabolites in tumor cells. In brain cancer patients, it is surprising that the concurrent use of anti-seizure drugs that induce hepatic CYPs does not significantly alter the pharmacokinetics of the parent drug (He et al., 2004).

***Therapeutic Uses.*** The recommended dosage of procarbazine (MATULANE) for adults is 100 mg/m<sup>2</sup>/day for 10-14 days in combination regimens such as MOPP (nitrogen mustard, oncovin, procarbazine, and prednisone) for Hodgkin's disease. The drug rarely is used in current practice, the MOPP combination having been replaced by alternative drugs.

***Clinical Toxicity.*** The most common toxic effects include leukopenia and thrombocytopenia, which begin during the second week of therapy and reverse within 2 weeks off treatment. GI symptoms such as mild nausea and vomiting occur in most patients; diarrhea and rash are noted in 5-10% of cases. Behavioral disturbances also have been reported. Because procarbazine augments sedative effects, the concomitant use of CNS depressants should be avoided. The drug is a weak MAO inhibitor; it blocks the metabolism of catecholamines, sympathomimetics, and dietary tyramine and may provoke hypertension in patients concurrently exposed to these. Procarbazine has disulfiram-like actions, and therefore the ingestion of alcohol should be avoided. The drug is highly carcinogenic, mutagenic, and teratogenic and is associated with a 5-10% risk of acute leukemia in patients treated with MOPP. The highest risk is for patients who also receive radiation therapy. In addition, procarbazine is a potent immunosuppressive agent. It causes infertility, particularly in males.

## **PLATINUM COORDINATION COMPLEXES**

The platinum coordination complexes have broad antineoplastic activity and have become the foundation for treatment of ovarian, head and neck, bladder, esophagus, lung, and colon cancers. The analogs differ in their pharmacological properties, and oxaliplatin has mechanistic differences that may explain its unique activity in colorectal cancer (see “Mechanism of Action”) (Dolan and Fitch, 2007). Although cisplatin and other platinum complexes do not form carbonium ion intermediates like other alkylating agents or formally alkylate DNA, they covalently bind to nucleophilic sites on DNA and share many pharmacological attributes with alkylators.

**Chemistry.** Cisplatin and carboplatin are divalent, inorganic, water-soluble, platinum-containing complexes. Oxaliplatin, a tetravalent complex, does not display cross-resistance to the divalent compounds in some experimental tumors. The coordination of di- or tetravalent platinum with various organic adducts reduces its renal toxicity and stabilizes the metal ion, as compared to the inorganic divalent platinum ion.

**Mechanism of Action.** Cisplatin, carboplatin, and oxaliplatin enter cells by an active Cu<sup>2+</sup> transporter, CTR1, and in doing so rapidly degrade the transporter (Kruh, 2003). The compounds are actively extruded from cells by ATP7A and ATP7B copper transporters and by multidrug resistance protein 1 (MRP 1); variable expression of these transporters may contribute to clinical resistance (Dolan and Fitch, 2007). Inside the cell, the chloride, cyclohexane, or oxalate ligands of the three analogs are displaced by water molecules, yielding a positively charged and highly reactive molecule. In the primary cytotoxic reaction, the aquated species of the drug then reacts with nucleophilic sites on DNA and proteins.

Aquation of cisplatin is favored at the low concentrations of chloride inside the cell and in the urine. High concentrations of chloride stabilize the drug, explaining the effectiveness of chloride diuresis in preventing nephrotoxicity (see “Clinical Toxicities”). The activated platinum complexes can react with electron-rich molecules, such as sulfhydryls, and with various sites on DNA, forming both intrastrand and interstrand cross-links. The N-7 of guanine is a particularly reactive site, leading to platinum cross-links between adjacent guanines (GG intrastrand cross-links) on the same DNA strand; guanine–adenine cross-links also form and may contribute to cytotoxicity. Interstrand cross-links form less frequently. DNA-platinum adducts inhibit replication and transcription, lead to single- and double-stranded breaks and miscoding, and if recognized by p53 and other checkpoint proteins, cause induction of apoptosis. Although no quantitative relationship between platinum-DNA adduct formation and efficacy has been documented, the ability of patients to form and sustain platinum adducts appears to be an important predictor of clinical response (Reed et al., 1988). The analogs differ in the conformation of their adducts and the effects of adduct on DNA structure and function. Oxaliplatin and carboplatin are slower to form adducts. The oxaliplatin adducts are bulkier and less readily repaired, create a different pattern of distortion of the DNA helix, and differ from cisplatin adducts in the pattern of hydrogen bonding to adjacent segments of DNA (Sharma et al., 2007).

Unlike the other platinum analogs, oxaliplatin exhibits a cytotoxicity that does not depend on an active MMR system, which may explain its greater activity in colorectal cancer. It also seems less dependent on the presence of high mobility group (HMG) proteins that are required by the other platinum derivatives. Testicular cancers have a high concentration of HMG proteins and are quite sensitive to cisplatin. Basal-type breast cancers, such as those with BRCA1 and BRCA2 mutations, lack Her 2 amplification and hormone-receptor expression and appear to be uniquely susceptible to cisplatin through their upregulation of apoptotic pathways governed by p63 and p73 (Deyoung and Ellisen, 2007). The specificity of cisplatin with regard to phase of the cell cycle differs among cell types, although the effects of cross-linking are most pronounced during the S phase.

The platinum analogs are mutagenic, teratogenic, and carcinogenic. Cisplatin- or carboplatin-based chemotherapy for ovarian cancer is associated with a 4-fold increased risk of developing secondary leukemia.

***Resistance to Platinum Analogs.*** Resistance to the platinum analogs likely is multifactorial, and the compounds differ in their degree of cross-resistance. Carboplatin shares cross-resistance with cisplatin in most experimental tumors, while oxaliplatin does not. A number of factors influence sensitivity to platinum analogs in experimental cells, including intracellular drug accumulation, as determined by the uptake and efflux transporters; intracellular levels of glutathione and other sulfhydryls such as metallothionein that bind to and inactivate the drug (Meijer et al., 1990); and rates of repair of DNA adducts. Repair of platinum-DNA adducts requires participation of the NER pathway. Inhibition or loss of NER increases sensitivity to cisplatin in ovarian cancer patients, while overexpression of NER components is associated with poor response to cisplatin or oxaliplatin-based therapy in lung, colon, and gastric cancer (Paré et al., 2008). Higher levels of expression of the NER component, ERCC1, in tumor cells and peripheral white blood cells are associated with a lower response rate in patients with solid tumors (Dolan and Fitch, 2007).

Resistance to cisplatin, but not oxaliplatin, appears to be partly mediated through loss of function in the MMR proteins (hMLH1, hMLH2, or hMSH6), which recognize platinum-DNA adducts and initiate apoptosis.

In the absence of effective repair of DNA-platinum adducts, sensitive cells cannot replicate or transcribe affected portions of the DNA strand. However, it is clear that some DNA polymerases can bypass adducts, especially those created by cisplatin. Oxaliplatin adducts are less easily bypassed. It remains unproven whether these polymerases contribute to resistance. Cisplatin resistance related to loss of active uptake has been demonstrated in yeast; overexpression of copper efflux transporters, ATP7A and ATP7B, correlates with poor survival after cisplatin-based therapy for ovarian cancer (Kruh, 2003).

## **Cisplatin**

**Absorption, Fate, and Excretion.** After intravenous administration, cisplatin has an initial plasma elimination  $t_{1/2}$  of 25-50 minutes; concentrations of total (bound and unbound) drug fall thereafter, with a  $t_{1/2}$  of  $\geq 24$  hours. More than 90% of the platinum in the blood is covalently bound to plasma proteins. The unbound fraction, composed predominantly of parent drug, diminishes within minutes. High concentrations of cisplatin are found in the tissues of the

kidney, liver, intestine, and testes but poorly penetrate into the CNS. Only a small portion of the drug is excreted by the kidney during the first 6 hours; by 24 hours, up to 25% is excreted, and by 5 days, up to 43% of the administered dose is recovered in the urine, mostly covalently bound to protein and peptides. Biliary or intestinal excretion of cisplatin is minimal.

**Therapeutic Uses.** Cisplatin (PLATINOL, others) is given only by the intravenous route. The usual dosage is 20 mg/m<sup>2</sup>/day for 5 days, 20-30 mg weekly for 3-4 weeks, or 100 mg/m<sup>2</sup> given once every 4 weeks. *To prevent renal toxicity, it is important to establish a chloride diuresis by the infusion of 1-2 L of normal saline prior to treatment.* The appropriate amount of cisplatin then is diluted in a solution containing dextrose, saline, and mannitol and administered intravenously over 4-6 hours. Because aluminum reacts with and inactivates cisplatin, the drug should not come in contact with needles or other infusion equipment that contain aluminum during its preparation or administration.

Cisplatin, in combination with bleomycin, etoposide, ifosfamide, or vinblastine, cures 90% of patients with testicular cancer. Used with paclitaxel, cisplatin or carboplatin induces complete response in the majority of patients with carcinoma of the ovary. Cisplatin produces responses in cancers of the bladder, head and neck, cervix, and endometrium; all forms of carcinoma of the lung; anal and rectal carcinomas; and neoplasms of childhood. Interestingly, the drug also sensitizes cells to radiation therapy and enhances control of locally advanced lung, esophageal, and head and neck tumors when given with irradiation.

**Clinical Toxicities.** Cisplatin-induced nephrotoxicity has been largely abrogated by adequate pretreatment hydration and chloride diuresis. Amifostine (ETHYOL, others) is a thiophosphate cytoprotective agent that reduces renal toxicity associated with repeated administration of cisplatin, but is not commonly used. Ototoxicity caused by cisplatin is unaffected by diuresis and is manifested by tinnitus and high-frequency hearing loss. The ototoxicity can be unilateral or bilateral, tends to be more frequent and severe with repeated doses, and may be more pronounced in children. Marked nausea and vomiting occur in almost all patients and usually can be controlled with 5-HT<sub>3</sub> antagonists, NK1-receptor antagonists, and high-dose corticosteroids (see [Chapter 46](#)).

At higher doses, or after multiple cycles of treatment, cisplatin causes a progressive peripheral motor and sensory neuropathy, which may worsen after discontinuation of the drug and may be aggravated by subsequent or simultaneous treatment with taxanes or other neurotoxic drugs. Cisplatin causes mild to moderate myelosuppression, with transient leukopenia and thrombocytopenia. Anemia may become prominent after multiple cycles of treatment. Electrolyte disturbances, including hypomagnesemia, hypocalcemia, hypokalemia, and hypophosphatemia, are common. Hypocalcemia and hypomagnesemia secondary to tubular damage and renal electrolyte wasting may produce tetany if untreated. Routine measurement of  $Mg^{2+}$  concentrations in plasma is recommended. Hyperuricemia, hemolytic anemia, and cardiac abnormalities are rare side effects. Anaphylactic-like reactions, characterized by facial edema, bronchoconstriction, tachycardia, and hypotension, may occur within minutes after administration and should be treated by intravenous injection of epinephrine and with corticosteroids or antihistamines. Like other DNA adduct-forming drugs, cisplatin has been associated with the development of AML, usually  $\geq 4$  years after treatment.

## **Carboplatin**

The mechanisms of action and resistance and the spectrum of clinical activity of carboplatin (CBDCA, JM-8) are similar to cisplatin (see “Cisplatin”). However, the two drugs differ significantly in their chemical, pharmacokinetic, and toxicological properties.

Because carboplatin is much less reactive than cisplatin, the majority of drug in plasma remains in its parent form, unbound to proteins. Most drug is eliminated via renal excretion, with a  $t_{1/2}$  in plasma of  $\sim 2$  hours. A small fraction of platinum binds irreversibly to plasma proteins and disappears slowly, with a  $t_{1/2}$  of  $\geq 5$  days.

Carboplatin is relatively well tolerated clinically, causing less nausea, neurotoxicity, ototoxicity, and nephrotoxicity than cisplatin. Instead, the dose-limiting toxicity is myelosuppression, primarily thrombocytopenia. It is more likely to cause a hypersensitivity reaction; in patients with a mild reaction, premedication, graded doses of drug, and more prolonged infusion lead to desensitization.

Carboplatin and cisplatin are equally effective in the treatment of suboptimally debulked ovarian cancer, non-small cell lung cancer, and extensive-stage small cell lung cancer; however, carboplatin may be less effective than cisplatin in germ cell, head and neck, and esophageal cancers (Go and Adjei, 1999). Carboplatin is an effective alternative for responsive tumors in patients unable to tolerate cisplatin because of impaired renal function, refractory nausea, significant hearing impairment, or neuropathy, but doses must be adjusted for renal function. In addition, it may be used in high-dose therapy with bone marrow or peripheral stem cell rescue. The dose of carboplatin should be adjusted in proportion to the reduction in creatinine clearance (CrCl) for patients with a CrCl <60 mL/min. The following formula is useful for calculation of dose:

$$\text{Dose (mg)} = \text{AUC} \times (\text{GFR} + 25)$$

where the target AUC (area under the plasma concentration–time curve) is ~5-7 min/mg/mL for acceptable toxicity in patients receiving single-agent carboplatin (GFR = glomerular filtration rate).

Carboplatin (PARAPLATIN) is administered as an intravenous infusion over at least 15 minutes, using the above-mentioned formula for dose calculation, and is given once every 21-28 days.

## Oxaliplatin

**Absorption, Fate, and Excretion.** Oxaliplatin, like cisplatin, has a very brief  $t_{1/2}$  in plasma, probably as a result of its rapid uptake by tissues and its reactivity. Maximum concentrations in plasma range from 1-1.5  $\mu\text{g}$  platinum/mL for patients receiving 80-130  $\text{mg}/\text{m}^2$  intravenously and decline thereafter, with an initial  $t_{1/2}$  of 0.28 hour. Although the ultrafiltrable component has a slow terminal clearance from plasma, most of the low-molecular-weight platinum species represent inactive degradation products. These metabolites undergo renal excretion at a rate dependent on the CrCl. No dose adjustment is required for patients with a CrCl  $\geq 20$  mL/min; decreased renal function does not affect the rapid chemical inactivation of the drug in the systemic circulation and tissues (Takimoto et al., 2007). Dose adjustment is not required for hepatic dysfunction (Synold et al., 2007).

**Therapeutic Uses.** Oxaliplatin exhibits a range of antitumor activity (colorectal and gastric cancer) that differs from other platinum agents.

Oxaliplatin's effectiveness in colorectal cancer is perhaps due to its MMR- and HMG-independent effects (see "Mechanism of Action" under "Platinum Coordination Complexes"). It also suppresses expression of thymidylate synthase (TS), the target enzyme of 5-fluorouracil (5-FU) action, which may promote synergy of these two drugs (Fischel et al., 2002). In combination with 5-FU, it is approved for treatment of patients with colorectal cancer.

**Clinical Toxicity.** The dose-limiting toxicity of oxaliplatin is a peripheral neuropathy. An acute form, often triggered by exposure to cold liquids, manifests as paresthesias and/or dysesthesias in the upper and lower extremities, mouth, and throat. It may be caused by rapid release of oxalate, with depletion of calcium and magnesium, and responds to infusion of these electrolytes. A second type of peripheral neuropathy is more closely related to cumulative dose and has features similar to cisplatin neuropathy; 75% of patients receiving a cumulative dose of 1560 mg/m<sup>2</sup> experience some progressive sensory neurotoxicity, with dysesthesias, ataxia, and numbness of the extremities. Hematological toxicity is mild to moderate, except for rare immune-mediated cytopenias, and nausea is well controlled with 5-HT<sub>3</sub>-receptor antagonists. Like other platinum analogs, oxaliplatin causes leukemia and pulmonary fibrosis months to years after administration. Oxaliplatin may cause an acute allergic response with urticaria, hypotension, and bronchoconstriction.

## II. Antimetabolites

### FOLIC ACID ANALOGS

Folic acid is an essential dietary factor that is converted by enzymatic reduction to a series of tetrahydrofolate (FH<sub>4</sub>) cofactors that provide methyl groups for the synthesis of precursors of DNA (thymidylate and purines) and RNA (purines). Interference with FH<sub>4</sub> metabolism reduces the cellular capacity for one-carbon transfer and the necessary methylation reactions in the synthesis of purine ribonucleotides and thymidine monophosphate (TMP), thereby inhibiting DNA replication.

**History.** Antifolate chemotherapy occupies a special place in the history of cancer treatment: This class of drugs produced the first striking, although temporary, remissions in leukemia (Farber et al., 1948) and the first cure of a

solid tumor, choriocarcinoma (Berlin et al., 1963). Interest in folate antagonists further increased with the development of curative combination therapy for childhood acute lymphocytic leukemia; in this therapy, methotrexate played a critical role in both systemic treatment and intrathecal therapy. Introduction of high-dose regimens with “rescue” of host toxicity by the reduced folate, leucovorin (folinic acid, citrovorum factor, 5-formyl tetrahydrofolate, N<sup>5</sup>-formyl FH<sub>4</sub>), further extended the effectiveness of this drug to both systemic and CNS lymphomas, osteogenic sarcoma, and leukemias. Most recently, pemetrexed, an analog that differs from methotrexate in its transport properties and sites of action, has proven useful in treating mesothelioma and lung cancer.

Recognition that methotrexate, an inhibitor of dihydrofolate reductase (DHFR), also directly inhibits the folate-dependent enzymes of *de novo* purine and thymidylate synthesis led to development of antifolate analogs that specifically target these other folate-dependent enzymes ([Figure 61–5](#)). New inhibitors have resulted from synthetic modifications of the basic folate molecule (replacement of the N5 and/or N8 nitrogens of the pteridine ring and the N10 nitrogen of the bridge between the pteridine and benzoate rings of folate, as well as various side-chain substitutions). These new agents have greater capacity for transport into tumor cells (pralatrexate) and exert their primary inhibitory effect on TS (raltitrexed, *TOMUDEX*), early steps in purine biosynthesis (lometrexol), or both (the multitargeted antifolate, pemetrexed, *ALIMTA*) (Vogelzang et al., 2003; O’Connor et al., 2007).

**Figure 61–5.** Sites of action of methotrexate and its polygluta-mates. AICAR, aminoimidazole carboxamide; TMP, thymidine monophosphate; dUMP, deoxyuridine monophosphate;  $\text{FH}_2 \text{Glu}_n$ , dihydrofolate polyglutamate;  $\text{FH}_4 \text{Glu}_n$ , tetrahydrofolate polyglutamate; GAR, glycinamide ribonucleotide; IMP, inosine monophosphate; PRPP, 5-phosphoribosyl-1-pyrophosphate.

Aside from its antineoplastic activity, methotrexate also has been used with benefit in the therapy of psoriasis (see [Chapter 65](#)). Additionally, methotrexate inhibits cell-mediated immune reactions and is employed to suppress graft-versus-host disease in allogenic bone marrow and organ transplantation and for the treatment of dermatomyositis, rheumatoid arthritis, Wegener’s granulomatosis, and Crohn’s disease (see Chapters 35 and 47).

**Structure-Activity Relationship.** The primary target of methotrexate is the enzyme DHFR ([Figure 61-5](#)). Inhibition of DHFR leads to partial depletion of the FH<sub>4</sub> cofactors (5-10 methylene tetrahydrofolic acid and N-10 formyl tetrahydrofolic acid) required for the respective synthesis of thymidylate and purines. In addition, methotrexate, like its physiological counterparts (the folates), undergoes conversion to a series of polyglutamates (MTX-PGs) in both normal and tumor cells. These MTX-PGs constitute an intracellular storage form of folates and folate analogs and dramatically increase inhibitory potency of the analog for additional sites, including TS and two early enzymes in the purine biosynthetic pathway ([Figure 61-5](#)). Finally, the dihydrofolic acid polyglutamates that accumulate in cells behind the blocked DHFR reaction also act as inhibitors of TS and other enzymes ([Figure 61-5](#)) (Allegra et al., 1987b).

Because folic acid and many of its analogs are polar, they cross the blood-brain barrier poorly and require specific transport mechanisms to enter mammalian cells. Three inward folate transport systems are found on mammalian cells: 1) a folate receptor, which has high affinity for folic acid but much reduced ability to transport methotrexate and other analogs; 2) the reduced folate transporter, the major transit protein for methotrexate, raltitrexed, pemetrexed, and most analogs (Westerhof et al., 1995); and 3) a transporter that is active at low pH. The importance of transport in determining drug sensitivity is illustrated by the finding that the reduced folate transporter is highly expressed in the hyperdiploid subtype of acute lymphoblastic leukemia, due to the presence of multiple copies of chromosome 21, on which its gene resides; these cells have extreme sensitivity to methotrexate (Pui et al., 2004). Once in the cell, additional glutamyl residues are added to the molecule by the enzyme folylpolyglutamate synthetase. Intracellular methotrexate polyglutamates have been identified with up to six glutamyl residues. Because these higher polyglutamates are strongly charged and cross cellular membranes poorly, if at all, polyglutamation serves as a mechanism of entrapment and may account for the prolonged retention of methotrexate in chorionic epithelium (where it is a potent abortifacient); in tumors derived from this tissue, such as choriocarcinoma cells; and in normal tissues subject to cumulative drug toxicity, such as liver. Polyglutamylated folates and analogs have substantially greater affinity than the monoglutamate form for folate-

dependent enzymes that are required for purine and thymidylate synthesis and have at least equal affinity for DHFR.

New folate antagonists that are better substrates for the reduced folate carrier have been identified. In efforts to bypass the obligatory membrane transport system and to facilitate penetration of the blood-brain barrier, lipid-soluble folate antagonists also have been synthesized. Trimetrexate (NEUTREXIN), a lipid-soluble analog that lacks a terminal glutamate, was one of the first to be tested for clinical activity. The analog has modest antitumor activity, primarily in combination with leucovorin rescue. However, it is beneficial in the treatment of *P. jiroveci* (PNEUMOCYSTIS CARINII) pneumonia (Allegra et al., 1987a), where leucovorin provides differential rescue of the host but not the parasite.

The most important new folate analog, MTA or pemetrexed (ALIMTA) ([Figure 61–6](#)), is a pyrrole–pyrimidine structure. It is avidly transported into cells via the reduced folate carrier. It readily is converted to polyglutamates that inhibit TS and glycine amide ribonucleotide transformylase, as well as DHFR. It has shown activity against ovarian cancer, mesothelioma, and non-small cell adenocarcinomas of the lung (Vogelzang et al., 2003).

Inhibitors of DHFR differ in their relative potency for blocking enzymes from different species. Agents have been identified that have little effect on the human enzyme but have strong activity against bacterial and parasitic infections (see discussions of trimethoprim, [Chapter 52](#), and pyrimethamine, [Chapter 49](#)). By contrast, methotrexate effectively inhibits DHFR in all species investigated. Crystallographic studies have revealed the structural basis for the high affinity of methotrexate for DHFR (Blakley and Sorrentino, 1998) and the species specificity of the various DHFR inhibitors.

**Mechanism of Action.** To function as a cofactor in one-carbon transfer reactions, folate must first be reduced by DHFR to  $\text{FH}_4$ . Single-carbon fragments are added enzymatically to  $\text{FH}_4$  in various configurations and then may be transferred in specific synthetic reactions. In a key metabolic event catalyzed by TS ([Figure 61–5](#)), deoxyuridine monophosphate (dUMP) is converted to thymidine monophosphate (TMP), an essential component of DNA. In this reaction, a one-carbon group is transferred to dUMP from 5,10-methylene  $\text{FH}_4$ , and the reduced folate cofactor is oxidized to dihydrofolate ( $\text{FH}_2$ ). To function again as a cofactor,  $\text{FH}_2$  must be reduced to  $\text{FH}_4$  by

DHFR. Inhibitors such as methotrexate, with a high affinity for DHFR ( $K_i \sim 0.01\text{-}0.2 \text{ nM}$ ), prevent the formation of  $\text{FH}_4$  and allow an accumulation of the toxic inhibitory substrate,  $\text{FH}_2$  polyglutamate, behind the blocked reaction. The absence of reduced folates shuts down the one-carbon transfer reactions crucial for the *de novo* synthesis of purine nucleotides and thymidylate and interrupts the synthesis of DNA and RNA. The toxic effects of methotrexate may be terminated by administering leucovorin, a fully reduced folate coenzyme, which repletes the intracellular pool of  $\text{FH}_4$  cofactors.

As with most antimetabolites, methotrexate is only partially selective for tumor cells and kills rapidly dividing normal cells, such as those of the intestinal epithelium and bone marrow. Folate antagonists kill cells during the S phase of the cell cycle and are most effective when cells are proliferating rapidly.

**Figure 61–6.** Structures of folic acid and anti-folates. The shading identifies common structural features and areas of modification.

Pemetrexed and its polyglutamates have a somewhat different spectrum of biochemical actions. Like methotrexate, pemetrexed inhibits DHFR, but as a polyglutamate, it even more potently inhibits glycinamide ribonucleotide formyltransferase (GART) and thymidylate synthase (TS). Unlike methotrexate, it produces little change in the pool of reduced folates, indicating that the distal sites of inhibition (TS and GART) predominate. Its pattern of deoxynucleotide depletion, as studied in cell lines, also differs from methotrexate, as it causes a greater fall in thymidine triphosphate (TTP) than in other triphosphates (Chen et al., 1998). Like methotrexate, it induces p53 and cell-cycle arrest, but this effect does not seem to depend on downstream induction of p21. Pralatrexate is more effectively taken up and polyglutamated than methotrexate. Pralatrexate is approved for treatment of cutaneous T-cell lymphoma (O'Connor et al, 2007).

**Mechanisms of Resistance to Antifolates.** In experimental and clinical chemotherapy, acquired resistance to methotrexate affects each known step in methotrexate action, including:

- Impaired transport of methotrexate into cells
- Production of altered forms of DHFR that have decreased affinity for the inhibitor
- Increased concentrations of intracellular DHFR through gene amplification or altered gene regulation
- Decreased ability to synthesize methotrexate polyglutamates
- Increased expression of a drug efflux transporter of the MRP class (see [Chapter 5](#))

DHFR levels in leukemic cells increase within 24 hours after treatment of patients with methotrexate; this likely reflects induction of new enzyme synthesis. The unbound DHFR protein may bind to its own message and inhibit translational efficiency of its own synthesis, while the DHFR-MTX complex is ineffective in blocking the DHFR translation. With longer periods of drug exposure, tumor cell populations that contain markedly increased levels of DHFR emerge. These cells contain multiple gene copies of DHFR either in mitotically unstable double-minute chromosomes (extrachromosomal elements formed by amplification of DHFR genes in response to methotrexate treatment) or in stably integrated, homogeneously staining chromosomal regions or amplicons. First identified as an

explanation for resistance to methotrexate (Schimke et al., 1978), gene amplification of a target protein has since been implicated in the resistance to many antitumor agents, including 5-FU and pentostatin (2'-deoxycoformycin) and has been observed in patients with lung cancer (Curt et al., 1985) and leukemia. Impaired transport and polyglutamation have been implicated as mechanisms of resistance in childhood leukemia.

To overcome resistance, high doses of methotrexate may permit entry of the drug into transport-defective cells and may permit the intracellular accumulation of methotrexate in concentrations that inactivate high levels of DHFR.

The understanding of resistance to pemetrexed is incomplete. In various cell lines, resistance to this agent seems to arise from loss of influx transport, TS amplification, changes in purine biosynthetic pathways, or loss of polyglutamation.

**Absorption, Fate, and Excretion.** Methotrexate is readily absorbed from the GI tract at doses of  $<25 \text{ mg/m}^2$ , but larger doses are absorbed incompletely and are routinely administered intravenously. Peak concentrations of 1-10  $\mu\text{M}$  in the plasma are obtained after doses of 25-100  $\text{mg/m}^2$ , and concentrations of 0.1-1 mM are achieved after high-dose infusions of 1.5-20  $\text{g/m}^2$ . After intravenous administration, the drug disappears from plasma in a triphasic fashion (Sonneveld et al., 1986). The rapid distribution phase is followed by a second phase, which reflects renal clearance ( $t_{1/2}$  of  $\sim 2$ -3 hours). A third phase has a  $t_{1/2}$  of  $\sim 8$ -10 hours. This terminal phase of disappearance, if unduly prolonged by renal failure, may be responsible for major toxic effects of the drug on the marrow, GI epithelium, and skin. Distribution of methotrexate into body spaces, such as the pleural or peritoneal cavity, occurs slowly. However, if such spaces are expanded (e.g., by ascites or pleural effusion), they may act as a site of storage and slow release of the drug, resulting in prolonged elevation of plasma concentrations and more severe bone marrow toxicity.

Approximately 50% of methotrexate binds to plasma proteins and may be displaced from plasma albumin by a number of drugs, including sulfonamides, salicylates, tetracycline, chloramphenicol, and phenytoin; caution should be used if these drugs are given concomitantly. Up to 90% of a given dose is excreted unchanged in the urine within 48 hours, mostly

within the first 8-12 hours. Metabolism of methotrexate in humans usually is minimal. After high doses, however, metabolites are readily detectable; these include 7-hydroxy-methotrexate, which is potentially nephrotoxic. Renal excretion of methotrexate occurs through a combination of glomerular filtration and active tubular secretion. Therefore, the concurrent use of drugs that reduce renal blood flow (e.g., nonsteroidal anti-inflammatory agents), that are nephrotoxic (e.g., cisplatin), or that are weak organic acids (e.g., aspirin, piperacillin) can delay drug excretion and lead to severe myelosuppression. Particular caution must be exercised in treating patients with renal insufficiency. In such patients, the dose should be adjusted in proportion to decreases in renal function, and high-dose regimens should be avoided.

Methotrexate is retained in the form of polyglutamates for long periods—for example, for weeks in the kidneys and for several months in the liver.

It is important to emphasize that concentrations of methotrexate in CSF are only 3% of those in the systemic circulation at steady state; hence, neoplastic cells in the CNS probably are not killed by standard dosage regimens. When high doses of methotrexate are given ( $>1.5 \text{ g/m}^2$ ; see “Therapeutic Uses”), cytotoxic concentrations of methotrexate reach the CNS.

Pharmacogenetics may influence the response to antifolates and their toxicity. The C677T substitution in methylenetetrahydrofolate reductase reduces the activity of the enzyme that generates methylenetetrahydrofolate, the cofactor for TS, and thereby increases methotrexate toxicity (Pullarkat et al., 2001). The presence of this polymorphism in leukemic cells confers increased sensitivity to methotrexate and might also modulate the toxicity and therapeutic effect of pemetrexed, a predominant TS inhibitor. Likewise, polymorphisms in the promoter region of TS govern the translation efficiency of this message and, by governing the intracellular levels of TS, modulate the response and toxicity of both antifolates (Pui et al., 2004) and fluoropyrimidines.

**Therapeutic Uses.** Methotrexate (Amethopterin; *RHEUMATREX*, *TREXALL*, others) has been used in the treatment of severe, disabling psoriasis in doses of 2.5 mg orally for 5 days, followed by a rest period of at least 2 days, or 10-25 mg intravenously weekly. It also is used at low dosage to induce remission in refractory rheumatoid arthritis (Hoffmeister, 1983). Awareness

of the pharmacology, toxic potential, and drug interactions associated with methotrexate is a prerequisite for its use in these non-neoplastic disorders.

Methotrexate is a critical drug in the management of acute lymphoblastic leukemia (ALL) in children. High-dose methotrexate is of great value in remission induction and consolidation and in the maintenance of remissions in this highly curable disease. A 6- to 24-hour infusion of relatively large doses of methotrexate may be employed every 2-4 weeks ( $\geq 1-7.5 \text{ g/m}^2$ ) but only when leucovorin rescue follows within 24 hours of the methotrexate infusion. Such regimens produce cytotoxic concentrations of drug in the CSF and protect against leukemic meningitis. For maintenance therapy, it is administered weekly in doses of  $20 \text{ mg/m}^2$  orally. Outcome of treatment in children correlates inversely with the rate of drug clearance. During methotrexate infusion, high steady-state levels are associated with a lower leukemia relapse rate (Pui et al., 2004). Methotrexate is of limited value in adults with AML, except for treatment and prevention of leukemic meningitis. The intrathecal administration of methotrexate has been employed for treatment or prophylaxis of meningeal leukemia or lymphoma and for treatment of meningeal carcinomatosis. This route of administration achieves high concentrations of methotrexate in the CSF and also is effective in patients whose systemic disease has become resistant to methotrexate. The recommended intrathecal dose in all patients  $>3$  years of age is 12 mg (Bleyer, 1978). The dose is repeated every 4 days until malignant cells no longer are evident in the CSF. Leucovorin may be administered to counteract the potential toxicity of methotrexate that escapes into the systemic circulation, although this generally is not necessary. Because methotrexate administered into the lumbar space distributes poorly over the cerebral convexities, the drug may be given via an intraventricular Ommaya reservoir in the treatment of active intrathecal disease. Methotrexate is of established value in choriocarcinoma and related trophoblastic tumors of women; cure is achieved in  $\sim 75\%$  of advanced cases treated sequentially with methotrexate and dactinomycin and in  $>90\%$  when early diagnosis is made. In the treatment of choriocarcinoma, 1 mg/kg of methotrexate is administered intramuscularly every other day for four doses, alternating with leucovorin (0.1 mg/kg every other day). Courses are repeated at 3-week intervals, toxicity permitting, and urinary  $\beta$ -human chorionic gonadotropin titers are used as a guide for persistence of disease.

Beneficial effects also are observed in the combination therapy of Burkitt's and other non-Hodgkin's lymphomas. Methotrexate is a component of regimens for carcinomas of the breast, head and neck, ovary, and bladder. High-dose methotrexate with leucovorin rescue (HDM-L) is a standard agent for adjuvant therapy of osteosarcoma and produces a high complete response rate in CNS lymphomas. The administration of HDM-L has the potential for renal toxicity, probably related to the precipitation of the drug, a weak acid, in the acidic tubular fluid. Thus, vigorous hydration and alkalinization of urine pH are required prior to drug administration. HDM-L should be performed only by experienced clinicians who are familiar with hydration regimens and who have access to laboratories that monitor concentrations of methotrexate in plasma. If methotrexate values measured 48 hours after drug administration are 1  $\mu\text{M}$  or higher, higher doses (100  $\text{mg}/\text{m}^2$ ) of leucovorin must be given until the plasma concentration of methotrexate falls to  $<50$  nM (Stoller et al., 1977). With appropriate hydration and urine alkalinization, and in patients with normal renal function, the incidence of nephrotoxicity following HDM-L is  $<2\%$ . In patients who become oliguric, intermittent hemodialysis is ineffective in reducing methotrexate levels. Continuous-flow hemodialysis can eliminate methotrexate at  $\sim 50\%$  of the clearance rate in patients with intact renal function (Wall et al., 1996). Alternatively, a methotrexate-cleaving enzyme, carboxypeptidase G2, can be obtained from the Cancer Therapy Evaluation Program at the National Cancer Institute. When administered intravenously, it rapidly clears the drug (DeAngelis et al., 1996). Methotrexate concentrations in plasma fall by  $\geq 99\%$  within 5-15 minutes following enzyme administration, with insignificant rebound. Systemically administered carboxypeptidase G2 has little effect on methotrexate levels in the CSF.

**Clinical Toxicities.** As previously stated, the primary toxicities of antifolates affect the bone marrow and the intestinal epithelium and correct within 10-14 days. Myelosuppressed patients may be at risk for spontaneous hemorrhage or life-threatening infection, and they may require prophylactic transfusion of platelets and broad-spectrum antibiotics if febrile. Side effects usually reverse completely within 2 weeks, but prolonged myelosuppression may occur in patients with compromised renal function who have delayed excretion of the drug. The dosage of methotrexate (and likely pemetrexed) must be reduced in proportion to any reduction in  $\text{CrCl}$ .

Additional toxicities of methotrexate include alopecia, dermatitis, an allergic interstitial pneumonitis, nephrotoxicity (after high-dose therapy), defective oogenesis or spermatogenesis, abortion, and teratogenesis. Low-dose methotrexate may lead to cirrhosis after long-term continuous treatment, as in patients with psoriasis. Intrathecal administration of methotrexate often causes meningismus and an inflammatory response in the CSF. Seizures, coma, and death may occur rarely. Leucovorin does not reverse neurotoxicity.

A toxicity of particular significance in chronic administration to patients with psoriasis or rheumatoid arthritis is hepatic fibrosis and cirrhosis. Increased hepatic portal fibrosis is detected with higher frequency than in control patients after  $\geq 6$  months of continuous oral methotrexate treatment of psoriasis. Its presence mandates discontinuation of methotrexate. High-dose administration regularly causes acute elevation of hepatic transaminases, but these changes rapidly reverse and are not associated with permanent liver damage.

Folic acid antagonists are toxic to developing embryos. Methotrexate is highly effective when used with the prostaglandin analog misoprostol in inducing abortion in first-trimester pregnancy (Hausknecht, 1995).

Pemetrexed toxicity mirrors that of methotrexate, with the additional feature of a prominent erythematous and pruritic rash in 40% of patients. Dexamethasone, 4 mg twice daily on days -1, 0, and +1, markedly diminishes this toxicity. Unpredictably severe myelosuppression with pemetrexed, seen especially in patients with pre-existing homocystinemia and possibly reflecting folate deficiency, largely is eliminated by concurrent administration of low dosages of folic acid, 350-1000 mg/day, beginning 1-2 weeks prior to pemetrexed and continuing while the drug is administered. Patients should receive intramuscular vitamin B<sub>12</sub> (1 mg) with the first dose of pemetrexed to correct possible B<sub>12</sub> deficiency. These small doses of folate and B<sub>12</sub> do not compromise the therapeutic effect.

## **PYRIMIDINE ANALOGS**

The antimetabolites as a class encompass a diverse group of drugs that inhibit RNA and DNA function. The fluoropyrimidines and certain purine analogs (6-mercaptopurine and 6-thioguanine) inhibit the synthesis of

essential precursors of DNA. Others, such as the cytidine and adenosine nucleoside analogs, become incorporated into DNA and block its further elongation and function. Other inhibitory effects of these analogs may contribute to their cytotoxicity and even their ability to induce differentiation.

To understand the role of these drugs, it is useful to review the nomenclature of the DNA bases and their metabolic intermediates. Four bases, shown in [Figure 61–7](#), form DNA; these are two pyrimidines, thymine and cytosine, and two purines, guanine and adenine. Some bases (guanine) are found in mammalian cells as free bases, while others (the pyrimidines) are present in their active form only as nucleosides (a base attached to a ribose or deoxyribose). These precursor forms then are converted to a nucleoside triphosphate (base, sugar, and 5'-phosphate, also known as a nucleotide). Mammalian cells lack the ability to utilize cytosine, thymine, and adenine as bases, and so these bases are found in the bloodstream as nucleosides and in cells as nucleosides or nucleotides. The various purine and pyrimidine triphosphates form the intracellular pool of precursors for both RNA (with ribose sugars) and DNA (with deoxyribose sugars). The composition of RNA also differs from DNA in that RNA incorporates uracil instead of thymine as one of its bases.

### Modification of Base

#### CYTOSINE

#### GUANINE

#### THYMINE

#### ADENINE

### Modification of Deoxyribose

**Figure 61–7.** *Structural modification of base and deoxyribonucleoside analogs.* The yellow ellipses indicate sites modified to create antimetabolites. The specific substitutions are indicated in red for each drug. Modifications occur in the base ring systems, in their amino or hydroxyl side groups, and in the deoxyribose sugar found in deoxyribonucleosides.

Strategies for inhibiting DNA synthesis are based on the ability to create analogs of these precursors that readily enter tumor cells and become activated by intracellular enzyme. As an example, the first successful pyrimidine analog, 5-FU, is converted to a deoxynucleotide, fluorodeoxyuridine monophosphate (FdUMP), which in turn blocks the enzyme; TS, required for the physiological conversion of dUMP to dTMP, a component of DNA. Other analogs incorporate into DNA itself and thereby block its function.

Cells can make the purine and pyrimidine bases *de novo* and convert them to their active triphosphates (dNTPs). The dNTPs then act as substrates for DNA polymerase and become linked in 3'-5' phosphate ester bonds to form DNA strands; their base sequence provides the code for subsequent RNA and protein sequences.

As an alternative to synthesis of new precursor molecules, cells can salvage either free bases or their deoxynucleosides ([Figure 61-7](#)) from the bloodstream, presumably the products of degradation of DNA. Certain bases, such as uracil, guanine, and their analogs, can be taken up by cells and converted intracellularly to (deoxy) nucleotides by the addition of deoxyribose and phosphate groups. Antitumor analogs of these bases (5-FU, 6-thioguanine) can be formulated as simple substituted bases. Other bases, including cytosine, thymine, and adenine, and their analogs can only be utilized as deoxynucleosides, which are readily transported into cells and activated to deoxynucleotides by intracellular kinases. Thus, cytarabine (cytosine arabinoside; Ara-C), gemcitabine, 5-azacytidine, and adenosine analogs (cladribine), are nucleosides readily taken up by cells, converted to nucleotides, and incorporated into DNA ([Figure 61-8](#)).

Fludarabine phosphate, a nucleotide, is dephosphorylated rapidly in plasma, releasing the nucleoside that is readily taken up by cells. Analogs may differ from the physiological bases in a variety of ways: by altering in the purine or pyrimidine ring; by altering the sugar attached to the base, as in the arabinoside, Ara-C; or by altering both the base and sugar, as in fludarabine phosphate ([Figure 61-7](#)). These alterations produce inhibitory effects on vital enzymatic pathways and prevent DNA synthesis.

## **Fluorouracil, Capecitabine, and Floxuridine (Fluorodeoxyuridine)**

5-fluorouracil (5-FU)

**Mechanism of Action.** 5-FU requires enzymatic conversion to the nucleotide status (ribosylation and phosphorylation) in order to exert its cytotoxic activity ([Figure 61–9](#)). Several routes are available for the formation of floxuridine monophosphate (FUMP). 5-FU may be converted to fluorouridine by uridine phosphorylase and then to FUMP by uridine kinase, or it may react directly with 5-phosphoribosyl-1-pyrophosphate (PRPP), as catalyzed by orotate phosphoribosyl transferase, to form FUMP. Further metabolic pathways are available to FUMP. As the triphosphate FUTP, it is incorporated into RNA. In an alternative reaction sequence crucial for antineoplastic activity, it is reduced to FUDP by ribonucleotide reductase (RNR) to the deoxynucleotide level and forming of FdUMP. 5-FU also may be converted by thymidine phosphorylase to the deoxyriboside fluorodeoxyuridine (FUdR) and then by thymidine kinase to FdUMP, a potent inhibitor of thymidylate synthesis. This complex metabolic pathway for the generation of FdUMP may be bypassed through administration of floxuridine (fluorodeoxyuridine; FUdR), which is converted directly to FdUMP by thymidine kinase. FUdR rarely is used in clinical practice.

FdUMP inhibits TS and blocks the synthesis of TTP, a necessary constituent of DNA ([Figure 61–10](#)). The folate cofactor, 5,10-methylenetetrahydrofolate, and FdUMP form a covalently bound ternary complex with TS. This inhibited complex resembles the transition state formed during the enzymatic conversion of dUMP to thymidylate. The physiological complex of TS-folate-dUMP progresses to the synthesis of thymidylate by transfer of the methylene group and two hydrogen atoms from

folate to dUMP, but this reaction is blocked in the inhibited complex of TS-FdUMP by the stability of the fluorine carbon bond on FdUMP; sustained inhibition of the enzyme results.

**Figure 61–8.** Structures of available pyrimidine analogs.

5-FU is incorporated into both RNA and DNA. In 5-FU-treated cells, both fluorodeoxyuridine triphosphate (FdUTP) and deoxyuridine triphosphate (dUTP) (the substrate that accumulates behind the blocked TS reaction) incorporate into DNA in place of the depleted physiological TTP. The significance of the incorporation of FdUTP and dUTP into DNA is unclear. Presumably, the incorporation of deoxyuridylate and/or fluorodeoxyuridylate into DNA would call into action the excision-repair process. This process may result in DNA strand breakage because DNA repair requires TTP, but this substrate is lacking as a result of TS inhibition. 5-FU incorporation into RNA also causes toxicity as the result of major effects on both the processing and functions of RNA.

**Figure 61–9.** Activation pathways for 5-fluorouracil (5-FU) and 5-floxuridine (FUR). FUDP, floxuridine diphosphate; FUMP, floxuridine monophosphate; FUTP, floxuridine triphosphate; FUdR, fluorodeoxyuridine; FdUDP, fluorodeoxyuridine diphosphate; FdUMP, fluorodeoxyuridine monophosphate; FdUTP, fluorodeoxyuridine triphosphate; PRPP, 5-phosphoribosyl-1-pyrophosphate.

**Figure 61–10.** Site of action of 5-fluoro-2'-deoxyuridine-5'-phosphate (5-FdUMP). 5-FU, 5-fluorouracil; dUMP, deoxyuridine monophosphate; TMP, thymidine monophosphate; TTP, thymidine triphosphate; FdUMP, fluorodeoxyuridine monophosphate; FH<sub>2</sub>Glu<sub>n</sub>, dihydrofolate polyglutamate; FH<sub>4</sub>Glu<sub>n</sub>, tetrahydrofolate polyglutamate.

Resistance to the cytotoxic effects of 5-FU or FUdR has been ascribed to loss or decreased activity of the enzymes necessary for activation of 5-FU, amplification of TS (Washteyn, 1982), mutation of TS to a form that is not inhibited by FdUMP (Barbour et al., 1990), and high levels of the degradative enzymes dihydrouracil dehydrogenase and thymidine

phosphorylase (Van Triest et al., 2000). TS levels are finely controlled by an autoregulatory feedback mechanism wherein the unbound enzyme interacts with and inhibits the translational efficiency of its own mRNA, which provides for the rapid TS modulation needed for cellular division. When TS is bound to FdUMP, inhibition of translation is relieved, and levels of free TS rise, restoring thymidylate synthesis. Thus, TS autoregulation may be an important mechanism by which malignant cells become insensitive to the effects of 5-FU (Chu et al., 1991).

Some malignant cells appear to have insufficient concentrations of 5,10-methylenetetrahydrofolate, and thus cannot form maximal levels of the inhibited ternary complex with TS. Addition of exogenous folate in the form of N<sup>5</sup>-formyl FH<sub>4</sub> (leucovorin) increases formation of the complex and enhances responses to 5-FU in clinical trials (Grogan et al., 1993).

In addition to leucovorin, a number of other agents have been combined with 5-FU in attempts to enhance the cytotoxic activity through biochemical modulation. Methotrexate, by inhibiting purine synthesis and increasing cellular pools of PRPP, enhances the activation of 5-FU and increases antitumor activity of 5-FU when given prior to but not following 5-FU. In clinical trials, the combination of cisplatin and 5-FU has yielded impressive responses in tumors of the upper aerodigestive tract, but the molecular basis of their interaction is not well understood. Oxaliplatin, which downregulates TS expression, is commonly used with 5-FU and leucovorin for treating metastatic colorectal cancer. Perhaps the most important interaction is the enhancement of irradiation by fluoropyrimidines, the basis for which is unclear. 5-FU with simultaneous irradiation cures anal cancer and enhances local tumor control in head and neck, cervical, rectal, gastroesophageal, and pancreatic cancer.

**Absorption, Fate, and Excretion.** 5-FU is administered parenterally, because absorption after oral ingestion of the drug is unpredictable and incomplete. Metabolic degradation occurs in many tissues, particularly the liver. 5-FU is inactivated by reduction of the pyrimidine ring in a reaction carried out by dihydropyrimidine dehydrogenase (DPD), which is found in liver, intestinal mucosa, tumor cells, and other tissues. Inherited deficiency of this enzyme leads to greatly increased sensitivity to the drug (Milano et al., 1999). The rare individual who totally lacks this enzyme may experience profound drug toxicity following conventional doses of the drug. DPD

deficiency can be detected either by enzymatic or molecular assays using peripheral white blood cells or by determining the plasma ratio of 5-FU to its metabolite, 5-fluoro-5,6-dihydrouracil.

Intravenous administration of 5-FU produces peak plasma concentrations of 0.1-0.5 mM; plasma clearance is rapid (with a  $t_{1/2}$  of 10-20 minutes). Only 5-10% of a single intravenous dose of 5-FU is excreted intact in the urine. Although the liver contains high concentrations of DPD, the dose does not have to be modified in patients with hepatic dysfunction, presumably because of degradation of the drug at extrahepatic sites. Given by continuous intravenous infusion for 24-120 hours, 5-FU achieves steady-state plasma concentrations in the range of 0.5-0.8  $\mu$ M. 5-FU enters the CSF in minimal amounts.

## Therapeutic Uses

**5-Fluorouracil.** 5-FU produces partial responses in 10-20% of patients with metastatic colon carcinomas, upper GI tract carcinomas, and breast carcinomas but rarely is used as a single agent. 5-FU in combination with leucovorin and oxaliplatin or irinotecan in the adjuvant setting is associated with a survival advantage for patients with colorectal cancers.

For average-risk patients in good nutritional status with adequate hematopoietic function, the weekly dosage regimen employs 500-600 mg/m<sup>2</sup> with leucovorin once each week for 6 of 8 weeks. Other regimens use daily doses of 500 mg/m<sup>2</sup> for 5 days, repeated in monthly cycles. When used with leucovorin, doses of daily 5-FU for 5 days must be reduced to 375-425 mg/m<sup>2</sup> because of mucositis and diarrhea. 5-FU increasingly is used as a biweekly infusion, in which a loading dose is followed by a 48-hour continuous infusion, a schedule that has less overall toxicity as well as superior response rates and progression-free survival for patients with metastatic colon cancer (De Gramont et al., 1998).

**Floxuridine (FUdR).** FUdR (fluorodeoxyuridine; *FUDR*, others) is used primarily by continuous infusion into the hepatic artery for treatment of metastatic carcinoma of the colon or following resection of hepatic metastases (Kemeny et al., 1999); the response rate to such infusion is 40-50%, or double that observed with intravenous administration.

Intrahepatic arterial infusion for 14-21 days causes minimal systemic toxicity; however, there is a significant risk of biliary sclerosis if this route is used for multiple cycles of therapy. Treatment should be discontinued at the earliest manifestation of toxicity (usually stomatitis or diarrhea) because the maximal effects of bone marrow suppression and gut toxicity will not be evident until days 7-14.

**Capecitabine (XELODA).** Capecitabine, an orally administered prodrug of 5-FU, is approved for the treatment of 1) metastatic breast cancer in patients who have not responded to a regimen of paclitaxel and an anthracycline antibiotic; 2) metastatic breast cancer when used in combination with docetaxel in patients who have had a prior anthracycline-containing regimen; and 3) metastatic colorectal cancer.

The recommended dosage is 2500 mg/m<sup>2</sup>/day, given in two divided doses with food, for 2 weeks, followed by a rest period of 1 week. Capecitabine is well absorbed orally. It is rapidly de-esterified and deaminated, yielding high plasma concentrations of an inactive prodrug 5'-deoxyfluorodeoxyuridine (5'-dFdU), which disappears with a t<sub>1/2</sub> of ~1 hour. The conversion of 5'-dFdU to 5-FU by thymidine phosphorylase occurs in liver tissues, peripheral tissues, and tumors. 5-FU levels are <10% of those of 5'-dFdU, reaching a maximum of 0.3 mg/L or 1 μM at 2 hours. Liver dysfunction delays the conversion of the parent compound to 5'-dFdU and 5-FU, but there is no consistent effect on toxicity (Twelves et al., 1999).

**Combination Therapy.** Higher response rates are seen when 5-FU or capecitabine is used in combination with other agents (e.g., with cisplatin in head and neck cancer, with oxaliplatin or irinotecan in colon cancer).

The combination of 5-FU and oxaliplatin or irinotecan has become the standard first-line treatment for patients with metastatic colorectal cancer, although equivalent results are reported for capecitabine and oxaliplatin. 5-FU in combination regimens has improved survival in the adjuvant treatment for breast cancer and, with oxaliplatin and leucovorin, for colorectal cancer. 5-FU also is a potent radiation sensitizer. Beneficial effects also have been reported when combined with irradiation as primary treatment for locally advanced cancers of the esophagus, stomach, pancreas, cervix, anus, and head and neck. 5-FU produces very favorable results for the topical treatment of premalignant keratoses of the skin and multiple superficial basal cell carcinomas.

**Clinical Toxicities.** The clinical manifestations of toxicity caused by 5-FU and floxuridine are similar. The earliest untoward symptoms during a course of therapy are anorexia and nausea, followed by stomatitis and diarrhea, which constitute reliable warning signs that a sufficient dose has been administered. Mucosal ulcerations occur throughout the GI tract and may lead to fulminant diarrhea, shock, and death, particularly in patients who are DPD deficient. The major toxic effects of bolus-dose regimens result from the myelosuppressive action of 5-FU. The nadir of leukopenia usually is between days 9 and 14 after the first injection of drug. Thrombocytopenia and anemia also may occur. Loss of hair, occasionally progressing to total alopecia, nail changes, dermatitis, and increased pigmentation and atrophy of the skin may be encountered. Hand-foot syndrome, a particularly prominent adverse effect of capecitabine, consists of erythema, desquamation, pain, and sensitivity to touch of the palms and soles. Acute chest pain with evidence of ischemia in the electrocardiogram may result from coronary artery vasospasms during or shortly after 5-FU infusion. In general, myelosuppression, mucositis, and diarrhea occur less often with infusional regimens than with bolus regimens, while hand-foot syndrome occurs more often with infusional regimens than with bolus regimens. The significant risk of toxicity with fluoropyrimidines emphasizes the need for very skillful supervision by physicians familiar with the action and possible hazards.

Capecitabine causes much the same spectrum of toxicities as 5-FU (diarrhea, myelosuppression), but the hand-foot syndrome occurs more frequently and may require dose reduction or cessation of therapy.

## CYTIDINE ANALOGS

### Cytarabine (Cytosine Arabinoside; Ara-C)

Cytarabine (1- $\beta$ -D-arabinofuranosylcytosine; Ara-C) is the most important antimetabolite used in the therapy of AML. It is the single most effective agent for induction of remission in this disease.

**Mechanism of Action.** Ara-C is an analog of 2'-deoxycytidine with the 2'-hydroxyl in a position *trans* to the 3'-hydroxyl of the sugar ([Figure 61-7](#)). The 2'-hydroxyl hinders rotation of the pyrimidine base around the nucleoside bond and interferes with base pairing. The drug enters cells via a nucleoside transporter and is converted to its active form, the 5'-

monophosphate ribonucleotide, by deoxycytidine kinase (CdK), an enzyme that shows polymorphic expression among patients, as detailed in the following paragraphs.

Ara-C penetrates cells by a carrier-mediated process shared by physiological nucleosides. Several candidate carriers bring nucleosides into cells, but the hENT1 transporter appears to be the primary mediator of Ara-C influx. In infants and adults with ALL and t(4;11) mixed-lineage leukemia (MLL) translocation, high-dose Ara-C is particularly effective; in these patients, the nucleoside transporter, hENT1, is highly expressed (Pui et al., 2004), and its expression correlates with sensitivity to Ara-C. A single-point mutation in hENT1 conferred Ara-C resistance in a leukemic cell line (Cai et al., 2008). At extracellular drug concentrations  $>10 \mu\text{M}$  (levels achievable with high-dose Ara-C), the nucleoside transporter no longer limits drug accumulation, and intracellular metabolism to a triphosphate becomes rate limiting.

Ara-C must be “activated” by conversion to the 5'-monophosphate nucleotide (Ara-CMP), a reaction catalyzed by CdK. Polymorphisms of CdK may influence the rate of activation in individual patients (Lamba et al., 2007). Ara-CMP then reacts with appropriate deoxynucleotide kinases to form diphosphate and triphosphates (Ara-CDP and Ara-CTP). Ara-CTP competes with the physiological substrate deoxycytidine 5'-triphosphate (dCTP) for incorporation into DNA by DNA polymerases. The incorporated Ara-CMP residue is a potent inhibitor of DNA polymerase, both in replication and repair synthesis, and blocks the further elongation of the nascent DNA molecule. The block in elongation activates checkpoint kinases (ATR and chk-1), which initiate attempts to remove the offending nucleotide. If DNA breaks are not repaired, apoptosis ensues. Ara-C cytotoxicity correlates with the total Ara-C incorporated into DNA. Thus, incorporation of about five molecules of Ara-C per  $10^4$  bases of DNA decreases cellular clonogenicity by  $\sim 50\%$  (Kufe et al., 1984).

Ara-C exposure activates a complex system of secondary intracellular signals that determine whether a cell survives or undergoes apoptosis. It activates the transcription factor AP-1 and stimulates the formation of ceramide, a potent inducer of apoptosis. It causes an increase in the cell damage response factor NF- $\kappa$ B in leukemic cells and activates checkpoint kinases. Additionally, the level of expression of the anti-apoptotic BCL-2

and BCL-X<sub>L</sub> proteins correlates inversely with relative sensitivity to Ara-C (Ibrado et al., 1996). Thus, the lethality depends on the complex interplay of multiple factors, including transport, intracellular metabolism, and cellular response to DNA damage.

Low concentrations of Ara-C induce terminal differentiation of leukemic cells in tissue culture, an effect that is accompanied by decreased *c-myc* oncogene expression; molecular analysis of bone marrow specimens from some leukemic patients in remission after Ara-C therapy has revealed persistence of leukemic markers, suggesting that differentiation may have occurred.

Continuous inhibition of DNA synthesis for a duration equivalent to at least one cell cycle or 24 hours is necessary to expose most tumor cells during the S, or DNA-synthetic, phase of the cycle. The optimal interval between bolus doses of Ara-C is ~8-12 hours, a schedule that maintains intracellular concentrations of Ara-CTP at inhibitory levels during a multi-day cycle of treatment. Typical schedules for administration of Ara-C employ bolus doses every 12 hours or continuous drug infusion for 5-7 days.

Particular subtypes of AML derive benefit from high-dose Ara-C treatment; these include t(8;21), inv(16), t(9;16), and del(16), all of which involve core-binding factors that regulate hematopoiesis (Widemann et al., 1997). Approximately 20% of AML patients have leukemic cells with a *k-RAS* mutation, and these patients seem to derive greater benefit from high dose Ara-C regimens than do patients with wild type *k-RAS* (Neubauer et al., 2008).

**Mechanisms of Resistance to Cytarabine.** Response to Ara-C is strongly influenced by the relative activities of anabolic and catabolic enzymes that determine the proportion of drug converted to Ara-CTP. The rate-limiting activating enzyme, CdK, produces Ara-CMP. It is opposed by the degradative enzyme, cytidine deaminase, which converts Ara-C to a nontoxic metabolite, ara-uridine (Ara-U). Cytidine deaminase activity is high in many normal tissues, including intestinal mucosa, liver, and neutrophils, but lower in AML cells and other human tumors. A second degradative enzyme, dCMP deaminase, converts Ara-CMP to the inactive metabolite, Ara-UMP. Increased synthesis and retention of Ara-CTP in leukemic cells leads to a longer duration of complete remission in patients with AML (Preisler et al., 1985). As discussed above, the ability of cells to transport Ara-C also may

affect response. Clinical studies have implicated a loss of deoxycytidine kinase as the primary Mechanisms of Resistance to Ara-C in AML (Cai et al., 2008), although 5' nucleotidase, which degrades Ara-CMP, and possibly cytidine deaminase elevations, may play a role in AML resistance to Ara-C.

**Absorption, Fate, and Excretion.** Due to the presence of high concentrations of cytidine deaminase in the GI mucosa and liver, only ~20% of the drug reaches the circulation after *oral* Ara-C administration; thus, the drug must be given intravenously. Peak concentrations of 2-50  $\mu\text{M}$  are measurable in plasma after intravenous injection of 30-300  $\text{mg}/\text{m}^2$  but disappear rapidly ( $t_{1/2}$  of 10 minutes) from plasma.

Less than 10% of the injected dose is excreted unchanged in the urine within 12-24 hours, while most appears as the inactive deaminated product, Ara-U. Higher concentrations of Ara-C are found in CSF after continuous infusion than after rapid intravenous injection, but are far lower ( $\leq 10\%$ ) than concentrations in plasma. After *intrathecal* administration of the drug at a dose of 50  $\text{mg}/\text{m}^2$ , deamination proceeds slowly, with a  $t_{1/2}$  of 3-4 hours, and peak concentrations of 1-2  $\mu\text{M}$  are achieved. CSF concentrations remain above the threshold for cytotoxicity (0.4  $\mu\text{M}$ ) for  $\geq 24$  hours. A depot liposomal formulation of Ara-C (DEPOCYT) provides sustained release into the CSF. After a standard 50-mg dose, liposomal Ara-C remains above cytotoxic levels for an average of 12 days, thus avoiding the need for frequent lumbar punctures (Cole et al., 2003).

**Therapeutic Uses.** Two dosage schedules are recommended for administration of cytarabine (CYTOSAR-U, TARABINE PFS, others): 1) rapid intravenous infusion of 100  $\text{mg}/\text{m}^2$  every 12 hours for 5-7 days or 2) continuous intravenous infusion of 100-200  $\text{mg}/\text{m}^2/\text{day}$  for 5-7 days. In general, children tolerate higher doses than adults. Intrathecal doses of 30  $\text{mg}/\text{m}^2$  every 4 days have been used to treat meningeal or lymphomatous leukemia. The intrathecal administration of 50 mg for adults (or 35 mg for children) of liposomal cytarabine (DEPOCYT) every 2 weeks seems equally effective as the every-4-days regimen with the standard drug.

Ara-C is indicated for induction and maintenance of remission in AML and is useful in the treatment of other leukemias, such as ALL, CML in the blast phase, acute promyelocytic leukemia, and high-grade lymphomas. Because drug concentration in plasma rapidly falls below the level needed to saturate

transport and intercellular activation, clinicians have employed high-dose regimens (2-3 g/m<sup>2</sup> every 12 hours for 6-8 doses) to achieve 20- to 50 times higher serum levels, with improved results in remission induction and consolidation for AML. Injection of the liposomal formulation is indicated for the intrathecal treatment of lymphomatous meningitis.

**Clinical Toxicities.** Cytarabine is a potent myelosuppressive agent capable of producing acute, severe leukopenia, thrombocytopenia, and anemia with striking megaloblastic changes. Other toxic manifestations include GI disturbances, stomatitis, conjunctivitis, reversible hepatic enzyme elevations, noncardiogenic pulmonary edema, and dermatitis.

Onset of dyspnea, fever, and pulmonary infiltrates on chest computed tomography scans may follow 1-2 weeks after high-dose Ara-C and may be fatal in 10-20% of patients, especially in patients being treated for relapsed leukemia (Forghieri et al., 2007). Infectious or other causes of pulmonary infiltrates must be excluded in evaluating such patients. No specific therapy, other than Ara-C discontinuation, is indicated. Intrathecal Ara-C, either the free drug or the liposomal preparation, may cause arachnoiditis, seizures, delirium, myelopathy, or coma, especially if given concomitantly with systemic high-dose methotrexate or systemic Ara-C (Jabbour et al., 2007).

Cerebellar toxicity, manifesting as ataxia and slurred speech, and cerebral toxicity (seizures, dementia, and coma) may follow intrathecal administration or high-dose systemic administration, especially in patients >40 years of age and/or patients with poor renal function.

## **Azacitidine (5-Azacytidine)**

5-Azacytidine ([Figure 61-8](#)) and the closely related decitabine (2'-deoxy-5-azacytidine) have antileukemic activity and induce differentiation by virtue of their inhibition of DNA cytosine methyltransferase activity. Both drugs are approved for treatment of myelodysplasia, for which they induce normalization of bone marrow in 15-20% of patients and reduce transfusion requirement in one-third of patients. 5-Azacytidine improves survival.

The aza-nucleosides enter cells by the human equilibrative transporter, the presence of which correlates with sensitivity of cell lines (Stresemann and Lyko, 2008). The drugs incorporate into DNA, where they become covalently bound to the methyltransferase through their N-5 position, depleting

intracellular enzyme and leading to global demethylation of DNA and tumor cell differentiation and apoptosis. Decitabine also induces double-strand DNA breaks, perhaps as a consequence of the effort to repair the protein-DNA adduct. The azacytidine ring spontaneously opens in alkaline solution and has greater stability ( $t_{1/2}$  of 7 hours) at neutral pH. After subcutaneous administration of the standard dose of  $75 \text{ mg/m}^2$ , 5-azacytidine achieves peak drug levels of  $10 \text{ }\mu\text{M}$  and undergoes very rapid deamination by cytidine deaminase (plasma  $t_{1/2}$  of 20-40 minutes), with the product hydrolyzing to inactive metabolites. Due to the formation of intracellular nucleotides, which become incorporated into DNA, the effects of the aza-nucleosides persist for many hours.

The major toxicities of the aza-nucleosides include myelosuppression and mild GI symptoms. 5-Azacytidine produces rather severe nausea and vomiting when given intravenously in large doses ( $150\text{-}200 \text{ mg/m}^2/\text{day}$  for 5 days). The usual regimen for 5-azacytidine in myelodysplastic syndrome (MDS) is  $75 \text{ mg/m}^2/\text{day}$  for 7 days every 28 days, while decitabine is given in a dose of  $20 \text{ mg}$  intravenously every day for 5 days every 4 weeks (Oki et al., 2007). Best responses may become apparent only after two to five courses of treatment.

## Gemcitabine

Gemcitabine (2',2'-difluorodeoxycytidine; dFdC) ([Figure 61–8](#)), a difluoro analog of deoxycytidine, has become an important drug for patients with metastatic pancreatic; non-squamous, non-small cell lung; ovarian; and bladder cancer.

**Mechanism of Action.** Gemcitabine is carried into cells by three distinct nucleoside transporters: hENT, hCNT, and a nucleobase transporter found in malignant mesothelioma cells. The hENT transporter appears to be the major carrier. Intracellularly, deoxycytidine kinase phosphorylates gemcitabine to produce difluorodeoxycytidine monophosphate (dFdCMP), from which point it is converted to difluorodeoxycytidine di- and triphosphate (dFdCDP and dFdCTP). Although gemcitabine's anabolism and effects on DNA in general mimic those of cytarabine, there are distinct differences in kinetics of inhibition, additional enzymatic sites of action, different effects of incorporation into DNA, and a distinct spectrum of clinical activity. Unlike

that of cytarabine, the cytotoxicity of gemcitabine is not confined to the S phase of the cell cycle, and the drug is equally effective against confluent cells and cells in logarithmic growth phase. The cytotoxic activity may be a result of several actions on DNA synthesis. dFdCTP competes with dCTP as a weak inhibitor of DNA polymerase. dFdCDP is a stoichiometric inhibitor of RNR (Wang et al., 2007). It forms a complex with the RNR subunits and with ATP, resulting in depletion of deoxyribonucleotide pools necessary for DNA synthesis. Most important, dFdCTP incorporates into DNA and, after the incorporation of one more nucleotide, causes DNA strand termination (Heinemann et al., 1988). This “extra” nucleotide may be important in hiding the dFdCTP from DNA repair enzymes, as the incorporated dFdCMP appears resistant to repair. The ability of cells to incorporate dFdCTP into DNA is critical for gemcitabine-induced apoptosis. Gemcitabine is inactivated by cytidine deaminase, which is found both in tumor cells and throughout the body.

Preliminary evidence suggests that response to gemcitabine in pancreatic carcinoma tumors correlates positively with high expression of hENT (Giovannetti et al., 2006) and low expression of subunits of RNR, but resistance is found in tumors with low levels of deoxycytidine kinase and high levels of cytidine deaminase, the inactivating enzyme (Ohhashi et al., 2008). In mouse tumors, forced expression of the HMGA1 transcription factor also caused gemcitabine resistance (Liau and Whang, 2008), possibly through its effect on Akt-dependent survival pathways.

**Absorption, Fate, and Elimination.** Gemcitabine is administered as an intravenous infusion. The pharmacokinetics of the parent compound are largely determined by deamination in liver, plasma, and other organs, and the predominant urinary elimination product is difluorodeoxyuridine (dFdU). Although dFdU has modest toxicity at the usual concentrations found in plasma, in patients with significant renal dysfunction, dFdU and its triphosphate accumulate to high and potentially toxic levels (Koolen et al., 2009). Gemcitabine has a short plasma  $t_{1/2}$  of ~15 minutes, with women and elderly patients clearing the drug more slowly (Abbruzzese et al., 1991). Peak levels reach 20-60  $\mu\text{M}$  with doses of 1000  $\text{mg}/\text{m}^2$  given over 30 minutes intravenously. Clearance can vary widely among individuals but is not affected by renal failure.

Similar to that of cytarabine, conversion of gemcitabine to dFdCMP by deoxycytidine kinase is saturated at infusion rates of  $\sim 10 \text{ mg/m}^2/\text{min}$ , which produce plasma drug concentrations of  $\sim 10\text{-}20 \text{ }\mu\text{M}$ . In an attempt to increase dFdCTP formation, the duration of infusion at this maximum concentration has been extended to 100-150 minutes at a fixed rate of  $10 \text{ mg/min}$ . The 150-minute infusion produces a higher level of dFdCTP within peripheral blood mononuclear cells and increases the degree of myelosuppression but does not improve antitumor activity (Gandhi, 2007). The inhibition of DNA repair by gemcitabine may increase cytotoxicity of other agents, particularly platinum compounds, and with radiation therapy. Preclinical studies of tumor cell lines show that gemcitabine enhances formation of cisplatin-DNA adducts, presumably through suppression of nuclear excision repair.

**Therapeutic Uses.** The standard dosing schedule for gemcitabine (GEMZAR) is a 30-minute intravenous infusion of  $1\text{-}1.25 \text{ g/m}^2$  on days 1, 8, and 15 of each 21- to 28-day cycle, depending on the indication.

**Clinical Toxicities.** The principal toxicity of gemcitabine is myelosuppression. Longer-duration infusions lead to greater myelosuppression and hepatic toxicity. Nonhematological toxicities include a flu-like syndrome, asthenia, and rarely a posterior leukoencephalopathy syndrome. Mild elevation in liver transaminases may occur in  $\geq 40\%$  of patients and are reversible. Interstitial pneumonitis, at times progressing to acute respiratory distress syndrome (ARDS), may occur within the first two cycles of treatment and usually responds to corticosteroids. Rarely, patients on gemcitabine treatment for many months may develop a slowly progressive hemolytic uremic syndrome, necessitating drug discontinuation (Humphreys et al., 2004). Gemcitabine is a very potent radiosensitizer, likely the result of its inhibition of RNR, depletion of dATP, and inhibition of DNA repair (Flanagan et al., 2007) and should not be used with radiotherapy except in closely monitored clinical trials.

## PURINE ANALOGS

The pioneering studies of Hitchings and Elion begun in 1942 who identified analogs of naturally occurring purine bases with antileukemic and immunosuppressant properties. Their work led to the development of drugs not only for treatment of malignant diseases (mercaptopurine, thioguanine) but also for immunosuppression in auto-immune disease and organ

transplantation (azathioprine) and antiviral chemotherapy (acyclovir, ganciclovir, vidarabine, zidovudine) ([Figure 61–11](#)). The hypoxanthine analog allopurinol, a potent inhibitor of xanthine oxidase, is an important byproduct of this effort (see [Chapter 34](#)). Other purine analogs have valuable roles in cancer therapy. These include pentostatin (2'-deoxycoformycin), the first effective agent against hairy cell leukemia, cladribine (standard therapy for hairy cell leukemia), fludarabine phosphate (standard treatment for CLL), nelarabine (pediatric ALL), and clofarabine (T-cell leukemia/lymphoma). The apparent preferential activity of these agents in lymphoid malignancies may relate to their effective uptake, activation, and apoptotic effects in lymphoid tissue.

## 6-Thiopurine Analogs

6-Mercaptopurine (6-MP) and 6-thioguanine (6-TG) are approved agents for human leukemias and function as analogs of the natural purines, hypoxanthine and guanine. The substitution of sulfur for oxygen on C6 of the purine ring creates compounds that are readily transported into cells, including activated malignant cells. Nucleotides formed from 6-MP and 6-TG inhibit *de novo* purine synthesis and also become incorporated into nucleic acids. The structural formula of 6-MP and other purine analogs is shown in [Figure 61–11](#).

**Figure 61–11.** Structural formulas of adenosine and various purine analogs.

**Mechanism of Action.** Both 6-TG and 6-MP are excellent substrates for hypoxanthine guanine phosphoribosyl transferase (HGPRT) and are converted in a single step to the ribonucleotides 6-thioguanosine-5'-monophosphate (6-thioGMP) and 6-thioinosine-5'-monophosphate (T-IMP), respectively. Because T-IMP is a poor substrate for guanylyl kinase, the enzyme that converts guanosine monophosphate (GMP) to guanosine diphosphate (GDP), T-IMP accumulates intracellularly and in a second step is converted to 6-TGMP. T-IMP inhibits the new formation of ribosyl-5-

phosphate, as well as conversion of inosine-5'-monophosphate (IMP) to adenine and guanine nucleotides. Of these, the most important point of attack seems to be the reaction of glutamine and PRPP to form ribosyl-5-phosphate, the first committed step in the *de novo* pathway. 6-Thioguanine nucleotide is incorporated into DNA, where it induces strand breaks and base mispairing. Strand breaks depend on the presence of an intact MMR system, the absence of which leads to resistance.

**Mechanisms of Resistance to the Thiopurine Antimetabolites.** The most common mechanism of 6-MP resistance observed *in vitro* is deficiency or complete lack of the activating enzyme, HGPRT, or increased alkaline phosphate activity. Other mechanisms for resistance include 1) decreased drug uptake, or increased efflux due to one of several active transporters; 2) alteration in allosteric inhibition of ribosylamine 5-phosphate synthase; and 3) impaired recognition of DNA breaks and mismatches due to loss of a component (MSH6) of MMR (Karran and Attard, 2008; Cahill et al., 2007).

***Mercaptopurine Pharmacokinetics and Toxicity.*** Absorption of mercaptopurine is incomplete (10-50%) after oral ingestion; the drug is subject to first-pass metabolism by xanthine oxidase in the liver. Food or oral antibiotics decrease absorption. Oral bioavailability is increased when mercaptopurine is combined with high-dose methotrexate.

After an intravenous dose, the  $t_{1/2}$  of the drug in plasma is relatively short (~50 minutes in adults), due to rapid metabolic degradation by xanthine oxidase and by thiopurine methyltransferase (TPMT). Restricted brain distribution of mercaptopurine results from an efficient efflux transport system in the blood-brain barrier. In addition to the HGPRT-catalyzed anabolism of mercaptopurine, there are two other pathways for its metabolism. The first involves methylation of the sulfhydryl group and subsequent oxidation of the methylated derivatives. Activity of the enzyme TPMT reflects the inheritance of polymorphic alleles; up to 15% of the Caucasian population has decreased enzyme activity. Low levels of erythrocyte TPMT activity are associated with increased drug toxicity in individual patients and a lower risk of relapse (Pui et al., 2004). In patients with auto-immune disease treated with mercaptopurine, those with polymorphic alleles may experience bone marrow aplasia and life-threatening toxicity. Testing for these polymorphisms prior to treatment is recommended in this patient population.

High concentrations of 6-methylmercaptapurine nucleotides are formed in white blood cells and bone marrow following 6-MP administration. They are less potent than 6-MP nucleotides as metabolic inhibitors, and their significance in contributing to the activity of 6-MP is not known.

A relatively large percentage of the administered sulfur appears in the urine as inorganic sulfate, the result of enzymatic desulfuration. The second major pathway for 6-MP metabolism involves its oxidation by xanthine oxidase to 6-thiouric acid, an inactive metabolite. Oral doses of 6-MP should be reduced by 75% in patients receiving the xanthine oxidase inhibitor, allopurinol. No dose adjustment is required for intravenous dosing.

**Therapeutic Uses.** In the maintenance therapy of ALL, the initial daily oral dose of mercaptopurine (6-MP; *PURINETHOL*, others) is 50-100 mg/m<sup>2</sup> and is thereafter adjusted according to white blood cell and platelet count. The combination of methotrexate and 6-MP appears to be synergistic. By inhibiting the earliest steps in purine synthesis, methotrexate elevates the intracellular concentration of PRPP, a cofactor required for 6-MP activation.

**Clinical Toxicities.** The principal toxicity of 6-MP is bone marrow depression, although in general, this side effect develops more gradually than with folic acid antagonists; accordingly, thrombocytopenia, granulocytopenia, or anemia may not become apparent for several weeks. When depression of normal bone marrow elements occurs, dose reduction usually results in prompt recovery, although myelosuppression may be severe and prolonged in patients with a polymorphism affecting TPMT. Anorexia, nausea, or vomiting is seen in ~25% of adults, but stomatitis and diarrhea are rare; manifestations of GI effects are less frequent in children than in adults. Jaundice and hepatic enzyme elevations occur in up to one-third of adult patients treated with 6-MP and usually resolve upon discontinuation of therapy. Their appearance has been associated with bile stasis and hepatic necrosis on biopsy. 6-MP and its derivative, azathioprine, predispose to opportunistic infection such as reactivation of hepatitis B, fungal infection, and *Pneumocystis* pneumonia and an increased incidence of squamous cell malignancies of the skin. 6-MP has teratogenic effects during the first trimester of pregnancy, and AML has been reported after prolonged 6-MP therapy for Crohn's disease (Heizer and Peterson, 1998).

## **Fludarabine Phosphate**

This compound is a fluorinated, deamination-resistant, phosphorylated analog of the antiviral agent vidarabine (9-β-D-arabinofuranosyl-adenine). It is active in CLL and low-grade lymphomas. It has found important uses as a cytotoxic drug and as a potent immunosuppressant.

After rapid extracellular dephosphorylation to the nucleoside fludarabine, it is rephosphorylated intracellularly by deoxycytidine kinase to the active triphosphate derivative. This antimetabolite inhibits DNA polymerase, DNA primase, DNA ligase, and RNR and becomes incorporated into DNA and RNA. The nucleotide is an effective chain terminator when incorporated into DNA (Kamiya et al., 1996), and the incorporation of fludarabine into RNA inhibits RNA function, RNA processing, and mRNA translation (Plunkett and Gandhi, 1993).

In experimental tumors, resistance to fludarabine is associated with decreased activity of deoxycytidine kinase (the enzyme that phosphorylates the drug) (Mansson et al., 2003), increased drug efflux, and increased RNR activity. Its mechanism of immunosuppression and paradoxical stimulation of auto-immunity stems from the particular susceptibility of lymphoid cells to purine analogs and the specific effects on the CD4<sup>+</sup> subset of T cells, as well as its inhibition of regulatory T-cell responses.

**Absorption, Fate, and Excretion.** Fludarabine phosphate is administered both intravenously and orally and rapidly converts to fludarabine in the plasma. The median time to reach maximal concentrations of drug in plasma after oral administration is 1.5 hours, and oral bioavailability averages 55-

60%. The terminal  $t_{1/2}$  of fludarabine in plasma is ~10 hours. The compound is primarily (40-50%) eliminated by renal excretion.

**Therapeutic Uses.** Fludarabine phosphate (FLUDARA, OFORTA) is approved for intravenous and oral use and is equally active by both routes (Forconi et al., 2008). The recommended dose of fludarabine phosphate is 25 mg/m<sup>2</sup> daily for 5 days by intravenous infusion, or 40 mg/m<sup>2</sup> daily for 5 days by mouth. The drug is administered intravenously over 30 minutes to 2 hours. Dosage should be reduced in patients with renal impairment in proportion to the reduction in CrCl. Treatment may be repeated every 4 weeks, and gradual improvement in CLL usually occurs within two to three cycles.

Fludarabine phosphate is highly active alone or with rituximab and cyclophosphamide for the treatment of patients with CLL. Activity in CLL as a single agent is equal by either the oral or intravenous routes, as overall response rates in previously untreated patients approximate 80% and the duration of response averages 22 months. The synergy of fludarabine with alkylators may stem from the observation that it blocks the repair of double-strand DNA breaks and interstrand cross-links induced by alkylating agents. It also is effective in follicular B-cell lymphomas refractory to standard therapy. It is increasingly used as a potent immunosuppressive agent in nonmyeloablative allogeneic bone marrow transplantation, where it suppresses the host response and may encourage alloreactive donor T cells.

**Clinical Toxicities.** Oral and intravenous therapy cause myelosuppression (World Health Organization grade 3 or 4) in about half of patients, nausea and vomiting in a minor fraction, and uncommonly chills and fever, malaise, anorexia, peripheral neuropathy, and weakness. Lymphopenia and thrombocytopenia and cumulative side effects are expected. Depletion of CD4<sup>+</sup> T cells with therapy predisposes to opportunistic infections. Tumor lysis syndrome, a relatively infrequent complication, occurs primarily in previously untreated patients with CLL. Altered mental status, seizures, optic neuritis, and coma have been observed at higher doses and in older patients.

Auto-immune events may occur after fludarabine treatment. CLL patients may develop an acute hemolytic anemia or pure red cell aplasia during or following fludarabine treatment. Prolonged cytopenias, probably mediated by auto-immunity, also complicate fludarabine treatment. Myelodysplasia and acute leukemias may arise as late complications (Tam et al., 2008).

Pneumonitis is an occasional side effect and responds to corticosteroids. Because a significant fraction of drug is eliminated in the urine, patients with compromised renal function should be treated with caution, and initial doses should be reduced in proportion to the reduction in CrCl.

## Cladribine

An adenosine deaminase-resistant purine analog, cladribine (2-chlorodeoxyadenosine; 2-CdA), has potent and probably curative activity in hairy cell leukemia, CLL, and low-grade lymphomas. It is taken up by active nucleoside transport. After intracellular phosphorylation by deoxycytidine kinase and conversion to cladribine triphosphate, it is incorporated into DNA. It produces DNA strand breaks and depletion of NAD and ATP, leading to apoptosis. It is a potent inhibitor of RNR. The drug does not require cell division to be cytotoxic. Resistance is associated with loss of the activating enzyme, deoxycytidine kinase; increased expression of RNR (Cardoen et al., 2001); or increased active efflux by ABCG2 or other members of the ABC cassette family of transporters (de Wolf et al., 2008).

**Absorption, Fate, and Excretion.** Cladribine is moderately well absorbed orally (55%) but is routinely administered intravenously. The drug is excreted by the kidneys, with a terminal  $t_{1/2}$  in plasma of 6.7 hours (Liliemark and Juliusson, 1991). Cladribine crosses the blood-brain barrier and reaches CSF concentrations of ~25% of those seen in plasma. Doses should be adjusted for renal dysfunction.

**Therapeutic Uses.** Cladribine (LEUSTATIN, others) is administered as a single course of 0.09 mg/kg/day for 7 days by continuous intravenous infusion.

Cladribine is considered the drug of choice in hairy cell leukemia. Eighty percent of patients achieve a complete response after a single course of therapy. The drug also is active in CLL; low-grade lymphomas; Langerhans cell histiocytosis; CTCLs, including mycosis fungoides and the Sézary syndrome; and Waldenström macroglobulinemia.

**Clinical Toxicities.** The major dose-limiting toxicity of cladribine is myelosuppression. Cumulative thrombocytopenia may occur with repeated courses. Opportunistic infections are common and correlate with decreased CD4<sup>+</sup> cell counts. Other toxic effects include nausea, infections, high fever, headache, fatigue, skin rashes, and tumor lysis syndrome.

## **Clofarabine (2-Chloro-2'-Fluoro-Arabinosyladenine)**

This analog resulted from incorporating the 2-chloro, glycosylase-resistant substituent of cladribine and a 2'-fluoro-arabinosyl substitution, which further strengthens stability and enhances uptake and phosphorylation. The resulting compound is approved for pediatric ALL after failure of two prior therapies.

For these patients, it produces complete remissions in 20-30 % of patients. It has activity as well in pediatric and adult AML and in myelodysplasia. Its uptake and metabolic activation in tumor cells follow the same path as cladribine and the other purine nucleosides, although it is more readily phosphorylated by dCK. It incorporates into DNA, where it terminates DNA synthesis and leads to apoptosis.

**Absorption, Fate, and Distribution.** Clofarabine triphosphate has a long intracellular  $t_{1/2}$  of 24 hours. Its antitumor activity is ascribed to its incorporation into DNA, resulting in chain termination. Like fludarabine, clofarabine inhibits RNR (Bonate et al., 2006). In children, following administration of usual doses of 52 mg/m<sup>2</sup> given as a 2-hour infusion daily for 5 days, clofarabine has a primary elimination  $t_{1/2}$  in plasma of 6.5 hours, and the majority of drug is excreted unchanged in the urine. Doses should be adjusted according to reductions in CrCl, although precise guidelines are not available.

**Clinical Toxicities.** The primary toxicities are myelosuppression; a clinical syndrome of hypotension, tachypnea, pulmonary edema, organ dysfunction, and fever, all suggestive of capillary leak syndrome and cytokine release; elevated hepatic enzymes and increased bilirubin; nausea, vomiting, and diarrhea; and hypokalemia and hypophosphatemia. Evidence of capillary leak should lead to immediate discontinuation of the drug.

## Nelarabine (6-Methoxy-Arabinosyl-Guanine)

The only guanine nucleoside in clinical use, this agent has selective activity against acute T-cell leukemia (20% complete responses) and the closely related T-cell lymphoblastic lymphoma and is approved for use in relapsed/refractory patients. Its basic mechanism of action closely resembles that of the other purine nucleosides, in that it is incorporated into DNA and terminates DNA synthesis. It has selective toxicity for T lymphocytes and T-cell malignancies.

**Absorption, Fate, and Distribution.** Following infusion, the parent methoxy compound is rapidly activated in blood and tissues by adenosine deaminase-mediated cleavage of the methyl group, yielding the phosphorylase resistant Ara-G, which has a longer plasma  $t_{1/2}$  of 3 hours. The active metabolite is transported into tumor cells, where it is activated by CdK to the monophosphate and thence to a triphosphate. Ara-G triphosphate (Ara-GTP) is incorporated into DNA and terminates DNA synthesis (Sanford and Lyseng-Williamson, 2008). The drug and its metabolite, Ara-G, are primarily

eliminated by metabolism to guanine, and a smaller fraction is eliminated by renal excretion of Ara-G. The dose should not be adjusted for mild to moderate ( $\text{CrCl} > 50 \text{ mg/mL}$ ) renal dysfunction (Sanford and Lyseng-Williamson, 2008), but the drug should be used with close clinical monitoring in patients with more severe renal impairment. Adults are given a dose of  $1500 \text{ mg/m}^2$  intravenously as a 2-hour infusion on days 1, 3, and 5 of a 21-day cycle, and children are given a lower dose of  $650 \text{ mg/m}^2/\text{day}$  intravenously for 5 days and repeated every 21 days.

**Clinical Toxicities.** Side effects include myelosuppression and liver function test abnormalities, as well as frequent, serious neurological sequelae, such as seizures, delirium, somnolence, peripheral neuropathy, or Guillain-Barré syndrome. Neurological side effects may not be reversible.

## **Pentostatin (2'-Deoxycoformycin)**

Pentostatin (2'-deoxycoformycin; see [Figure 61–11](#)), a transition-state analog of the intermediate in the adenosine deaminase (ADA) reaction, potently inhibits ADA. Its effects mimic the phenotype of genetic ADA deficiency (severe immunodeficiency affecting both T- and B-cell functions). It was isolated from fermentation cultures of *Streptomyces antibioticus*. Inhibition of ADA by pentostatin leads to accumulation of intracellular adenosine and deoxyadenosine nucleotides, which can block DNA synthesis by inhibiting RNR. Deoxyadenosine also inactivates *S*-adenosyl homocysteine hydrolase. The resulting accumulation of *S*-adenosyl homocysteine is particularly toxic to lymphocytes. Pentostatin also can inhibit RNA synthesis, and its triphosphate derivative is incorporated into DNA, resulting in strand breakage. Although the precise mechanism of cytotoxicity is not known, it is probable that the imbalance in purine nucleotide pools accounts for its antineoplastic effect in hairy cell leukemia and T-cell lymphomas.

**Absorption, Fate, and Excretion.** Pentostatin is administered intravenously, and a single dose of  $4 \text{ mg/m}^2$  has a mean terminal  $t_{1/2}$  of 5.7 hours. The drug is eliminated almost entirely by renal excretion. Proportional reduction of dosage is recommended in patients with renal impairment as measured by reduced  $\text{CrCl}$ .

**Therapeutic Uses.** The recommended dose is  $4 \text{ mg/m}^2$  administered every other week intravenously. After hydration with 500-1000 mL of 5% dextrose

in half-normal (0.45%) saline, the drug is administered by rapid intravenous injection or by infusion over a period of  $\leq 30$  minutes, followed by an additional 500 mL of fluids.

Pentostatin is extremely effective in producing complete remissions (58%) and partial responses (28%) in hairy cell leukemia (Grever et al., 2003). It largely has been superseded by cladribine.

**Clinical Toxicities.** Toxic manifestations include myelosuppression, GI symptoms, skin rashes, and abnormal liver function studies. Depletion of normal T cells occurs, and neutropenic fever and opportunistic infections may result. Immunosuppression may persist for several years after discontinuation of pentostatin therapy. At high doses ( $10 \text{ mg/m}^2$ ), major renal and neurological complications are encountered. Pentostatin in combination with fludarabine phosphate may result in severe or even fatal pulmonary toxicity.

### III. Natural Products

#### MICROTUBULE-DAMAGING AGENTS

Several anticancer agents act through the microtubules, either causing disorganized stabilization of microtubules in areas away from the centriole or causing destabilization of the mitotic spindle, interfering with mitosis. The vinca alkaloids are effective in the treatment of hematological malignancies, breast, germ cell, and lung cancers, whereas the taxanes have become leading agents in the treatment of ovarian, breast, head and neck, and lung cancers. A new class of agents, the epothilones, resembles the taxanes in their action but has limited cross-resistance with taxanes; the only approved epothilone in the U.S., ixabepilone, is indicated for metastatic breast cancer.

#### VINCA ALKALOIDS

**History.** The beneficial properties of the Madagascar periwinkle plant, *Catharanthus roseus* (formerly called *Vinca rosea*), a species of myrtle, have been described in medicinal folklore. Periwinkle extracts attracted interest because of their hypoglycemic effects in diabetes. Purified alkaloids, including vinblastine and vincristine, caused regression of an acute lymphocytic leukemia in mice and were among the earliest clinical agents for

treatment of leukemias, lymphomas, and testicular cancer. A closely related derivative, vinorelbine, has important activity against lung and breast cancer.

**Chemistry.** The vinca alkaloids are asymmetrical dimeric compounds formed by condensation of the vindoline and catharanthine subunits.

	$R_1$	$R_2$	$R_3$
<b>Structure A</b>			
VINBLASTINE	$-\text{CH}_3$	$-\text{C}(=\text{O})-\text{OCH}_3$	$-\text{O}-\text{C}(=\text{O})-\text{CH}_3$
VINCRISTINE	$-\text{CH}=\text{O}$	$-\text{C}(=\text{O})-\text{OCH}_3$	$-\text{O}-\text{C}(=\text{O})-\text{CH}_3$
VINDESINE	$-\text{CH}_3$	$-\text{C}(=\text{O})-\text{NH}_2$	$-\text{OH}$
<b>Structure B</b>			
VINORELBINE	$-\text{CH}_3$	$-\text{C}(=\text{O})-\text{OCH}_3$	$-\text{O}-\text{C}(=\text{O})-\text{CH}_3$

**Mechanism of Action.** The vinca alkaloids are cell-cycle-specific agents and, in common with other drugs such as colchicine, podophyllotoxin, the taxanes, and the epothilones, block cells in mitosis. The biological activities of the vincas can be explained by their ability to bind specifically to  $\beta$  tubulin and to block its polymerization with  $\alpha$  tubulin into microtubules.

When cells are incubated with vinblastine, the microtubules dissolve and highly regular crystals form, containing 1 mole of bound vinblastine per mole of tubulin. Cell division arrests in metaphase. In the absence of an intact mitotic spindle, duplicated chromosomes cannot align along the division plate. They disperse throughout the cytoplasm (exploded mitosis) or may clump in unusual groupings, such as balls or stars. Cells blocked in mitosis undergo changes characteristic of apoptosis.

In addition to their key role in the formation of mitotic spindles, microtubules are found in high concentration in the brain and contribute to other cellular functions such as movement, phagocytosis, and axonal transport. Side effects of the vinca alkaloids, such as their neurotoxicity, may relate to disruption of these functions.

**Drug Resistance.** Despite their structural similarity, the vinca alkaloids have unique individual patterns of clinical effectiveness (see the individual vinca alkaloid sections). However, in most experimental systems, they share cross-resistance. Their antitumor effects are blocked by multidrug resistance mediated by the *mdr* gene and its glycoprotein. Tumor cells become cross-resistant to a wide range of chemically dissimilar agents (the vinca alkaloids, epipodophyllotoxins, anthracyclines, and taxanes). Chromosomal abnormalities consistent with gene amplification have been observed in resistant cells in culture, and the cells contain markedly increased levels of the P-glycoprotein, a membrane efflux transporter (Endicott and Ling, 1989).  $Ca^{2+}$  channel blockers such as verapamil can reverse resistance of this type *in vitro*; however, clinical trials of resistance-reversing agents have been disappointing. Other membrane transporters, such as the MRP and the closely related breast cancer resistance protein, may mediate multidrug resistance. Still other forms of resistance to vinca alkaloids stem from mutations in  $\beta$  tubulin or in the relative expression of isoforms of  $\beta$  tubulin; both changes prevent the inhibitors from effectively binding to their target.

**Cytotoxic Actions.** The very limited myelosuppressive action of vincristine makes it a valuable component of several combination therapy regimens for leukemia and lymphoma, while the lack of severe neurotoxicity of vinblastine is a decided advantage in lymphomas and in combination with cisplatin against testicular cancer. Vinorelbine, which causes a mild neurotoxicity as well as myelosuppression, has an intermediate toxicity profile. Vincristine is a standard component of regimens for treating pediatric leukemias,

lymphomas, and solid tumors, such as Wilms tumor, neuroblastoma, and rhabdomyosarcoma. In large-cell non-Hodgkin's lymphomas, vincristine remains an important agent, particularly when used in the CHOP regimen with cyclophosphamide, doxorubicin, and prednisone. Vinblastine is employed in treating bladder cancer, testicular carcinomas, and Hodgkin's disease. Vinorelbine has activity against non-small cell lung cancer and breast cancer.

**Absorption, Fate, and Excretion.** The liver cytochromes extensively metabolize all three agents, and the metabolites are excreted in the bile (Robieux et al., 1996). Only a small fraction of a dose (<15%) is found in the urine unchanged. In patients with hepatic dysfunction (bilirubin >3 mg/dL), a 50-75% reduction in dose of any of the vinca alkaloids is advisable, although firm guidelines for dose adjustment have not been established. The pharmacokinetics of each of the three drugs are similar, with an elimination  $t_{1/2}$  of 20 hours for vincristine, 23 hours for vinblastine, and 24 hours for vinorelbine.

## Vinblastine

**Therapeutic Uses.** Vinblastine sulfate (VELBAN, others) is given intravenously; special precautions must be taken against subcutaneous extravasation, because this may cause painful irritation and ulceration. The drug should not be injected into an extremity with impaired circulation. After a single dose of 0.3 mg/kg of body weight, myelosuppression reaches its maximum in 7-10 days. If a moderate level of leukopenia ( $\sim 3000$  cells/mm<sup>3</sup>) is not attained, the weekly dose may be increased gradually by increments of 0.05 mg/kg of body weight. In regimens designed to cure testicular cancer, vinblastine is used in doses of 0.3 mg/kg every 3 weeks. Doses should be reduced by 50% for patients with plasma bilirubin >1.5 mg/dL.

One important clinical use of vinblastine is with bleomycin and cisplatin (see "Therapeutic Uses" under "Bleomycin") in the curative therapy of metastatic testicular tumors, although it has been supplanted by etoposide or ifosfamide in this disease. It is a component of the standard curative regimen for Hodgkin's disease [doxorubicin (ADRIAMYCIN), bleomycin, vinblastine, and dacarbazine (ABVD)]. It also is active in Kaposi sarcoma, neuroblastoma, Langerhans cell histiocytosis, carcinoma of the breast, and choriocarcinoma.

**Clinical Toxicities.** The nadir of the leukopenia that follows the administration of vinblastine usually occurs within 7-10 days, after which recovery ensues within 7 days. Other toxic effects of vinblastine include mild neurological manifestations. GI disturbances including nausea, vomiting, anorexia, and diarrhea may be encountered. The syndrome of inappropriate secretion of antidiuretic hormone has been reported. Loss of hair, stomatitis, and dermatitis occur infrequently. Extravasation during injection may lead to cellulitis and phlebitis.

## Vincristine

**Therapeutic Uses.** Vincristine sulfate (VINCASAR PFS, others) used together with glucocorticoids is the treatment of choice to induce remissions in childhood leukemia and in combination with alkylating agents and anthracycline for pediatric sarcomas; the common intravenous dosage for vincristine is  $2 \text{ mg/m}^2$  of body surface area at weekly or longer intervals. Vincristine seems to be tolerated better by children than by adults, who may experience severe, progressive neurological toxicity and require a lower dose of  $1.4 \text{ mg/m}^2$ . Administration of the drug more frequently than every 7 days or at higher doses increases the toxic manifestations without proportional improvement in the response rate. Precautions also should be used to avoid extravasation during intravenous administration of vincristine. Doses should be reduced by 50% or 75% for patients with plasma bilirubin  $>1.5 \text{ mg/dL}$  or  $>3 \text{ mg/dL}$ , respectively.

**Clinical Toxicities.** The clinical toxicity of vincristine is mostly neurological. Early sensory changes do not warrant dose reduction. The more severe neurological manifestations may be avoided or reversed by either suspending therapy or reducing the dosage upon first evidence of motor dysfunction. Severe constipation, sometimes resulting in colicky abdominal pain and obstruction, may be prevented by a prophylactic program of laxatives and hydrophilic (bulk-forming) agents and usually is a problem only with doses  $>2 \text{ mg/m}^2$ .

Alopecia occurs in ~20% of patients given vincristine; however, the alopecia is always reversible, frequently without cessation of therapy. Modest leukopenia may follow vincristine administration. Thrombocytopenia, anemia, GI cholic and obstipation, and the syndrome of inappropriate secretion of antidiuretic hormone are less common adverse

effects. Inadvertent injection of vincristine into the CSF causes a devastating and often fatal irreversible coma and seizures (Williams et al., 1983). CSF exchange has averted a fatal outcome in anecdotal reports.

## Vinorelbine

Vinorelbine (NAVELBINE, others) is administered in normal saline as an intravenous infusion over 6-10 minutes. When used alone, it is given at doses of 30 mg/m<sup>2</sup> either weekly or for 2 out of every 3 weeks. When used with cisplatin for the treatment of non-small cell lung cancer, it is given at doses of 25 mg/m<sup>2</sup> either weekly or for 3 out of every 4 weeks. A lower dose (20-25 mg/m<sup>2</sup>) may be required for patients who have received prior chemotherapy, and dosage adjustment is necessary for hematological toxicity. Its primary toxicity is granulocytopenia, with only modest thrombocytopenia and less neurotoxicity than other vinca alkaloids. Vinorelbine may cause allergic reactions and mild, reversible changes in liver enzymes. An oral formulation of vinorelbine is active in non-small cell lung carcinoma, and phase III studies are ongoing (Krzakowski et al., 2008). Similar to the other vincas, doses should be reduced by 50% or 75% in patients with plasma bilirubin 2.1-3 mg/dL or >3 mg/dL, respectively.

## TAXANES

The first compound of this series, paclitaxel (TAXOL, others), was isolated from the bark of the Western yew tree in 1971 and presented significant problems in formulation because of its poor aqueous solubility. It was reformulated and approved by the U.S. Food and Drug Administration (FDA) in 2005 as an albumin-bound nanoparticle solution for infusion (nab-paclitaxel, *ABRAXANE*). Paclitaxel and its congeneric, the semisynthetic docetaxel (TAXOTERE), exhibit unique pharmacological properties as inhibitors of mitosis, differing from the vinca alkaloids and colchicine derivatives in that they bind to a different  $\beta$ -tubulin site and promote rather than inhibit microtubule formation. The taxanes have a central role in the therapy of ovarian, breast, lung, GI, genitourinary, and head and neck cancers (Rowinsky and Donehower, 1995).

**Chemistry.** Paclitaxel is a diterpenoid compound that contains a complex eight-member taxane ring as its nucleus ([Figure 61-12](#)). The side chain

linked to the taxane ring at C13 is essential for its antitumor activity. Modification of the side chain has led to identification of the more potent analog, docetaxel ([Figure 61–12](#)), which shares the same spectrum of clinical activity as paclitaxel, but differs in its toxicity. Originally purified as the parent molecule from yew bark, paclitaxel now can be obtained for commercial purposes by semisynthesis from 10-desacetylbaccatin, a precursor found in yew needles. It also has been successfully synthesized (Nicolaou et al., 1994) in a complex series of reactions. Paclitaxel has very limited water solubility and is administered in a vehicle of 50% ethanol and 50% polyethoxylated castor oil (CREMOPHOR EL); this vehicle likely is responsible for a high rate of hypersensitivity reactions. Patients receiving this formulation are protected by pretreatment with a histamine H<sub>1</sub>-receptor antagonist such as diphenhydramine, an H<sub>2</sub>-receptor antagonist such as cimetidine (see [Chapter 32](#)), and a glucocorticoid such as dexamethasone (see [Chapter 42](#)).

Nab-paclitaxel is soluble in aqueous solutions and can be administered safely without prophylactic antihistamines or steroids. This form of paclitaxel has increased cellular uptake via an albumin-specific mechanism.

Docetaxel, somewhat more soluble than paclitaxel, is administered in polysorbate 80 and is associated with a lower incidence of hypersensitivity reactions than paclitaxel dissolved in *CREMOPHOR*. However, pretreatment with dexamethasone for 3 days starting 1 day prior to therapy is required to prevent progressive fluid retention and minimize the severity of hypersensitivity reactions.

**Figure 61–12.** Chemical structures of paclitaxel and its more potent analog, docetaxel.

**Mechanism of Action.** Interest in paclitaxel was stimulated by the drug's unique ability to promote microtubule formation at cold temperatures and in the absence of GTP. It binds specifically to the  $\beta$ -tubulin subunit of microtubules and antagonizes the disassembly of this key cytoskeletal protein, with the result that bundles of microtubules and aberrant structures derived from microtubules appear in the mitotic phase of the cell cycle. Arrest in mitosis follows. Cell killing is dependent on both drug concentration and duration of cell exposure. Drugs that block cell-cycle progression prior to mitosis antagonize the toxic effects of taxanes.

Drug interactions have been noted; the sequence of cisplatin preceding paclitaxel decreases paclitaxel clearance and produces greater toxicity than the opposite schedule (Rowinsky and Donehower, 1995). Paclitaxel decreases doxorubicin clearance and enhances cardiotoxicity, while docetaxel has no apparent effect on anthracycline pharmacokinetics.

In cultured tumor cells, resistance to taxanes is associated in some lines with increased expression of the *mdr-1* gene and its product, P-glycoprotein;

other resistant cells have  $\beta$ -tubulin mutations, and these latter cells may display heightened sensitivity to vinca alkaloids (Cabral, 1983). Other resistant cell lines display an increase in survivin, an anti-apoptotic factor,  $\alpha$  aurora kinase, an enzyme that promotes completion of mitosis. The taxanes preferentially bind to the  $\beta$ II-tubulin subunit of microtubules; therefore, cells may become resistant by upregulating the  $\beta$ III-isoform of tubulin (Ranganathan et al., 1998). The basis of clinical drug resistance is not known. Cell death occurs by apoptosis, but the effectiveness of paclitaxel against experimental tumors does not depend on an intact p53 gene product.

Preclinical studies have suggested that nab-paclitaxel has an increased antitumor effect in breast cancer and a higher intratumoral drug concentration compared to cremophor-delivered paclitaxel. The reasons are not clear but may relate to maintenance of the drug in the nanoparticle micellar system or to increased expression of SPARC [Secreted Protein, Acidic and Rich in Cysteine; aka osteonectin, a matri-cellular linkage protein expressed in pro-fibrotic states and linked to myriad pathologies [Kos and Wilding, 2010; Chlenski and Cohn, 2010]] on tumor cells, leading to an increased drug uptake.

**Absorption, Fate, and Excretion.** Paclitaxel is administered as a 3-hour infusion of 135-175 mg/m<sup>2</sup> every 3 weeks or as a weekly 1-hour infusion of 80-100 mg/m<sup>2</sup>. Prolonged infusions (96 hours) also have been evaluated in different tumor histologies and are active. The drug undergoes extensive metabolism by hepatic CYPs (primarily CYP2C8 with a contribution of CYP3A4); <10% of a dose is excreted in the urine intact. The primary metabolite identified thus far is 6-OH paclitaxel, which is inactive, but multiple additional hydroxylation products are found in plasma (Cresteil et al., 1994).

Paclitaxel clearance is nonlinear and decreases with increasing dose or dose rate. In studies of 96-hour infusions of 140 mg/m<sup>2</sup> (35 mg/m<sup>2</sup>/day), the presence of hepatic metastases >2 cm in diameter decreased clearance and led to high drug concentrations in plasma and greater myelosuppression. Paclitaxel disappears from the plasma compartment with a  $t_{1/2}$  of 10-14 hours and a clearance of 15-18 L/hr/m<sup>2</sup>. The critical plasma concentration for inhibiting bone marrow elements depends on duration of exposure but likely lies at ~50-100 nM (Huizing et al., 1993).

Nab-paclitaxel achieves a higher serum concentration of paclitaxel compared to *CREMOPHOR*-solubilized paclitaxel, but the increased clearance of nab-paclitaxel results in a similar drug exposure (Gardner et al., 2008). Nab-paclitaxel is most often administered intravenously over 30 minutes at 260 mg/m<sup>2</sup> every 3 weeks; however, alternate dosing regimens are being evaluated. Like the other taxanes, nab-paclitaxel should not be given to patients with an absolute neutrophil count <1500 cells/mm<sup>3</sup>. Docetaxel pharmacokinetics are similar to those of paclitaxel, with an elimination t<sub>1/2</sub> of ~12 hours. Clearance is primarily through CYP3A4- and CYP3A5-mediated hydroxylation, leading to inactive metabolites (Clarke and Rivory, 1999). In contrast to paclitaxel, the pharmacokinetics of docetaxel are linear for doses ≤115 mg/m<sup>2</sup>.

Dose reductions in patients with abnormal hepatic function have been suggested, and 50-75% doses of taxanes should be used in the presence of hepatic metastases >2 cm in size or in patients with abnormal serum bilirubin. Drugs that induce CYP2C8 or CYP3A4, such as phenytoin and phenobarbital, or those that inhibit the same cytochromes, such as antifungal imidazoles, significantly alter drug clearance and toxicity.

Paclitaxel clearance is markedly delayed by cyclosporine A and a number of other drugs employed experimentally as inhibitors of the P-glycoprotein. This inhibition may be due to a block of CYP-mediated metabolism or effects on biliary excretion of the parent drug or metabolites.

**Therapeutic Uses.** The taxanes have become central components of regimens for treating metastatic ovarian, breast, lung, GI, genitourinary, and head and neck cancers. In current regimens, these drugs are administered once weekly or once every 3 weeks. The appropriate use of the steroid-sparing nab-paclitaxel still is being evaluated in clinical trials; in a randomized phase III study comparing 175 mg/m<sup>2</sup> of paclitaxel to 260 mg/m<sup>2</sup> of nab-paclitaxel in women with metastatic breast cancer, the nab-paclitaxel arm had a higher response rate and longer time to progression compared to the paclitaxel arm (Gradishar et al., 2005).

**Clinical Toxicities.** Paclitaxel exerts its primary toxic effects on the bone marrow. Neutropenia usually occurs 8-11 days after a dose and reverses rapidly by days 15-21. Used with filgrastim [granulocyte-colony stimulating factor (G-CSF)], doses as high as 250 mg/m<sup>2</sup> over 24 hours are well

tolerated, and peripheral neuropathy becomes dose limiting. Many patients experience myalgias for several days after receiving paclitaxel. In high-dose schedules, or with prolonged use, a stocking-glove sensory neuropathy can be disabling, particularly in patients with underlying diabetic neuropathy or concurrent cisplatin therapy. Mucositis is prominent in 72- or 96-hour infusions and in the weekly schedule.

Hypersensitivity reactions occurred in patients receiving paclitaxel infusions of short duration (1-6 hours) but have largely been averted by pretreatment with dexamethasone, diphenhydramine, and histamine H<sub>2</sub>-receptor antagonists, as noted above. Premedication is not necessary with 96-hour infusions. Many patients experience asymptomatic bradycardia, and occasional episodes of silent ventricular tachycardia also occur and resolve spontaneously during 3- or 24-hour infusions.

Nab-paclitaxel produces increased rates of peripheral neuropathy compared to *CREMOPHOR*-delivered paclitaxel but rarely causes hypersensitivity reactions.

Docetaxel causes greater degrees of neutropenia than paclitaxel but less peripheral neuropathy and asthenia and less frequent hypersensitivity. Fluid retention is a progressive problem with multiple cycles of docetaxel therapy, leading to peripheral edema, pleural and peritoneal fluid, and pulmonary edema in extreme cases. Oral dexamethasone, 8 mg/day, begun 1 day prior to drug infusion and continuing for 3 days, greatly ameliorates fluid retention. In rare cases, docetaxel may cause a progressive interstitial pneumonitis, with respiratory failure supervening if the drug is not discontinued (Read et al., 2002).

## **ESTRAMUSTINE**

Estramustine (EMCYT) is a combination of estradiol coupled to normustine (nornitrogen mustard) through a carbamate link. Estramustine has weaker estrogenic and antineoplastic activity than estradiol and other alkylating agents. Although the intent of the combination was to enhance the uptake of the alkylating agent into estradiol-sensitive prostate cancer cells, estramustine does not function *in vivo* as an alkylating agent but rather binds to  $\beta$  tubulin and microtubule-associated proteins, causing microtubule disassembly and antimitotic actions.

Estramustine is used solely for the treatment of metastatic or locally advanced hormone refractory prostate cancer (Kitamura, 2001) at an initial dosage of 14 mg/kg/day in three or four divided doses.

**Absorption, Fate, and Excretion.** Following oral administration, at least 75% of a dose of estramustine is absorbed from the GI tract and rapidly dephosphorylated. Estramustine undergoes extensive first-pass metabolism by CYP1A2 and CYP3A4 to an active oxidized 17-keto derivative, estramustine, and to multiple inactive products; both active forms accumulate in the prostate. Some hydrolysis of the carbamate linkage occurs in the liver, releasing estradiol, estrone, and the normustine group. Estramustine and estromustine have a plasma  $t_{1/2}$  of 10 and 14 hours, respectively, and are excreted as inactive metabolites, mainly in the feces (Bergenheim and Henriksson, 1998). Estramustine inhibits the clearance of taxanes.

**Clinical Toxicities.** In addition to myelosuppression, estramustine also possesses estrogenic side effects (gynecomastia, impotence, elevated risk of thrombosis, and fluid retention), hypercalcemia, acute attacks of porphyria, impaired glucose tolerance, and hypersensitivity reactions, including angioedema.

## EPOTHILONES

Microtubule-damaging compounds are limited by difficulties in formulation, drug delivery, and susceptibility to multidrug resistance. A new group of microtubule-targeting drugs, the epothilones, overcomes these problems in experimental systems. Several epothilones currently are in various stages of clinical development. Ixabepilone (IXEMPRA) is approved for breast cancer treatment. Others in the pipeline include the epothilone B analogs patupilone (EPO906) and 21-aminoepothilone B (BMS-310705), the epothilone D analog KOS-1584 (R1645), and the synthetic sagopilone.

**Chemistry.** The epothilones are 16-membered polyketides discovered as cytotoxic metabolites from a strain of *Sorangium cellulosum*, a myxobacterium originally isolated from soil on the bank of the Zambezi River in southern Africa (Gerth et al., 1996).

Six natural epothilones (A-F), and synthetic and semisynthetic analogs are in various stages of development (Lee and Swain, 2008). Most trials of

epothilones to date have evaluated compounds of the subtypes A, B, and D, which differ in their functional groups at carbon 12.

Initial studies of the natural epothilone compounds A, B, and D showed good *in vitro* cytotoxic activity at nanomolar concentrations, epothilone B having roughly twice the potency as epothilones A and D (Lee and Swain, 2008). The early *in vivo* activity in animals, however, was disappointing due to instability of their lactone ring. Modification of epothilone B by substituting a nitrogen for the lactone oxygen yielded ixabepilone, which is not susceptible to esterases.

**Mechanism of Action.** The epothilones resemble taxanes in that they bind to  $\beta$  tubulin and trigger microtubule nucleation at multiple sites away from the centriole. This chaotic microtubule stabilization triggers cell-cycle arrest at the G2-M interface and apoptosis. Epothilones bind to a site distinct from that of taxanes. In colon cancer cell lines, p53 and Bax trigger apoptosis in ixabepilone-treated cells.

*In vitro* studies suggest that ixabepilone is less susceptible to P-glycoprotein-mediated multidrug resistance when compared to taxanes. Other mechanisms implicated in epothilone resistance include mutation of the  $\beta$ -tubulin binding site and upregulation of isoforms of  $\beta$  tubulin.

**Absorption, Distribution, and Excretion.** Ixabepilone is administered intravenously. Because of its minimal aqueous solubility, it is delivered in the solubilizing agent, polyoxyethylated castor oil/ethanol (CREMOPHOR EL). CREMOPHOR has been implicated as the cause of infusion reactions associated with paclitaxel and with other drug formulations, but such reactions are infrequent when administration is preceded by premedication with H<sub>1</sub> and H<sub>2</sub>

antagonists. The drug is cleared by hepatic CYPs and has a plasma  $t_{1/2}$  of 52 hours.

**Therapeutic Uses.** In a phase III study for registration, patients with metastatic breast cancer resistant to or pretreated with anthracyclines and resistant to taxanes had an improved progression-free survival of 1.6 months with ixabepilone plus capecitabine compared to capecitabine alone ( $p = .0003$ ) (Thomas et al., 2007).

Ixabepilone also is indicated as monotherapy for metastatic breast cancer in patients who have previously progressed through treatment with anthracyclines, taxanes, and capecitabine.

The recommended dose of ixabepilone as monotherapy or in combination with capecitabine is 40 mg/m<sup>2</sup> administered over 3 hours every 3 weeks. Note that because of additive myelosuppression, the phase III trial used an attenuated dose of capecitabine (2000 mg/m<sup>2</sup>) administered with ixabepilone compared to 2500 mg/m<sup>2</sup> when capecitabine was administered alone. Patients should be premedicated with both an H<sub>1</sub> and H<sub>2</sub> antagonist before receiving ixabepilone to minimize hypersensitivity reactions.

The combination of ixabepilone and capecitabine is contraindicated in patients with a baseline neutrophil count <1500 cells/mm<sup>3</sup>, a platelet count <100,000 cells/mm<sup>3</sup>, serum transaminases >2.5 × ULN or bilirubin above normal. In patients receiving ixabepilone monotherapy with mild to moderate hepatic dysfunction (bilirubin <1.5 × ULN or 1.5-3 × ULN, respectively), starting doses of 32 and 20 mg/m<sup>2</sup> are recommended due to delayed drug clearance.

**Toxicities.** Epothilones have toxicities similar to those of the taxanes, namely neutropenia peripheral sensory neuropathy, fatigue, diarrhea, and asthenia. Grade 3/4 peripheral sensory neuropathy was seen in 21% of patients receiving combined therapy with ixabepilone and capecitabine and in 14% of patients receiving monotherapy. Ixabepilone in combination with capecitabine causes a 68% rate of grade 3/4 neutropenia; it causes a 54% rate of grade 3/4 neutropenia when given as monotherapy.

## CAMPTOTHECIN ANALOGS

The camptothecins are potent, cytotoxic antineoplastic agents that target the nuclear enzyme topoisomerase I. The lead compound in this class, camptothecin, was isolated from the Chinese tree *Camptotheca acuminata* in 1966. Initial efforts to develop the compound as a sodium salt were compromised by severe and unpredictable toxicity, principally myelosuppression and hemorrhagic cystitis. Elucidation of the mechanism of action and a better understanding of its physicochemical properties during the 1980s led to the development of more soluble and less toxic analogs. Irinotecan and topotecan, currently the only camptothecin analogs approved for clinical use, have activity in colorectal, ovarian, and small cell lung cancer.

**Chemistry.** All camptothecins have a fused five-ring backbone that includes a labile lactone ring ([Figure 61–13](#)). The hydroxyl group and S-conformation of the chiral center at C20 in the lactone ring are required for biological activity. Appropriate substitutions on the A and B rings of the quinoline subunit enhance water solubility and increase potency for inhibiting topoisomerase I. Topotecan [(S)-9-dimethylaminoethyl-10-hydroxycamptothecin hydrochloride] is a semisynthetic molecule with a basic dimethylamino group that increases its water solubility. Irinotecan (7-ethyl-10-[4-(1-piperidino)-1-piperidino] carbonyloxycamptothecin, or CPT-11) differs from topotecan in that it is a prodrug. The carbamate bond between the camptothecin moiety and the dibasic bispiperidine side chain at position C10 (which makes the molecule water soluble) is cleaved by a carboxylesterase to form the active metabolite, SN-38 (see [Chapter 6](#)).

	<u>C-10</u>	<u>C-9</u>	<u>C-7</u>
Camptothecin	H	H	H
Topotecan	OH	(CH <sub>3</sub> ) <sub>2</sub> NHCH <sub>2</sub>	H
Irinotecan		H	CH <sub>2</sub> CH <sub>3</sub>
SN-38	OH	H	CH <sub>2</sub> CH <sub>3</sub>

**Figure 61–13.** Chemical structures of camptothecin and its analogs.

**Mechanism of Action.** The DNA topoisomerases are nuclear enzymes that reduce torsional stress in supercoiled DNA, allowing selected regions of DNA to become sufficiently untangled and relaxed to permit replication, repair, and transcription. Two classes of topoisomerase (I and II) mediate DNA strand breakage and resealing, and both have become the target of cancer chemotherapies. Camptothecin analogs inhibit the function of topoisomerase I, while a number of different chemical entities (e.g., anthracyclines, epipodophyllotoxins, acridines) inhibit topoisomerase II. Topoisomerase I binds covalently to double-stranded DNA through a reversible transesterification reaction. This reaction yields an intermediate complex in which the tyrosine of the enzyme is bound to the 3'-phosphate end of the DNA strand, creating a single-strand DNA break. This “cleavable complex” allows for relaxation of the DNA torsional strain, either by passage of the intact single-strand through the nick or by free rotation of the DNA about the noncleaved strand. Once the DNA torsional strain has been relieved, the topoisomerase I reseals the cleavage and dissociates from the newly relaxed double helix.

The camptothecins bind to and stabilize the normally transient DNA-topoisomerase I cleavable complex. Although the initial cleavage action of topoisomerase I is not affected, the re-ligation step is inhibited, leading to the accumulation of single-stranded breaks in DNA. These lesions are reversible

and not by themselves toxic to the cell. However, the collision of a DNA replication fork with this cleaved strand of DNA causes an irreversible double-strand DNA break, ultimately leading to cell death (Tsao et al., 1993). Camptothecins are therefore S phase-specific drugs, because ongoing DNA synthesis is necessary for cytotoxicity. This has important clinical implications. S phase-specific cytotoxic agents generally require prolonged exposures of tumor cells to drug concentrations above a minimum threshold to optimize therapeutic efficacy. In fact, preclinical studies of low-dose, protracted administration of camptothecin analogs have less toxicity, and equal or greater antitumor activity, than shorter, more intense courses.

The precise sequence of events that leads from drug-induced DNA damage to cell death has not been fully elucidated. *In vitro*, camptothecin-induced DNA damage abolishes the activation of the p34<sup>cdc2</sup>/cyclin B complex, leading to cell-cycle arrest at the G2 phase (Tsao et al., 1993). Treatment with camptothecins can induce the transcription of *c-fos* and *c-jun* early-response genes, and this occurs in association with internucleosomal DNA fragmentation, a characteristic of programmed cell death.

**Mechanisms of Resistance.** A variety of mechanisms of resistance to topoisomerase I-targeted agents have been characterized *in vitro*, although little is known about their significance in the clinical setting. Decreased intracellular drug accumulation may underlie resistance in cell lines. Topotecan, but not SN-38 or irinotecan, is a substrate for P-glycoprotein. However, the clinical relevance of P-glycoprotein-mediated efflux as a Mechanism of Resistance against topotecan remains unclear, as the magnitude of the effect in preclinical studies was found to be substantially lower than that observed with other MDR substrates, such as etoposide or doxorubicin. Other reports have associated topotecan and irinotecan resistance with the MRP class of transporters (Miyake et al., 1999). Cell lines that lack carboxylesterase activity demonstrate resistance to irinotecan (Van Ark-Otte et al., 1998), but in patients, the liver and red blood cells may have sufficient carboxylesterase activity to convert irinotecan to SN-38. Camptothecin resistance also may result from decreased expression or mutation of topoisomerase I. Although a good correlation has been found in certain tumor cell lines between sensitivity to camptothecin analogs and topoisomerase I levels (Sugimoto et al., 1990), clinical studies have not confirmed this association. Chromosomal deletions or hypermethylation of

the topoisomerase I gene are possible mechanisms of decreased topoisomerase I expression in resistant cells. A transient downregulation of topoisomerase I has been demonstrated following prolonged exposure to camptothecins *in vitro* and *in vivo*. Mutations leading to reduced topoisomerase I enzyme catalytic activity or DNA-binding affinity have been associated with experimental camptothecin resistance (Tamura et al., 1991). In addition, enzyme phosphorylation or polyADP ribosylation may reduce the activity of topoisomerase I and its susceptibility to inhibition. Finally, exposure of cells to topoisomerase I-targeted agents upregulates topoisomerase II, an alternative enzyme for DNA strand passage.

Very little is known about how the cell deals with the stabilized DNA-topoisomerase complexes. Cellular repair processes may not readily recognize the drug-enzyme-DNA complex. However, an enzyme with specific tyrosyl-DNA phosphodiesterase activity may be involved in the disassembly of topoisomerase I-DNA complexes (Yang et al., 1996).

### **Absorption, Fate, and Excretion**

**Topotecan.** Topotecan is approved for intravenous administration. However, there has been interest in developing an oral dosage form for the drug, which has a bioavailability of 30-40% in cancer patients. Topotecan exhibits linear pharmacokinetics, and it is rapidly eliminated from systemic circulation. The biological  $t_{1/2}$  of total topotecan, which ranges from 3.5-4.1 hours, is relatively short compared to that of other camptothecins. Only 20-35% of the total drug in plasma is found to be in the active lactone form. Within 24 hours, 30-40% of the administered dose appears in the urine. Doses should be reduced in proportion to reductions in CrCl. Although several oxidative metabolites have been identified, hepatic metabolism appears to be a relatively minor route of drug elimination. Unlike most other camptothecins considered for clinical development, plasma protein binding of topotecan is low, at only 7-35%, which may explain its relatively greater CNS penetration.

**Irinotecan.** The conversion of irinotecan to SN-38 is mediated predominantly by carboxylesterases in the liver. Although SN-38 can be measured in plasma shortly after beginning an intravenous infusion of irinotecan, the AUC of SN-38 is only ~4% of the AUC of irinotecan, suggesting that only a relatively small fraction of the dose is ultimately

converted to the active form of the drug. Irinotecan exhibits linear pharmacokinetics at doses evaluated in cancer patients. In comparison to topotecan, a relatively large fraction of both irinotecan and SN-38 are present in plasma as the biologically active intact lactone form. Another potential advantage of this analog is that the  $t_{1/2}$  of SN-38 is 11.5 hours, which is much longer than the  $t_{1/2}$  of topotecan. CSF penetration of SN-38 in humans has not been characterized yet, although in rhesus monkeys, it is only 14%, significantly lower than that observed for topotecan.

In contrast to topotecan, hepatic metabolism represents an important route of elimination for both irinotecan and SN-38. Oxidative metabolites have been identified in plasma, all of which result from CYP3A-mediated reactions directed at the bispiperidine side chain. These metabolites are not significantly converted to SN-38. The total body clearance of irinotecan was found to be two times greater in brain cancer patients taking antiseizure drugs that induce hepatic CYPs, further attesting to the importance of oxidative hepatic metabolism as a route of elimination for this drug (Gilbert et al., 2003).

Glucuronidation of the hydroxyl group at position C10 (resulting from cleavage of the bispiperidine promoiety) produces the only known metabolite of SN-38. Biliary excretion appears to be the primary elimination route of irinotecan, SN-38, and their metabolites, although urinary excretion also contributes significantly (14-37%). Uridine diphosphate-glucuronosyltransferase 1A1 (UGT1A1), converts SN-38 to its inactive derivative (Iyer et al., 1998). The extent of SN-38 glucuronidation inversely correlates with the risk of severe diarrhea after irinotecan therapy. UGT1A1 also glucuronidates bilirubin. Polymorphisms of this enzyme are associated with familial hyperbilirubinemia syndromes such as Crigler-Najjar syndrome and Gilbert syndrome. Crigler-Najjar syndrome is rare (one in a million births), but Gilbert syndrome occurs in up to 15% of the general population and results in a mild hyperbilirubinemia that may be clinically silent. The presence of UGT enzyme polymorphisms may have a major impact on the clinical use of irinotecan. A positive correlation has been found between baseline serum unconjugated bilirubin concentration and both severity of neutropenia and the AUC of irinotecan and SN-38 in patients treated with irinotecan. Moreover, severe irinotecan toxicity has been observed in cancer patients with Gilbert syndrome, presumably due to decreased

glucuronidation of SN-38. The presence of bacterial glucuronidase in the intestinal lumen potentially can contribute to irinotecan's GI toxicity by releasing unconjugated SN-38 from the inactive glucuronide metabolite excreted in the bile.

## **Therapeutic Uses**

**Topotecan.** Topotecan (HYCAMTIN) is indicated for previously treated patients with ovarian and small cell lung cancer. Its significant hematological toxicity has limited its use in combination with other active agents in these diseases (e.g., cisplatin).

The recommended dosing regimen of topotecan for ovarian cancer and small cell lung cancer is a 30-minute infusion of 1.5 mg/m<sup>2</sup>/day for 5 consecutive days every 3 weeks. For cervical cancer in conjunction with cisplatin, the dose of topotecan is 0.75 mg/m<sup>2</sup> on days 1, 2, and 3, repeated every 21 days. Because a significant fraction of the topotecan administered is excreted in the urine, patients with decreased CrCl may experience increased toxicity (O'Reilly et al., 1996). Therefore, the dose of topotecan should be reduced to 0.75 mg/m<sup>2</sup>/day in patients with moderate renal dysfunction (CrCl of 20-40 mL/min), and topotecan should not be administered to patients with severe renal impairment (CrCl <20 mL/min). Hepatic dysfunction does not alter topotecan clearance and toxicity. A baseline neutrophil count >1500 cells/mm<sup>3</sup> and a platelet count >100,000 is necessary prior to topotecan administration. For small cell lung cancer, oral therapy can be used at a dosage of 2.3 mg/m<sup>2</sup>/day for 5 consecutive days repeated every 21 days. The oral dose is reduced to 1.8 mg/m<sup>2</sup> for patients with a CrCl of 30-49 mL/min.

**Irinotecan.** Approved single-agent dosage schedules of irinotecan (CAMPTOSAR, others) in the U.S. include 125 mg/m<sup>2</sup> as a 90-minute infusion administered weekly (on days 1, 8, 15, and 22) for 4 out of 6 weeks, and 350 mg/m<sup>2</sup> given every 3 weeks. In patients with advanced colorectal cancer, irinotecan is used as first-line therapy in combination with fluoropyrimidines or as a single agent or in combination with cetuximab following failure of a 5-FU/oxaliplatin regimen.

## **Clinical Toxicities**

**Topotecan.** The dose-limiting toxicity with all dosing schedules is neutropenia, with or without thrombocytopenia. The incidence of severe neutropenia at the recommended phase II dose of 1.5 mg/m<sup>2</sup> daily for 5 days every 3 weeks may be as high as 81%, with a 26% incidence of febrile neutropenia. In patients with hematological malignancies, GI side effects such as mucositis and diarrhea become dose limiting. Other less common and generally mild topotecan-related toxicities include nausea and vomiting, elevated liver transaminases, fever, fatigue, and rash.

**Irinotecan.** The dose-limiting toxicity with all dosing schedules is delayed diarrhea, with or without neutropenia. In the initial studies, up to 35% of patients experienced severe diarrhea. Adoption of an intensive regimen of loperamide (4 mg of loperamide starting at the onset of any loose stool beginning more than a few hours after receiving therapy, followed by 2 mg every 2 hours) (see [Chapter 47](#)) has effectively reduced this incidence by more than half. However, once severe diarrhea occurs, standard doses of antidiarrheal agents tend to be ineffective. Diarrhea generally resolves within a week and, unless associated with fever and neutropenia, rarely is fatal.

The second most common irinotecan-associated toxicity is myelosuppression. Severe neutropenia occurs in 14-47% of the patients treated with the every-3-weeks schedule and is less frequently encountered among patients treated with the weekly schedule. Febrile neutropenia is observed in 3% of patients and may be fatal, particularly when associated with concomitant diarrhea. A cholinergic syndrome resulting from the inhibition of acetylcholinesterase activity by irinotecan may occur within the first 24 hours after irinotecan administration. Symptoms include acute diarrhea, diaphoresis, hypersalivation, abdominal cramps, visual accommodation disturbances, lacrimation, rhinorrhea, and less often, asymptomatic bradycardia. These effects are short lasting and respond within minutes to atropine. Atropine may be prophylactically administered to patients who have previously experienced a cholinergic reaction. Other common and generally manageable toxicities include nausea and vomiting, fatigue, vasodilation or skin flushing, mucositis, elevation in liver transaminases, and alopecia. Finally, there have been case reports of dyspnea and interstitial pneumonitis associated with irinotecan therapy in Japanese patients with lung cancer (Fukuoka et al., 1992).

# ANTIBIOTICS

## Dactionmycin (Actionmycin D)

The first anticancer antibiotics were the series of actionmycins discovered by Waksman and colleagues in 1940. The most important of these, actionmycin D, has beneficial effects in the treatment of solid tumors in children and choriocarcinoma in adult women.

**Chemistry and Structure-Activity Relationships.** The actionmycins are chromopeptides. Most contain the same chromophore, the planar phenoxazone actionsin, which is responsible for their yellow-red color. The differences among naturally occurring actionmycins are confined to variations in the structure of the amino acids of the peptide side chains.

**Mechanism of Action.** The capacity of actionmycins to bind with double-helical DNA is responsible for their biological activity and cytotoxicity. X-ray studies of a crystalline complex between dactionmycin and deoxyguanosine permitted formulation of a model that explains the binding of the drug to DNA (Sobell, 1973). The planar phenoxazone ring intercalates between adjacent guanine–cytosine base pairs of DNA, while the polypeptide chains extend along the minor groove of the helix. The summation of these interactions provides great stability to the dactionmycin-DNA complex, and as a result of the binding of dactionmycin, the transcription of DNA by RNA polymerase is blocked. The DNA-dependent RNA polymerases are much more sensitive to the effects of dactionmycin than are the DNA polymerases. In addition, dactionmycin causes single-

strand breaks in DNA, possibly through a free-radical intermediate or as a result of the action of topoisomerase II.

**Cytotoxic Action.** Dactionmycin inhibits rapidly proliferating cells of normal and neoplastic origin and, on a molar basis, is among the most potent antitumor agents known. The drug may produce alopecia and, when extravasated subcutaneously, causes marked local inflammation. Erythema, sometimes progressing to necrosis, has been noted in areas of the skin exposed to X-ray radiation before, during, or after administration of dactionmycin.

**Absorption, Fate, and Excretion.** Dactionmycin is administered by intravenous injection. Metabolism of the drug is minimal. The drug is excreted in both bile and urine and disappears from plasma with a terminal  $t_{1/2}$  of 36 hours. Dactionmycin does not cross the blood-brain barrier.

**Therapeutic Uses.** A wide variety of single-agent and combination chemotherapy regimens with dactionmycin (actionmycin D; *cosmegen*) are employed. The usual daily dose of dactionmycin is 10-15  $\mu\text{g}/\text{kg}$ ; this is given intravenously for 5 days; if no manifestations of toxicity are encountered, additional courses may be given at intervals of 2-4 weeks. In other regimens, 3-6  $\mu\text{g}/\text{kg}/\text{day}$ , for a total of 125  $\mu\text{g}/\text{kg}$ , and weekly maintenance doses of 7.5  $\mu\text{g}/\text{kg}$  have been used. If infiltrated during administration, the drug is extremely corrosive to soft tissues.

The most important clinical use of dactionmycin is in the treatment of rhabdomyosarcoma and Wilms tumor in children, where it is curative in combination with primary surgery, radiotherapy, and other drugs, particularly vincristine and cyclophosphamide. Ewing, Kaposi, and soft-tissue sarcomas also respond. Dactionmycin and methotrexate form a curative therapy for choriocarcinoma.

**Clinical Toxicities.** Toxic manifestations include anorexia, nausea, and vomiting, usually beginning a few hours after administration. Hematopoietic suppression with pancytopenia may occur in the first week after completion of therapy. Proctitis, diarrhea, glossitis, cheilitis, and ulcerations of the oral mucosa are common; dermatological manifestations include alopecia, as well as erythema, desquamation, and increased inflammation and pigmentation in areas previously or concomitantly subjected to X-ray radiation. Severe injury may occur as a result of local drug extravasation.

## Anthracyclines and Anthracenediones

Anthracyclines are derived from the fungus *Streptomyces peucetius* var. *caesius*. Idarubicin and epirubicin are analogs of the naturally produced anthracyclines doxorubicin and daunorubicin, differing only slightly in chemical structure, but having somewhat distinct patterns of clinical activity. Daunorubicin and idarubicin primarily have been used in the acute leukemias, whereas doxorubicin and epirubicin display broader activity against human solid tumors. These agents, which all possess potential for generating free radicals, cause an unusual and often irreversible cardiomyopathy, the occurrence of which is related to the total dose of the drug. The structurally similar agent mitoxantrone has useful activity against prostate cancer and AML, and is used in high-dose chemotherapy, but has less cardiotoxicity.

**Chemistry.** The anthracycline antibiotics have a tetracyclic ring structure attached to an unusual sugar, daunosamine. Cytotoxic agents of this class all have quinone and hydroquinone moieties on adjacent rings that permit the gain and loss of electrons. Although there are marked differences in the clinical uses of daunorubicin and doxorubicin, their chemical structures differ only by a single hydroxyl group on C-14 (substituent  $R_4$  on the diagram below). Idarubicin is 4-demethoxydaunorubicin (alteration in substituent  $R_1$ ), a synthetic derivative of daunorubicin; epirubicin is an epimer at the 4' position of the sugar. Mitoxantrone, an anthracenedione, lacks a glycosidic side group.

	DOXORUBICIN	DAUNORUBICIN	EPIRUBICIN	IDARUBICIN
$R_1 =$	OCH <sub>3</sub>	OCH <sub>3</sub>	OCH <sub>3</sub>	H
$R_2 =$	H	H	OH	H
$R_3 =$	OH	OH	H	OH
$R_4 =$	OH	H	OH	H

**Mechanism of Action.** A number of important biochemical effects have been described for the anthracyclines and anthracenediones, all of which could contribute to their therapeutic and toxic effects. These compounds can intercalate with DNA, directly affecting transcription and replication. A more important action is the ability to form a tripartite complex with topoisomerase II and DNA. Topoisomerase II is an ATP-dependent enzyme that binds to DNA and produces double-strand breaks at the 3'-phosphate backbone, allowing strand passage and uncoiling of super-coiled DNA. Following strand passage, topoisomerase II re-ligates the DNA strands. This enzymatic function is essential for DNA replication and repair. Formation of the tripartite complex with anthracyclines or with etoposide inhibits the re-ligation of the broken DNA strands, leading to apoptosis. Defects in DNA double-strand break repair sensitize cells to damage by these drugs, while overexpression of transcription-linked DNA repair may contribute to resistance.

Anthracyclines, by virtue of their quinone groups, also generate free radicals in solution and in both normal and malignant tissues (Myers, 1988). Anthracyclines can form semiquinone radical intermediates that can react with O<sub>2</sub> to produce superoxide anion radicals. These can generate both hydrogen peroxide and hydroxyl radicals, which attack DNA (Serrano et al., 1999) and oxidize DNA bases. The production of free radicals is significantly stimulated by the interaction of doxorubicin with iron (Myers, 1988). Enzymatic defenses such as superoxide dismutase and catalase protect cells against the toxicity of the anthracyclines, and these defenses can be augmented by exogenous antioxidants such as alpha tocopherol or by an iron chelator, dexrazoxane (ZINECARD, others), which protects against cardiac toxicity (Swain et al., 1997).

Exposure of cells to anthracyclines leads to apoptosis; mediators of this process include the p53 DNA-damage sensor and activated caspases (proteases), although ceramide, a lipid breakdown product, and the Fas receptor-ligand system also have been implicated (Friesen et al., 1996).

As discussed in “Drug Resistance” under “Vinca Alkaloids,” multidrug resistance is observed in tumor cell populations exposed to anthracyclines. Attempts to reverse or prevent the emergence of resistance through the simultaneous use of inhibitors of the P-glycoprotein (Ca<sup>++</sup> channel blockers, steroidal compounds, and others) have yielded inconclusive results,

primarily due to confounding effects of these inhibitors on anthracycline pharmacokinetics and metabolism. Anthracyclines also are exported from tumor cells by members of the MRP transporter family and by the breast cancer resistance protein, a “half” transporter (Doyle et al., 1998). Other biochemical changes in resistant cells include increased glutathione peroxidase activity, decreased activity or mutation of topoisomerase II, and enhanced ability to repair DNA strand breaks.

**Absorption, Fate, and Excretion.** Daunorubicin, doxorubicin, epirubicin, and idarubicin usually are administered intravenously and are cleared by a complex pattern of hepatic metabolism and biliary excretion. The plasma disappearance curves for doxorubicin and daunorubicin are multiphasic, with a terminal  $t_{1/2}$  of 30 hours. All anthracyclines are converted to an active alcohol intermediate that plays a variable role in their therapeutic activity. Idarubicin has a  $t_{1/2}$  of 15 hours, and its active metabolite, idarubicinol, has a  $t_{1/2}$  of 40 hours. The drugs rapidly enter the heart, kidneys, lungs, liver, and spleen. They do not cross the blood-brain barrier.

Daunorubicin and doxorubicin are eliminated by metabolic conversion to a variety of aglycones and other inactive products. Idarubicin is primarily metabolized to idarubicinol, which accumulates in plasma and likely contributes significantly to its activity. Clearance of anthracyclines and their active alcohol metabolites is delayed in the presence of hepatic dysfunction, and at least a 50% initial reduction in dose should be considered in patients with abnormal serum bilirubin levels (Twelves et al., 1998).

## **Therapeutic Use**

**Idarubicin.** The recommended dosage for idarubicin (IDAMYCIN PFS) is 12 mg/m<sup>2</sup>/day for 3 days by intravenous injection in combination with cytarabine. Slow injection over 10-15 minutes is recommended to avoid extravasation, as with other anthracyclines. It has less cardiotoxicity than the other anthracyclines.

**Daunorubicin.** Daunorubicin (daunomycin, rubidomycin; CERUBIDINE, others) is available for intravenous use. The recommended dosage is 25-45 mg/m<sup>2</sup>/day for 3 days. The agent is administered with appropriate care to prevent extravasation, because severe local vesicant action may result. Total doses of >1000 mg/m<sup>2</sup> are associated with a high risk of cardiotoxicity.

Patients should be advised that daunorubicin may impart a red color to the urine.

Daunorubicin and idarubicin also are used in the treatment of AML in combination with Ara-C.

**Clinical Toxicities.** The toxic manifestations of daunorubicin as well as idarubicin include bone marrow depression, stomatitis, alopecia, GI disturbances, and rash. Cardiac toxicity is a peculiar adverse effect observed with these agents. It is characterized by tachycardia, arrhythmias, dyspnea, hypotension, pericardial effusion, and congestive heart failure poorly responsive to digitalis (see “Clinical Toxicities” under “Doxorubicin”).

## **Doxorubicin**

**Therapeutic Uses.** Doxorubicin is available for intravenous use. The recommended dose is 60-75 mg/m<sup>2</sup>, administered as a single rapid intravenous infusion that is repeated after 21 days. Care should be taken to avoid extravasation, because severe local vesicant action and tissue necrosis may result. A doxorubicin liposomal product (DOXIL) is available for treatment of AIDS-related Kaposi sarcoma and is given intravenously in a dose of 20 mg/m<sup>2</sup> over 60 minutes and repeated every 3 weeks. The liposomal formulation also is approved for ovarian cancer at a dose of 50 mg/m<sup>2</sup> every 4 weeks and as a treatment for multiple myeloma (in conjunction with bortezomib), where it is given as a 30-mg/m<sup>2</sup> dose on day 4 of each 21-day cycle. Patients should be advised that the drug may impart a red color to the urine.

Doxorubicin is effective in malignant lymphomas. In combination with cyclophosphamide, vinca alkaloids, and other agents, it is an important ingredient for the successful treatment of lymphomas. It is a valuable component of various regimens of chemotherapy for adjuvant and metastatic carcinoma of the breast. The drug also is particularly beneficial in pediatric and adult sarcomas, including osteogenic, Ewing, and soft-tissue sarcomas.

**Clinical Toxicities.** The toxic manifestations of doxorubicin are similar to those of daunorubicin. Myelosuppression is a major dose-limiting complication, with leukopenia usually reaching a nadir during the second week of therapy and recovering by the fourth week; thrombocytopenia and anemia follow a similar pattern but usually are less pronounced. Stomatitis,

mucositis, diarrhea, and alopecia are common but reversible. Erythematous streaking near the site of infusion (“*ADRIAMYCIN* flare”) is a benign local allergic reaction and should not be confused with extravasation. Facial flushing, conjunctivitis, and lacrimation may occur rarely. The drug may produce severe local toxicity in irradiated tissues (e.g., the skin, heart, lung, esophagus, and GI mucosa) even when the two therapies are not administered concomitantly.

Cardiomyopathy is the most important long-term toxicity. Two types of cardiomyopathies may occur:

- An acute form is characterized by abnormal electrocardiographic changes, including ST- and T-wave alterations and arrhythmias. This is brief and rarely a serious problem. An acute reversible reduction in ejection fraction is observed in some patients in the 24 hours after a single dose, and plasma troponin T, a cardiac enzyme released with myocardial damage, may increase in a minority of patients in the first few days following drug administration (Lipshultz et al., 2004). Acute myocardial damage, the “pericarditis–myocarditis syndrome,” may begin in the days following drug infusion and is characterized by severe disturbances in impulse conduction and frank congestive heart failure, often associated with pericardial effusion.
- Chronic, cumulative dose-related toxicity (usually total doses of  $\geq 550 \text{ mg/m}^2$ ) progress to congestive heart failure. The mortality rate in patients with congestive failure approaches 50%. Total doses of doxorubicin as low as  $250 \text{ mg/m}^2$  can cause pathological changes in the myocardium, as demonstrated by subendocardial biopsies. Nonspecific alterations, including a decrease in the number of myocardial fibrils, mitochondrial changes, and cellular degeneration, are visible by electron microscopy. The most promising noninvasive techniques used to detect the early development of drug-induced congestive heart failure are radionuclide cineangiography, which assesses ejection fraction, and echocardiography, which reveals abnormalities in contractility and ventricular dimensions. Sequential echocardiograms have detected structural abnormalities in 25% of children who received up to  $300 \text{ mg/m}^2$  of doxorubicin, although  $<10\%$  have clinical manifestations of cardiac disease in long-term follow-up. Although no completely practical and reliable predictive tests are available, the frequency of clinically apparent cardiomyopathy is 1-10% at total doses  $<450 \text{ mg/m}^2$ . The risk increases markedly, with estimates as high as 20% at total doses of  $550 \text{ mg/m}^2$ . This total dosage should be exceeded only under exceptional circumstances or with the concomitant use of dexrazoxane, a cardioprotective iron-chelating agent that appears not to compromise the anticancer activity of the drug (Swain et al., 1997). Cardiac irradiation, administration of high doses of cyclophosphamide or another anthracycline, or concomitant trastuzumab (Slamon et al., 2001) increases the risk of cardiotoxicity. Late-onset cardiac toxicity, with congestive heart failure years after treatment, may occur in both pediatric and adult populations. In children treated with anthracyclines, there is a 3- to 10-fold elevated risk of arrhythmias, congestive heart failure, and sudden death in adult life. A total dose limit of  $300 \text{ mg/m}^2$  is advised for pediatric cases. Concomitant administration of dexrazoxane may reduce troponin T elevations and avert later cardiotoxicity (Lipshultz et al., 2004).

## **Epirubicin (ELLENCE, others)**

This anthracycline is indicated as a component of adjunctive therapy for treatment of breast cancer. It is administered in doses of 100-120 mg/m<sup>2</sup> intravenously every 3-4 weeks. Total doses >900 mg/m<sup>2</sup> sharply increase the risk of cardiotoxicity. Its toxicity profile is the same as that of doxorubicin.

### **Valrubicin (VALSTAR)**

Valrubicin is a semi-synthetic analog of doxorubicin, used exclusively for intravesicular treatment of bladder cancer. Eight hundred mg are instilled into the bladder once a week for 6 weeks. Less than 10% of instilled drug is absorbed systemically. Side effects relate to bladder irritation (Kuznetsov et al., 2001).

### **Mitoxantrone**

Mitoxantrone has been approved for use in AML, prostate cancer, and late-stage, secondary progressive multiple sclerosis. Mitoxantrone has limited ability to produce quinone-type free radicals and causes less cardiac toxicity than does doxorubicin. It produces acute myelosuppression, cardiac toxicity, and mucositis as its major toxicities; the drug causes less nausea, vomiting, and alopecia than does doxorubicin.

Mitoxantrone (NOVANTRONE, others) is administered by intravenous infusion. To induce remission in acute nonlymphocytic leukemia in adults, the drug is given in a daily dose of 12 mg/m<sup>2</sup> for 3 days with cytarabine. It also is used in advanced hormone-resistant prostate cancer in a dose of 12-14 mg/m<sup>2</sup> every 21 days.

## **EPIPODOPHYLLOTOXINS**

Podophyllotoxin, extracted from the mandrake plant (mayapple; *Podophyllum peltatum*), was used as a folk remedy by the American Indians and early colonists for its emetic, cathartic, and anthelmintic effects. Two synthetic derivatives have significant therapeutic activity in pediatric leukemia, small cell carcinomas of the lung, testicular tumors, Hodgkin's disease, and large cell lymphomas.

These derivatives, shown below, are etoposide (VP-16-213) and teniposide (VM-26). Although podophyllotoxin binds to tubulin, etoposide

and teniposide have no effect on microtubular structure or function at usual concentrations.

**Mechanism of Action.** Etoposide and teniposide are similar in their actions and in the spectrum of human tumors affected. Like the anthracyclines, they form a ternary complex with topoisomerase II and DNA and prevent resealing of the break that normally follows topoisomerase binding to DNA. The enzyme remains bound to the free end of the broken DNA strand, leading to an accumulation of DNA breaks and cell death. Cells in the S and G<sub>2</sub> phases of the cell cycle are most sensitive to etoposide and teniposide. Resistant cells demonstrate 1) amplification of the *mdr-1* gene that encodes the P-glycoprotein drug efflux transporter, 2) mutation or decreased expression of topoisomerase II, or 3) mutations of the p53 tumor suppressor gene, a required component of the apoptotic pathway (Lowe et al., 1993).

## Etoposide

**Absorption, Fate, and Excretion.** Oral administration of etoposide results in variable absorption that averages ~50%. After intravenous injection, peak plasma concentrations of 30 µg/mL are achieved; there is a biphasic pattern of clearance with a terminal t<sub>1/2</sub> of ~6-8 hours in patients with normal renal

function. Approximately 40% of an administered dose is excreted intact in the urine. In patients with compromised renal function, dosage should be reduced in proportion to the reduction in CrCl (Arbuck et al., 1986). In patients with advanced liver disease, increased toxicity may result from a low serum albumin (decreased drug binding) and elevated bilirubin (which displaces etoposide from albumin). However, guidelines for dose reduction in this circumstance have not been defined. Drug concentrations in the CSF average 1-10% of those in plasma.

**Therapeutic Uses.** The intravenous dose of etoposide (VEPESID, others) for testicular cancer in combination therapy is 50-100 mg/m<sup>2</sup> for 5 days, or 100 mg/m<sup>2</sup> on alternate days for three doses. For small cell carcinoma of the lung, the dosage in combination therapy is 35 mg/m<sup>2</sup>/day intravenously for 4 days or 50 mg/m<sup>2</sup>/day intravenously for 5 days. The oral dose for small cell lung cancer is twice the IV dose. Cycles of therapy usually are repeated every 3-4 weeks. When given intravenously, the drug should be administered slowly over a 30- to 60-minute period to avoid hypotension and bronchospasm, which likely result from the additives used to dissolve etoposide, a relatively insoluble compound.

A disturbing complication of etoposide therapy has emerged in long-term follow-up of patients with childhood acute lymphoblastic leukemia, who develop an unusual form of acute nonlymphocytic leukemia with a translocation in chromosome 11q23. At this locus is a gene (the MLL gene) that regulates the proliferation of pluripotent stem cells. The leukemic cells have the cytological appearance of acute monocytic or monomyelocytic leukemia but may express lymphoid surface markers. Another distinguishing feature of etoposide-related leukemia is the short time interval between the end of treatment and the onset of leukemia (1-3 years), compared to the 4- to 5-year interval for secondary leukemias related to alkylating agents, and the absence of a myelodysplastic period preceding leukemia (Pui et al., 1995). Patients receiving weekly or twice-weekly doses of etoposide, with cumulative doses >2000 mg/m<sup>2</sup>, seem to be at higher risk of leukemia.

Etoposide primarily is used for treatment of testicular tumors, in combination with bleomycin and cisplatin, and in combination with cisplatin and ifosfamide for small cell carcinoma of the lung. It also is active against non-Hodgkin's lymphomas, acute nonlymphocytic leukemia, and Kaposi sarcoma associated with acquired immunodeficiency syndrome (AIDS).

Etoposide has a favorable toxicity profile for dose escalation in that its primary acute toxicity is myelosuppression. In combination with ifosfamide and carboplatin, it frequently is used for high-dose chemotherapy in total doses of 1500-2000 mg/m<sup>2</sup> (Josting et al., 2000).

**Clinical Toxicities.** The dose-limiting toxicity of etoposide is leukopenia, with a nadir at 10-14 days and recovery by 3 weeks. Thrombocytopenia occurs less often and usually is not severe. Nausea, vomiting, stomatitis, and diarrhea complicate treatment in ~15% of patients. Alopecia is a common but reversible adverse effect. Hepatic toxicity is particularly evident after high-dose treatment. For both etoposide and teniposide, toxicity increases in patients with decreased serum albumin, an effect related to decreased protein binding of the drug.

## **Teniposide**

Teniposide (VUMON) is administered intravenously. It has a multiphasic pattern of clearance from plasma; after distribution, a t<sub>1/2</sub> of 4 hours and another t<sub>1/2</sub> of 10-40 hours are observed. Approximately 45% of the drug is excreted in the urine, but in contrast to etoposide, as much as 80% is recovered as metabolites. Anticonvulsants such as phenytoin increase the hepatic metabolism of teniposide and reduce systemic exposure (Baker et al., 1992). Dosage need not be reduced for patients with impaired renal function. Less than 1% of the drug crosses the blood-brain barrier. Teniposide is available for treatment of refractory ALL in children and is synergistic with cytarabine. It is administered by intravenous infusion in dosages that range from 50 mg/m<sup>2</sup>/day for 5 days to 165 mg/m<sup>2</sup>/day twice weekly. The drug has limited utility and primarily is given for acute leukemia in children and monocytic leukemia in infants, as well as glioblastoma, neuroblastoma, and brain metastases from small cell carcinomas of the lung. Myelosuppression, nausea, and vomiting are its primary toxic effects.

## **DRUGS OF DIVERSE MECHANISM OF ACTION**

### **Bleomycin**

The bleomycins, a unique group of DNA-cleaving antibiotics, were discovered by Umezawa and colleagues as fermentation products of *Streptomyces verticillus*. The drug currently employed clinically is a mixture of the two copper-chelating peptides, bleomycins A<sub>2</sub> and B<sub>2</sub>. The various bleomycins differ only in their terminal amino acid ([Figure 61–14](#)).

Bleomycins have attracted interest because of their significant antitumor activity against both Hodgkin's lymphoma and testicular tumors. They are minimally myelo- and immunosuppressive but cause unusual cutaneous side effects and pulmonary fibrosis. Because their toxicities do not overlap with those of other cytotoxic drugs, and because of their unique mechanism of action, bleomycin maintains an important role in treating Hodgkin's disease and testicular cancer.

**Chemistry.** The bleomycins are water-soluble, basic glycopeptides ([Figure 61–14](#)). The core of the bleomycin molecule assumes a metal-binding cage consisting of a pyrimidine chromophore linked to propionamide, a β-aminoalanine amide side chain, and the sugars, l-gulose and 3-O-carbamoyl-d-mannose. Bound in this complex are either Fe<sup>2+</sup> or Cu<sup>2+</sup>. Attached to the metal ion binding core are a tripeptide chain and a terminal, DNA-binding bithiazole carboxylic acid.

**Mechanism of Action.** Bleomycin's cytotoxicity results from its ability to cause oxidative damage to the deoxyribose of thymidylate and other nucleotides, leading to single- and double-stranded breaks in DNA. Studies *in vitro* indicate that bleomycin causes accumulation of cells in the G<sub>2</sub> phase of the cell cycle, and many of these cells display chromosomal aberrations, including chromatid breaks, gaps, and fragments, as well as translocations (Twentyman, 1983).

Bleomycin cleaves DNA by generating free radicals. In the presence of O<sub>2</sub> and a reducing agent, such as dithiothreitol, the metal–drug complex becomes activated and functions as a ferrous oxidase, transferring electrons from Fe<sup>2+</sup> to molecular oxygen to produce oxygen radicals (Burger, 1998). Metalbleomycin complexes can be activated by reaction with the flavin enzyme, NADPH-cytochrome P450 reductase. Bleomycin binds to DNA, and the activated complex generates free radicals that are responsible for abstraction of a proton at the 3' position of the deoxyribose backbone of the DNA chain, opening the deoxyribose ring and generating a strand break in

DNA. The process for repair of this break is poorly understood, but an excess of breaks generates apoptosis.

**Figure 61–14.** Chemical structures of bleomycin A<sub>2</sub> and B<sub>2</sub>.

Bleomycin is degraded by a specific hydrolase found in various normal tissues, including liver. Hydrolase activity is low in skin and lung, perhaps contributing to the serious toxicity at those sites. Some bleomycin-resistant cells contain high levels of hydrolase activity (Sebti et al., 1991). In other cell lines, resistance has been attributed to decreased uptake, repair of strand breaks, or drug inactivation by thiols or thiol-rich proteins. A polymorphism of the hydrolase gene, SNP A1450G, has been identified in 10% of patients with testicular cancer, and the G/G genotype is associated with a 20% decreased survival in patients treated with bleomycin combination therapy, suggesting that this single nucleotide polymorphism is associated with increased hydrolase activity (de Haas et al., 2008).

**Absorption, Fate, and Excretion.** Bleomycin is administered intravenously, intramuscularly, or subcutaneously or instilled into the bladder for local treatment of bladder cancer. After intravenous infusion, relatively high drug concentrations are detected in the skin and lungs of experimental animals, and these organs become major sites of toxicity. Having a high molecular mass, bleomycin crosses the blood-brain barrier poorly.

After intravenous administration of a bolus dose of 15 mg/m<sup>2</sup>, peak concentrations of 1-5 mg/mL are achieved in plasma. The half-time for elimination is ~3 hours. About two-thirds of the drug are excreted intact in the urine. Concentrations in plasma are greatly elevated if usual doses are given to patients with renal impairment and if such patients are at high risk of developing pulmonary toxicity. Doses of bleomycin should be reduced in the presence of a CrCl <60 mL/min (Dalglish et al., 1984).

**Therapeutic Uses.** The recommended dose of bleomycin (BLENOXANE, others) is 10-20 units/m<sup>2</sup> given weekly or twice weekly by the intravenous, intramuscular, or subcutaneous route. A test dose of ≤2 units before the first two doses is recommended for lymphoma patients. A variety of regimens are employed clinically, with bleomycin doses expressed in units. In treating testicular cancer, a standard total dose of 30 mg is given weekly for 3 consecutive weeks, and for three to four cycles of treatment. Total courses exceeding 250 mg should be given with caution, and usually only in high-risk testicular cancer treatment, because of a marked increase in the risk of pulmonary toxicity above this total dose. Bleomycin also may be instilled into the pleural cavity in doses of 5-60 mg (depending on the technique) to ablate the pleural space in patients with malignant effusions.

Bleomycin is highly effective against germ cell tumors of the testis and ovary. In testicular cancer, it is curative when used with cisplatin and vinblastine or cisplatin and etoposide. It is a component of the standard curative ABVD regimen (doxorubicin [adriamycin], bleomycin, vinblastine, and dacarbazine) for Hodgkin's lymphoma.

**Clinical Toxicities.** Because bleomycin causes little myelosuppression, it has significant advantages in combination with other cytotoxic drugs. However, it does cause a constellation of cutaneous toxicities, including hyperpigmentation, hyperkeratosis, erythema, and even ulceration. Rarely, patients with severe skin toxicity may experience Raynaud's phenomenon. Skin changes may begin with tenderness and swelling of the distal digits and progress to erythematous, ulcerating lesions over the elbows, knuckles, and other pressure areas. Healing of these lesions often leaves a residual hyperpigmentation, and lesions may recur when patients are treated with other antineoplastic drugs. Rarely, bleomycin causes a flagellate dermatitis consisting of bands of pruritic erythema on the arms, back, scalp, and hands. This rash responds readily to topical corticosteroids.

The most serious adverse reaction to bleomycin is pulmonary toxicity, which begins with a dry cough, fine rales, and diffuse basilar infiltrates on X-ray and may progress to life-threatening pulmonary fibrosis. Radiological changes of bleomycin-induced lung disease may be indistinguishable from interstitial infection or tumor, and show strong PET-positivity, but may progress from patchy infiltrates to dense fibrosis, cavitation and pneumothorax, atelectasis, or lobar collapse. Approximately 5-10% of patients receiving bleomycin develop clinically apparent pulmonary toxicity, and ~1% die of this complication (O'Sullivan et al., 2003). Most who recover experience a significant improvement in pulmonary function, but fibrosis may be irreversible. Pulmonary function tests are not of predictive value for detecting early onset of this complication. The CO diffusion capacity declines in patients receiving doses >250 mg. The risk of pulmonary toxicity is related to total dose, with a significant increase in risk in total doses >250 mg and in patients >40 years of age, in those with a CrCl of <80 mL/min, and in those with underlying pulmonary disease; single doses of  $\geq 30$  mg/m<sup>2</sup> also are associated with an increased risk of pulmonary toxicity. Administration of high inspired O<sub>2</sub> concentrations during anesthesia or respiratory therapy may aggravate or precipitate pulmonary toxicity in patients previously treated with the drug. There is no known specific therapy for bleomycin lung injury except for symptomatic management and standard pulmonary care. Steroids are of variable benefit, with greatest effectiveness in the earliest inflammatory stages of the lesion.

The etiology of bleomycin pulmonary toxicity has been investigated in rodent models (Moeller et al., 2008). These studies implicate various factors secreted by macrophages, including cytokines (such as transforming growth factor  $\beta$  [TGF $\beta$ ] and tumor necrosis factor  $\alpha$  [TNF $\alpha$ ]), and chemokines (such as CCL2 and CXCL12), as causative factors in leading to fibrosis in response to epithelial damage. Other contributing factors may be disordered coagulation cascades and imbalances in eicosanoids, leading to overproduction of profibrotic leukotrienes and underproduction of antifibrotic prostaglandins. Fibroblasts are recruited to the site of injury by release of lysophosphatide acid from inflammatory cells and contribute to the development of fibrosis (Tager et al., 2008). Various agents (e.g., thalidomide, anti-Her 2 antibodies, PPAR- $\gamma$  agonists, *N*-acetylcysteine, anticoagulants, pirfenidone, and bosentan) have attenuated bleomycin toxicity in the animal model, given either before or after the toxic agent. The last four

agents are being evaluated in clinical trials for the treatment of idiopathic pulmonary fibrosis (Walter et al., 2006), for which bleomycin lung disease in rodents is the primary disease model.

Other toxic reactions to bleomycin include hyperthermia, headache, nausea and vomiting, and a peculiar acute fulminant reaction observed in patients with lymphomas. This reaction is characterized by profound hyperthermia, hypotension, and sustained cardiorespiratory collapse; it does not appear to be a classical anaphylactic reaction and possibly may be related to release of an endogenous pyrogen. This reaction has occurred in ~1% of patients with lymphomas or testicular cancer.

## Mitomycin

This antibiotic was isolated from *Streptococcus caespitosus* by Wakaki and associates in 1958. It has limited clinical utility, having been replaced by less toxic and more effective drugs in most settings, with the exception of anal cancers, for which it is curative.

Mitomycin contains an azauridine group and a quinone group in its structure, as well as a mitosane ring, and each of these participates in the alkylation reactions with DNA.

**Mechanism of Action.** After intracellular enzymatic or spontaneous chemical reduction of the quinone and loss of the methoxy group, mitomycin becomes a bifunctional or trifunctional alkylating agent. Reduction occurs preferentially in hypoxic cells in some experimental systems. The drug inhibits DNA synthesis and cross-links DNA at the N6 position of adenine and at the O6 and N7 positions of guanine. Attempts to repair DNA lead to strand breaks. Mitomycin is a potent radiosensitizer, teratogen, and carcinogen in rodents. Resistance has been ascribed to deficient activation, intracellular inactivation of the reduced quinone, and P-glycoprotein-mediated drug efflux (Dorr, 1988).

**Absorption, Fate, and Excretion.** Mitomycin is administered intravenously. It disappears rapidly from the blood after injection, with a  $t_{1/2}$  of 25-90 minutes. Peak concentrations in plasma are 0.4  $\mu\text{g/mL}$  after doses of 20  $\text{mg/m}^2$  (Dorr, 1988). The drug distributes widely throughout the body but is not detected in the CNS. Inactivation occurs by hepatic metabolism or chemical conjugation with sulfhydryls. Less than 10% of the active drug is excreted in the urine or the bile.

**Therapeutic Uses.** Mitomycin (mitomycin-C; *MUTAMYCIN*, others) is administered by intravenous infusion; extravasation may result in severe local injury. The usual dose (6-20  $\text{mg/m}^2$ ) is given as a single bolus every 6-8 weeks. Dosage is modified based on hematological recovery. Mitomycin also may be used by direct instillation into the bladder to treat superficial carcinomas (Boccardo et al., 1994).

Mitomycin is used in combination with 5-FU and cisplatin, for anal cancer. Mitomycin is used off label (in the form of an extemporaneously compounded eye drop) as an adjunct to surgery to inhibit wound healing and reduce scarring; it appears to have benefit in the management of malignant and nonmalignant ophthalmic pathologies (see the review by Abraham, 2006).

**Clinical Toxicities.** The major toxic effect is myelosuppression, characterized by marked leukopenia and thrombocytopenia; after higher doses, the nadirs may be delayed and cumulative, with recovery only after 6-8 weeks of pancytopenia. Nausea, vomiting, diarrhea, stomatitis, rash, fever, and malaise also are observed. A hemolytic uremic syndrome represents the most dangerous toxic manifestation of mitomycin and is believed to result from drug-induced endothelial damage. Patients who have received  $>50$   $\text{mg/m}^2$  total dose may acutely develop hemolysis, neurological abnormalities, interstitial pneumonia, and glomerular damage resulting in renal failure. The incidence of renal failure increases to 28% in patients who receive total doses of  $\geq 70$   $\text{mg/m}^2$ . There is no effective treatment for the disorder. It must be recognized early, and mitomycin must be discontinued immediately. Mitomycin causes interstitial pulmonary fibrosis, and total doses  $>30$   $\text{mg/m}^2$  have infrequently led to congestive heart failure. It also may potentiate the cardiotoxicity of doxorubicin when used in combination with this drug.

## Mitotane

Mitotane (*o,p'*-DDD), a compound chemically similar to the insecticides DDT and DDD, is used in the treatment of neoplasms derived from the adrenal cortex. In studies of the toxicology of related insecticides in dogs, it was noted that the adrenal cortex was severely damaged, an effect caused by the presence of the *o,p'* isomer of DDD.

**Cytotoxic Action.** The mechanism of action of mitotane has not been elucidated, but its relatively selective destruction of adrenocortical cells, normal or neoplastic, is well established. Thus, administration of the drug causes a rapid reduction in the levels of adrenocorticosteroids and their metabolites in blood and urine, a response that is useful in both guiding dosage and following the course of hyperadrenocorticism (Cushing's syndrome) resulting from an adrenal tumor or adrenal hyperplasia. It does not damage other organs.

**Absorption, Fate, and Excretion.** Approximately 40% of mitotane is absorbed after oral administration. After daily doses of 5-15 g, concentrations of 10-90  $\mu\text{g/mL}$  of unchanged drug and 30-50  $\mu\text{g/mL}$  of a metabolite are present in the blood. After discontinuation of therapy, plasma concentrations of mitotane are still measurable for 6-9 weeks. Although the drug is found in all tissues, fat is the primary site of storage. A water-soluble metabolite of mitotane found in the urine constitutes 25% of an oral or parenteral dose. About 60% of an oral dose is excreted unchanged in the stool.

**Therapeutic Uses.** Mitotane (LYSODREN) is administered in initial daily oral doses of 2-6 g, usually in three or four divided portions, and usually increased to 9-10 g/day if tolerated. The maximal tolerated dose may vary from 2-16 g/day. Treatment should continue for at least 3 months; if beneficial effects are observed, therapy should be maintained indefinitely. Spironolactone should not be administered concomitantly, because it

interferes with the adrenal suppression produced by mitotane (Wortsman and Soler, 1977).

Treatment with mitotane is indicated for the palliation of inoperable adrenocortical carcinoma, producing symptomatic benefit in 30-50% of such patients.

**Clinical Toxicity.** Although the administration of mitotane produces anorexia and nausea in most patients, somnolence and lethargy in ~34%, and dermatitis in 15-20%, these effects do not contraindicate the use of the drug at lower doses. Because this drug damages the adrenal cortex, administration of replacement doses of adrenocorticosteroids is necessary (Hogan et al., 1978).

## **Trabectedin**

Trabectedin (YONDELIS) is the only drug used clinically that is derived from a sea animal. It was isolated from the marine tunicate, Ecteinascidin turbinate, as part of the National Cancer Institute's natural products discovery program. Trabectedin is designated as an orphan drug in the U.S. for ovarian cancer, sarcoma, and pancreatic cancer and is approved in the E.U. for second-line treatment of soft-tissue sarcomas and ovarian cancer.

TRABECTEDIN

***Mechanism of Action.*** This large structure binds to the minor groove of DNA, allowing the alkylation of the N2 position of guanine and bending the helix toward the major groove (Tavecchio et al., 2008). A portion of the molecule protrudes from the minor groove and may play a role in attracting repair or transcription complexes. The bulky DNA adduct is recognized by the transcription-coupled nucleotide excision repair complex, and these proteins initiate attempts to repair the damaged strand, converting the adduct to a double-stranded break. Tumor cell sensitivity to trabectedin exhibits interesting molecular features. Trabectedin has particular cytotoxic effects on cells that lack components of the Fanconi anemia complex or those that lack the ability to repair double-strand DNA breaks through homologous recombination (Soares et al., 2007). Unlike cisplatin and other DNA adduct-forming drugs, its activity requires the presence of intact components of NER, including XPG, which may be important for initiation of single breaks and attempts at adduct removal (Stevens et al., 2008).

***Absorption, Fate, and Excretion.*** Trabectedin is administered as a 24-hour infusion of 1.3 mg/m<sup>2</sup> every 3 weeks. Its approval in Europe was based on a trial in soft-tissue sarcoma in which a superior time to progression was found with the longer infusion, as compared to a more convenient 3-hour

infusion. It is administered with dexamethasone, 4 mg BID, starting 24 hours before drug infusion to diminish hepatic toxicity. The drug is slowly cleared by CYP3A4, with a plasma  $t_{1/2}$  of ~24-40 hours.

**Therapeutic Uses.** Trabectedin is approved outside the U.S. for second-line treatment of soft-tissue sarcomas and for ovarian cancer in combination with a doxorubicin formulation (DOXIL). It produces a very high (>50%) disease control rate in myxoid liposarcomas, a tumor characterized by a particular genomic translocation, although the reasons for this sensitivity are unclear (Grosso et al., 2009).

**Toxicity.** Without dexamethasone pretreatment, trabectedin causes significant hepatic enzyme elevations and fatigue in at least one-third of patients. With the steroid, the increases in transaminase are less pronounced and rapidly reverse (Grosso et al., 2009). Other toxicities include mild myelosuppression and, rarely, rhabdomyolysis.

## ENZYMES

### L-Asparaginase

In 1953, Kidd reported that guinea pig serum had anti-leukemic effects and identified L-asparaginase (L-ASP) as the source of this activity (Kidd, 1953). Fifteen years later, the purified enzyme from *Escherichia coli* proved to have dramatic antitumor activity against malignant lymphoid cells, based on the dependence of those tumors on exogenous sources of L-asparagine (Broome, 1981). The enzyme has become a standard agent for treating ALL.

**Mechanism of Action.** Most normal tissues are able to synthesize L-asparagine in amounts sufficient for protein synthesis, but lymphocytic leukemias lack adequate amounts of asparagine synthetase, and derive the required amino acid from plasma. L-ASP, by catalyzing the hydrolysis of circulating asparagine to aspartic acid and ammonia, deprives these malignant cells of asparagine, leading to cell death. L-ASP is used in combination with other agents, including methotrexate, doxorubicin, vincristine, and prednisone for the treatment of ALL and for high-grade lymphomas.

Resistance arises through induction of asparagine synthetase in tumor cells. For unknown reasons, hyperdiploid ALL cells or those with

translocations involving the TEL oncogene are particularly sensitive to *L*-ASP (Pui et al., 2004), while cells containing the *bcr-abl* translocation, more common in adult ALL, are more resistant.

**Absorption, Fate, Excretion, and Therapeutic Use.** *L*-Asparaginase (ELSPAR), a 144-kDa tetramer, is given intramuscularly or intravenously, but usually by the former route. After intravenous administration, *E. coli*-derived *L*-ASP has a clearance rate from plasma of 0.035 mL/min/kg, a volume of distribution that approximates the volume of plasma in humans, and a  $t_{1/2}$  of 24 hours (Asselin et al., 1993). It is given in doses of 6000-10,000 IU every third day for 3-4 weeks, although doses up to 25,000 IU once per week may be more effective in childhood ALL (Moghrabi et al., 2007). Enzyme levels must be maintained at >0.2 IU/mL in plasma to deplete asparagine in the bloodstream. Pegaspargase (*PEG-L-ASPARAGINASE*; *ONCASPAR*) a preparation in which the enzyme is conjugated to 5000-Da units of monomethoxy polyethylene glycol, has much slower clearance from plasma ( $t_{1/2}$  of 6-7 days), and it is administered in doses of 2500 IU/m<sup>2</sup> intramuscularly no more frequently than every 14 days, producing rapid and complete depletion of plasma and tumor cell asparagine for 21 days in most patients (Appel et al., 2008). Pegaspargase has much reduced immunogenicity (<20% of patients develop antibodies) (Hawkins et al., 2004) and has been approved for first-line ALL therapy.

Intermittent dosage regimens and longer durations of treatment increase the risk of inducing hypersensitivity. In hypersensitive patients, neutralizing antibodies inactivate *L*-ASP. Not all patients with neutralizing antibodies experience clinical hypersensitivity, although enzyme may be inactivated and therapy may be ineffective. In previously untreated ALL, pegaspargase produces more rapid clearance of lymphoblasts from bone marrow than does the *E. coli* preparation and circumvents the rapid antibody-mediated clearance seen with *E. coli* enzyme in relapsed patients (Avramis et al., 2002). Asparaginase preparations only partially deplete CSF asparagine.

**Clinical Toxicity.** *L*-ASP toxicities result from its antigenicity as a foreign protein and its inhibition of protein synthesis. Hypersensitivity reactions, including urticaria and full-blown anaphylaxis, occur in 5-20% of patients and may be fatal. These reactions usually are heralded by the earlier appearance of circulating neutralizing antibody and accelerated enzyme clearance from plasma. In these patients, pegaspargase is a safe and effective

alternative. So-called “silent” enzyme inactivation by antibodies occurs in a higher percentage of patients than overt hypersensitivity and may be associated with a negative clinical outcome, especially in high-risk ALL patients (Mann et al., 2007).

Other toxicities result from inhibition of protein synthesis in normal tissues (e.g., hyperglycemia due to insulin deficiency, clotting abnormalities due to deficient clotting factors, hypertriglyceridemia due to effects on lipoprotein production, hypoalbuminemia). Pancreatitis may result from extreme triglyceridemia and has been treated by plasma exchange. The clotting problems may take the form of spontaneous thrombosis—more frequent in thrombophilic patients with underlying deficiencies in factor S, factor C, antithrombin III mutation, or factor V Leiden—or, less frequently, hemorrhagic episodes (Caruso et al., 2006). Thrombosis of cortical sinus vessels frequently goes unrecognized. Brain magnetic resonance imaging studies should be considered in patients treated with *L*-ASP who present with seizures, headache, or altered mental status. Intracranial hemorrhage in the first week of *L*-ASP treatment is an infrequent but devastating complication. *L*-ASP suppresses immune function as well.

*L*-ASP terminates the antitumor activity of methotrexate when given shortly after the antimetabolite. By lowering serum albumin concentrations, it may decrease protein binding and accelerate plasma clearance of other drugs.

## HYDROXYUREA

The synthesis of hydroxyurea (HU) was first reported in 1869, but its potential anticancer activity was not recognized until 90 years later, when the drug was found to inhibit the growth of both leukemia and solid tumors. This drug has unique and surprisingly diverse biological effects as an antileukemic drug, radiation sensitizer, and an inducer of fetal hemoglobin in patients with sickle cell disease. The drug is orally administered, and its toxicity in most patients is modest and limited to myelosuppression.

**Cytotoxic Action.** HU inhibits the enzyme ribonucleoside diphosphate reductase, which catalyzes the reductive conversion of ribonucleotides to deoxyribonucleotides, a rate-limiting step in the biosynthesis of DNA. HU

binds the iron molecules that are essential for activation of a tyrosyl radical in the catalytic subunit (hRRM2) of RNR. The drug is specific for the S phase of the cell cycle, during which RNR concentrations are maximal. It causes cells to arrest at or near the G<sub>1</sub>-S interface through both p53-dependent and -independent mechanisms.

Because cells are highly sensitive to irradiation at the G<sub>1</sub>-S boundary, HU and irradiation cause synergistic antitumor effects. Through depletion of physiological deoxynucleotides, HU potentiates the antiproliferative effects of DNA-damaging agents such as cisplatin, alkylating agents, or topoisomerase II inhibitors and facilitates the incorporation of antimetabolites such as Ara-C, gemcitabine, and fludarabine into DNA. It also promotes degradation of the p21 cell-cycle checkpoint and thereby enhances the effects of HDAC (histone deacetylase) inhibitors *in vitro* (Kramer et al., 2008). The role of nitric oxide release in its differentiating activity and in its antitumor effects is uncertain but intriguing (Cokic et al., 2003).

HU has become the primary drug for improving the control of sickle cell (HbS) disease in adults and is also used for inducing fetal hemoglobin (HbF) in thalassemia HbC and HbC/S patients (Brawley et al., 2008). It reduces vaso-occlusive events, painful crises, hospitalizations, and the need for blood transfusions in patients with sickle cell disease. It does so via several potential mechanisms. Increased synthesis of HbF promotes solubility of hemoglobin and prevents sickling. The mechanism of HbF production is uncertain. It may simply result from suppression of erythroid precursor proliferation with compensatory stimulation of a distinct set of fetal Hb-producing cells. Sar1a, a specific promoter that upregulates in response to HU, induces HbF synthesis (Kumkhaek, 2008). Polymorphisms in this promoter may explain differential responses to HU. An alternative mechanism for HbF production has been offered because of the ability of HU to generate nitric oxide both *in vitro* and *in vivo*, causing nitrosylation of small-molecular-weight GTPases, a process that stimulates  $\gamma$ -globin production in erythroid precursors. Another property of HU that may be relevant is its ability to reduce L-selectin expression and thereby to inhibit adhesion of red cells and neutrophils to vascular endothelium. Also, by suppressing the production of neutrophils, it decreases their contribution to vascular occlusion.

Tumor cells become resistant to HU through increased synthesis of the hRRM2 subunit of ribonucleoside diphosphate reductase, thus restoring enzyme activity.

**Absorption, Fate, and Excretion.** The oral bioavailability of HU is excellent (80-100%), and comparable plasma concentrations are seen after oral or intravenous dosing. Peak plasma concentrations are reached 1-1.5 hours after oral doses of 15-80 mg/kg. HU disappears from plasma with a  $t_{1/2}$  of 3.5-4.5 hours. The drug readily crosses the blood-brain barrier, and it appears in significant quantities in human breast milk. From 40-80% of the drug is recovered in the urine within 12 hours after either intravenous or oral administration. Although precise guidelines are not available, it is advisable to modify initial doses for patients with abnormal renal function until individual tolerance can be assessed. Animal studies suggest that metabolism of HU does occur, but the extent and significance of its metabolism in humans have not been established.

**Therapeutic Uses.** In cancer treatment, two dosage schedules for HU (HYDREA, DROXIA, others), alone or in combination with other drugs, are most commonly used in a variety of solid tumors: 1) intermittent therapy with 80 mg/kg administered orally as a single dose every third day or 2) continuous therapy with 20-30 mg/kg administered as a single daily dose. In patients with essential thrombocythemia and in sickle cell disease, HU is given in a daily dose of 15 mg/kg, adjusting that dose upward or downward according to blood counts. The neutrophil count responds within 1-2 weeks to discontinuation of the drug. In treating subjects with sickle cell and related diseases, a neutrophil count of at least 2500 cells/mL should be maintained (Platt, 2008). Treatment typically is continued for 6 weeks in malignant diseases to determine its effectiveness; if satisfactory results are obtained, therapy can be continued indefinitely, although leukocyte counts at weekly intervals are advisable.

The principal use of HU has been as a myelosuppressive agent in various myeloproliferative syndromes, particularly CML, polycythemia vera, myeloid metaplasia, and essential thrombocytosis, for controlling high platelet or white cell counts. Many of the myeloproliferative syndromes harbor activating mutations of JAK2, a gene that is downregulated by HU. In essential thrombocythemia, it is the drug of choice for patients with a platelet count  $>1.5$  million cells/mm<sup>3</sup> or with a history of arterial or venous

thrombosis. In this disease, it dramatically lowers the risk of thrombosis by lowering the platelet, neutrophil, and red cell counts and by reducing expression of L-selectin and increasing nitric oxide production by neutrophils.

In CML, HU has been largely replaced by imatinib. Although it has produced anecdotal, temporary remissions in patients with solid tumors (e.g., head and neck cancers, cervical cancers), HU rarely is used in such patients as a single agent. HU is a potent radiosensitizer as a consequence of its inhibition of RNR (Flanagan et al., 2007) and has been incorporated into several treatment regimens with concurrent irradiation (i.e., cervical carcinoma, primary brain tumors, head and neck cancer, non-small-cell lung cancer).

**Clinical Toxicity.** Leukopenia, anemia, and occasionally thrombocytopenia—are the major toxic effects; recovery of the bone marrow is prompt if the drug is discontinued for a few days. Other adverse reactions include a desquamative interstitial pneumonitis, GI disturbances, and mild dermatological reactions; more rarely, stomatitis, alopecia, and neurological manifestations have been encountered. Increased skin and fingernail pigmentation may occur, as well as painful leg ulcers, especially in elderly patients or in those with renal dysfunction. HU does not increase the risk of secondary leukemia in patients with myeloproliferative disorders or sickle cell disease. It is a potent teratogen in all animal species tested and should not be used in women with childbearing potential (Platt, 2008).

## **DIFFERENTIATING AGENTS**

One of the hallmarks of malignant transformation is a block in differentiation. It is not clear whether the block is complete or partial, in that tumor cells with the features of stem cells can be found in most tumors, while the greater bulk of tumor cells do not carry the markers or the biological potential of continuous proliferation. Nonetheless, there is growing evidence that many human tumors are generated by mutations that block specific steps in differentiation, an example being the t(15;17) translocation in APL (acute promyelocytic leukemia). This translocation joins the retinoic acid receptor- $\alpha$  (RAR- $\alpha$ , a dimerizing protein critical for differentiation) and the PML gene, which encodes a transcription factor important in inhibiting proliferation and promoting myeloid differentiation. Four other translocation

partners for APL have been identified in less common varieties of APL. Under physiological conditions, RAR- $\alpha$  binds retinoic acid and regulates the expression of a number of specific genes that control myeloid differentiation. The oncogenic PML-RAR- $\alpha$  gene produces a protein that binds retinoids with much decreased affinity, lacks PML regulatory function, and fails to upregulate transcription factors (C/EBP and PU.1) that promote myeloid differentiation (Collins, 2008). The fusion protein forms homo- and heterodimers that regulate expression of genes that increase leukemic stem cell renewal, suppress checkpoint and apoptotic signals, and suppress expression of DNA repair functions, thereby enhancing mutability of APL cells. Epigenetic regulation of gene expression by histone acetylation and methylation also is disrupted by the fusion protein.

A number of chemical entities (vitamin D and its analogs, retinoids, benzamides and other inhibitors of histone deacetylase, various cytotoxics and biological agents, and inhibitors of DNA methylation) can induce differentiation in tumor cell lines *in vitro*. Fittingly, the first and best example of differentiating therapy was discovered in the treatment of APL (Wang and Chen, 2008).

## RETINOIDS

**Tretinoin.** The biology and pharmacology of retinoids and related compounds are discussed in detail in [Chapter 65](#). The most important of these for cancer treatment is tretinoin (all-trans retinoic acid; ATRA), which induces a high rate of complete remission in APL as a single agent and, in combination with anthracyclines, cures most patients with this disease.

Under physiological conditions, the RAR- $\alpha$  receptor dimerizes with the retinoid X receptor to form a complex that binds ATRA tightly. ATRA binding displaces a repressor from the complex and promotes differentiation of cells of multiple lineages. In APL cells, physiological concentrations of retinoid are inadequate to displace the repressor. Pharmacological concentrations, however, are effective in activating the differentiation program and in promoting degradation of the PML-RAR- $\alpha$  fusion gene (Collins, 2008). ATRA also binds and activates RAR- $\gamma$  and thereby promotes stem-cell renewal, perhaps through its effects on the microenvironment (Drumea et al., 2008), and this action may help restore normal bone marrow renewal. Resistance to ATRA arises by further mutation

of the fusion gene, abolishing ATRA binding; by induction of the CYP26A1 in liver or leukemic cells; or by loss of expression of the PML–RAR- $\alpha$  fusion gene (Roussel and Lanotte, 2001). Sensitivity can be restored by transfection of a functional PML–RAR- $\alpha$  gene.

**Clinical Pharmacology.** The usual dosing regimen of orally administered ATRA (VESANOID, others) is 45 mg/m<sup>2</sup>/day until 30 days after remission is achieved (maximum course of therapy is 90 days). ATRA as a single agent reverses the hemorrhagic diathesis associated with APL and induces a high rate of temporary remission. However, clinical trials have clearly established the benefit of giving ATRA in combination with an anthracycline for remission induction, achieving  $\geq 80\%$  relapse-free long-term survival.

ATRA concentrations reach 400 ng/mL in plasma. ATRA is cleared by a CYP3A4-mediated elimination with a  $t_{1/2}$  of <1 hour. Treatment with inducers of CYP3A4 leads to more rapid drug disappearance and, in some patients, resistance to ATRA (Gallagher, 2002). Inhibitors, such as antifungal imidazoles, block its degradation and may lead to hypercalcemia and renal failure (Cordoba et al., 2008), which responds to diuresis, bisphosphonates, and ATRA discontinuation. Corticosteroids and chemotherapy sharply decrease the occurrence of “retinoic acid syndrome,” which is characterized by fever, dyspnea, weight gain, pulmonary infiltrates, and pleural or pericardial effusions. When used as a single agent for remission induction, especially in patients with  $>5000$  leukemic cells/mm<sup>3</sup> in the peripheral blood, ATRA induces an outpouring of cytokines and mature-appearing neutrophils of leukemic origin. These cells express high concentrations of integrins and other adhesion molecules on their surface and clog small vessels in the pulmonary circulation, leading to significant morbidity in 15–20% of patients. The syndrome of respiratory distress, pleural and pericardial effusions, and mental status changes may have a fatal outcome. Pretreatment dexamethasone should be given to patients with leukemic cell counts of  $>5,000$ /mL to counteract “retinoic acid syndrome”.

**Toxicity.** Retinoids as a class, including ATRA, cause dry skin, cheilitis, reversible hepatic enzyme abnormalities, bone tenderness, pseudotumor cerebri, hypercalcemia, and hyperlipidemia, and as mentioned in the previous paragraph, the retinoic acid syndrome.

## **Arsenic Trioxide (ATO)**

Although recognized as a heavy metal toxin for centuries, arsenicals attracted interest as a medicinal agent nearly a century ago for syphilis and parasitic disease, and eventually CML. Arsenic trioxide has become a highly effective treatment for relapsed APL, producing complete responses in >85% of such patients (Wang and Chen, 2008). It now is a standard treatment for patients who relapse after ATRA and chemotherapy, cures a significant fraction of these patients, and has entered trials as primary therapy in combination with ATRA and chemotherapy. The chemistry and toxicity of arsenic is considered in detail in [Chapter 67](#).

The basis for its antitumor activity remains uncertain. APL cells have high levels of reactive oxygen species (ROS) and are quite sensitive to further ROS induction. ATO inhibits thioredoxin reductase and thereby generates ROS. It inactivates glutathione and other sulfhydryls that scavenge ROS and thereby aggravates ROS damage. Cells exposed to ATO also upregulate p53, Jun kinase, and caspases associated with the intrinsic pathway of apoptosis and downregulate anti-apoptotic proteins such as bcl-2. Of particular relevance to APL, it promotes the phosphorylation, sumoylation, and degradation of the APL fusion protein (Lallemand-Breitenbach et al., 2008), as well as the degradation of NF- $\kappa$ B, a transcription factor that stimulates angiogenesis and dampens apoptotic responses in cells with DNA damage. ATO's cytotoxic effects are antagonized by cell survival signals emanating from activation of components of the PI3 kinase cell survival pathway, including Akt kinase, S6 kinase, and mammalian target of rapamycin (mTOR). Inhibition of mTOR by rapamycin enhances its cytotoxic activity in culture systems.

It induces differentiation of leukemic cell lines *in vitro*, and in both experimental and human leukemias *in vivo*, but the mechanisms of differentiation and their relationship to the above pharmacological activities are not known.

**Clinical Pharmacology.** ATO (TRISENOX) is well absorbed orally, but in cancer treatment is administered as a 2-hour intravenous infusion in dosages of 0.15 mg/kg/day for up to 60 days, until remission is documented. Consolidation therapy begins after a 3-week break. It enters cells via one of several glucose transporters. The primary mechanism of elimination is through enzymatic methylation. Methylated metabolites have uncertain biological effects. Peak steady-state concentrations of arsenic in plasma

reached 5-7  $\mu\text{M}$  in one study in adults, while 20-fold lower levels were reported in children using more specific atomic absorption methods (Fox, 2008). Multiple methylated metabolites form rapidly and are excreted in urine. Less than 20% of administered drug is excreted unchanged in the urine. No dose reductions are indicated for hepatic or renal dysfunction.

**Toxicity.** Pharmacological doses of ATO are well tolerated. Patients may experience reversible side effects, including hyperglycemia, hepatic enzyme elevations, fatigue, dysesthesias, and light-headedness. Ten percent or fewer of patients will experience a leukocyte maturation syndrome similar to that seen with ATRA, including pulmonary distress, effusions, and mental status changes. Oxygen, corticosteroids, and temporary discontinuation of ATO lead to full reversal of this syndrome (Soignet et al., 1998). Another important and potentially dangerous side effect is lengthening of the QT interval on the electrocardiogram in 40% of patients, but rarely do patients develop torsades de pointes, a dangerous form of ventricular tachycardia. Simultaneous treatment with other QT-prolonging drugs, such as macrolide antibiotics, quinidine, or methadone, should be avoided. QT prolongation by ATO results from inhibition of the rapid  $\text{K}^+$  efflux channels in myocardial tissue by  $\text{As}_2\text{O}_3$ . This change leads to slow repolarization of myocardium, and ventricular arrhythmias. Monitoring of serum electrolytes and repletion of serum  $\text{K}^+$  in patients with hypokalemia are precautionary measures in patients receiving ATO therapy. In patients exhibiting a significantly prolonged QT ( $>470$  milliseconds), treatment should be suspended,  $\text{K}^+$  supplemented, and therapy resumed only if the QT returns to normal. Torsades de pointes requires treatment with intravenous magnesium sulfate,  $\text{K}^+$  repletion, and defibrillation if the arrhythmia persists (Gupta et al., 2007) (see [Chapter 29](#)).

## Histone Deacetylase Inhibitors

**Vorinostat.** A new field of cancer research, called epigenetics, concerns the control of cell proliferation and differentiation by processes beyond pure genetic alterations. These processes include cellular modification of expression of genes by microRNAs, histones, and proteins, and post-translational modification of proteins. Vorinostat (ZOLINZA), also known as suberoylanilide hydroxamic acid (SAHA), is unique as an epigenetic modifier that directly affects histone function ([Figure 61–15](#)). To understand

its action, it is important to review the complex structure of DNA, which wraps itself around histone proteins to form the nucleosome. This higher-order packaging controls gene expression. Acetylation of lysine residues on histones increases the spatial distance between DNA strands and the protein core, allowing access for transcription factor complexes, and thereby enhancing transcriptional activity. Acetyl groups are added by histone acetyltransferases and removed by histone deacetylases (HDACs). HDAC inhibitors such as vorinostat increase histone acetylation and thus enhance gene transcription. Many nonhistone proteins also are subject to lysine acetylation and thus are affected by treatment with HDAC inhibitors. The role of their acetylation status in the antitumor action of HDAC inhibitors is unclear.

**Mechanism of Action.** Vorinostat is a hydroxamic acid modeled after hybrid polar compounds, such as hexamethylene bisacetamide (HMBA); as a class, these compounds cause differentiation of malignant cells *in vitro*, as do other classes of compounds with HDAC-inhibitory activity, including cyclic tetrapeptides, benzamides, and short-chain aliphatic acids. These compounds bind to a critical  $Zn^{++}$  ion in the active site of HDAC enzymes. Vorinostat inhibits the enzymatic activity of HDACs at micromolar concentrations. An important distinction between vorinostat and other HDAC inhibitors is that vorinostat and the hydroxymates are pan-HDAC inhibitors, whereas other compounds have selectivity for HDAC isoenzyme subsets. The biological and clinical implications of this specificity are not clear, and the specific mechanism by which HDAC inhibitors exert their antitumor activity is uncertain. They induce cell-cycle arrest, differentiation, and apoptosis of cancer cells; nonmalignant cells are relatively resistant to these effects. They increase transcription of cell-cycle regulators, affect levels of nuclear transcription factors, and induce pro-apoptotic genes. HDAC inhibition directly blocks function of the chaperone HSP90 and stabilizes the tumor suppressor p53 (Bolden et al., 2006).

**Absorption, Fate, and Excretion.** Vorinostat is administered as a once-daily oral dose of 400 mg. It is inactivated by glucuronidation of the hydroxyl amine group, followed by hydrolysis of the terminal carboxamide bond and further oxidation of the aliphatic side chain ([Figure 61–15](#)). The metabolites are pharmacologically inactive. The terminal  $t_{1/2}$  of vorinostat in plasma is ~2 hours. Interestingly, histones remain hyperacetylated up to 10 hours after

an oral dose of vorinostat, suggesting that its effects persist beyond drug metabolism and elimination.

**Figure 61–15.** Chemical structures of vorinostat (*A*), and its metabolites, vorinostat *O*-glucuronide (*B*) and 4-anilino-4-oxobutanoic acid (*C*).

**Therapeutic Uses.** Vorinostat is approved for use in refractory cutaneous T-cell lymphoma (CTCL). In patients with refractory CTCL, vorinostat produced an overall response rate of 30%, with a median time to progression of 5 months (Duvic et al., 2007). Vorinostat and other HDAC inhibitors, including romidepsin (depsipeptide; FK228) and MGCD 0103, have shown activity in CTCL, other B- and T-cell lymphomas, and myeloid leukemia.

**Toxicity.** The most common side effects of vorinostat are fatigue, nausea, diarrhea, and thrombocytopenia. Deep venous thrombosis and pulmonary embolism were infrequent but serious adverse events in CTCL patients receiving vorinostat. Most HDAC inhibitors in development cause QTc prolongation, although no serious cardiac toxicity has been reported with vorinostat. A small number of patients receiving infusional depsipeptide romidepsin (see below) and the hydroxamate dacinostat (NVP-LAQ 824) have developed ventricular arrhythmias while on treatment, but the causal relationship to the drugs has not been clearly established, and the cardiac risk may be lower with orally administered and/or less potent HDAC inhibitors (Piekarz et al., 2006). Caution is advised when using HDAC inhibitors in patients with underlying cardiac abnormalities, and careful

monitoring of the QTc interval and correction of electrolyte ( $K^+$ ,  $Mg^{++}$ ) abnormalities is necessary.

**Romidepsin.** Romidepsin, a bicyclic polypeptide derived from a soil bacterium, inhibits HDAC at low nanomolar concentrations and is approved for treatment of CTCL and for peripheral T-cell lymphomas. In a Phase II trial it produced complete responses in 4 patients with CTCL, and partial responses in 20, from a total of 71 patients treated. Its primary toxicities include GI complaints (nausea vomiting) and transient myelosuppression. Its administration leads to T-wave flattening, but without clear cardiac toxicity (Piekarz et al., 2009).

## *Chapter 62*

# **Targeted Therapies: Tyrosine Kinase Inhibitors, Monoclonal Antibodies, and Cytokines**

Bruce A. Chabner, Jeffrey Barnes, Joel Neal, Erin Olson, Hamza Mujagic, Lecia Sequist, Wynham Wilson, Dan L. Longo, Constantine Mitsiades, and Paul Richardson

Strategies for cancer drug discovery have evolved in step with the explosion of knowledge about the molecular underpinnings of cancer. Many new drugs either recently approved or in late stages of evaluation were designed to block the fundamental mutations that cause specific cancers: aberrant growth factor receptors, dysregulated intracellular signaling pathways, defective DNA repair and apoptosis, and tumor angiogenesis. The primary tools for inhibiting these new targets are either monoclonal antibodies that attack cell surface receptors and antigens, or synthetic small molecules that enter cells and engage critical enzymes. These two classes of drugs have very different pharmacological properties.

Monoclonal antibodies kill tumor cells by blocking cell surface receptor function and by recruiting immune cells and complement to the antigen–antibody complex. They may be armed to carry toxins or radionuclides to the cells of interest, thereby enhancing their cytotoxic effects. They generally are specific for a single receptor, have a long plasma  $t_{1/2}$ , and require only intermittent administration. Small molecules may attack the same targets and pathways as the monoclonals, but may also exert their effect by entering cells and inhibiting enzymatic functions (usually tyrosine kinase reactions). The small molecules often inhibit multiple enzymatic sites, have a broad spectrum of target kinases, and tend to be substrates of hepatic CYPs with a  $t_{1/2}$  of 12–24 hours, and thus require daily oral administration. The two classes of drug, when targeted against the same pathway, may have significantly different spectra of antitumor activity. Thus, monoclonal antibodies to the epidermal growth factor receptor (EGFR) are effective in the treatment of head and neck and colon cancers, while small molecules, such as erlotinib and

gefitinib, attack the intracellular tyrosine kinase function of the same receptor and have a different spectrum of antitumor activity (non-small cell lung cancer).

Because of the central importance of the specific target in cancer chemotherapy, we will center this discussion around the target rather than the specific type of drug.

## **PROTEIN TYROSINE KINASE INHIBITORS**

Protein kinases are critical components of signal transduction pathways that regulate cell growth and adaptation to the extracellular environment. These signaling pathways influence gene transcription and/or DNA synthesis, as well as cytoplasmic events. The human genome contains ~550 protein kinases and 130 phosphoprotein phosphatases that regulate the phosphorylation states of key signaling molecules. Protein kinases can be classified into three different categories: kinases that specifically phosphorylate tyrosine residues, kinases that phosphorylate serine and threonine residues, and kinases with activity toward all three residues. Tyrosine kinases can be further subdivided into proteins that have an extracellular ligand-binding domain (receptor tyrosine kinases) and enzymes that are confined to the cytoplasm or nuclear cellular compartment (nonreceptor tyrosine kinases). Growth factors and other ligands bind to and activate the receptor tyrosine kinases under physiological conditions. In a growing number of human malignancies, mutations that constitutively activate protein tyrosine kinases are implicated in malignant transformation; thus, protein tyrosine kinases are targets for cancer therapy.

### **Inhibitors of the BCR-ABL Kinase: Imatinib, Dasatinib, and Nilotinib**

Imatinib mesylate (STI 571, GLEEVEC, GLIVEC) was the first molecularly targeted protein kinase inhibitor to receive FDA approval. It targets the BCR-ABL tyrosine kinase, which underlies chronic myelogenous leukemia (CML). A single molecular event, in this case the 9:22 translocation, leads to expression of the Abelson proto-oncogene kinase ABL fused to BCR (breakpoint cluster region), yielding a constitutively activated protein kinase, BCR-ABL, and then the malignant phenotype. Imatinib and the related compounds dasatinib and nilotinib induce clinical and molecular remissions

in >90% of CML patients in the chronic phase of disease. Imatinib effectively treats other tumors that carry related tyrosine kinase mutations, including GI stromal tumors (driven by c-KIT mutation) (Blanke et al., 2008), and hypereosinophilia syndrome, chronic myelomonocytic leukemia, and dermatofibrosarcoma protuberans (all driven by mutations that activate the platelet-derived growth factor receptor, PDGFR) (Sirvent et al., 2003).

**Chemistry.** Imatinib was identified through high-throughput screening against the BCR-ABL kinase. The lead compound of this series, a 2-phenylaminopyrimidine, had low potency and poor specificity, inhibiting both serine/threonine and tyrosine kinases (Buchdunger et al., 2001). The addition of a 3'-pyridyl group at the 3' position of the pyrimidine enhanced its potency. Further modifications resulted in improved activity against PDGFR and c-KIT and loss of serine/threonine kinase inhibition. Introduction of *N*-methylpiperazine as a polar side chain greatly improved water solubility and oral bioavailability, yielding imatinib, an inhibitor of the closed, or inactive, configuration of the kinase:

Dasatinib (BMS-354825, SPRYCEL), a second-generation BCR-ABL inhibitor, was developed using a series of substituted 2-(aminopyridyl) and 2-(aminopyrimidinyl) thiazol-5-carboxyamides. It inhibits the Src kinase, and unlike imatinib, it binds both the open and closed configurations of the BCR-ABL kinase (Shah et al., 2004).

Nilotinib (AMN107, TASIGNA) was designed to have increased potency and specificity compared to imatinib. Its structure, based on crystallographic studies of the BCR-ABL kinase, promotes hydrogen bonding to Glu286 and Asp381 (Weisberg et al., 2005) and overcomes mutations that cause imatinib resistance.

**Mechanism of Action.** Crystallographic and mutagenesis studies indicate that imatinib and nilotinib bind to a segment of the kinase domain that fixes the enzyme in a closed or nonfunctional state, in which the protein is unable to bind its substrate/phosphate donor, ATP (Weisberg et al., 2005). The three BCR-ABL kinase inhibitors differ in their potency of inhibition, their binding specificities, and their susceptibility to resistance mutations in the target enzyme. Dasatinib [(IC<sub>50</sub>) = <1 nM] and nilotinib [(IC<sub>50</sub>) = <20 nM] (Weisberg, 2005) inhibit BCR-ABL kinase more potently than does imatinib [(IC<sub>50</sub>) = 100 nM].

**Mechanisms of Resistance.** Resistance to the tyrosine kinase inhibitors arises from point mutations in three separate segments of the kinase domain ([Figure 62-1](#)). The contact points between imatinib and the enzyme become sites of mutations in drug-resistant leukemic cells; these mutations prevent tight binding of the drug and lock the enzyme in its open configuration, in which it has access to substrate. Most such mutations hold the enzyme in its open and enzymatically active confirmation. The most common resistance mutations affect amino acids 255 and 315, both of which serve as contact points for imatinib; these mutations confer high-level resistance to imatinib and nilotinib. Dasatinib is unaffected by mutation at 255 but is ineffective in the presence of mutation at 315. Nilotinib retains inhibitory activity in the

presence of most point mutations (except at 315) that confer resistance to imatinib (Weisberg et al., 2005; O’Hare et al., 2005).

Other mutations affect the phosphate-binding region and the “activation loop” of the domain with varying degrees of associated resistance. Some mutations, such as at amino acids 351 and 355, do not affect response to dasatinib or nilotinib but confer low levels of resistance to imatinib (O’Hare et al., 2005; Corbin et al., 2003).

**Figure 62–1** The relative frequency of BCR-ABL kinase domain mutations detected at 31 different positions in clinical specimens from 245 patients in whom mutations were detected (219 with chronic myelocytic leukemia and 26 with Ph<sup>+</sup> acute lymphoblastic leukemia). (Reproduced with permission from Hughes et al., 2006. Copyright © 2006 American Society of Hematology. Copyright restrictions may apply.)

This finding may explain the clinical response of some resistant patients to dose escalation of imatinib.

Molecular studies of circulating tumor cells have detected resistance-mediating kinase mutations *prior* to initiation of therapy, particularly in patients with Ph<sup>+</sup> acute lymphoblastic leukemia (ALL) (Roche-Lestienne et al., 2003) or CML in blastic crisis. This finding strongly supports the

hypothesis that drug-resistant cells arise through spontaneous mutation and expand under the selective pressure of drug exposure. Mutations may become detectable in the peripheral blood of patients receiving imatinib in the accelerated phase and in the late (>4 years from diagnosis) chronic phase of CML (Branford et al., 2003), heralding the onset of drug resistance.

Mechanisms other than BCR-ABL kinase mutation play a minor role in resistance to imatinib. Amplification of the wild-type kinase gene, leading to overexpression of the enzyme, has been identified in tumor samples from patients resistant to treatment (Morel et al., 2003). The multidrug resistant (*MDR*) gene, which codes for a drug efflux protein, confers resistance experimentally but has not been implicated in clinical resistance.

Finally, Philadelphia chromosome-negative clones lacking the BCR-ABL translocation and displaying the karyotype of myelodysplastic cells may emerge in patients receiving imatinib for CML and may progress to myelodysplasia (MDS) and to acute myelocytic leukemia (AML). Their origin is unclear.

## Pharmacokinetics

***Imatinib.*** Imatinib is well absorbed after oral administration and reaches maximal plasma concentrations within 2-4 hours. The elimination  $t_{1/2}$  of imatinib and its major active metabolite, the *N*-desmethyl derivative, are ~18 and 40 hours, respectively. Mean imatinib area under the curve (AUC) increases proportionally with increasing dose in the range 25-1000 mg (Peng et al., 2004). Food does not change the pharmacokinetic profile of imatinib. Doses >300 mg/day achieve trough levels of 1  $\mu$ M, which correspond to *in vitro* levels required to kill BCR-ABL-expressing cells. Inhibition of the BCR-ABL tyrosine kinase in white blood cells from patients with CML reaches a maximum in the dose range of 250-750 mg/day. Nonrandomized studies suggest that response may be restored in a minority of resistant patients with doses of 600 or 800 mg/day, as opposed to the standard 400 mg/day (Kantarjian et al., 2004). In the treatment of GI stromal cell tumors (GIST), higher doses (600 mg/day) may improve response rates.

CYP3A4 is the major enzyme responsible for metabolism of imatinib. CYPs 1A2, 2D6, 2C9, and 2C19 play minor roles in its metabolism. Clinicians must be cautious in introducing drugs that might interact with imatinib and CYP3A4. A single dose of ketoconazole, an inhibitor of

CYP3A4, increases the maximal imatinib concentration in plasma and its plasma AUC by 26% and 40%, respectively. Co-administration of imatinib and rifampin, an inducer of CYP3A4, lowers the plasma imatinib AUC by 70%. Likewise, imatinib, as a competitive CYP3A4 substrate, inhibits the metabolism of simvastatin and increases its plasma AUC by 3.5-fold (O'Brien et al., 2003).

**Dasatinib.** Dasatinib also is well absorbed after oral administration. As for other BCR-ABL kinase inhibitors, the bioavailability of dasatinib is significantly reduced at neutral gastric pH, resulting from antacids and H<sub>2</sub> blockers, but is unaffected by food. The plasma  $t_{1/2}$  of dasatinib is 3-5 hours, and clearance depends on CYP3A4 metabolism. Its metabolites are inactive. Dasatinib exhibits dose proportional increases in AUC, and its clearance is constant over the dose range of 15-240 mg/day. No significant changes in dasatinib pharmacokinetics were observed on repeated dosing or administration of food. Dasatinib was originally approved at a dose of 70 mg twice a day. A randomized phase III trial comparing 50 mg twice daily, 70 mg twice daily, 100 mg daily, and 140 mg daily concluded that all four schedules were equally effective in patients with CML, although the 100-mg daily dose improved progression-free survival (Shah et al., 2008).

Dasatinib is metabolized primarily by CYP3A4, although FMO3 and UGT also contribute to a minor degree. Dasatinib plasma concentrations are affected by inducers and inhibitors of CYP3A4 in a similar fashion to imatinib.

**Nilotinib.** Approximately 30% of an oral dose of nilotinib (400 mg twice daily) is absorbed after administration, and the drug achieves peak concentrations in plasma 3 hours after dosing. Unlike the other BCR-ABL inhibitors, nilotinib's bioavailability increases significantly in the presence of food (Kantarjian et al., 2006). The drug has a long plasma  $t_{1/2}$  (~17 hours), and plasma concentrations reach a steady state only after 8 days of daily dosing. Doses >400 mg/day are associated with nonlinear increases in median serum concentrations, indicating saturation of GI absorption.

Like dasatinib and imatinib, nilotinib undergoes elimination through metabolism by CYP3A4; metabolism is affected by inducers, inhibitors, and competitors of the CYP3A4 pathway. Nilotinib is a substrate and inhibitor of P-glycoprotein.

**Pharmacokinetics and Clinical Uses.** These protein tyrosine kinase inhibitors have efficacy in diseases in which the ABL, *kit*, or PDGFR have dominant roles in driving the proliferation of the tumor, reflecting the presence of a mutation that results in constitutive activation of the kinase, either by fusion with another protein or via point mutations. Thus, imatinib shows remarkable therapeutic benefits in patients with chronic-phase CML (BCR-ABL), GIST (*kit* mutation positive), chronic myelomonocytic leukemia (EVT6-PDGFR translocation), hypereosinophilia syndrome (FIP1L1-PDGFR), and dermatofibrosarcoma protuberans (constitutive production of the ligand for PDGFR) (Druker, 2004). It is the agent of choice for GIST patients with metastatic disease and as adjuvant therapy of *c-kit*-positive GIST (DeMatteo et al., 2009). GIST biology is particularly instructive, as patients with an exon 11 mutation of *kit* have a significantly higher partial response rate (72%) than those with no detectable *kit* mutations (9%) (Heinrich et al., 2003). The currently recommended dose of imatinib is 400-600 mg/day. Dasatinib is approved for patients with CML resistant or intolerant to imatinib in both chronic (100 mg/day) and advanced phases of disease (70 mg twice daily), and for use combined with cytotoxic chemotherapy in patients with Ph<sup>+</sup> ALL who are resistant or intolerant to prior therapies. Nilotinib is approved for patients with CML resistant to or intolerant of prior imatinib therapy.

**Toxicity.** Imatinib, dasatinib, and nilotinib cause GI distress (diarrhea, nausea, and vomiting), but these symptoms usually are easily controlled. All three drugs promote fluid retention, which may lead to dependent edema, and peri-orbital swelling. Dasatinib may cause pleural effusions. Nilotinib may prolong the QT interval, and should be used with caution in patients with underlying heart disease or arrhythmias, although ventricular arrhythmias have not been reported. Significant myelosuppression occurs infrequently but may require transfusion support, dose reduction, or discontinuation of the drug. All three drugs in this class can be associated with hepatotoxicity. Most nonhematological adverse reactions are self limited and respond to dose adjustments. After the adverse reactions, such as edema, myelosuppression, or GI symptoms have resolved, the drug may be reinitiated and titrated back to effective doses.

# EPIDERMAL GROWTH FACTOR RECEPTOR INHIBITORS

The EGFR belongs to the ErbB family of transmembrane receptor tyrosine kinases. EGFR, also known as ErbB1 or HER1, is essential for the growth and differentiation of epithelial cells. Ligand binding to the extracellular domain of EGFR family members causes receptor dimerization and stimulates the protein tyrosine kinase activity of the intracellular domain, resulting in autophosphorylation of several Tyr residues in the C-terminal domain. Recognition of the phosphotyrosines by other proteins initiates protein-protein interactions that result in stimulation of a variety of signaling pathways, including MAPK, PI3K/Akt, and STAT pathways ([Figure 62–2](#)) (Schlessinger, 2000). In epithelial cancers, overexpression (or mutational activations) of the EGFR is a common finding and, to some extent, creates a dependence on EGFR signaling in these tumors (Hynes and Lane, 2005).

Two separate classes of drugs that target the EGFR pathway have become important agents in the therapy of solid tumors. The EGFR tyrosine kinase inhibitors erlotinib and gefitinib bind to the kinase domain and block the enzymatic function of EGFR. The monoclonal antibodies cetuximab and panitumumab bind specifically to the extracellular domain of EGFR. They inhibit EGFR-dependent signaling through inhibition of ligand-dependent activation and receptor dimerization, downregulation of EGFR expression, and induction of antibody-dependent cell-mediated cytotoxicity (Ciardiello and Tortora, 2008).

## Gefitinib

**Chemistry.** Gefitinib was identified through screens that demonstrated its inhibition of EGFR tyrosine kinase activity and ability to kill EGFR-dependent cell lines.

**Figure 62–2 Growth factor signaling.** Binding of agonist ligands to growth factor receptors causes receptor dimerization and activation of cytosolic protein kinase domains, leading to activation of multiple signaling pathways. Shown here are the RAS/MAPK/ERK, PI3K, and SMAD pathways, each of which is activated by receptors or crosstalk from adjacent pathways. Their signals regulate proliferation, metabolism, survival, and the synthesis of other growth factors, such as the vascular endothelial growth factor (VEGF).

**Mechanism of Action.** Gefitinib inhibits the EGFR tyrosine kinase by virtue of competitive blockade of ATP binding. Gefitinib has an  $IC_{50}$  of 20-80 nM for the EGFR enzyme but is significantly less potent against HER2

(ErbB2/neu). Gefitinib has antitumor activity in human xenograft tumors that exhibit high levels of EGFR expression.

**Absorption, Distribution, and Elimination** Following oral administration of gefitinib, peak plasma concentrations are achieved within 3-7 hours, and oral bioavailability approaches 60%. Administration of 225 mg/day orally results in steady-state levels of 200 ng/mL after 7-10 doses. The mean terminal  $t_{1/2}$  is 41 hours. Elimination of gefitinib primarily occurs by hepatic CYP3A4 metabolism.

**Therapeutic Uses.** Gefitinib initially was approved for the third-line treatment of patients with non-small cell lung cancer based on promising results in two small clinical trials. However, a larger, randomized, placebo-controlled trial failed to show an effect on survival, leading the FDA to restrict its use to patients who have previously received clinical benefit from the drug (Thatcher et al., 2005). Gefitinib continues to be widely used outside the U.S. Two large trials have failed to demonstrate a benefit of gefitinib in combination with chemotherapy. The standard dose is 250 mg daily.

Retrospective analysis of multiple studies revealed that patients who were nonsmokers, Asians, or women were most likely to respond to gefitinib. Tumors from these patients frequently have characteristic activating mutations in *EGFR* (Sequist and Lynch, 2008). These mutations mostly fall into two groups: 1) small in-frame deletions within exon 19 and 2) the L858R point mutation. Trials that randomized never- and light-smoking patients to first-line gefitinib or to chemotherapy demonstrated a 70% response rate to gefitinib in patients with an activating *EGFR* mutation, compared with responses in only 1% in patients without an *EGFR* mutation. In patients with *EGFR*-mutant tumors, the response rate to gefitinib was double the response to standard chemotherapy. Therefore, mounting evidence supports the use of gefitinib, and potentially erlotinib, as first-line therapy in patients selected for the presence of sensitizing *EGFR* mutations.

**Adverse Effects and Drug Interactions.** Diarrhea and pustular/papular rash occur in ~50% of patients taking gefitinib. Other side effects include dry skin, nausea, vomiting, pruritus, anorexia, and fatigue. Most adverse effects occur within the first month of therapy and are tolerable when managed with supportive medications and dose reductions. Asymptomatic increases in liver transaminases may necessitate dose reduction or discontinuation of

therapy. Interstitial lung disease, often associated with symptoms of cough and dyspnea, occurs in <2% of patients receiving gefitinib but may have a fatal outcome.

Exposure to gefitinib is not significantly altered by food; however, co-administration of drugs that cause sustained elevations in gastric pH reduce mean gefitinib AUC by 47%. Metabolism of gefitinib is predominantly via CYP3A4. Substances that induce CYP3A4 activity (e.g., phenytoin, carbamazepine, rifampin, barbiturates, St. John's wort) decrease gefitinib plasma concentrations and efficacy; conversely, inhibitors of CYP3A4 (e.g., itraconazole, ketoconazole) increase plasma concentrations. Patients using warfarin should be monitored closely for elevation of the INR while taking gefitinib.

## Erlotinib

Erlotinib (TARCEVA) is a quinazolinamine inhibitor of HER1/EGFR tyrosine kinase.

**Mechanism of Action.** Erlotinib is a potent inhibitor of the EGFR tyrosine kinase. Like gefitinib, erlotinib competitively inhibits ATP binding at the active site of the kinase. Erlotinib has an  $IC_{50}$  of 2 nM for the EGFR kinase. Tumors harboring *k-ras* mutations and *EML4-ALK* translocations do not respond to EGFR kinase inhibitors.

**Absorption, Distribution, and Excretion.** Erlotinib is ~60% absorbed after oral administration but should not be taken with food, which increases its bioavailability to ~100%. Peak plasma levels occur 4 hours after an oral dose. Erlotinib has a  $t_{1/2}$  of 36 hours and is metabolized by CYP3A4 and to a lesser extent by CYPs 1A2 and 1A1. The standard daily dose of erlotinib results in a plasma AUC approximately one order of magnitude greater than the AUC of gefitinib.

**Therapeutic Uses.** Erlotinib is approved for second-line treatment of patients with locally advanced or metastatic non-small cell lung cancer. FDA approval was based on an improvement in overall survival in a large multi-national trial comparing oral erlotinib, 150 mg daily, to placebo (Shepherd et al., 2005). Results from two subsequent trials showed no clinical benefit from the combination of erlotinib with platinum-based chemotherapy as compared to chemotherapy alone.

Erlotinib also is approved for first-line treatment of patients with locally advanced, unresectable, or metastatic pancreatic cancer in combination with gemcitabine. A large double-blinded study of 569 patients demonstrated a modest 2-week improvement in overall survival in patients who received 100 mg of erlotinib plus gemcitabine, as compared with patients who received gemcitabine alone (Moore et al., 2007). The recommended dose of erlotinib in non-small cell lung cancer is a 150-mg tablet daily. In pancreatic cancer, the dose is a 100-mg tablet daily. It should be taken at least 1 hour before or 2 hours after a meal.

**Adverse Effects and Drug Interactions.** As with gefitinib, the most common adverse reactions in patients receiving erlotinib are diarrhea, an acneform rash, anorexia, and fatigue. Serious or fatal interstitial lung disease occurs with a frequency of 0.7-2.5%. Hepatic function deserves close monitoring because serious or fatal hepatic failure due to erlotinib has been reported, particularly in patients with baseline hepatic dysfunction. Other rare but serious toxicities include GI perforation, renal failure, arterial thrombosis, microangiopathic hemolytic anemia, hand-foot skin reaction, and corneal perforation or ulceration. Erlotinib therapy may cause rare cases of Stevens-Johnson syndrome/toxic epidermal necrolysis.

Concurrent use of proton-pump inhibitors decreases the bioavailability of erlotinib by 50%. As with gefitinib, plasma levels can vary dramatically due to drug interactions with inducers or inhibitors of CYP3A4. Patients using warfarin may experience elevations of the international normalized ratio (INR) while taking erlotinib. Smoking accelerates metabolic clearance of erlotinib by 24% and may decrease its antitumor effects.

## **Resistance to Gefitinib and Erlotinib**

Patients with non-small cell lung cancer who initially respond to erlotinib or gefitinib have tumors that are dependent on the EGFR signaling pathway.

Clinical response to these agents is strongly associated with the presence of sensitizing mutations in EGFR as described in “Therapeutic Uses” under “Gefitinib,” but response is less strongly correlated with overexpression or amplification of EGFR (Sequist and Lynch, 2008). Therapy directed at the EGFR may delay disease progression in patients with non–small cell lung cancers that lack activating *EGFR* mutations, although response rates approach zero in these patients. The subset of non–small cell lung tumors harboring *k-ras* mutations and *EML4-ALK* translocations do not respond to EGFR inhibitors.

Tumors containing mutations in *EGFR* initially respond to erlotinib and gefitinib but eventually progress. Resistance arises through several different mechanisms. A secondary mutation in the *EGFR* gatekeeper residue, T790M, prevents binding of drug to the kinase domain and confers resistance (Kobayashi et al., 2005). Irreversible *EGFR* inhibitors currently are in clinical development to overcome this mechanism. Amplification of the *met* oncogene provides an alternative pathway to clinical resistance by activating cell growth signals downstream of *EGFR* (Engelman et al., 2007). *MET*-amplified tumors respond *in vitro* to the simultaneous inhibition of EGFR and *MET*. Other potential mechanisms of resistance include activation of downstream mediators, efflux of drug, and altered receptor trafficking.

## Cetuximab

Cetuximab is a monoclonal antibody to the extracellular domain of the EGFR. Such antibodies, although sharing the same target with erlotinib and gefitinib and having a similar side effect profile, have a different spectrum of antitumor activity.

**Chemistry** Cetuximab (*erbitux*) is a recombinant chimeric human/mouse immunoglobulin G1 (IgG<sub>1</sub>) antibody that binds to the extracellular domain of EGFR. It consists of the Fv regions of a murine anti-EGFR antibody with human IgG<sub>1</sub> heavy- and κ light-chain constant regions.

**Mechanism of Action.** Cetuximab binds specifically to the extracellular domain of EGFR and prevents ligand-dependent signaling and receptor dimerization, thereby blocking cell growth and survival signals. Cetuximab also may mediate antibody-dependent cellular cytotoxicity against tumor cells.

**Absorption, Distribution, and Elimination.** Cetuximab exhibits nonlinear pharmacokinetic characteristics. Following intravenous administration, steady-state levels are achieved by the third weekly infusion. The volume of distribution approximates the intravascular space of 2-3 L/m<sup>2</sup>. Therapeutic doses that saturate total body receptor pools of EGFR follow zero-order kinetics for elimination. Clearance occurs via EGFR binding and internalization and by degradation in the reticuloendothelial system.

## **Therapeutic Uses**

**Head and Neck Cancer.** Cetuximab won FDA approval based on an improvement in overall survival when used in combination with radiation therapy for locally or regionally advanced squamous cell carcinoma of the head and neck (HNSCC). It received a second indication as monotherapy for patients with metastatic or recurrent HNSCC who had failed platinum-based chemotherapy. It has become a useful agent in combination with cisplatin-based chemotherapy, where it has shown an improvement in survival compared to chemotherapy alone (Vermorke et al., 2008).

**Metastatic Colon Cancer.** Cetuximab received approval as a single agent for the treatment of EGFR-positive metastatic colorectal cancer; cetuximab is used in patients who cannot tolerate irinotecan-based therapy and in combination with irinotecan for patients refractory to oxaliplatin, irinotecan, and 5-fluorouracil (5-FU). In the first-line setting, cetuximab may improve survival in combination with 5-FU/leucovorin and irinotecan or oxaliplatin (Bokemeyer et al., 2009). Numerous trials now have shown that the 40-50% of colorectal tumors carrying mutations in the *k-ras* oncogene are resistant to the effects of cetuximab. The antibody yields a response rate of 1% in patients with mutant tumors, compared to 12% in *k-ras* wild-type tumors (Karapetis et al., 2008). Cetuximab enhances the effectiveness of chemotherapy in patients with *k-ras* mutant tumors but not *k-ras* wild-type tumors (Bokemeyer et al., 2009).

The standard dose of cetuximab is a single loading dose of 400 mg/m<sup>2</sup> intravenously, followed by weekly doses of 250 mg/m<sup>2</sup> intravenously for the duration of treatment.

**Adverse Effects.** Side effects associated with cetuximab treatment include an acneform rash in the majority of patients. Patients also may experience pruritus, nail changes, headache, and diarrhea. Other rare but serious adverse

effects include cardiopulmonary arrest, interstitial lung disease, and hypomagnesemia. In addition, patients can develop anaphylactoid reactions during infusion, which may be related to pre-existing IgE antibodies that are more prevalent in patients from the southern U.S.

## **Panitumumab**

**Chemistry.** Panitumumab (VECTIBIX) is a recombinant, fully humanized IgG<sub>2κ</sub> antibody that binds specifically to the extracellular domain of EGFR. Unlike cetuximab, it does not mediate antibody-dependent cell-mediated cytotoxicity.

**Absorption, Distribution, and Elimination.** Panitumumab exhibits nonlinear pharmacokinetic characteristics. Following intravenous administration every 2 weeks, steady-state levels are achieved by the third infusion. The mean elimination  $t_{1/2}$  is 7.5 days.

**Therapeutic Uses.** Panitumumab improves progression-free survival in patients with metastatic colorectal carcinoma, as demonstrated in patients with EGFR-expressing tumors who had two or more previous therapies (Van Cutsem et al., 2008). The dose of panitumumab is 6 mg/kg intravenously given once every 2 weeks.

**Adverse Effects.** The adverse effects with panitumumab are similar to cetuximab and include rash and dermatological toxicity, severe infusion reactions, pulmonary fibrosis, and electrolyte abnormalities.

## **HER2/neu Inhibitors**

Both antibodies (trastuzumab) and small molecules (lapatinib and others in clinical trial) have striking antitumor effects in patients with HER2-positive breast cancer, and have become essential therapeutic agents in combination with cytotoxic chemotherapy for this aggressive malignancy.

**Trastuzumab.** Trastuzumab (HERCEPTIN) is a humanized monoclonal antibody that binds to the external domain of HER2/neu (ErbB2).

Thirty percent of breast cancers overexpress this receptor due to gene amplification on chromosome 17. Amplification of the receptor is associated with lower response rates to hormonal therapies and to most cytotoxic drugs, with the exception of anthracyclines (Slamon et al., 1989). Patients with

HER2/neu-amplified tumors have higher recurrence rates after standard adjuvant therapy and poorer overall survival, as compared to patients with HER2-nonamplified tumors. The internal domain of the HER2/neu glycoprotein encodes a tyrosine kinase that activates downstream signal, enhances metastatic potential, and inhibits apoptosis. Trastuzumab exerts its antitumor effects through several putative mechanisms of action (Nahta and Esteva, 2003): inhibition of homo- or heterodimerization of receptor, thereby preventing receptor kinase activation and downstream signaling; initiation of Fc $\gamma$ -receptor-mediated antibody-dependent cellular cytotoxicity; and blockade of the angiogenic effects of HER2 signaling.

Trastuzumab was the first monoclonal antibody to be approved for the treatment of a solid tumor. Currently, it is approved for HER2/neu-overexpressing metastatic breast cancer, in combination with paclitaxel as initial treatment or as monotherapy following chemotherapy relapse (Vogel et al., 2002). Trastuzumab synergizes with other cytotoxic agents in HER2/neu-overexpressing cancers (Slamon et al., 2001). HER2/neu expression also is found in subsets of patients with gastric, esophageal, lung, and other solid tumors, but clinical studies of the effects of trastuzumab in these tumors have not yet been completed.

***Pharmacokinetics and Toxicity.*** Trastuzumab has dose-dependent pharmacokinetics with a mean  $t_{1/2}$  of 5.8 days on the 2-mg/kg maintenance dose. Steady-state levels are achieved between 16 and 32 weeks, with mean trough and peak concentrations of  $\sim 79$  and 123  $\mu\text{g/mL}$ , respectively (Baselga, 2000). The infusional effects of trastuzumab are typical of other monoclonal antibodies and include fever, chills, nausea, dyspnea, and rashes. Premedication with diphenhydramine and acetaminophen is indicated. The most serious toxicity of trastuzumab is cardiac failure; reasons for cardiotoxicity are poorly understood, although the HER2 antigen is highly expressed in the developing heart during embryogenesis, and HER2 knockout mice fail to survive because of cardiomyopathy (Crone et al., 2002). Cardiac failure is a potentially disabling or fatal side effect unless it is recognized early and the drug is discontinued (Seidman et al., 2002). Before initializing therapy, baseline electrocardiogram and cardiac ejection fraction measurement should be obtained to rule out underlying heart disease, and patients deserve careful clinical follow-up thereafter for signs or symptoms of congestive heart failure, such as cough, weight gain, or edema. When

trastuzumab is used as a single agent, <5% of patients will experience a decrease in left-ventricular ejection fraction, and 1% will have clinical signs of congestive failure. However, left-ventricular dysfunction occurs in up to 20% of patients who received the antibody in combination with doxorubicin and cyclophosphamide. The risk of cardiac toxicity is greatly reduced with taxane–trastuzumab combinations.

**Lapatinib.** Small molecules can inhibit receptor tyrosine kinase activity of ErbB2 (HER2/neu) and have antitumor activity in patients who have developed progressive disease on trastuzumab (Moy and Goss, 2007). Lapatinib and other pan-HER inhibitors block both ErbB1 and ErbB2 and bind to an internal site on the receptor (usually the ATP-binding pocket), compared to the external binding site of trastuzumab. Lapatinib also inhibits a truncated form of the HER2 receptor that lacks a trastuzumab-binding domain. These differences may account for the activity of lapatinib in trastuzumab-resistant patients.

Lapatinib (TYKERB) is FDA-approved for HER2-amplified, trastuzumab-refractory breast cancer, in combination with the fluoropyrimidine analog, capecitabine. In its critical phase III trial, lapatinib plus capecitabine improved disease-free survival by 4.4 months and increased the disease response rate to 22% versus 14% in the control group treated with capecitabine alone. As a small molecule, lapatinib crosses the blood-brain barrier more readily than inhibitor antibodies and has produced anecdotal responses in patients with brain metastases and decreased the incidence of brain metastases in its phase III trial (Geyer et al., 2006).

**Pharmacokinetics and Toxicity.** The drug is administered orally, 1250 mg/day. It is metabolized by CYP3A4 to a number of inactive products, as well as to an oxidized intermediate that has activity against ErbB1 but not ErbB2. The plasma  $t_{1/2}$  of 14 hours allows parent drug accumulation over the

period of treatment. Concurrent administration of inducers and inhibitors of CYP3A4 shorten and prolong the drug's  $t_{1/2}$ , respectively, and may necessitate adjustment of the dose. Lapatinib toxicities include mild diarrhea, cramping, and exacerbation of gastro-esophageal reflux. When lapatinib is combined with capecitabine, diarrhea becomes a significant side effect in one-third of patients. Lapatinib's inhibition of ErbB1 (EGFR) causes an acneform rash in one-third of patients; the rash can be effectively controlled in most cases with topical or oral antibiotics and topical benzoyl peroxide gel. Unlike trastuzumab, lapatinib has not produced a clear signal of cardiac toxicity (Medina and Goodin, 2008); nonetheless, because it targets ErbB2, lapatinib should be used with caution in combination with other cardiotoxic drugs and with careful surveillance in patients who have underlying heart disease.

## INHIBITORS OF ANGIOGENESIS

In 1971, Judah Folkman opened the field of anti-angiogenesis therapy when he hypothesized that the induction of new blood vessel formation—angiogenesis—is an essential property of cancers (Folkman, 1971). Although this revolutionary hypothesis was initially greeted with skepticism, angiogenesis now is firmly established as one of the hallmarks of cancer.

Cancer cells secrete angiogenic factors that induce the formation of new blood vessels and guarantee the flow of nutrients to the tumor cells. Angiogenic factors secreted by tumors include VEGF (*vascular* endothelial growth factor), FGF (*fibroblast* growth factor), TGF- $\beta$  (*transforming* growth factor  $\beta$ ) and PDGF (*platelet* -derived growth factor). Multiple tumor types overexpress these angiogenic factors. Several animal models have demonstrated that tumor secretion of proangiogenic factors turns on an “angiogenic switch,” a process essential to tumor growth and metastasis. Strikingly, in multiple experimental models, blockade of these proangiogenic molecules halts tumor growth, and in human cancers, anti-angiogenic drugs also have inhibitory effects.

Jain has proposed an additional mechanism for the efficacy of angiogenesis inhibitors (Jain, 2009), based on the observation that the leaky capillaries within tumors have increased permeability and cause an increase in tumor interstitial pressure. This increased pressure inhibits blood flow, decreases oxygenation, and prevents drug delivery within the tumor.

Antibodies directed at the primary angiogenic factor, VEGF, decrease interstitial pressure within tumors and reverse the changes in oxygenation and blood flow. By “normalizing” interstitial pressure and improving blood flow, anti-angiogenic agents enhance the ability of chemotherapeutic agents to reach the tumor. Hence, an additional benefit of anti-angiogenic molecules may be their ability to increase the delivery of chemotherapy to the tumor. This hypothesis seems to be validated in the synergy observed when cytotoxic chemotherapy is combined with anti-VEGF antibodies.

The best studied of the angiogenic factors is VEGF. VEGF initiates endothelial cell proliferation when it binds to a member of the VEGF receptor (VEGFR) family, a group of highly homologous receptors with intracellular tyrosine kinase domains that includes VEGFR1 (FLT1), VEGFR2 (KDR), and VEGFR3 (FLT4). The binding of VEGF to its receptor activates the intracellular VEGFR tyrosine kinase activity and initiates mitogenic and anti-apoptotic signaling pathways within the endothelial cell.

The cognate interaction between VEGF and its receptor creates several opportunities for pharmacological inhibition of this pathway. Antibodies targeting VEGF, such as bevacizumab, sterically hinder the interaction of VEGF with its receptor. As an alternative to VEGF antibody therapy, the investigational drug aflibercept (VEGF Trap), a recombinant molecule that utilizes the VEGFR1-binding domain to sequester VEGF, acts as a “soluble decoy receptor” for VEGF.

Alternatively, the propagation of proangiogenic signals can be abrogated by the inhibition of the tyrosine kinase activity of VEGFR. Three small molecules (pazopanib, sorafenib, and sunitinib) that inhibit the kinase function of VEGFR-2 have been approved for clinical use. Although bevacizumab and the small molecules share a similar spectrum of toxicities, they have somewhat different spectra of clinical activity and significant differences in pharmacokinetics.

**Bevacizumab** *Bevacizumab* (AVASTIN), a humanized antibody directed against VEGF-A, was the first FDA-approved molecule that specifically targeted angiogenesis. As a single agent, it delays progression of renal-cell cancer, and, in combination with cytotoxic chemotherapy, effectively treats lung, colorectal, and breast cancers.

In clear-cell renal-cell carcinoma, a cancer notoriously resistant to traditional chemotherapeutic agents, single-agent bevacizumab increases

survival by 3 months (Yang et al., 2003). Clear-cell renal-cell cancer, a highly vascular tumor, presents a particularly attractive target for bevacizumab and other anti-angiogenic agents because mutations or DNA methylation affecting the von Hippel-Lindau (*VHL*) gene are a constant feature of renal-cell carcinomas. The *VHL* gene product functions as an inhibitor of the angiogenic pathway. Thus, a loss of VHL protein activates hypoxia inducible factor 2 (HIF-2), a transcription factor that promotes synthesis of VEGF and other hypoxic response proteins. In 2009, the FDA approved bevacizumab in combination with interferon- $\alpha$  for the treatment of metastatic renal-cell carcinoma.

Bevacizumab is approved as a single agent following prior therapy for glioblastoma. In all other cancers, bevacizumab has little apparent single-agent activity but improves survival in epithelial cancers in combination with standard chemotherapeutic agents (Sandler et al., 2006). Bevacizumab with carboplatin and paclitaxel increases survival in non-small lung cancer by 2 months. Likewise, bevacizumab combined with FOLFOX (5-FU, leucovorin, and oxaliplatin) or FOLFIRI (5-FU, leucovorin, and irinotecan) improves survival by 5 months in metastatic colon cancer. Finally, the combination of bevacizumab with docetaxel increases progression-free survival in patients with metastatic breast cancer (Miller et al., 2007). Trials testing bevacizumab in glioblastoma multiforme have yielded promising results with minimal evidence of intracranial hemorrhage.

Clinical uses of bevacizumab now have expanded beyond the realm of oncology. In wet age-related macular degeneration, abnormal choroidal neovascularization often leads to rapid visual loss. A slightly altered version of bevacizumab called ranibizumab (*LUCENTIS*), in which the Fc region has been deleted, effectively treats wet macular degeneration. Bevacizumab restores hearing in patients with progressive deafness due to neurofibromatosis type 2-related tumors (Plotkin et al., 2009).

**Clinical Pharmacology.** Bevacizumab is administered intravenously as a 30- to 90-minute infusion. In metastatic colon cancer, in conjunction with combination chemotherapy, the dose of bevacizumab is 5 mg/kg every 2 weeks. In metastatic non-small cell lung cancer, doses of 15 mg/kg are given every 3 weeks with chemotherapy. For treatment of metastatic breast cancer, patients receive 10 mg/kg of bevacizumab every 2 weeks in combination with paclitaxel or docetaxel. The differing doses of bevacizumab reflect the

varying designs of approval-directed trials. The optimal dosage in each case has not yet been defined. The antibody has a plasma  $t_{1/2}$  of 4 weeks.

**Toxicity.** Bevacizumab causes a wide range of class-related adverse effects. A prominent concern with this class of agents was the potential for vessel injury and bleeding, noticed in patients with squamous-cell lung cancer (Johnson et al., 2004). Bevacizumab is contraindicated for patients who have a history of hemoptysis, brain metastasis, or a bleeding diathesis, but in appropriately selected patients, the rate of life-threatening pulmonary hemorrhage is <2% (Sandler et al., 2006).

The safety of operating on patients treated with bevacizumab continues to be a major concern because of the risk of bleeding and poor wound healing. In a pooled analysis of two large clinical trials of colon cancer, patients who needed surgery while being treated with bevacizumab had a higher rate (13% versus 3.4%) of serious wound healing complications than patients treated with placebo (Scappaticci et al., 2007). In light of these data and because of the long  $t_{1/2}$  of bevacizumab, elective surgery should be delayed for at least 4 weeks from the last dose of antibody, and treatment should be not resumed for at least 4 weeks after surgery.

Other toxicities characteristic of anti-angiogenic drugs include hypertension and proteinuria. A majority of patients receiving the drug require anti-hypertensive therapy, particularly those receiving higher doses and more prolonged treatment (Sandler et al., 2006; Hurwitz et al., 2004; Miller et al., 2007). The mechanism driving this hypertension is still unclear but may relate, in part, to decreased endothelial nitric oxide production. Physicians should carefully monitor the blood pressure of all patients on bevacizumab and intervene with anti-hypertensives when appropriate. Case reports describe patients with poorly controlled hypertension developing a reversible posterior leukoencephalopathy during bevacizumab treatment. Bevacizumab also is rarely associated with congestive heart failure, probably secondary to hypertension (Miller et al., 2007).

Patients often develop proteinuria during bevacizumab treatment, but it usually is an asymptomatic finding and rarely associated with nephrotic syndrome (Gressett and Shah, 2009).

The most dreaded vascular toxicity of anti-angiogenic agents is an arterial thromboembolic event (i.e., stroke or myocardial infarction). A meta-

analysis found that the rate of arterial thromboembolic events in patients receiving bevacizumab-containing regimens reached 3.8% compared to the control rate of 1.7% (Scappaticci et al., 2007). To reduce the risk of arterial thromboembolic events, clinicians should carefully evaluate a patient's risk factors (age >65 years, clotting diathesis, a past history of arterial thromboembolic events) before starting the drug.

GI perforation, a potentially life-threatening complication of bevacizumab, has been observed with particular frequency (up to 11%) in patients with ovarian cancer, perhaps related to the presence of peritoneal carcinomatosis and to prior abdominal surgery. In colon cancer patients, colonic perforation occurs infrequently during bevacizumab treatment but increases in frequency in patients with intact primary colonic tumors, peritoneal carcinomatosis, peptic ulcer disease, chemotherapy-associated colitis, diverticulitis, or prior abdominal radiation treatment (Gressett and Shah, 2009). The rate of colon perforation is <1% in breast and lung cancer patients receiving the antibody.

**Sunitinib.** Sunitinib (SUTENT) competitively inhibits the binding of ATP to the tyrosine kinase domain on the VEGF receptor-2, a mechanism it shares with sorafenib (see "Sorafenib"). Sunitinib also inhibits other protein tyrosine kinases (FLT3, PDGFR- $\alpha$ , PDGFR- $\beta$ , RET, CSF-1R, and c-KIT) at concentrations of 5-100 nM (Fabian et al., 2005).

Sunitinib has activity in metastatic renal-cell cancer, producing a higher response rate (31%) and a longer progression-free survival than any other approved anti-angiogenic drug (Motzer et al., 2007). Sunitinib also is approved for treatment of advanced renal-cell carcinoma and GIST that have developed resistance to imatinib as a consequence of *c-KIT* mutations (Heinrich et al., 2008). Specific *c-KIT* mutations correlate with response to sunitinib. For example, patients with *c-KIT* exon 9 mutations have a response rate of 37%, whereas patients with *c-KIT* exon 11 mutations have only a 5% response rate.

**Pharmacokinetics and Dosing.** Sunitinib is administered orally in doses of 50 mg once a day. The typical cycle of sunitinib is 4 weeks on treatment followed by 2 weeks off treatment. The dosage and schedule of sunitinib can be increased or decreased according to toxicity (hypertension, fatigue). Dosages <25 mg/day typically are ineffective. Sunitinib is metabolized by CYP3A4 to produce an active metabolite, SU12662, the  $t_{1/2}$  of which is 80-110 hours; steady-state levels of the metabolite are reached after ~2 weeks of repeated administration of the parent drug. Further metabolism results in the formation of inactive products. The pharmacokinetics of sunitinib are not affected by food intake.

**Toxicity.** The main toxicities of bevacizumab are shared by all anti-angiogenic inhibitors, including sunitinib and sorafenib. Specifically, patients taking sunitinib can experience bleeding, hypertension, proteinuria, and, uncommonly, arterial thromboembolic events and intestinal perforation. However, because sunitinib is a multi-targeted tyrosine kinase inhibitor, it has a broader side-effect profile than bevacizumab.

Fatigue, the most common side effect of sunitinib, affects 50-70% of patients and may be disabling. Hypothyroidism occurs in 40-60% of patients. Bone marrow suppression and diarrhea also are common side effects; severe neutropenia (neutrophils <1000/mL) develop in 10% of patients. Less common side effects include congestive heart failure (usually in association with hypertension) and hand-foot syndrome. To monitor for these side effects, it is essential to check blood counts and thyroid function at regular intervals. Periodic echocardiograms also are recommended.

**Sorafenib** Sorafenib (NEXAVAR), like sunitinib, targets multiple protein tyrosine kinases (VEGFR1, VEGFR2, VEGFR3, PDGFR- $\beta$ , c-KIT, FLT-3, and b-RAF) and inhibits their catalytic activities at concentrations of 20-90 nM (Fabian et al., 2005).

**Absorption, Distribution, and Elimination.** Sorafenib, an oral medication, is given in daily doses of 400 mg twice a day. Patients typically begin treatment taking 200 mg once a day and increase dosage as tolerated. Unlike sunitinib, sorafenib is given every day without treatment breaks. Sorafenib is metabolized to inactive products by CYP3A4 with a  $t_{1/2}$  of 20-27 hours; with repeated administration, steady-state concentrations are reached within 1 week.

**Therapeutic Uses.** Sorafenib is the only drug currently approved for treatment of hepatocellular carcinoma. In these otherwise refractory patients, sorafenib increased median survival by 3 months compared to placebo (10.7 versus 7.9 months) (Llovet et al., 2008). The response rate to sorafenib was low (2%), suggesting that sorafenib primarily has a cytostatic effect. Sorafenib also is approved in metastatic renal-cell cancer, based on improvement in progression-free survival in patients with previously treated disease (Escudier et al., 2007). Because of its higher initial response rate, sunitinib generally is the preferred first-line therapy in this disease.

**Adverse Effects.** Sorafenib patients can experience the vascular toxicities (bleeding, hypertension, and arterial thromboembolic events) seen with other anti-angiogenic medications. More common adverse effects include fatigue, nausea, diarrhea, anorexia, and rash; uncommonly, one may notice bone marrow suppression and GI perforation (Escudier et al., 2007).

## THALIDOMIDE

Among agents with anti-angiogenic activity, the immunomodulatory analogs (IMiDs), thalidomide and lenalidomide, have a most unusual history and a multiplicity of biological and immunological effects. Their classification as anti-angiogenics is convenient but tentative. Thalidomide originally entered development in the 1950s for the treatment of pregnancy-associated morning sickness but was withdrawn from the market due to the tragic consequences of teratogenicity and dysmelia (stunted limb growth) (Franks et al., 2004). It

re-entered clinical practice, initially because of its clinical efficacy in erythema nodosum leprosum, for which it received approval in 1998 (see [Chapter 56](#)). Further research revealed its anti-angiogenic and immunomodulatory effects, and these findings triggered experimental trials in cancer, most notably against multiple myeloma (MM). Both thalidomide and lenalidomide possess potent activity in newly diagnosed and heavily pretreated relapsed/refractory MM patients (Richardson et al., 2007). Lenalidomide also has striking clinical activity in the 5q- subset of myelodysplastic syndrome (MDS) and has been approved for this indication. A specific gene array profile identifies MDS patients who lack the 5q- abnormality but respond to lenalidomide (Ebert et al., 2008).

\*Denotes the chiral center.

**Mechanisms of Action.** The precise mechanisms responsible for these drugs' clinical effects are unclear. Thalidomide's enantiomeric interconversion and spontaneous cleavage to multiple short-lived and poorly characterized metabolites, as well as its species-specific *in vivo* metabolic activation, confound the interpretation of preclinical *in vitro* and *in vivo* mechanistic studies. At least four distinct, but potentially complementary, mechanisms have been proposed to explain the antitumor activity of IMiDs ([Figure 62-3](#)):

- Direct anti-proliferative/pro-apoptotic antitumor effects. They inhibit the anti-apoptotic effects of NF- $\kappa$ B and the anti-apoptotic Bcl-2 family member A1/Bfl-1 (Mitsiades et al., 2002a).
- Indirect inhibition of tumor cell growth and survival by abrogation of cell interactions with adhesion molecules (Hideshima et al., 2000).
- Inhibition of interleukin-6 (IL-6) and tumor necrosis factor  $\alpha$  (TNF  $\alpha$ ) production, release, and signaling, leading to anti-angiogenic effects.

**Figure 62–3** Schematic overview of proposed mechanisms of antimyeloma activity of thalidomide and its derivatives. Some biological hallmarks of the malignant phenotype are indicated in light-blue boxes. The proposed sites of action for thalidomide (letters inside red and green circles) are hypothesized to also be operative for thalidomide derivatives. **A.** Direct anti–multiple myeloma (MM) effect on tumor cells, including G<sub>1</sub> growth arrest and/or apoptosis, even against MM cells resistant to conventional therapy. This is due to the disruption of the anti-apoptotic effect of BCL-2 family members, blocking NF-κB signaling, and inhibition of the production of interleukin-6 (IL-6). **B.** Inhibition of MM-cell adhesion to bone marrow stromal cells partially due to the reduction of IL-6 release. **C.** Decreased angiogenesis due to the inhibition of cytokine and growth factor production and release. **D.** Enhanced T-cell production of cytokines, such as IL-2 and interferon-γ (IFN-

$\gamma$ ), that increase the number and cytotoxic functionality of natural killer (NK) cells. VEGF, vascular endothelial growth factor.

- Immunomodulation through enhancement of natural killer (NK) and T cell-mediated cytotoxicity. Their antagonism of anti-apoptotic pathways and their anti-angiogenic effects could account for the clinical synergy with glucocorticoids and bortezomib against MM (Mitsiades et al., 2002b).

## THALIDOMIDE

**Pharmacokinetics and Therapeutic Use.** Thalidomide (THALOMID) exists at physiological pH as a racemic mixture of cell-permeable and rapidly interconverting non-polar S(-) and R(+) isomers, the equilibrium favoring the R product. The R-enantiomer is associated with the teratogenic and biological activities, while the S accounts for the sedative properties of thalidomide.

Thalidomide is given in dosages of 200-1200 mg/day. In treating MM, doses usually are escalated by 200 mg/day every 2 weeks until dose-limiting side effects (sedation, fatigue, constipation, or a sensory neuropathy) supervene. With extended treatment, the neuropathy may necessitate dose reduction or discontinuation of treatment for a period of time. Thalidomide absorption from the GI tract is slow and highly variable [4 hours mean time to reach peak concentration ( $T_{max}$ ), with a range of 1-7 hours]. It distributes throughout most tissues and organs, without significant binding to plasma proteins. Peak levels are achieved in 3-4 hours, and the  $t_{1/2}$  of disappearance of the enantiomers is ~6 hours. Elimination of thalidomide is mainly by spontaneous hydrolysis in all body fluids; the S-enantiomer is cleared more rapidly than the R-enantiomer. Thalidomide and its metabolites are excreted in the urine, while the non-absorbed portion of the drug is excreted unchanged in feces, but clearance of active drug is primarily attributable to hydrolysis. The inactive hydrolysis products undergo a complex pattern of CYP-mediated metabolism. Studies in elderly prostate cancer patients showed a significantly longer plasma  $t_{1/2}$  at highest doses (1200 mg daily) versus lowest doses (200 mg daily) (Figg et al., 1999). No dose adjustment is necessary in the presence of renal failure.

Thalidomide enhances the sedative effects of barbiturates and alcohol and the catatonic effects of chlorpromazine and reserpine. Conversely, CNS

stimulants (such as methamphetamine and methylphenidate) counteract the depressant effects of thalidomide.

**Lenalidomide** Lenalidomide (*REVLIMID*) constitutes the lead compound in the new class of immunomodulatory thalidomide derivatives and exhibits a panoply of pharmacological properties (direct suppression of the tumor cell growth in culture, T-cell and NK-cell activation, suppression of TNF  $\alpha$  and other cytokines, anti-angiogenesis, and promotion of hematopoietic stem cell differentiation) (List, 2007).

**Pharmacokinetics and Therapeutic Use.** The standard dosage of lenalidomide is 25 mg/day for 21 days of a 28-day cycle. The drug is rapidly absorbed following oral administration, reaching peak plasma levels within 1.5 hours. The  $C_{max}$  and AUC values increase proportionately with increasing dose, over a single-dose range of 5-400 mg. The  $t_{1/2}$  of parent drug in plasma is 9 hours at the 400-mg dose. Approximately 70% of the orally administered dose of lenalidomide is excreted intact by the kidney. The AUC progressively rises in patients with moderate to severe renal failure (creatinine clearance <50 mL/min). Based on pharmacokinetic considerations, downward dose adjustments to 10 mg/day for creatinine clearance of 30-50 mL/h and to the same dose every 2 days for creatinine clearance <30 mL/h are recommended for patients with renal failure. The safety and efficacy of these adjusted doses have not been established in prospective studies (Chen et al., 2007).

This orally administered agent has exhibited potent antitumor activity in MM, MDS, and chronic lymphocytic leukemia (CLL); causes fewer adverse side effects; and lacks the teratogenicity of thalidomide.

### **Adverse Effects of Thalidomide and Lenalidomide**

Thalidomide is well tolerated at doses <200 mg daily. The most common adverse effects reported in cancer patients are sedation and constipation, while the most serious one is peripheral sensory neuropathy, which occurs in 10-30% of patients with MM or other malignancies in a dose- and time-dependent manner (Richardson et al., 2004). Thalidomide-related neuropathy is an asymmetrical, painful, peripheral paresthesia with sensory loss, commonly presenting with numbness of toes and feet, muscle cramps, weakness, signs of pyramidal tract involvement, and carpal tunnel syndrome. The incidence of peripheral neuropathy increases with higher cumulative

doses of thalidomide, especially in elderly patients. Although symptoms improve upon drug discontinuation, long-standing sensory loss may not reverse. Particular caution should apply in cancer patients with pre-existing neuropathy (e.g., related to diabetes) or prior exposure to drugs that can cause peripheral neuropathy (e.g., vinca alkaloids, bortezomib), especially because there has been little progress in defining effective strategies to alleviate neuropathic symptoms.

Adverse effects of lenalidomide are much less severe, as it causes little sedation, constipation, or neuropathy. The drug depresses bone marrow function and is associated with significant leukopenia in 20% of patients. In rare instances, patients develop hepatotoxicity and renal dysfunction. In some CLL patients, lenalidomide causes dramatic lymph node swelling and tumor lysis, a syndrome called the tumor flare reaction. Patients with renal dysfunction receiving the standard dose of 25 mg/day are particularly prone to this reaction; thus, clinical trials in CLL are proceeding at much lower doses of 10 mg/day, with escalation as tolerated. CLL patients should receive pretreatment hydration and allopurinol to avoid the consequences of tumor swelling and tumor lysis. A negative interaction with rituximab, an anti-CD20 antibody, may result from lenalidomide's downregulation of CD20, an interaction that has clinical implications for their combined use in lymphoid malignancies (Lapalombella et al., 2008).

Thromboembolic events occur with increased frequency in patients receiving thalidomide or lenalidomide, but particularly in combination with glucocorticoids and with anthracyclines (Musallam et al., 2008). Anticoagulation reduces this risk and seems indicated in patients presenting with risk factors for clotting, but anticoagulant prophylaxis has not been evaluated prospectively.

## **PROTEASOME INHIBITION: BORTEZOMIB**

Bortezomib (VELCADE), an inhibitor of proteasome-mediated protein degradation, has earned a central role in the treatment of MM.

**Chemistry.** Bortezomib, [(1R)-3-methyl-1-[[[(2S)-1-oxo-3-phenyl-2-[(pyrazinylcarbonyl)amino]propyl]amino]butyl]boronic acid, has a unique boron-containing structure:

**Mechanism of Action.** Bortezomib binds to the  $\beta 5$  subunit of the 20S core of the 26S proteasome and reversibly inhibits its chymotrypsin-like activity (Adams, 2004). This event disrupts multiple intracellular signaling cascades, leading to apoptosis. A most important consequence of proteasome inhibition is its effect on NF- $\kappa$ B, a key transcription factor that promotes cell damage response and cell survival. Most NF- $\kappa$ B is found in the cytosol bound to I $\kappa$ B; in this form, NF- $\kappa$ B is restricted to the cytosol and cannot enter to the nucleus to regulate transcription. In response to stress signals resulting from hypoxia, chemotherapy, and DNA damage, I $\kappa$ B becomes ubiquitinated and then degraded via the proteasome. Its degradation releases NF- $\kappa$ B, which enters the nucleus, where it transcriptionally activates a host of genes involved in cell survival (e.g., cell adhesion proteins E-selectin, ICAM-1, and VCAM-1), as well as proliferative (e.g., cyclin-D1) or anti-apoptotic molecules (e.g., cIAPs, BCL-2). NF- $\kappa$ B is highly expressed in many human tumors, including MM, and may be a key factor in tumor cell survival in a hypoxic environment and during chemotherapy. Bortezomib blocks proteasomal degradation of I $\kappa$ B, thereby preventing the transcriptional activity of NF- $\kappa$ B and downregulating survival responses.

NF- $\kappa$ B inhibition may not account for the full spectrum of effects triggered by proteasome inhibition, because bortezomib also disrupts the ubiquitin-proteasomal degradation of p21, p27, p53, and other key regulators of the cell cycle and initiators of apoptosis. Bortezomib activates the cell's stereotypical "unfolded protein response" or UPR, in which abnormal protein conformation activates adaptive signaling pathways in the cell. The composite effect leads to irreversible commitment of MM cells to apoptosis (Mitsiades et al., 2002). In clinical trials, bortezomib also sensitizes tumor cells to cytotoxic drugs, including alkylators and anthracyclines, and to IMiDs and inhibitors of histone deacetylase (Orlowski et al., 2007).

**Absorption, Fate, and Excretion.** The recommended starting dose of bortezomib is 1.3 mg/m<sup>2</sup> given as an intravenous bolus on days 1, 4, 8, and 11 of every 21-day cycle (with a 10-day rest period per cycle). At least 72 hours should elapse between doses. Drug administration should be withheld until resolution of any grade 3 nonhematological toxicity or grade 4 hematological toxicity, and subsequent doses should be reduced 25%.

After intravenous administration of 1-1.3 mg/m<sup>2</sup> of bortezomib, the drug exhibits a terminal t<sub>1/2</sub> in plasma of 5.5 hours (Papandreou et al., 2004). The median peak plasma concentration averages 509 ng/mL after a 1.3-mg/m<sup>2</sup> bolus injection. Peak proteasome inhibition reaches 60% within 1 hour and declines thereafter, with a t<sub>1/2</sub> of ~24 hours.

Bortezomib clearance results from the deboronation of 90% of the parent compound, followed by hydroxylation of the boron-free product by CYPs 3A4 and 2D6; administration of this drug with potent inducers or inhibitors/substrates of CYP3A4 requires caution. No dose adjustment is required for patients with renal dysfunction.

**Therapeutic Uses and Toxicity.** Bortezomib is FDA approved as initial therapy for MM and as therapy for MM after relapse from other drugs (Kane et al., 2003). It also has received approval for relapsed or refractory mantle cell lymphoma. The drug is active in myeloma, including the induction of complete responses in up to 30% of patients when used in combination with other drugs (i.e., thalidomide, lenalidomide, liposomal doxorubicin, or dexamethasone) (San Miguel et al., 2008).

Bortezomib toxicities include thrombocytopenia (28%), fatigue (12%), peripheral neuropathy (12%), and neutropenia, anemia, vomiting, diarrhea, limb pain, dehydration, nausea, or weakness. Peripheral neuropathy, the most chronic of the toxicities, develops most frequently in patients with a prior history of neuropathy secondary to prior drug treatment (e.g., thalidomide) or diabetes or with prolonged use. Dose reductions or discontinuation of bortezomib ameliorates the neuropathic symptoms. Injection of bortezomib may precipitate hypotension, especially in volume-depleted patients, in those who have a history of syncope, or in patients taking anti-hypertensive medications. High-dose bortezomib causes hypotension and congestive heart failure in animals; cardiac toxicity occurs rarely in humans, but congestive failure and prolonged QT-interval have been reported.

## mTOR INHIBITORS: RAPAMYCIN ANALOGS

Rapamycin (sirolimus) is a fungal fermentation product that inhibits the proper functioning of a serine/threonine protein kinase in mammalian cells eponymously named *mammalian target of rapamycin*, or mTOR, an effector PI3 kinase signaling. The PI3K/PKB(Akt)/mTOR pathway responds to a variety of signals from growth factors (e.g., insulin, interleukins, EGF) that modulate cell growth, translation, metabolism, and apoptosis. The activation of the PI3K pathway is opposed by the phosphatase activity of the tumor suppressor, PTEN. Activating mutations and amplification of genes in the receptor-PI3K pathway, and loss of function alterations in PTEN, occur frequently in cancer cells, with the result that PI3K signaling is exaggerated and cells lose growth control and exhibit enhanced survival (decreased apoptosis).

Rapamycin and its congeners, temsirolimus and everolimus, are well-established first-line drugs in post-transplant immunosuppression. More recently, mTOR inhibitors have found important applications in oncology for treatment of renal and hepatocellular cancer and mantle cell lymphomas.

***Mechanisms of Action and Resistance.*** The rapamycins inhibit an enzyme complex, mTORC1, which occupies a downstream position in the PI3 kinase pathway ([Figure 62-4](#)). mTOR forms the mTORC1 complex with a member

of the FK506-binding protein family, FKBP12. Among other actions, mTORC1 phosphorylates S6 kinase and also relieves the inhibitory effect of 4EBP on initiation factor elf-4E, thereby promoting protein synthesis and metabolism. The antitumor actions of the rapamycins result from their binding to FKBP12 and inhibition of mTORC1. Rapamycin and its congeners have immunosuppressant effects, inhibit cell-cycle progression and angiogenesis, and promote apoptosis.

Resistance to mTOR inhibitors is incompletely understood but may arise through the action of a second mTOR complex, mTORC2, which is unaffected by rapamycins and which regulates AKT kinase. Experimental work suggests that inhibition of mTORC1 leads to mTORC2 activation of AKT kinase and the MAP kinase pathway, and these actions may be responsible for incomplete responses or resistance of rapamycins (Carracedo et al., 2008). Dual mTORC1 and mTORC2 inhibitors are in clinical development.

**Absorption, Fate, and Excretion.** The FDA has approved both temsirolimus and everolimus for treatment of renal cancer. Temsirolimus prolongs survival and delays disease progression in patients with advanced and poor- or intermediate-risk renal cancer, as compared to standard interferon- $\alpha$  treatment. Everolimus, as compared to placebo, prolongs survival in patients who had failed initial treatment with anti-angiogenic drugs (Motzer et al., 2008). mTOR inhibitors also have antitumor activity against mantle cell lymphomas (Ansell et al., 2008) and are under active investigation in combination with hormonal therapies, EGFR inhibitors, and cytotoxic drugs.

For renal-cell cancer, temsirolimus is given in weekly doses of 25 mg, intravenously, while everolimus is administered orally in doses of 10 mg daily. Both drugs should be administered in the fasting state at least 1 hour before a meal. Both parent molecules are metabolized by CYP3A4. Temsirolimus has a plasma  $t_{1/2}$  of 30 hours; its primary metabolite, sirolimus, has a longer  $t_{1/2}$  of 53 hours. Because sirolimus has equivalent activity as an inhibitor of mTORC1, and has a greater AUC, sirolimus is likely the more important contributor to antitumor action in patients (Hutson et al., 2008). Everolimus has a plasma  $t_{1/2}$  of 30 hours, and on a weekly schedule at doses of 20 mg, it maintains inhibition of mTORC1 for 7 days in white blood cells (O'Donnell et al., 2008). At their usual clinical doses, both agents provide peak drug levels of  $\sim 1 \mu\text{M}$ .

**Figure 62–4** *Insulin-like growth factor 1 receptor (IGF-1R) and other tyrosine kinase (TK) growth factor receptors signal through multiple pathways. A key pathway is regulated by phosphatidylinositol-3 kinase (PI3K) and its downstream partner, the mammalian target of rapamycin (mTOR). Rapamycins complex with FKBP12 to inhibit the mTORC1 complex. mTORC2 remains unaffected and responds by upregulating Akt, driving signals through the inhibited mTORC1. The various downstream outputs of the two complexes are shown. Phosphorylation of 4EBP by mTOR inhibits the capacity of 4EBP to inhibit eif-4E and slow metabolism. 4EBP, eukaryotic initiation factor 4e (eif-4E) binding protein; S6K1, S6 kinase 1; FKBP12, the immunophilin target (binding protein) for tacrolimus (FK506).*

Both drugs are susceptible to interactions with other agents that affect CYP3A4 activity. Ketoconazole, a CYP3A4 inhibitor, causes a 2- to 3-fold increase in the AUCs of both temsirolimus and sirolimus, while inducers of metabolism such as rifampin or phenytoin can decrease the  $C_{P_{max}}$  of

temsirolimus by 36% and decrease the AUC of its metabolite by >50%. The dose of temsirolimus should be doubled in the presence of inducers and reduced by half in the presence of ketoconazole (Hutson et al., 2008). Hepatic dysfunction delays drug clearance; for everolimus, the dose should be reduced to 5 mg daily for patients with moderate hepatic impairment (Child-Pugh class B); guidelines for dose reduction of temsirolimus in such patients have not been established. The drugs' pharmacokinetics do not depend on renal function, and hemodialysis does not hasten temsirolimus clearance.

Higher-dose intravenous temsirolimus regimens, up to 175 mg/week, have been explored in mantle cell lymphoma and in other diseases, as has oral temsirolimus administration. Poor oral bioavailability hampers the oral route of administration, as <20% of drug or active metabolite reaches the plasma (Buckner et al., 2010).

***Clinical Toxicity.*** The rapamycin analogs have very similar patterns of toxicity. The most prominent side effects are a mild maculopapular rash, mucositis, anemia, and fatigue, each occurring in 30-50% of patients. A minority of patients will develop leukopenia or thrombocytopenia with progressive cycles of treatment, and these effects are reversed if therapy is discontinued. Less common side effects include hyperglycemia, hypertriglyceridemia, and, rarely, pulmonary infiltrates and interstitial lung disease. Pulmonary infiltrates emerge in 8% of patients receiving everolimus and in a smaller percentage of those treated with temsirolimus. In patients showing minor radiological changes, but without symptoms, drug administration may be continued. If symptoms such as cough or shortness of breath develop or radiological changes progress, the drug should be discontinued. Prednisone may hasten the resolution of radiological changes and symptoms (Hutson et al., 2008).

## **BIOLOGICAL RESPONSE MODIFIERS**

Biological response modifiers include cytokines or monoclonal antibodies that beneficially affect the patient's biological response to a neoplasm. Included are agents that act indirectly to mediate their antitumor effects (e.g., by enhancing the immunological response to neoplastic cells) or directly, binding to receptors on the tumor cells and delivering toxins or radionuclides. Recombinant DNA technology has greatly facilitated the

identification and production of a number of human proteins with potent effects on the function and growth of both normal and neoplastic cells. Proteins that currently are in clinical use include the interferons (see [Chapters 35](#) and [58](#)); interleukins (see [Chapter 35](#)); hematopoietic growth factors such as erythropoietin, filgrastim [granulocyte colony-stimulating factor (G-CSF)], and sargramostim [granulocyte-macrophage colony-stimulating factor (GM-CSF)] (see [Chapter 37](#)); and monoclonal antibodies.

## Monoclonal Antibodies

Since the discovery of methods for fusing mouse myeloma cells with B lymphocytes, it has been possible to produce a single species of murine antibody that recognizes a specific antigen. Cancer cells express antigens that are attractive targets for monoclonal antibody-based therapy ([Table 62-1](#)). Immunization of mice with human tumor cell extracts has led to the isolation of monoclonal Abs reactive against unique or highly expressed target antigens, and a few of these monoclonals possess antitumor activity. Because murine antibodies have a short  $t_{1/2}$  in humans, activate human immune effector mechanisms poorly, and induce a human anti-mouse antibody immune response, they usually are chimerized by substituting major portions of the human IgG molecule. Presently, monoclonal antibodies have received FDA approval for lymphoid and solid tumor malignancies. Available agents include rituximab (Coiffier et al., 2002) and alemtuzumab (Keating et al., 2002) for lymphoid malignancies, trastuzumab (Vogel et al., 2002) for breast cancer, bevacizumab (Sandler et al., 2006) for colon and lung cancer, and cetuximab and panitumumab (Van Cutsem et al., 2007) for colorectal cancer and head and neck cancer. The nomenclature adopted for naming therapeutic monoclonal antibodies is to terminate the name in *-ximab* for chimeric antibodies and *-umab* for fully humanized antibodies.

Unmodified monoclonal antibodies may kill tumor cells by a variety of mechanisms [e.g., antibody-dependent cellular cytotoxicity (ADCC), complement-dependent cytotoxicity (CDC), and direct induction of apoptosis by antigen binding], but the clinically relevant mechanisms for most antibodies are uncertain (Villamor et al., 2003). Monoclonal antibodies also may be linked to a toxin (immunotoxins), such as gemtuzumab ozogamicin (MYLOTARG) (Larson et al., 2005) or denileukin difitox (ONTAK) (Negro-Vilar et al., 2007), or conjugated to a radioactive isotope, as in the case of

<sup>90</sup>Yttrium (<sup>90</sup>Y)-ibritumomab tiuxetan (ZEVALIN) (Witzig et al., 2002) ([Table 62–1](#)). Genetic polymorphisms affecting the target antigen or complement receptors may influence response (Cartron et al., 2002).

## Unarmed Monoclonal Antibodies

**Rituximab.** Rituximab (RITUXAN) is a chimeric monoclonal antibody that targets the CD20 B-cell antigen ([Tables 62–1](#) and [62–2](#)) (Maloney et al., 1997). CD20 is found on cells from the pre-B cell stage through its terminal differentiation to plasma cells and is expressed on 90% of B-cell neoplasms. The biological functions of CD20 are uncertain, although incubation of B cells with anti-CD20 antibody has variable effects on cell-cycle progression, depending on the monoclonal antibody type. Monoclonal antibody binding to CD20 generates transmembrane signals that produce autophosphorylation and activation of serine/tyrosine protein kinases, induction of *c-myc* oncogene expression, and expression of major histocompatibility complex class II molecules. CD20 also may regulate transmembrane Ca<sup>2+</sup> conductance through its function as a Ca<sup>2+</sup> channel. It is unclear which of these actions relates to the pharmacological effect of rituximab.

### **Table 62–1 Monoclonal Antibodies Approved for Hematopoietic and Solid Tumors**

ANTIGEN AND TUMOR CELL TARGETS	ANTIGEN FUNCTION	NAKED ANTIBODIES	RADIOISOTOPE-BASED ANTIBODIES	TOXIN-BASED ANTIBODIES
<b>Antigen: CD20</b> Tumor type: B-cell lymphoma and CLL	Proliferation/differentiation	Rituximab (chimeric)	<sup>131</sup> I-tositumomab; <sup>90</sup> Y-ibritumomab tiuxetan	None
<b>Antigen: CD52</b> Tumor type: B-cell CLL and T-cell lymphoma	Unknown	Alemtuzumab (humanized)	None	None
<b>Antigen: CD33</b> Tumor type: acute myelocytic leukemia	Unknown	Gemtuzumab (humanized)	None	Gemtuzumab ozogamicin
<b>Antigen: HER2/neu (ErbB2)</b> Tumor type: breast cancer	Tyrosine kinase	Trastuzumab (humanized)	None	None
<b>Antigen: EGFR (ErbB1)</b> Tumor type: colorectal, NSCLC, pancreatic, breast	Tyrosine kinase	Cetuximab (chimeric)	None	None
<b>Antigen: VEGF</b> Tumor type: colorectal cancer	Angiogenesis	Bevacizumab (humanized)	None	None

CLL, chronic lymphocytic leukemia; EGFR, epidermal growth factor receptor; NSCLC, non-small cell lung cancer; VEGF, vascular endothelial growth factor.

Rituximab is approved as a single agent for relapsed indolent lymphomas and significantly enhances response and survival in combination with chemotherapy for the initial treatment of diffuse large B-cell lymphoma. It remains effective in patients who relapse after initial treatment with rituximab-based combinations. Rituximab improves response rates when added to combination chemotherapy for other indolent B-cell non-Hodgkin's lymphomas (NHLs), including CLL, mantle cell lymphoma, Waldenström macroglobulinemia, and marginal zone lymphomas (Cheson and Leonard, 2008). Maintenance of remission with rituximab delays time to progression and improves overall survival in indolent NHL (van Oers et al., 2006). It is increasingly used for treatment of autoimmune diseases such as rheumatological disease, thrombotic thrombocytopenic purpura, autoimmune hemolytic anemias, cryoglobulin-induced renal disease and multiple sclerosis.

**Pharmacokinetics and Dosing.** Rituximab has a  $t_{1/2}$  of ~22 days (Maloney et al., 1997). The drug is administered by intravenous infusion both as a single agent and in combination with chemotherapy at a dose of 375 mg/m<sup>2</sup>. As a single agent, it is given weekly for 4 weeks, with maintenance dosing every 3-6 months. In combination regimens, the drug may be administered every 3-4 weeks, with chemotherapy, for up to eight doses. As maintenance therapy

following 6-8 cycles of combination chemotherapy, rituximab may be given once weekly for four doses, at 6-month intervals, for up to 16 doses.

During the first administration, the rate of infusion should be increased slowly to prevent serious hypersensitivity reactions. Infusions should begin at 50 mg/h, and in the absence of infusion reactions, the rate can increase in 50-mg/h increments every 30 minutes to a maximum rate of 400 mg/h. On subsequent infusion in the absence of reactions, infusions may start at 100 mg/hr and increase in 100-mg/h increments every 30 minutes to a maximum rate of 400 mg/h. Pretreatment with antihistamines, acetaminophen, and glucocorticoids decreases the risk of hypersensitivity reactions.

Patients with large numbers of circulating tumor cells (as in CLL) are at increased risk for tumor lysis syndrome; in these patients, the initial dose should be no more than 50 mg/m<sup>2</sup> on day 1 of treatment, and patients should receive standard tumor lysis prophylaxis. The remainder of the dose can then be given on day 3.

**Table 62—2 Dose and Toxicity of Monoclonal Antibody–Based Drugs**

DRUG	MECHANISM	DOSE AND SCHEDULE	MAJOR TOXICITY
Rituximab	ADCC; CDC; apoptosis	375-mg/m <sup>2</sup> IV infusion weekly for 4 weeks	Infusion-related toxicity with fever, rash, and dyspnea; B-cell depletion; late-onset neutropenia
Alemtuzumab	ADCC; CDC; apoptosis	Escalating doses of 3, 10, 30 mg/m <sup>2</sup> IV three times/week followed by 30 mg/m <sup>2</sup> three times/week for 4-12 weeks	Infusion-related toxicity, T-cell depletion with increased infection; hematopoietic suppression; pancytopenia
Trastuzumab	ADCC; apoptosis; inhibition of arrest HER2 signaling with G <sub>1</sub> arrest	Loading dose of 4-mg/kg infusion followed by 2 mg/kg weekly	Cardiomyopathy; infusion-related toxicity
Cetuximab	Inhibition of EGFR signaling; apoptosis; ADCC	Loading dose of 400-mg/kg infusion followed by 250 mg/kg weekly	Infusion-related toxicity; skin rash in 75%
Bevacizumab	Inhibition of angiogenesis/neovascularization	5 mg/kg IV every 14 days until disease progression	Hypertension; pulmonary hemorrhage; GI perforation; proteinuria; congestive heart failure
Denileukin diftitox	Targeted diphtheria toxin with inhibition of protein synthesis	9-18 µg/kg/day IV for the first 5 days every 3 weeks	Fever; arthralgia; asthenia; hypotension
Gemtuzumab ozogamicin	Double-strand DNA breaks and apoptosis	Two doses of 9 mg/m <sup>2</sup> IV separated by 14 days	Infusion-related toxicity; hematopoietic suppression; mucosal hepatic (VOD); skin toxicity
<sup>90</sup> Y-ibritumomab tiuxetan	Targeted radiotherapy	0.4 mCi/kg IV	Hematological toxicity; myelodysplasia
<sup>131</sup> I-tositumomab	Targeted radiotherapy	Patient-specific dosimetry	Hematological toxicity; myelodysplasia

ADCC, antibody-dependent cellular cytotoxicity; CDC, complement-dependent cytotoxicity; EGFR, epidermal growth factor receptor; intravenous; VOD, veno-occlusive disease.

**Resistance and Toxicity.** Resistance to rituximab may emerge through downregulation of CD20, impaired antibody-dependent cellular cytotoxicity, decreased complement activation, limited effects on signaling and induction of apoptosis, and inadequate blood levels (Maloney et al., 2002). Polymorphisms in two of the receptors for the antibody Fc region responsible for complement activation, Fcγ RIIIa and Fcγ RIIa, may predict the clinical response to rituximab monotherapy in patients with follicular lymphoma but not in CLL (Cartron et al., 2002).

Rituximab infusional reactions can be life-threatening, but with pretreatment are usually mild and limited to fever, chills, throat itching, urticaria, and mild hypotension. All respond to decreased infusion rates and antihistamines. Uncommonly, patients may develop severe mucocutaneous skin reactions, including Stevens-Johnson syndrome. Rituximab may cause reactivation of hepatitis B virus or rarely, JC virus (with progressive multifocal leukoencephalopathy) (Kranick et al., 2007). Patients should be screened for hepatitis B before initiation of therapy. Hypogammaglobulinemia and autoimmune syndromes (idiopathic thrombocytopenic purpura, thrombotic thrombocytopenic purpura, autoimmune hemolytic anemia, pure red cell aplasia, and delayed neutropenia) may supervene 1-5 months after administration (Cattaneo et al., 2006).

**OFATUMUMAB** Ofatumumab (ARZERRA) is a second monoclonal antibody that binds to CD20 at sites on the major and minor extracellular loops of CD20, distinct from the site targeted by rituximab. Binding of the drug results in B-cell lysis (both CDC and ADCC). Ofatumumab is approved for treating patients with CLL after failure of fludarabine and alemtuzumab.

A complex dosing scheme is used, beginning with small (300 mg) doses on day 1, followed by higher doses (up to 2 g/week) for 7 weeks, followed by 2 g every 4 weeks for four additional doses. Slow rates of infusion are recommended for the initial dose and for the first 2 hours of subsequent infusions.

Ofatumumab's primary toxicities consist of immunosuppression and opportunistic infection, hypersensitivity reactions during antibody infusion, and myelosuppression, which may be prolonged. Blood counts should be monitored during treatment. Rarely, patients may develop reactivation of viral infections, leading to progressive multifocal leukoencephalopathy or

hepatitis B progression. The drug should not be administered to patients with active hepatitis B infection; liver function should be monitored closely in hepatitis B carriers.

**Alemtuzumab.** Alemtuzumab (CAMPATH) is a humanized IgG- $\kappa$  monoclonal antibody, composed of a rat antigen-binding region within human constant regions and variable framework. The drug binds to CD52 antigen present on the surface of a subset of normal neutrophils and on all B and T lymphocytes, on testicular elements and sperm, and on most B- and T-cell lymphomas (Kumar et al., 2003). Consistently high levels of CD52 expression on lymphoid tumor cells and the lack of CD52 modulation with antibody binding make this antigen a favorable target for unconjugated monoclonal antibodies. Alemtuzumab can induce tumor cell death through ADCC and CDC.

**Pharmacokinetics and Dosing.** Alemtuzumab is administered intravenously in dosages of 30 mg/day three times per week. Premedication with diphenhydramine (50 mg) and acetaminophen (650 mg) should precede drug infusion. Because of hypersensitivity, dosing begins with a 3-mg infusion, followed by a 10-mg dose 2 days later and, if well tolerated, a 30-mg dose 2 days later. The drug has an initial mean  $t_{1/2}$  of 1 hour, but after multiple doses, the  $t_{1/2}$  extends to 12 days, and steady-state plasma levels are reached at approximately week 6 of treatment, presumably through saturation of CD52-binding sites. Clinical activity has been demonstrated in both B- and T-cell low-grade lymphomas and CLL, including patients with disease refractory to purine analogs (Hillmen et al., 2007). In chemotherapy-refractory CLL, overall response rates are ~40%, with complete responses of 6% in multiple series. Response rates in patients with untreated CLL are higher (overall response rates of 83% and complete responses of 24%).

**Toxicity.** The most concerning toxicities include acute infusion reactions and depletion of normal neutrophils and T cells ([Table 62-2](#)). Serious myelosuppression, with depletion of all blood lineages, occurs in the majority of patients and may represent either direct marrow toxicity or autoimmune responses. Immunosuppression by the antibody leads to a significant risk of fungal, viral, and other opportunistic infections (*Listeria*), particularly in patients who have previously received purine analogs (Keating et al., 2002; Hillmen et al., 2007). Patients should receive antibiotic prophylaxis against *Pneumocystis carinii* and herpes virus during treatment and for at least 2 months following therapy with alemtuzumab. Because

reactivation of cytomegalovirus (CMV) infections may follow antibody use, patients should be monitored for symptoms and signs of viremia, hepatitis, and pneumonia. CD4<sup>+</sup> T-cell counts may remain profoundly depleted (<200 cells/ $\mu$ L) for 1 year. Alemtuzumab does not combine well with chemotherapy in standard regimens because of significant infectious complications (Gallamini et al., 2007).

## Monoclonal Antibody–Cytotoxic Conjugates

***Gemtuzumab ozogamicin.*** Gemtuzumab ozogamicin (MYLOTARG) consists of a humanized monoclonal antibody against CD33 covalently linked to a semisynthetic derivative of calicheamicin, a potent enediyne antitumor antibiotic (Bernstein, 2000). The CD33 antigen is present on most hematopoietic cells, on >80% of AMLs, and on most myeloid cells in patients with myelodysplasias. However, other normal cell types lack CD33 expression, making this antigen attractive for targeted therapy. CD33 has no known biological function, although monoclonal antibody cross-linking inhibits normal and myeloid leukemia cell proliferation. Following its binding to CD33, gemtuzumab ozogamicin undergoes endocytosis, and cleavage of calicheamicin from the antibody takes place within the lysosome. The potent toxin then enters the nucleus, binds in the minor groove of DNA, and causes double-strand DNA breaks and cell death (Zein et al., 1988).

**Clinical Pharmacology.** The antibody conjugate produces a 30% complete response rate in relapsed AML, when administered at a dose of 9 mg/m<sup>2</sup> for up to 3 doses at 2-week intervals (Sievers et al., 2001). Pharmacokinetics of gemtuzumab ozogamicin at the standard 9-mg/m<sup>2</sup> dose are described by a  $t_{1/2}$  of total and unconjugated calicheamicin of 41 and 143 hours, respectively (Dowell et al., 2001). Following a second dose, the  $t_{1/2}$  of drug-antibody conjugate increases to 64 hours and the AUC increases to twice that of the initial dose. Most patients require two to three doses to achieve remission. The drug currently is approved in patients >60 years of age with AML in first relapse.

The primary toxicities of gemtuzumab ozogamicin include myelosuppression in all patients treated and hepatocellular damage in 30-40% of patients, manifested by hyperbilirubinemia and enzyme elevations. It also causes a syndrome that resembles hepatic veno-occlusive disease

(tender, enlarged liver and rising serum bilirubin) when patients subsequently undergo myeloablative therapy or when gemtuzumab ozogamicin follows high-dose chemotherapy (Wadleigh et al., 2003). This syndrome reflects injury to hepatic sinusoids rather than venules. Defibrotide, an orphan drug, may prevent severe or fatal hepatic injury in patients who develop signs of hepatic failure while receiving a stem cell transplant following gemtuzumab ozogamicin (Versluys et al., 2004). Prolonged myelosuppression, particularly delayed recovery of platelet counts, may complicate the patient's course following remission induction with gemtuzumab ozogamicin.

## Radioimmunoconjugates

Radioimmunoconjugates provide targeted delivery of radionuclides to tumor cells ([Tables 62–1](#) and [62–2](#)) (Witzig et al., 2002; Horning et al., 2005).  $^{131}\text{I}$  Iodine ( $^{131}\text{I}$ ) is a favored radioisotope because it is readily available, relatively inexpensive, and easily conjugated to a monoclonal antibody. The  $\gamma$  particles emitted by  $^{131}\text{I}$  can be used for both imaging and therapy, but protein-iodine conjugates have the drawback of releasing free  $^{131}\text{I}$  and  $^{131}\text{I}$ -tyrosine into the blood, and thus present a health hazard to caregivers, family, and others in contact with the patient. The  $\beta$ -emitter  $^{90}\text{Y}$  has emerged as an attractive alternative to  $^{131}\text{I}$ , based on its higher energy and longer path length. These features suggest that it may be more effective in tumors with larger diameters. It also has a short  $t_{1/2}$  and remains conjugated, even after endocytosis, providing a safer profile for outpatient use.

Currently available radioimmunoconjugates consist of murine monoclonal antibodies against CD20 conjugated with  $^{131}\text{I}$  [tositumomab (BEXXAR)] or  $^{90}\text{Y}$  [ibritumomab tiuxetan (ZEVALIN)]. Both drugs have shown response rates in relapsed lymphoma of 65-80%. They require significant collaboration between medical oncologists and nuclear medicine departments for administration. When using Zevalin, an initial dose of unlabeled rituximab is administered, followed by an imaging dose of Indium-111-labeled Zevalin. Biodistribution is determined, allowing calculation of a therapeutic dose of  $^{90}\text{Y}$  Zevalin. A pretreatment dose of rituximab then is administered to saturate nonspecific binding sites, followed by the therapeutic dose of  $^{90}\text{Y}$  Zevalin. The steps in Bexxar administration closely follow those of Zevalin.

An imaging dose precedes the therapeutic dose given 1 week later. These agents cause antibody-related hypersensitivity, bone marrow suppression, and secondary leukemias.

## Interleukin-2

IL-2 is a 133–amino acid glycoprotein encoded by a gene on chromosome 4q26-27; its molecular weight is 15 kDa (Smith, 1988). It bears structural homology to IL-4, IL-15, and GM-CSF. IL-2 is produced by activated T cells and NK cells; it acts to promote activated T-cell proliferation and enhanced killing by NK cells. Responsiveness depends on expression of the IL-2 receptor. Resting T cells and nearly all types of tumor cells lack receptor expression and are unresponsive to IL-2.

The IL-2 receptor has three components: 1) an  $\alpha$  chain, a 55-kDa protein (CD25) involved mainly in IL-2 binding; 2) a  $\beta$  chain, a 75-kDa protein involved in intracellular signaling; and 3) a  $\gamma$  chain, a 64-kDa protein that is a component of many cytokine receptors (IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21) and also is involved in signaling (Waldmann, 1991). IL-2 affinity for the three-component receptor is 10 pM; in the absence of the  $\alpha$  chain, IL-2-binding affinity is reduced by a factor of 100.

***Mechanism of Action.*** IL-2 stimulates the proliferation of activated T cells and the secretion of cytokines from NK cells and monocytes. IL-2 stimulation increases cytotoxic killing by T cells and NK cells. The mechanism of tumor cell killing has not been precisely defined but is presumed to be the result of enhanced killing by immune effector cells.

**Pharmacokinetics.** The serum  $t_{1/2}$  of IL-2 after intravenous administration has an  $\alpha$  phase of about 13 minutes and a  $\beta$  phase of about 90 minutes (Konrad et al., 1990). After a bolus dose of 6 million IU/m<sup>2</sup>, peak serum levels are nearly 2,000 IU/mL. The same dose given subcutaneously achieves peak levels of 32-42 IU/mL in 2-6 hours. Six million IU/m<sup>2</sup> given by continuous intravenous infusion reaches a steady-state level of 123 IU/mL within 2 hours. IL-2 is excreted in the urine as an inactive metabolite. Encapsulation of IL-2 in liposomes or conjugation of IL-2 to polyethylene glycol alters its distribution and  $t_{1/2}$ ; these forms are not FDA-approved.

***Clinical Use.*** Aldesleukin (PROLEUKIN) possess the biological activities of human native IL-2. The drug is approved for use in metastatic renal-cell

cancer (Rosenberg, 2000) and metastatic melanoma (McDermott, 2009). High-dose IL-2 produces an overall response rate of ~19% in patients with renal-cell cancer, and 8% achieve a complete response. Responses last a median of 8-9 years. Patients whose tumors express carbonic anhydrase IX have a higher likelihood of response (Atkins, 2009). High-dose IL-2 induces an overall response rate of ~16% in patients with metastatic melanoma, and 6% achieve a complete response. Responses last a median of ~5 years. Low-dose IL-2 also produces responses, but the duration of the responses may be less than with high-dose IL-2. The issue of appropriate dosage is controversial.

Aldesleukin may be administered in several ways. High-dose IL-2 is 600,000-720,000 IU/kg administered by intravenous bolus every 8 hours until dose-limiting toxicity appears or 14 total doses have been given; the schedule may be repeated after 9 days of rest for a maximum of 28 doses. Low-dose IL-2 is 60,000 or 72,000 IU/kg given by intravenous bolus every 8 hours for 15 doses. A third regimen involves delivery of 18 million units/m<sup>2</sup> daily by continuous intravenous infusion for 5 days. Chronic administration doses are 250,000 IU/kg subcutaneously daily for 5 days followed by 125,000 IU/kg daily for 6 weeks.

**Toxicity.** IL-2 toxicities are dominated by the capillary leak syndrome (Schwartz et al., 2002). Intravascular fluid leaks into the extravascular space, tissues, and lung, producing hypotension, edema, respiratory difficulties, confusion, tachycardia, oliguric renal failure, and electrolyte problems, including hypokalemia, hypomagnesemia, hypocalcemia, and hypophosphatemia. Symptoms include fever, chills, malaise, nausea, vomiting, and diarrhea. Laboratory abnormalities include thrombocytopenia, abnormal liver function tests, and neutropenia. Most patients develop a pruritic skin rash over most of the body surface. Hypothyroidism may occur. Arrhythmias are a rare complication.

These toxicities can be variable in grade but are often life-threatening, yet nearly all are reversible within 24-48 hours of discontinuing therapy. In view of the toxicities, patients should have a good performance status and normal renal and hepatic function before beginning therapy and should be closely supervised during drug administration.

**Denileukin Diftitox.** Denileukin Diftitox (*ontak*) is an immunotoxin made from the genetic recombination of IL-2 and the catalytically active fragment

of diphtheria toxin (Foss et al., 2001). The limited tissue expression of the high-affinity IL-2R makes this an attractive target for an immunotoxin, as cells that do not express the IL-2R or express only the intermediate- or low-affinity receptor types are significantly less sensitive to this agent. Introduction of the diphtheria toxin fragment into cells leads to ADP-ribosylation and inactivation of eukaryotic elongation factor EF-2, inhibition of protein synthesis, and thence, cell death.

Denileukin diftitox is FDA-approved for the treatment of recurrent/refractory cutaneous T-cell lymphomas. It should be administered at 9 or 18  $\mu\text{g}/\text{kg}/\text{day}$  by intravenous infusion over 30-60 minutes for 5 consecutive days every 21 days for eight cycles. Response rates of 30-37% have been achieved in such patients with denileukin diftitox, with a median response duration of 6.9 months (Olsen et al., 2001). Additional patients derived clinical benefit but did not meet the objective criteria for response. The systemic exposure to denileukin diftitox is variable but proportional to dose. The drug has a distribution  $t_{1/2}$  of 2-5 minutes with a terminal  $t_{1/2}$  of  $\sim 70$  minutes. Immunological reactivity to denileukin diftitox can be detected in virtually all patients after treatment but does not preclude clinical benefit with continued treatment. Denileukin diftitox clearance in later cycles of treatment accelerates by 2- to 3-fold as a result of development of antibodies, but serum levels exceed those required to produce cell death in IL-2R-expressing cell lines (1-10 ng/mL for  $>90$  minutes). Patients with a history of hypersensitivity reactions to diphtheria toxin or IL-2 should not be treated. Significant toxicities associated with denileukin diftitox typically are acute hypersensitivity reactions, a vascular leak syndrome, and constitutional toxicities; glucocorticoid premedication significantly decreases toxicity (Foss et al., 2001).

## **Colony-Stimulating Factors**

As noted in the preceding sections, many agents used for cancer chemotherapy suppress the production of multiple types of hematopoietic cells, and bone marrow suppression often has limited the delivery of chemotherapy on schedule and at prescribed doses. The availability of recombinant growth factors for erythrocytes (i.e., erythropoietin), granulocytes (i.e., G-CSF), and granulocytes and macrophages (i.e., GM-CSF) have advanced the ability to use combination therapy or high-dose

therapy with diminished complications such as febrile neutropenia. The individual growth factors and specifics of supportive use of these agents are described in detail in [Chapter 37](#).

## *Chapter 63*

# **Natural Products in Cancer Chemotherapy: Hormones and Related Agents**

**Beverly Moy, Richard J. Lee, and Matthew Smith**

The growth of a number of cancers is hormone dependent or regulated by hormones. Research in the fields of fertility, birth control, and menopause has yielded valuable hormone analogs and antagonists for the treatment of both breast and prostate cancer. These molecules interrupt the stimulatory axis created by systemic pools of androgens and estrogens, inhibit hormone production or binding to receptors, and ultimately block the complex expression of genes that promotes tumor growth and survival. These drugs have proven effective in extending survival and delaying or preventing tumor recurrence in breast cancer and prostate cancer.

## **GLUCOCORTICOIDS**

The pharmacology, major therapeutic uses, and toxic effects of the glucocorticoids are discussed in [Chapter 42](#). Only the applications of these drugs in the treatment of neoplastic disease are considered here. Glucocorticoids act through their binding to a specific physiological receptor that translocates to the nucleus and induces anti-proliferative and apoptotic responses in sensitive cells. Because of their lympholytic effects and their ability to suppress mitosis in lymphocytes, glucocorticoids are used as cytotoxic agents in the treatment of acute leukemia in children and malignant lymphoma in children and adults.

In acute lymphoblastic or undifferentiated leukemia of childhood, glucocorticoids may produce prompt clinical improvement and objective hematological remissions in  $\leq 30\%$  of children. Although these responses frequently are characterized by complete disappearance of all detectable leukemic cells from the peripheral blood and bone marrow, the duration of remission is brief. Remissions occur more rapidly with glucocorticoids than with antimetabolites, and there is no evidence of cross-resistance to

unrelated agents. For these reasons, therapy is initiated with prednisone and vincristine, often followed by an anthracycline or methotrexate, and *L*-asparaginase. Glucocorticoids are a valuable component of curative regimens for other lymphoid malignancies, including Hodgkin's disease, non-Hodgkin's lymphoma, multiple myeloma, and chronic lymphocytic leukemia (CLL). Glucocorticoids are extremely helpful in controlling auto-immune hemolytic anemia and thrombocytopenia associated with CLL.

The glucocorticoids, particularly dexamethasone, are used in conjunction with radiotherapy to reduce edema related to tumors in critical areas such as the superior mediastinum, brain, and spinal cord. Doses of 4-6 mg every 6 hours have dramatic effects in restoring neurological function in patients with cerebral metastases, but these effects are temporary. Acute changes in dexamethasone dosage can lead to a rapid recrudescence of symptoms. Dexamethasone should not be discontinued abruptly in patients receiving radiotherapy or chemotherapy for brain metastases. Gradual tapering of the dosage may be undertaken if a clinical response to definitive antitumor therapy has been achieved. The antitumor effects of glucocorticoids are mediated by their binding to the glucocorticoid receptor, which activates a program of gene expression that leads to apoptosis.

Several glucocorticoids are available and at equivalent dosages exert similar effects (see [Chapter 42](#)). Prednisone, e.g., usually is administered orally in doses as high as 60-100 mg, or even higher, for the first few days and gradually reduced to levels of 20-40 mg/day. A continuous attempt should be made to establish the lowest possible dosage required to control the manifestations of the disease. These agents, when used chronically, exert a wide range of side effects, including glucose intolerance, immunosuppression, osteoporosis, and psychosis (see [Chapter 42](#)). Dexamethasone is the preferred agent for remission induction in multiple myeloma, usually in combination with melphalan, anthracyclines, vincristine, bortezomib, or thalidomide.

## **PROGESTINS**

Progestational agents (see [Chapters 40](#) and [66](#)) have been used as second-line hormonal therapy for metastatic hormone-dependent breast cancer and in the management of endometrial carcinoma previously treated by surgery and radiotherapy. In addition, progestins stimulate appetite and restore a sense of

well-being in cachectic patients with advanced stages of cancer and acquired immunodeficiency syndrome (AIDS). Although progesterone itself is poorly absorbed when given orally and must be used with an oil carrier when given intramuscularly, there are synthetic progesterone preparations.

Medroxyprogesterone (DEPO-PROVERA, others) can be administered intramuscularly in doses of 400-1000 mg weekly. An alternative and more commonly used oral agent is megestrol acetate (MEGACE, others; 40-320 mg daily in divided doses). Hydroxyprogesterone (not available in the U.S.) usually is administered intramuscularly in doses of 1000 mg one or more times weekly. Beneficial effects have been observed in approximately one-third of patients with endometrial cancer. The response of breast cancer to megestrol is predicted by both the presence of estrogen receptors (ERs) and the evidence of response to a prior hormonal treatment. The effect of progestin therapy in breast cancer appears to be dose dependent, with some patients demonstrating second responses following escalation of megestrol to 1600 mg/day. Clinical use of progestins in breast cancer has been largely superseded by the advent of tamoxifen and the aromatase inhibitors (AIs). Responses to progestational agents also have been reported in metastatic carcinomas of the prostate and kidney.

## **ESTROGENS AND ANDROGENS**

Discussions of the pharmacology of the estrogens and androgens appear in [Chapters 40](#), [41](#), and [66](#). These agents are of value in certain neoplastic diseases, notably those of the prostate and mammary gland, because these organs are dependent on hormones for their growth, function, and morphological integrity. Carcinomas arising from these organs often retain the hormonal responsiveness of their normal counterpart tissues. By changing the hormonal environment of such tumors, it is possible to alter the course of the neoplastic process.

### **Estrogens and Androgens in the Treatment of Mammary Carcinoma**

High doses of estrogen have long been recognized as effective treatment of breast cancer. However, serious side effects such as thromboembolism prompted the development of alternate strategies. Paradoxically, anti-estrogens also are effective, as seen by remission of disease achieved with

oophorectomy. Thus, because of equivalent efficacy and more favorable side effects, anti-estrogens such as tamoxifen and the AIs have replaced estrogens or androgens for breast cancer. The presence of the ERs and progesterone receptors (PRs) on tumor tissue serves as a biomarker for response to hormonal therapy in breast cancer and identifies the subset of patients with a  $\geq 60\%$  likelihood of responding. The response rate to anti-estrogen treatment is somewhat lower in the subset of patients with tumors that are ER+ or PR+ but also positive for human epidermal growth factor receptors HER1/neu amplification. In contrast, ER-negative and PR-negative carcinomas do not respond to hormonal therapy.

Responses to hormonal therapy may not be apparent clinically or by imaging for 8-12 weeks. If the disease responds or remains stable on a given treatment, the medication typically should be continued until the disease progresses or unwanted toxicities develop. The duration of an induced remission in patients with metastatic disease averages 6-12 months but sometimes can last for many years.

## Anti-Estrogen Therapy

Anti-estrogen approaches for the therapy of hormone receptor-positive breast cancer include the use of selective estrogen-receptor modulators (SERMs), selective estrogen-receptor downregulators (SERDs), and AIs ([Table 63-1](#)).

***Selective Estrogen-Receptor Modulators.*** SERMs bind to the ER and exert either estrogenic or anti-estrogenic effects, depending on the specific organ. Tamoxifen citrate is the most widely studied anti-estrogenic treatment in breast cancer. The recent decline in breast cancer mortality in Western countries is believed to be partly due to the common use of tamoxifen, especially in the adjuvant setting. However, in addition to its estrogen antagonist effects in breast cancer, tamoxifen also exerts estrogenic agonist effects on non-breast tissues, thus influencing the overall therapeutic index of the drug. Therefore, several novel anti-estrogen compounds that offer the potential for enhanced efficacy and reduced toxicity compared with tamoxifen have been developed. These novel anti-estrogens can be divided into tamoxifen analogs [e.g., toremifene (FARESTON), droloxifene, idoxifene], “fixed ring” compounds [e.g., raloxifene (EVISTA), lasofoxifene, arzoxifene, miproxifene, levormeloxifene, EM652], and the SERDs [e.g., fulvestrant

(FASLODEX), SR 16234, and ZK 191703, the latter also termed “pure anti-estrogens”] (Howell et al., 2004a).

**Tamoxifen.** Tamoxifen was first synthesized in 1966 and initially developed as an oral contraceptive but instead was found to induce ovulation and proved to have anti-proliferative effects on estrogen-dependent breast cancer cell lines. For >3 decades, tamoxifen has been studied for use in various stages of breast cancer. It has become a standard agent as a result of its anticancer activity and good tolerability profile. Tamoxifen is prescribed for the prevention of breast cancer in high-risk patients, for the adjuvant therapy of early-stage breast cancer, and for the therapy of advanced breast cancer. It also prevents the development of breast cancer in women at high risk based on a strong family history, prior nonmalignant breast pathology, or inheritance of the BRCA1 or BRCA2 genes.

**Table 63–1 Clinical Uses for Anti-Estrogen Therapy in ER+ Breast Cancer**

DRUG	DISEASE SETTING			
	ADJUVANT (premen)	ADJUVANT (postmen)	METASTATIC (premen)	METASTATIC (postmen)
Tamoxifen	Yes (5 yr)	Yes (before AI for 2-5 yr)	Yes	Yes
Fulvestrant	No	No	No	Yes (PD on TAM or AI)
Anastrozole	No	Yes (upfront or after TAM)	No	Yes
Letrozole	No	Yes (upfront or after TAM)	No	Yes
Exemestane	No	Yes (upfront or after TAM)	No	Yes
Toremifene	No	Yes	No	Yes

Premen, premenopausal; Postmen, postmenopausal; AI, aromatase inhibitor; PD, progressive disease; TAM, tamoxifen; ER, estrogen receptor.

**Mechanism of Action.** Tamoxifen is a competitive inhibitor of estradiol binding to the ER.

There are two subtypes of estrogen receptors: ER $\alpha$  and ER $\beta$ , which have different tissue distributions and can either homo- or heterodimerize. Binding of estradiol and SERMs to the estrogen-binding sites of the ERs initiates a change in conformation of the ER, dissociation of the ER from heat-shock proteins, and inhibition of ER dimerization. Dimerization facilitates the binding of the ER to specific DNA estrogen-response elements (EREs) in the vicinity of estrogen-regulated genes. Co-regulator proteins interact with the receptor to act as co-repressors or co-activators of gene expression. At least 50 transcriptional activating factors transduce and modulate the effects of

estrogen on target genes. Differences in tissue distribution of ER subtypes, the function of co-regulator proteins, and the various transcriptional activating factors likely explain the variability of response to tamoxifen in hormone receptor-positive (ER<sup>+</sup>) breast cancer and its agonist and antagonist activities in noncancerous tissues. Other organs displaying agonist effects of tamoxifen include the uterine endometrium (endometrial hypertrophy, vaginal bleeding, and endometrial cancer), the coagulation system (thromboembolism), bone metabolism (increase in bone mineral density [BMD]), and liver (alterations of blood lipid profile).

**Absorption, Fate, and Excretion.** The usual oral dose of tamoxifen in the U.S. is 20 mg once a day. Doses as high as 200 mg/day have been used in the therapy of breast cancer, but high doses are associated with retinal degeneration.

Tamoxifen is readily absorbed following oral administration, with peak concentrations measurable after 3-7 hours and steady-state levels being reached at 4-6 weeks. Metabolism of tamoxifen is complex and principally involves CYPs 3A4/5, and 2D6 in the formation of *N*-desmethyl tamoxifen, and CYP2D6 to form 4-hydroxytamoxifen, a more potent metabolite ([Figure 63-1](#)). Both metabolites can be further converted to 4-hydroxy-*N*-desmethyltamoxifen, which retains high affinity for the ER. The parent drug has a terminal  $t_{1/2}$  of 7 days; the  $t_{1/2}$  of *N*-desmethyltamoxifen and 4-hydroxytamoxifen are significantly longer (14 days). After enterohepatic circulation, glucuronides and other metabolites are excreted in the stool; excretion in the urine is minimal.

**Therapeutic Uses.** The usual oral dose of tamoxifen in the U.S. is 20 mg once a day.

Tamoxifen is used for the endocrine treatment of women with ER<sup>+</sup> metastatic breast cancer or following primary tumor excision as adjuvant therapy. For the adjuvant treatment of premenopausal women, tamoxifen is given for 5 years, or in postmenopausal women, for 2 years, followed by an AI. In patients with high risk of recurrence, it may be sequenced after adjuvant chemotherapy. Tamoxifen is used in premenopausal women with ER<sup>+</sup> tumors. Disease response rates are similar to those seen in postmenopausal patients. Alternative or additional anti-estrogen strategies in

premenopausal women include oophorectomy or gonadotropin-releasing hormone analogs.

**Figure 63–1** *Tamoxifen and its metabolites.*

The combination of tamoxifen and a gonadotropin-releasing hormone analog in premenopausal women (to reduce high estrogen levels resulting from tamoxifen effects on the gonadal-pituitary axis) yields better response rates and improved overall survival than either drug alone (Klijn et al., 2000).

The NOLVADEX Adjuvant Trial Organization (NATO) study indicated an overall disease-free survival advantage for patients receiving tamoxifen versus placebo. Five years of adjuvant therapy with tamoxifen yielded superior results compared to 1 or 2 years of therapy (Swedish Breast Cancer Cooperative Group, 1996; Early Breast Cancer Trialists' Collaborative Group, 1998). Therefore, although the optimal duration of tamoxifen has not been fully determined, randomized trials have demonstrated superiority of 5 years over shorter durations. One clinical trial evaluating the administration of tamoxifen for >5 years failed to show benefit of continued therapy and a

trend toward worse outcomes in women who received tamoxifen therapy over a longer duration (Fisher et al., 2001).

Tamoxifen also has shown effectiveness (a 40-50% reduction in tumor incidence) in initial trials for preventing breast cancer in women at increased risk (Vogel et al, 2010). These studies were prompted by preclinical experiments showing prevention of tumors in animal models and also by the observation of reduced contralateral new primary breast tumors in women receiving adjuvant tamoxifen for early-stage breast cancer (Early Breast Cancer Trialists' Collaborative Group, 1998; Fisher et al., 2001). Tamoxifen only reduces ER+ tumors without affecting ER-negative tumors, which contribute disproportionately to breast cancer mortality.

**Toxicity.** The common adverse reactions to tamoxifen include vasomotor symptoms (hot flashes), atrophy of the lining of the vagina, hair loss, nausea, and vomiting. These may occur in  $\leq 25\%$  of patients and rarely are sufficiently severe to require discontinuation of therapy. Menstrual irregularities, vaginal bleeding and discharge, pruritus vulvae, and dermatitis occur with increasing severity in postmenopausal women.

Tamoxifen also increases the incidence of endometrial cancer by 2- to 3-fold, particularly in postmenopausal women who receive 20 mg/day for  $\geq 2$  years. In general, tamoxifen-associated endometrial cancers are reported as low-grade and early-stage tumors. Standard practice guidelines from the National Comprehensive Cancer Network alert physicians to the evaluation of abnormal vaginal bleeding in women with an intact uterus.

Tamoxifen increases the risk of thromboembolic events, which increase with the age of a patient and also in the perioperative period. Hence, it often is recommended to discontinue tamoxifen prior to elective surgery. Because tamoxifen is associated with thromboembolism, some authorities suggest that the pretreatment evaluation of breast cancer patients should include screening for coagulation abnormalities (factor V Leiden, protein C, antithrombin III defects) and for a history of thromboembolic disease. Presence of these risk factors should lead to exclusion of women from treatment. Note that no clear causative association between the presence of the factor V Leiden mutation and tamoxifen-induced thromboembolism has been found (Abramson, 2006).

Like estrogen, tamoxifen is a hepatic carcinogen in animals, although increases in primary hepatocellular carcinoma have not been reported in patients on the drug. Tamoxifen causes retinal deposits, decreased visual

acuity, and cataracts in occasional patients, although the frequency of these changes is more common in patients on high doses of drug.

In addition to its ability to prevent recurrence or the development of primary breast cancer, tamoxifen has other end-organ benefits related to its partial estrogenic action. For example, it may slow the development of osteoporosis in postmenopausal women. Like certain estrogens, tamoxifen lowers total serum cholesterol, low-density-lipoprotein cholesterol, and lipoproteins and raises apolipoprotein A-I levels, potentially decreasing the risk of myocardial infarction.

***Tamoxifen Resistance.*** Despite its benefits, initial or acquired resistance to tamoxifen frequently occurs (Moy and Goss, 2006). Polymorphisms in CYP2D6 that reduce its activity lead to lower plasma levels of 4-OH tamoxifen, a potent metabolite, and are associated with higher risks of disease relapse and a lower incidence of hot flashes (Goetz et al., 2005). CYP2D6 is responsible for the activation of tamoxifen to its active metabolite endoxifen ([Figure 63–1](#)). Crosstalk between the ER and HER2/neu pathway also has been implicated in tamoxifen resistance. The paired box 2 gene product (PAX2) has been identified as a crucial mediator of ER repression of ErbB2 by tamoxifen (Hurtado et al., 2008). Interactions between PAX2 and the ER co-activator AIB-1/SRC-3 determine tamoxifen response in breast cancer cells.

***Toremifene.*** Toremifene (FARESTON) is a triphenylethylene derivative of tamoxifen and has a similar pharmacological profile ([Figure 63–2](#)). Toremifene is indicated for the treatment of breast cancer in women with tumors that are ER<sup>+</sup> or of unknown receptor status.

In preclinical models, toremifene has activity against breast cancer cells *in vitro* and *in vivo* similar to that of tamoxifen. Unlike tamoxifen, however, toremifene is not hepatocarcinogenic in experimental animals. Two adjuvant studies have compared efficacy of these two agents and, in particular, long-term tolerability and safety, in early-stage breast cancer. There were no significant differences in efficacy or tolerability after a median follow-up of 4.4 years, and the number of subsequent second cancers was similar (Howell et al., 2004a). However, *in vitro* in a low-estrogen environment, toremifene has less estrogen agonist effect than tamoxifen. This may make toremifene more effective in combination with an AI than tamoxifen, and this possibility is the subject of ongoing clinical trials.

## Selective Estrogen Receptor Downregulators

SERDs, also termed “pure anti-estrogens,” include fulvestrant and a host of agents in experimental trials (RU 58668, SR 16234, ZD 164384, and ZK 191703). SERDs, unlike SERMs, are devoid of any estrogen agonist activity.

**Toremifene**

**Fulvestrant**

**Figure 63–2** Chemical structures of toremifene and fulvestrant.

**Fulvestrant.** Fulvestrant (FASLODEX) is the first agent approved by the U.S. Food and Drug Administration (FDA) in the class of ER downregulators ([Figure 63–2](#)). This new class of hormone antagonists was hypothesized to have an improved safety profile, faster onset, and longer duration of action than the SERMs due to their pure ER antagonist activity (Robertson, 2002). Fulvestrant is approved for postmenopausal women with hormone receptor–positive metastatic breast cancer that has progressed on tamoxifen.

***Mechanism of Action.*** Fulvestrant is a steroidal anti-estrogen that binds to the ER with an affinity >100 times that of tamoxifen. The drug inhibits the binding of estrogen but also alters the receptor structure such that the receptor is targeted for proteasomal degradation; fulvestrant also may inhibit receptor dimerization. Unlike tamoxifen, which stabilizes or even increases ER expression, fulvestrant reduces the number of ER molecules in cells, both *in vitro* and *in vivo*; as a consequence of this ER downregulation, the drug abolishes ER-mediated transcription of estrogen-dependent genes (Howell et al., 2004b).

***Absorption, Fate, and Excretion.*** Maximum plasma concentrations are reached ~7 days after intramuscular administration of fulvestrant and are maintained over 1 month. The plasma  $t_{1/2}$  is ~40 days. Steady-state concentrations are reached after three to six monthly injections. There is extensive and rapid distribution and extensive protein binding of this highly lipophilic drug.

Various pathways, similar to those of steroid metabolism (oxidation, aromatic hydroxylation, and conjugation), extensively metabolize fulvestrant. CYP3A4 appears to be the only CYP isoenzyme involved in the metabolism of fulvestrant. However, several preclinical and clinical studies indicate that fulvestrant is not subject to CYP3A4 interactions that might affect its pharmacokinetics, safety, or efficacy; however, the effects of *strong* CYP3A4 inhibitors have not been studied. The putative metabolites possess no estrogenic activity, and only the 17-keto compound demonstrates a level of anti-estrogenic activity, which is ~22% that of fulvestrant. Less than 1% of the parent drug is excreted intact in the urine.

***Dosing.*** The approved dosing for fulvestrant is 250 mg by intramuscular injection monthly. Because pharmacokinetic data have shown that it takes ~3-6 months for fulvestrant to reach steady-state levels with monthly dosing, alternative regimens have been studied. A loading dose regimen of 500 mg on day 0, 250 mg on days 14 and 28, and then 250 mg each month (McCormack and Sapunar, 2008) yields maximum fulvestrant concentrations in plasma an average of 12 days after the first dose and maintains those levels thereafter.

***Therapeutic Uses.*** Fulvestrant is used in postmenopausal women as anti-estrogen therapy of hormone receptor-positive metastatic breast cancer after progression on first-line anti-estrogen therapy such as tamoxifen (Strasser-

Weippl and Goss, 2004). Fulvestrant is at least as effective in this setting as the third-generation AI anastrozole.

Fulvestrant 250 mg (administered as a once-monthly 5-mL intramuscular injection) also has been compared with tamoxifen 20 mg (orally once daily) in a trial of postmenopausal women with ER<sup>+</sup> and/or PR<sup>+</sup> or ER/PR-unknown metastatic breast cancer who had not previously received endocrine or chemotherapy. In patients with ER<sup>+</sup> and/or PR<sup>+</sup> disease, there was no difference between fulvestrant and tamoxifen in time to disease progression or overall response rate (Vergote and Robertson, 2004). The long time to steady-state plasma levels for fulvestrant has brought into question the results of studies that lacked a loading dose, and trials are in progress to test the relative efficacy of giving an initial loading dose followed by regular monthly injections.

***Toxicity and Adverse Effects.*** Fulvestrant generally is well tolerated, the most common adverse effects being nausea, asthenia, pain, vasodilation (hot flashes), and headache. The risk of injection site reactions, seen in ~7% of patients, is reduced by giving the injection slowly. In the study comparing anastrozole and fulvestrant in tamoxifen-resistant patients, the drugs had equivalent quality-of-life outcome measures (Vergote and Robertson, 2004).

## **AROMATASE INHIBITORS**

Aromatase Inhibitors (AIs; [Figure 63–3](#)) block the function of the aromatase enzyme that converts androgens to estrogens. AIs now are considered the standard of care for adjuvant treatment of postmenopausal women with hormone receptor–positive breast cancer, either as initial therapy or sequenced after tamoxifen.

**Figure 63–3** Structure of the main aromatase inhibitors and the natural substrate androstenedione.

Aromatase activity is the product of the *CYP19* gene. *CYP19* is highly expressed in human placenta and in granulosa cells of ovarian follicles, where its expression depends on cyclical gonadotropin stimulation. Aromatase also is present, at lower levels, in several nonglandular tissues, including subcutaneous fat, liver, muscle, brain, and normal breast and in breast-cancer tissue. The aromatase enzyme is responsible for the conversion of adrenal androgens and gonadal androstenedione and testosterone to the estrogens, estrone (E1) and estradiol (E2), respectively ([Figure 63–4](#)). In postmenopausal women, this conversion is the primary source of circulating estrogens, while estrogen production in premenopausal women primarily is from the ovaries.

In postmenopausal women, AIs can suppress most peripheral aromatase activity, leading to profound estrogen deprivation. This strategy of estrogen

deprivation of ER<sup>+</sup> breast cancer cells stands in contrast to the ER antagonist activity that SERMs and SERDs exert.

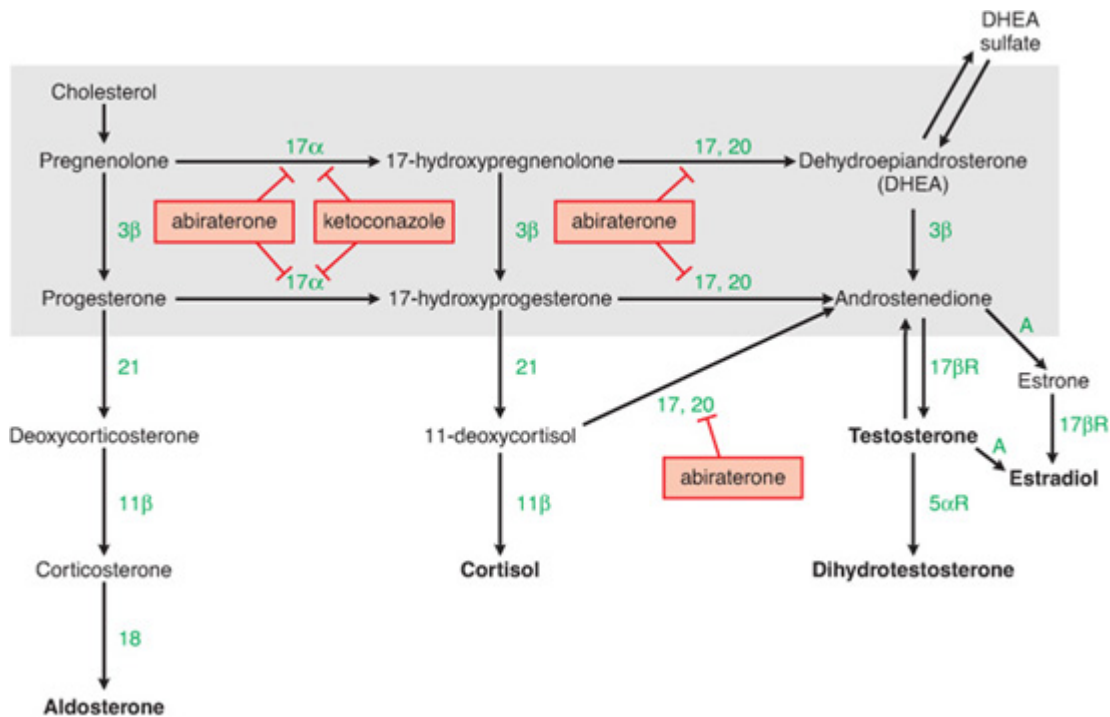

Based on their sequence of development, AIs are classified as first, second, or third generation. In addition, they are further classified as type 1 (steroidal) or type 2 (nonsteroidal) AIs according to their structure and mechanism of action. Type 1 inhibitors are steroidal analogs of androstenedione ([Figure 63–3](#)). Androstenedione analogs bind covalently to the same site on the aromatase molecule, but unlike androstenedione, they bind irreversibly because of their conversion to reactive intermediates by aromatase. Thus, they commonly are known as aromatase inactivators. Type 2 inhibitors are nonsteroidal and bind reversibly to the heme group of the enzyme.

## Third-Generation Aromatase Inhibitors

The third-generation inhibitors, developed in the 1990s, include the type 1 steroidal agent exemestane and the type 2 nonsteroidal imidazoles anastrozole and letrozole. Currently, third-generation AIs are used as part of the standard of care for treatment of early-stage and advanced breast cancer in postmenopausal women.

**Anastrozole.** Anastrozole is a potent and selective triazole AI.

**Mechanism of Action.** Anastrozole, like letrozole, binds competitively and specifically to the heme of the CYP19. Anastrozole, 1 mg or 10 mg, administered once daily for 28 days, reduces total body androgen aromatization by 96.7% or 98.1%, respectively. In addition, anastrozole reduces aromatization in large, ER<sup>+</sup> breast tumors.

**Figure 63–4** *Steroid synthesis pathways.* The enclosed area contains the pathways used by the adrenal glands and gonads. Enzymes are labeled in green, inhibitors in red. 11 $\beta$ : 11 $\beta$ -hydroxylase; 17,20: C-17,20-lyase (also CYP17); 17 $\alpha$ : 17 $\alpha$ -hydroxylase (CYP17); 17 $\beta$ R: 17 $\beta$ -reductase; 18: aldosterone synthase; 21: 21-hydroxylase; 3 $\beta$ : 3 $\beta$ -hydroxysteroid dehydrogenase; 5 $\alpha$ R: 5 $\alpha$ -reductase; A: aromatase.

**Absorption, Fate, and Excretion.** Anastrozole is absorbed rapidly after oral administration, reaching maximal plasma concentrations after 2 hours. Repeated dosing increases plasma concentrations of anastrozole, and steady-state is attained after 7 days. Although a high-fat breakfast slows absorption, the meal does not significantly alter the ultimate steady-state concentration achieved with multiple dosing. Anastrozole is metabolized by *N*-dealkylation, hydroxylation, and glucuronidation. The main metabolite of anastrozole is a triazole. In addition, several other metabolites with no pharmacological activity are formed. Less than 10% of the drug is excreted as the unmetabolized parent compound. The principal excretory pathway is via the liver and biliary tract. The elimination  $t_{1/2}$  is ~50 hours. The pharmacokinetics of anastrozole, which can be affected by drug interactions via the CYP system, are not altered by co-administration of tamoxifen or cimetidine (Köberle and Thürlimann, 2001).

***Therapeutic Uses.*** Anastrozole (ARIMIDEX), 1 mg administered orally once daily, is approved for upfront adjuvant hormonal therapy in postmenopausal women with early-stage breast cancer and as treatment for advanced breast cancer. In early-stage breast cancer, anastrozole is significantly more effective than tamoxifen in delaying time to tumor recurrence and decreasing the odds of a primary contralateral tumor (Baum et al., 2002). In advanced breast cancer, the results of two large, randomized trials in postmenopausal women with disease progression while taking tamoxifen showed a statistically significant survival advantage with anastrozole 1 mg/day versus megestrol acetate 40 mg four times daily. In another phase III clinical trial on women with ER<sup>+</sup> or PR<sup>+</sup> metastatic breast cancer, anastrozole showed a statistically significant advantage over tamoxifen in median time to disease progression (Bonnetterre et al., 2001).

***Adverse Effects and Toxicity.*** Compared to tamoxifen, anastrozole has been associated with a significantly lower incidence of vaginal bleeding, vaginal discharge, hot flashes, endometrial cancer, ischemic cerebrovascular events, venous thromboembolic events, and deep venous thrombosis, including pulmonary embolism. Anastrozole is associated with a higher incidence of musculoskeletal disorders and fracture than tamoxifen. In the advanced disease setting, anastrozole is as well tolerated as megestrol and causes less weight gain. In addition, anastrozole is as well tolerated as tamoxifen, with a low rate of withdrawal due to drug-related adverse events (2%).

The estrogen depletion caused by anastrozole and other AIs raises the concern of bone loss. Compared with tamoxifen, treatment with anastrozole results in significantly lower BMD in the lumbar spine and total hip (Eastell et al., 2008). Bisphosphonates prevent AI-induced bone loss in postmenopausal women (Brufsky et al., 2007).

Anastrozole has no clinically significant effect on adrenal glucocorticoid or mineralocorticoid synthesis in postmenopausal women. Anastrozole also does not affect ACTH-stimulated release of cortisol or aldosterone, plasma concentrations of FSH or LH in postmenopausal women, or TSH levels.

***Letrozole.*** Letrozole is approved for upfront adjuvant hormonal therapy in postmenopausal women with early-stage breast cancer and as treatment for advanced breast cancer.

**Actions.** In postmenopausal women with primary breast cancer, letrozole inhibits estrogen aromatization by 99% and reduces local aromatization within the tumors. The drug has no significant effect on the synthesis of adrenal steroids or thyroid hormone and does not alter levels of a range of other hormones. Letrozole also reduces cellular markers of proliferation to a significantly greater extent than tamoxifen in human estrogen-dependent tumors that overexpress HER1 and HER2/neu.

Letrozole increases the levels of bone resorption markers in healthy postmenopausal women and in those with a history of breast disease but without current active disease. Letrozole has not demonstrated a consistent effect on serum lipid levels in healthy women or postmenopausal women with breast cancer.

**Absorption, Fate, and Excretion.** Letrozole is rapidly absorbed after oral administration, and maximum plasma levels are reached ~1 hour after ingestion. Letrozole has a bioavailability of 99.9%. Steady-state plasma concentrations of letrozole are reached after 2-6 weeks of treatment. Following metabolism by CYP2A6 and CYP3A4, letrozole is eliminated as an inactive carbinol metabolite mainly via the kidneys. The total body clearance is low (2.2 L/h); the elimination  $t_{1/2}$  is ~41 hours.

**Therapeutic Uses.** The usual dose of letrozole (*FEMARA*) is 2.5 mg administered orally once daily. In early-stage breast cancer, extending adjuvant endocrine therapy with letrozole (beyond the standard 5-year period of tamoxifen) improves disease-free survival compared with placebo and improves overall survival in the subset of patients with positive axillary nodes (Goss et al., 2004). Furthermore, upfront letrozole is significantly more effective than upfront tamoxifen in terms of time to tumor recurrence and odds of a primary contralateral tumor (Thürlimann et al., 2005).

In advanced breast cancer, letrozole is superior to tamoxifen as first-line treatment; time to disease progression is significantly longer and objective response rate is significantly greater with letrozole, but median overall survival is similar between groups (Mouridsen et al., 2003). As second-line therapy of advanced breast cancer that has progressed on tamoxifen or after oophorectomy, letrozole has efficacy equal to that of anastrozole and similar to or better than that of megestrol.

***Adverse Effects and Toxicity.*** Letrozole is well tolerated; the most common treatment-related adverse events are hot flashes, nausea, and hair thinning. In patients with tumors that progressed on anti-estrogen therapy, letrozole was tolerated at least as well as, or better than, megestrol. In the trial of extended adjuvant therapy, adverse events reported more frequently with letrozole than placebo were hot flashes, arthralgia, myalgia, and arthritis, but patients discontinued letrozole no more frequently than placebo in this double-blind trial. Letrozole has a low overall incidence of cardiovascular side effects (Mouridsen et al., 2007).

A greater number of new diagnoses of osteoporosis occurred among women receiving letrozole. Compared with tamoxifen, the use of upfront letrozole results in significantly more clinical fractures. Bisphosphonates prevent letrozole-induced bone loss in postmenopausal women (Brufsky et al., 2007).

***Exemestane.*** Exemestane (AROMASIN) is a more potent, orally administered analog of the natural aromatase substrate, androstenedione, and lowers estrogen levels more effectively than does its predecessor, formestane.

***Mechanism of Action.*** In contrast to the reversible competitive inhibitors of aromatase (anastrozole and letrozole), exemestane irreversibly inactivates the enzyme and is referred to as a “suicide substrate.” Doses of 25 mg/day inhibit aromatase activity by 98% and lower plasma estrone and estradiol levels by ~90% in postmenopausal women.

***Absorption, Fate, and Excretion.*** Exemestane is rapidly absorbed from the GI tract, reaching maximum plasma levels after 2 hours. Its absorption is increased by 40% after a high-fat meal. Exemestane is highly protein bound in plasma and has a terminal  $t_{1/2}$  of ~24 hours. It is extensively metabolized in the liver to inactive metabolites. A key metabolite, 17-hydroxyexemestane, which is formed by reduction of the 17-oxo group via 17- $\beta$ -hydroxysteroid dehydrogenase, has weak androgenic activity, which also could contribute to antitumor activity. The elimination  $t_{1/2}$  of the parent drug is 24 hours. Although significant quantities of active metabolites are excreted in the urine, no dosage adjustments are recommended in patients with renal dysfunction.

***Therapeutic Uses.*** Exemestane (AROMASIN), 25 mg administered orally once daily, is approved for disease progression in postmenopausal women who completed 2-3 years of adjuvant tamoxifen based on results from a

randomized clinical trial in women with ER<sup>+</sup> breast cancer. Women who had completed 2-3 years of adjuvant tamoxifen were randomized to complete a total of 5 years of adjuvant treatment with tamoxifen or exemestane (Coombes et al., 2004). The unadjusted hazard ratio in the exemestane group versus the tamoxifen group was 0.68, representing a 32% reduction in risk and corresponding to an absolute benefit in terms of disease-free survival of 4.7% at 3 years after randomization. Overall survival was not significantly different in the two groups.

In advanced breast cancer, exemestane improves time to disease progression compared with tamoxifen as first-line treatment (Paridaens et al., 2008). Exemestane also has been evaluated in a phase III trial against megestrol in women with disease progressing on prior anti-estrogen therapy. Patients receiving exemestane had a similar response rate but improved time to disease progression and time to treatment failure and had a longer duration of survival compared with those taking megestrol acetate. Responses to treatment also have been shown in women with disease progressing on prior nonsteroidal AIs.

***Clinical Toxicity.*** Exemestane generally is well tolerated. Discontinuations due to toxicity are uncommon (2.8%). Hot flashes, nausea, fatigue, increased sweating, peripheral edema, and increased appetite have been reported. In the trial comparing exemestane to tamoxifen in early-stage breast cancer, exemestane caused more frequent arthralgia and diarrhea but less frequent vaginal bleeding and muscle cramps. Visual disturbances and clinical fractures were more common with exemestane (Coombes et al., 2004).

Whether exemestane negatively affects long-term bone metabolism remains to be determined. The drug has less androgenic activity than formestane but otherwise has a similar toxicity profile.

## **HORMONE THERAPY IN PROSTATE CANCER**

Androgens stimulate the growth of normal and cancerous prostate cells. The critical role of androgens for prostate cancer growth was established in 1941 and led to the awarding of a Nobel Prize in 1966 to Dr. Charles Huggins (Huggins and Hodges, 1941; Huggins et al., 1941). These findings

established androgen deprivation therapy as the mainstay of treatment for patients with advanced prostate cancer.

Localized prostate cancer frequently is curable with surgery or radiation therapy. However, when distant metastases are present, hormone therapy is the primary treatment. Standard approaches either reduce the concentration of endogenous androgens or inhibit their effects. Androgen deprivation therapy (ADT) is the standard first-line treatment (Sharifi et al., 2005). ADT is accomplished via surgical castration (bilateral orchiectomy) or medical castration (using gonadotropin-releasing hormone [GnRH] agonists or antagonists). Other hormone therapy approaches are used in second-line treatment and include anti-androgens, estrogens, and inhibitors of steroidogenesis (see the discussion later in this section).

ADT is considered palliative, not curative, treatment (Walsh et al., 2001). ADT can alleviate cancer-related symptoms, produce objective responses, and normalize serum prostate-specific antigen (PSA) in >90% of patients. ADT provides important quality-of-life benefits, including reduction of bone pain and reduction of rates of pathological fracture, spinal cord compression, and ureteral obstruction (Huggins et al., 1941). It also prolongs survival (Sharifi et al., 2005).

The duration of response to ADT for patients with metastatic disease is variable but typically lasts 14-20 months (Crawford et al., 1989; Eisenberger et al., 1998). Disease progression despite ADT signifies a castration-resistant state. However, many men respond to secondary hormonal manipulations. Despite castrate levels of testosterone, low-level androgen (DHEA) synthesis from the adrenal glands may permit the continued androgen-driven growth of prostate cancer cells. Therefore, anti-androgens (which competitively bind the androgen receptor [AR]), inhibitors of steroidogenesis (such as ketoconazole), and estrogens frequently are employed as secondary hormone therapies. Unlike the nearly universal response to ADT, only the minority of patients experience symptomatic relief or tumor regression when treated with secondary hormone therapies. When patients become refractory to further hormonal therapies, their disease is considered androgen independent. In these patients, the next treatment option usually is cytotoxic chemotherapy; docetaxel has a proven survival benefit, with average overall survival of 18 months (Petrylak et al., 2004; Tannock et al., 2004).

Common side effects of androgen deprivation include vasomotor flushing, loss of libido, impotence, gynecomastia, fatigue, anemia, weight gain, decreased insulin sensitivity, altered lipid profiles, osteoporosis and fractures, and loss of muscle mass (Saylor and Smith, 2009). The spectrum of side effects of GnRH agonists is distinct from the metabolic syndrome (Smith, 2008). ADT is associated with an increased risk of diabetes and coronary heart disease (Keating et al., 2006). However, retrospective analyses have not revealed a compelling increase in cardiovascular mortality due to GnRH agonists (Efstathiou et al., 2008; Efstathiou et al., 2009). Skeletal-related events due to ADT, including fractures, may be mitigated by bisphosphonate therapy, such as zoledronic acid (ZOMETA) (Saad et al., 2002) or inhibitors of osteoclast activation, such as denosumab (Smith et al., 2009).

Anti-androgens, when compared with GnRH agonists, cause more gynecomastia, mastodynia, and hepatotoxicity but less vasomotor flushing, and loss of bone mineral density (BMD) (McLeod, 1997). Estrogens cause a hypercoagulable state and increase cardiovascular mortality in prostate cancer patients and are no longer standard treatment options (Byar and Corle, 1988).

## **Gonadotropin-Releasing Hormone Agonists and Antagonists**

The biosynthesis of androgens, primarily in the testes and adrenals, is described in [Chapter 41](#), and the regulation of Leydig cell synthetic activity by the hypothalamic–pituitary axis is considered there as well. Pharmacological castration was first reported in 1982 (Tolis et al., 1982). In the U.S., the most common form of ADT involves chemical suppression of the pituitary gland with GnRH agonists. Synthetic GnRH analogs ([Table 63–2](#)) have greater receptor affinity and reduced susceptibility to enzymatic degradation than the naturally occurring GnRH molecule and are 100-fold more potent (Schally et al., 1980). GnRH (also termed luteinizing hormone–releasing hormone, LHRH) agonists bind to GnRH receptors on pituitary gonadotropin-producing cells, causing an initial release of both LH and FSH and a subsequent increase in testosterone production from testicular Leydig cells. After ~1 week of therapy, GnRH receptors are downregulated on the gonadotropin-producing cells, causing a decline in the pituitary response

(Conn and Crowley, 1991). The fall in serum LH leads to a decrease in testosterone production to castrate levels within 3-4 weeks of the first treatment. Subsequent treatments maintain testosterone at castrate levels (Limonta et al., 2001).

During the transient rise in LH, the resultant testosterone surge may induce an acute stimulation of prostate cancer growth and a “flare” of symptoms from metastatic deposits. Patients may experience an increase in bone pain or obstructive bladder symptoms lasting for 2-3 weeks (Waxman et al., 1985). The flare phenomenon can be effectively counteracted with concurrent administration of 2-4 weeks of oral anti-androgen therapy, which may inhibit the action of the increased serum testosterone levels (Kuhn et al., 1989).

Current depot forms of GnRH agonists are the result of progressive improvements in drug development. GnRH agonists in common use include leuprolide (LUPRON, others), goserelin (ZOLADEX), triptorelin (TRELSTAR), histrelin (VANTAS), and buserelin (SUPREFACT; not available in the U.S.). Long-acting preparations of both leuprolide and goserelin are available in doses that are approved for 3-, 4-, and 6-month administrations.

Leuprolide and goserelin have been compared with orchiectomy in randomized trials. A meta-analysis of 10 such randomized trials found equivalence in overall survival, progression-related outcomes, and time to treatment failure (Kaisary et al., 1991; Seidenfeld et al., 2000; Turkes et al., 1987; Vogelzang et al., 1995).

Combined androgen blockade (CAB) requires administration of ADT with an anti-androgen. The theoretical advantage is that the GnRH agonist will deplete testicular androgens, while the anti-androgen competes at the receptor with residual androgens made by the adrenal glands. CAB provides maximal relief of androgen stimulation. Numerous large trials have compared CAB with ADT monotherapy, with variable results. Several meta-analyses of these trials suggest a benefit for CAB in 5-year survival but not at earlier time points (Samson et al., 2002; Schmitt et al., 1999). Toxicity and costs associated with CAB are higher than with ADT alone.

GnRH antagonists have been developed to suppress testosterone while avoiding the flare phenomenon of GnRH agonists. Other than avoidance of the initial flare, GnRH antagonist therapy offers no apparent advantage compared with GnRH agonists. The first available GnRH antagonist, abarelix (PLENAXIS), rapidly achieves medical castration (Trachtenberg et

al., 2002). However, local reactions and anaphylaxis have discouraged its clinical acceptance and have led to its withdrawal from the market. A second GnRH antagonist, degarelix, is not associated with systemic allergic reactions and is approved for prostate cancer in the U.S. (Klotz et al., 2008).

## Anti-Androgens

Anti-androgens bind to ARs and competitively inhibit the binding of testosterone and dihydrotestosterone. Unlike castration, anti-androgen therapy by itself does not decrease LH production; therefore, testosterone levels are normal or increased. Men treated with anti-androgen monotherapy maintain some degree of potency and libido and do not have the same spectrum of side effects seen with castration.

Currently, anti-androgen monotherapy is not indicated as first-line treatment for patients with advanced prostate cancer. Numerous studies have examined the effectiveness of anti-androgens compared with surgical castration, GnRH agonists, or treatment with diethylstilbestrol (DES; discontinued in the U.S.). A meta-analysis of eight trials indicated that nonsteroidal anti-androgens had equivalent overall survival relative to castration, although the association between nonsteroidal anti-androgens and decreased survival approached statistical significance (Seidenfeld et al., 2000). Anti-androgens most commonly are used in clinical practice as secondary hormone therapy or in CAB.

**Table 63–2 Structures of GnRH and Decapeptide GnRH Analogs**

AMINO ACID RESIDUE	1	2	3	4	5	6	7	8	9	10	DOSAGE FORM
<b>Agonists</b>											
GnRH (GONADORELIN)	PyroGlu	His	Trp	Ser	Tyr	Gly	Leu	Arg	Pro	Gly-NH <sub>2</sub>	
Leuprolide (LUPRON, ELJGARD)						D-Leu			Pro-NHEt		IM, SC, depot
Buserelin						D-Ser(tBu)			Pro-NHEt		SC, IN
Nafarelin (SYNAREL)						D-Nal				Gly-NH <sub>2</sub>	IN
Deslorelin (not available in U.S.)						D-Trp			Pro-NHEt		SC, IM, depot
Histrelin (VANTAS)						D-His (ImBzl)			Pro-NHEt		SC, depot
Triptorelin (TRELSTAR DEPO, LA)						D-Trp				Gly-NH <sub>2</sub>	IM, depot
Goserelin (ZOLADEX)						D-Ser(tBu)				AzGly-NH <sub>2</sub>	SC implant
<b>Antagonists</b>											
Cetrorelix (CETROTIDE)	Ac-D-Nal	D-Cpa	D-Pal			D-Cit				D-Ala-NH <sub>2</sub>	SC
Ganirelix (not available in U.S.)	Ac-D-Nal	D-Cpa	D-Pal			D-hArg(Et) <sub>2</sub>		D-hArg(Et) <sub>2</sub>		D-Ala-NH <sub>2</sub>	SC
Abarelix	Ac-D-Nal	D-Cpa	D-Pal		Tyr(N-Me)	D-Asn		Lys(iPr)		D-Ala-NH <sub>2</sub>	SC depot
Degarelix (FIRMAGON)	Ac-D-Nal	D-Cpa	D-Pal		4Aph HO	4Aph (Cbm)		Lys		D-Ala-NH <sub>2</sub>	SC

A line (—) indicates identity with amino acid of the parent compound, GnRH.

Ac, acetyl; NHEt, N-ethylamide; tBu, t-butyl; D-Nal, 3-(2-naphthyl)-D-alanyl; ImBzl, imidobenzyl; Cpa, chlorophenylalanyl; Pal, 3-pyridylalanyl; AzGly, azaglycyl; hArg(Et)<sub>2</sub>, ethyl homoarginine; 4Aph (Cbm), 4-acetyl phenylalanine (carbamoyl); L, imido; IV, intravenous; SC, subcutaneous; IN, intranasal; IM, intramuscular.

**Available Anti-Androgens.** Anti-androgens are classified as steroidal, including cyproterone and megestrol, or nonsteroidal, including flutamide, bicalutamide (CASODEX, others), and nilutamide (NILANDRON) ([Figure 63–5](#)).

Cyproterone is associated with liver toxicity and has inferior efficacy compared with other forms of ADT (Schroder et al., 1999; Thorpe et al., 1996). Cyproterone is used in the E.U. for treatment of men with metastatic prostate cancer but is not available in the U.S. Neither bicalutamide nor flutamide is approved as monotherapy at any dose for treatment of prostate cancer in the U.S.

**Mechanism of Action of Nonsteroidal Anti-Androgens.** The nonsteroidal anti-androgens are taken orally and inhibit ligand binding and consequent AR translocation from the cytoplasm to the nucleus.

***Flutamide.*** Flutamide has a  $t_{1/2}$  of 5 hours and therefore is given as a 250-mg dose every 8 hours. Its major metabolite, hydroxyflutamide, is biologically active; there are at least five other minor metabolites (Luo et al., 1997). The common side effects include diarrhea, breast tenderness, and nipple tenderness. Less commonly, nausea, vomiting, and hepatotoxicity occur (Wysowski and Fourcroy, 1996; Wysowski et al., 1993).

### Steroidal anti-androgens

cyproterone

megestrol

### Non-steroidal anti-androgens

flutamide

nilutamide

bicalutamide

**Figure 63–5** *Anti-androgens.*

**Bicalutamide.** Bicalutamide (CASODEX, others) has a serum  $t_{1/2}$  of 5-6 days and is taken once daily at a dosage of 50 mg/day when given with a GnRH agonist. Both enantiomers of bicalutamide undergo glucuronidation to inactive metabolites, and the parent compounds and metabolites are eliminated in bile and urine. The elimination  $t_{1/2}$  of bicalutamide is increased in severe hepatic insufficiency and is unchanged in renal insufficiency.

Bicalutamide is well tolerated at higher doses with rare additional side effects. Daily bicalutamide (either low or high dose) is significantly inferior compared with surgical or medical castration (Bales and Chodak, 1996; Tyrrell et al., 1998). Although the ease of administration and favorable toxicity are attractive, concerns about inferior survival has limited the use of bicalutamide monotherapy.

**Nilutamide.** Nilutamide (NILADRON) is a second-generation anti-androgen with an elimination  $t_{1/2}$  of 45 hours, allowing once-daily administration at 150 mg/day. Common side effects include mild nausea, alcohol intolerance (5-20%), and diminished ocular adaptation to darkness (25-40%); rarely, interstitial pneumonitis occurs (Decensi et al., 1991; Pfitzenmeyer et al., 1992). It is metabolized to five known products that are all excreted in the urine. Nilutamide appears to offer no benefit over the first-generation drugs above and has the least favorable toxicity profile (Dole and Holdsworth, 1997).

**Estrogens.** High estrogen levels can reduce testosterone to castrate levels in 1-2 weeks via negative feedback on the hypothalamic– pituitary axis. Estrogen also may compete with androgens for steroid hormone receptors and may thereby exert a cytotoxic effect on prostate cancer cells (Landström et al., 1994). Numerous estrogenic compounds have been tested in prostate cancer. Estrogens are associated with increased myocardial infarctions, strokes, and pulmonary emboli and increased mortality, as well as impotence, loss of libido, and lethargy. One benefit is that estrogens prevent bone loss (Scherr et al., 2002).

Most early studies on the use of estrogens used DES and were conducted between 1960 and 1975 by the Veterans Administration Cooperative Urological Research Group (VACURG). Two studies compared orchiectomy to different doses of DES to placebo (Byar, 1973; Byar and Corle, 1988). DES was as effective as orchiectomy for metastatic prostate cancer but was associated with an increase in cardiovascular events, including myocardial infarction, cerebrovascular accident, and pulmonary embolism (Bailar and Byar, 1970; Byar, 1973; de Voogt et al., 1986; Waymont et al., 1992). Due to its cardiovascular toxicity and unacceptable mortality at any dose level, DES is not indicated for prostate cancer treatment and is not available in North America for that purpose. Other synthetic estrogens have a similar associated cardiovascular toxicity to that of DES but without the efficacy. These compounds include conjugated estrogens (*premarin*, others), ethinyl estradiol, medroxyprogesterone acetate (*PROVERA*, others), and chlorotrianisene (no longer marketed in the U.S.).

**Inhibitors of Steroidogenesis.** In the castrate state, AR signaling, despite low steroid levels, supports continued prostate cancer growth. AR signaling may occur due to androgens produced from nongonadal sources, AR gene

mutations, or AR gene amplification. Nongonadal sources of androgens include the adrenal glands and the prostate cancer cells themselves ([Figure 63–4](#)). Androstenedione, produced by the adrenal glands, is converted to testosterone in peripheral tissues and tumors (Stanbrough et al., 2006). Intratumoral *de novo* androgen synthesis also may provide sufficient androgen for AR-driven cell proliferation (Montgomery et al., 2008).

Ketoconazole is an antifungal agent that interrupts the synthesis of an essential fungal membrane sterol. In an unrelated action, ketoconazole inhibits both testicular and adrenal steroidogenesis by blocking CYPs, primarily CYP17 (17 $\alpha$ -hydroxylase). Ketoconazole is administered off label as secondary hormone therapy to reduce adrenal androgen synthesis in castration-resistant prostate cancer (Small et al., 2004). Ketoconazole causes significant diarrhea and hepatic enzyme elevations that limit its use as initial hormone therapy. Consequent poor patient adherence deters from its efficacy. Ketoconazole is given in doses of 200 mg or 400 mg three times daily. Hydrocortisone supplementation is co-administered to compensate for inhibition of adrenal steroidogenesis at the 400-mg dose level. A related compound, itraconazole, inhibits the activation of Smoothed (SMO), a component of the Hedgehog (Hh) signaling pathway (Kim et al., 2010), which is overly active in certain cancers. Thus, this class of antifungal agents may act by several distinct mechanisms and prove useful in treating other cancers.

Abiraterone is an irreversible inhibitor of both 17 $\alpha$ -hydroxylase and C-17,20-lyase CYP17 activity, with greater potency and selectivity compared with ketoconazole. The parent compound, abiraterone acetate, is orally bioavailable and has been well tolerated in castration-resistant prostate cancer patients as secondary hormone therapy in phase I and II studies (Attard et al., 2009; Attard et al., 2008). With continuous administration, abiraterone increases ACTH levels, resulting in mineralocorticoid excess. Therefore, abiraterone acetate is administered with daily low-dose glucocorticoids, such as prednisone. Ongoing phase III trials will evaluate the efficacy and appropriate timing of abiraterone therapy for prostate cancer patients.

## **Ocular Pharmacology**

Jeffrey D. Henderer and Christopher J. Rapuano

### **OVERVIEW OF OCULAR ANATOMY, PHYSIOLOGY, AND BIOCHEMISTRY**

The eye is a specialized sensory organ that is relatively secluded from systemic access by the blood-retinal, blood-aqueous, and blood-vitreous barriers; as a consequence, the eye exhibits some unusual pharmacodynamic and pharmacokinetic properties. Because of its anatomical isolation, the eye offers a unique, organ-specific pharmacological laboratory in which to study the autonomic nervous system and the effects of inflammation and infectious diseases. No other organ in the body is so readily accessible or as visible for observation; however, the eye also presents some unique challenges as well as opportunities for drug delivery (Robinson, 1993).

### **Extraocular Structures**

The eye is protected by the eyelids and by the orbit, a bony cavity of the skull that has multiple fissures and foramina that conduct nerves, muscles, and vessels ([Figure 64–1](#)). In the orbit, connective (i.e., Tenon's capsule) and adipose tissues and six extraocular muscles support and align the eyes for vision. The retrobulbar region lies immediately behind the eye (or *globe*). Understanding ocular and orbital anatomy is important for safe periocular drug delivery, including subconjunctival, sub-Tenon's, and retrobulbar injections.

The eyelids serve several functions. Foremost, their dense sensory innervation and eyelashes protect the eye from mechanical and chemical injuries. Blinking, a coordinated movement of the orbicularis oculi, levator palpebrae, and Müller's muscles, serves to distribute tears over the cornea and conjunctiva. In humans, the average blink rate is 15-20 times/minute. The external surface of the eyelids is covered by a thin layer of skin; the internal surface is lined with the palpebral portion of the conjunctiva, which is a vascularized mucous membrane continuous with the bulbar conjunctiva. At

the reflection of the palpebral and bulbar conjunctivae is a space called the fornix, located superiorly and inferiorly behind the upper and lower lids, respectively. Topical medications usually are placed in the inferior fornix, also known as the inferior culde-sac.

The lacrimal system consists of secretory glandular and excretory ductal elements ([Figure 64-2](#)). The secretory system is composed of the main lacrimal gland, which is located in the temporal outer portion of the orbit, and accessory glands, also known as the glands of Krause and Wolfring, located in the conjunctiva. The lacrimal gland is innervated by the autonomic nervous system ([Table 64-1](#) and [Chapter 8](#)). The parasympathetic innervation is clinically relevant because a patient may complain of dry eye symptoms while taking medications with anticholinergic side effects, such as tricyclic antidepressants ([Chapter 15](#)), antihistamines ([Chapter 32](#)), and drugs used in the management of Parkinson disease ([Chapter 22](#)). Located just posterior to the eyelashes are meibomian glands, which secrete oils that retard evaporation of the tear film. Abnormalities in gland function, as in acne rosacea and meibomitis, can greatly affect tear film stability.

Conceptually, tears constitute a trilaminar lubrication barrier covering the conjunctiva and cornea. The anterior layer is composed primarily of lipids secreted by the meibomian glands. The middle aqueous layer, produced by the main lacrimal gland and accessory lacrimal glands, constitutes ~98% of the tear film. Adherent to the corneal epithelium, the posterior layer is a mixture of mucins produced by goblet cells in the conjunctiva. Tears also contain nutrients, enzymes, and immunoglobulins to support and protect the cornea.

The tear drainage system starts through small puncta located on the medial aspects of both the upper and lower eyelids ([Figure 64-2](#)). With blinking, tears enter the puncta and continue to drain through the canaliculi, lacrimal sac, nasolacrimal duct, and then into the nose. The nose is lined by a highly vascular mucosal epithelium; consequently, topically applied medications that pass through this nasolacrimal system have direct access to the systemic circulation.

**Figure 64–1** *Anatomy of the globe in relationship to the orbit and eyelids.* Various routes of administration of anesthesia are demonstrated by the blue needle pathways.

## Ocular Structures

The eye is divided into anterior and posterior segments ([Figure 64–3A](#)). Anterior segment structures include the cornea, limbus, anterior and posterior chambers, trabecular meshwork, canal of Schlemm (Schlemm’s canal), iris, lens, zonule, and ciliary body. The posterior segment includes the vitreous, retina, choroid, sclera, and optic nerve.

### *Anterior Segment*

**Cornea.** The cornea is a transparent and avascular tissue organized into five layers: epithelium, Bowman’s membrane, stroma, Descemet’s membrane, and endothelium ([Figure 64–3B](#)). Representing an important barrier to foreign matter, including drugs, the hydrophobic epithelial layer comprises five to six cell layers. The basal epithelial cells lie on a basement membrane that is adjacent to Bowman’s membrane, a layer of collagen fibers. Constituting ~90% of the corneal thickness, the stroma, a hydrophilic layer, is uniquely organized with collagen lamellae synthesized by keratocytes. Beneath the stroma lies Descemet’s membrane, the basement membrane of the corneal

endothelium. Lying most posteriorly, the endothelium is a monolayer of cells adhering to each other by tight junctions. These cells maintain corneal integrity by active transport processes and serve as a hydrophobic barrier. Hence, drug absorption across the cornea requires penetration of the trilaminar hydrophobic–hydrophilic–hydrophobic domains of the various anatomical layers.

**Figure 64–2.** *Anatomy of the lacrimal system.*

**Table 64–1 Autonomic Pharmacology of the Eye and Related Structures**

TISSUE	ADRENERGIC RECEPTORS		CHOLINERGIC RECEPTORS	
	SUBTYPE	RESPONSE	SUBTYPE	RESPONSE
Corneal epithelium	$\beta_2$	Unknown	$M^a$	Unknown
Corneal endothelium	$\beta_2$	Unknown	Undefined	Unknown
Iris radial muscle	$\alpha_1$	Mydriasis		
Iris sphincter muscle			$M_3$	Miosis
Trabecular meshwork	$\beta_2$	Unknown		
Ciliary epithelium <sup>b</sup>	$\alpha_2/\beta_2$	Aqueous production		
Ciliary muscle	$\beta_2$	Relaxation <sup>c</sup>	$M_3$	Accommodation
Lacrimal gland	$\alpha_1$	Secretion	$M_2, M_3$	Secretion
Retinal pigment epithelium	$\alpha_1/\beta_2$	$H_2O$ transport/unknown		

<sup>a</sup>Although acetylcholine and choline acetyltransferase are abundant in the corneal epithelium of most species, the function of this neurotransmitter in this tissue is unknown. <sup>b</sup>The ciliary epithelium also is the target of carbonic anhydrase inhibitors. Carbonic anhydrase isoenzyme II is localized to both the pigmented and nonpigmented ciliary epithelium. <sup>c</sup>Although  $\beta_2$  adrenergic receptors mediate ciliary body smooth muscle relaxation, there is no clinically significant effect on accommodation.

At the periphery of the cornea and adjacent to the sclera lies a transitional zone (1-2 mm wide) called the limbus. Limbal structures include the conjunctival epithelium, which contains the corneal epithelial stem cells, Tenon’s capsule, episclera, corneoscleral stroma, canal of Schlemm, and trabecular meshwork ([Figure 64–3B](#)). Limbal blood vessels, as well as the tears, provide important nutrients and immunological defense mechanisms for

the cornea. The anterior chamber holds ~250  $\mu\text{L}$  of aqueous humor. The peripheral anterior chamber angle is formed by the cornea and the iris root. The trabecular meshwork and canal of Schlemm are located just above the apex of this angle. The posterior chamber, which holds ~50  $\mu\text{L}$  of aqueous humor, is defined by the boundaries of the ciliary body processes, posterior surface of the iris, and lens surface.

***Aqueous Humor Dynamics and Regulation of Intraocular Pressure.***

Aqueous humor is secreted by the ciliary processes and flows from the posterior chamber, through the pupil, and into the anterior chamber and leaves the eye primarily by the trabecular meshwork and canal of Schlemm. From the canal of Schlemm, aqueous humor drains into an episcleral venous plexus and into the systemic circulation. This conventional pathway accounts for 80-95% of aqueous humor outflow and is the main target for cholinergic drugs used in glaucoma therapy. Another outflow pathway is the uveoscleral route (i.e., fluid flows through the ciliary muscles and into the suprachoroidal space), which is the target of selective prostanoids (see “Glaucoma” and [Chapter 33](#)).

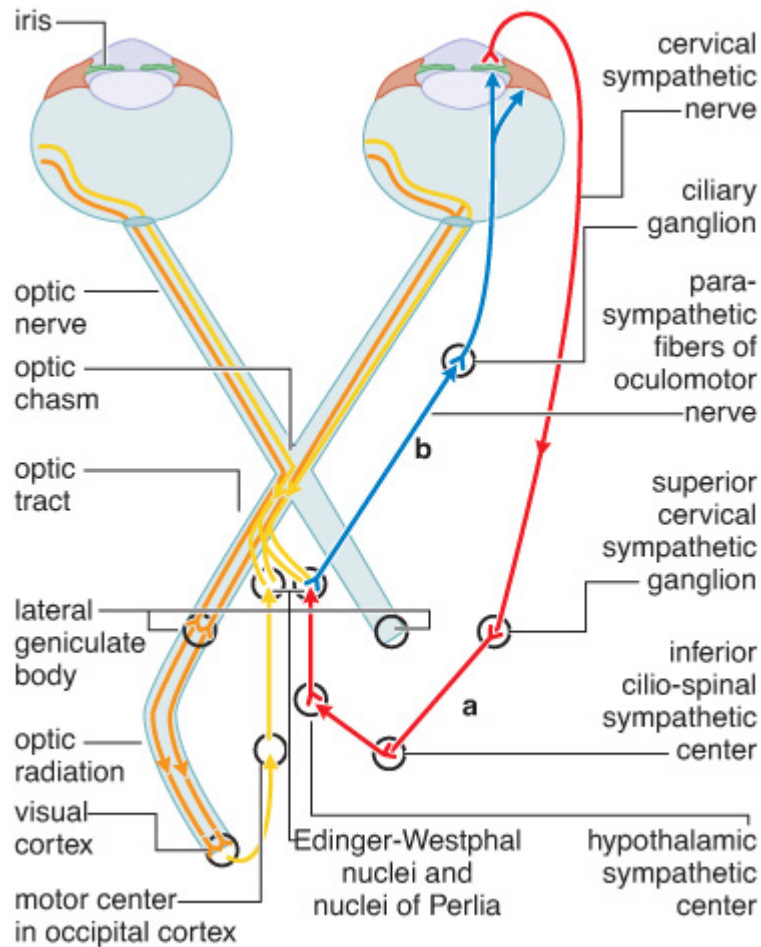

The peripheral anterior chamber angle is an important anatomical structure for differentiating two forms of glaucoma: *open-angle glaucoma*, which is by far the most common form of glaucoma in the U.S., and *angle-closure glaucoma*. Current medical therapy of open-angle glaucoma is aimed at decreasing aqueous humor production and/or increasing aqueous outflow. The preferred management for angle-closure glaucoma is surgical iridectomy, by either laser or incision, but short-term medical management may be necessary to reduce the acute intraocular pressure (IOP) elevation and to clear the cornea prior to surgery. Long-term IOP reduction may be necessary, especially if the peripheral iris has permanently covered the trabecular meshwork. In anatomically susceptible eyes, anticholinergic, sympathomimetic, and antihistaminic drugs can lead to partial dilation of the pupil and a change in the vectors of force between the iris and the lens. The aqueous humor then is prevented from passing through the pupil from the posterior chamber to the anterior chamber. The change in the lens-iris relationship leads to an increase in pressure in the posterior chamber, causing the iris base to be pushed against the angle wall, thereby covering the trabecular meshwork and closing the filtration angle and markedly elevating the IOP. The result is known as an acute attack of pupillary-block angle-closure glaucoma. Unfortunately, individuals with susceptible angles usually

are not aware of a risk of angle-closure glaucoma. Furthermore, drug warning labels do not always specify the type of glaucoma for which this rare risk exists. Thus, unwarranted concern is raised among patients who have open-angle glaucoma who need not be concerned about taking these drugs.

***Iris and Pupil.*** The iris is the most anterior portion of the uveal tract, which also includes the ciliary body and choroid. The anterior surface of the iris is the stroma, a loosely organized structure containing melanocytes, blood vessels, smooth muscle, and parasympathetic and sympathetic nerves. Differences in iris color reflect individual variation in the number of melanocytes located in the stroma. Individual variation may be an important consideration for ocular drug distribution due to drug-melanin binding (see “Distribution”). The posterior surface of the iris is a densely pigmented bilayer of epithelial cells. Anterior to the pigmented epithelium, the dilator smooth muscle is oriented radially and is innervated by the sympathetic nervous system ([Figure 64–4](#)), which causes mydriasis (dilation). At the pupillary margin, the sphincter smooth muscle is organized in a circular band with parasympathetic innervation, which, when stimulated, causes miosis (constriction). The use of pharmacological agents to dilate normal pupils (i.e., for clinical purposes such as examining the ocular fundus) and to evaluate the pharmacological response of the pupil (e.g., unequal pupils, or anisocoria, seen in Horner’s syndrome or Adie’s pupil) is summarized in [Table 64–2](#). [Figure 64–5](#) provides a flowchart for the diagnostic evaluation of anisocoria.

**Figure 64–3** *A. Anatomy of the eye. B. Enlargement of the anterior segment, revealing the cornea, angle structures, lens, and ciliary body.* (Adapted with permission from Riordan-Eva P. *Anatomy and embryology of the eye*. **Figure 64–4** *Autonomic innervation of the eye by the sympathetic (a) and parasympathetic (b) nervous systems.* (Adapted with permission from Wybar KC, Kerr-Muir M. Bailliere’s Concise Medical Textbooks, Ophthalmology, 3rd ed. Bailliere Tindall, New York, 1984. Copyright © Elsevier.)

**Ciliary Body.** The ciliary body serves two very specialized roles in the eye:

- secretion of aqueous humor by the epithelial bilayer
- accommodation by the ciliary muscle

The anterior portion of the ciliary body, called the pars plicata, is composed of 70-80 ciliary processes with intricate folds. The posterior portion is the pars plana. The ciliary muscle is organized into outer longitudinal, middle radial, and inner circular layers. Coordinated contraction of this smooth muscle apparatus by the parasympathetic nervous system causes the zonule suspending the lens to relax, allowing the lens to become more convex and to shift slightly forward. This process, known as *accommodation*, permits focusing on near objects and may be

pharmacologically blocked by muscarinic cholinergic antagonists, through the process called *cycloplegia*. Contraction of the ciliary muscle also puts traction on the scleral spur and hence widens the spaces within the trabecular meshwork. This latter effect accounts for at least some of the IOP-lowering effect of both directly acting and indirectly acting parasympathomimetic drugs.

**Lens.** The lens, a transparent biconvex structure, is suspended by *zonules*, specialized fibers emanating from the ciliary body. The lens is ~10 mm in diameter and is enclosed in a capsule. The bulk of the lens is composed of fibers derived from proliferating lens epithelial cells located under the anterior portion of the lens capsule. These lens fibers are continuously produced throughout life. Aging, in addition to certain medications, such as corticosteroids, and certain diseases, such as diabetes mellitus, cause the lens to become opacified, which is termed a *cataract*.

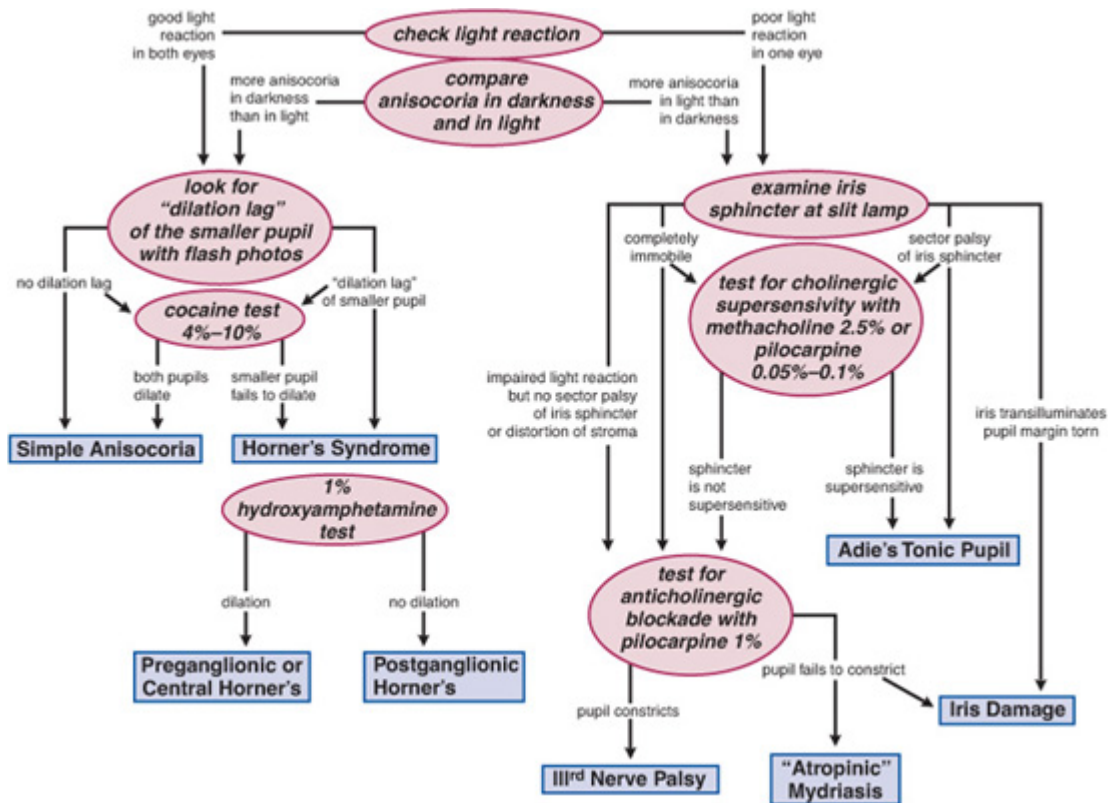

**Table 64—2 Effects of Pharmacological Agents on the Pupil**

CLINICAL SETTING	DRUG	PUPILLARY RESPONSE
Normal	Sympathomimetic drugs	Dilation (mydriasis)
Normal	Parasympathomimetic drugs	Constriction (miosis)
Horner's syndrome	Cocaine 4-10%	No dilation
Preganglionic Horner's	Hydroxyamphetamine 1%	Dilation
Postganglionic Horner's	Hydroxyamphetamine 1%	No dilation
Adie's pupil	Pilocarpine 0.05-0.1% <sup>a</sup>	Constriction
Normal	Opioids (oral or intravenous)	Pinpoint pupils

Topically applied ophthalmic drugs unless otherwise noted. <sup>a</sup>This percentage of pilocarpine is not commercially available and usually is prepared by the physician administering the test or by a pharmacist. This test also requires that no prior manipulation of the cornea (i.e., tonometry for measuring intraocular pressure or testing corneal sensation) be done so that the normal integrity of the corneal barrier is intact. Normal pupils will not respond to this weak dilution of pilocarpine; however, an Adie's pupil manifests a denervation supersensitivity and is, therefore, pharmacodynamically responsive to this dilute cholinergic agonist.

**Posterior Segment.** Because of the anatomical and vascular barriers to both local and systemic access, drug delivery to the eye's posterior pole is particularly challenging.

**Sclera.** The outermost coat of the eye, the sclera, covers the posterior portion of the globe. The external surface of the scleral shell is covered by an episcleral vascular coat, by Tenon's capsule, and by the conjunctiva. The tendons of the six extraocular muscles insert collagen fibers into the superficial scleral. Numerous blood vessels pierce the sclera through emissaria to both supply and drain the choroid, ciliary body, optic nerve, and iris.

**Figure 64–5** *Anisocoria evaluation flowsheet.* (Adapted with permission from Thompson and Pilley, 1976. Copyright © Elsevier.)

Inside the scleral shell, the vascular choroid nourishes the outer retina by a capillary system in the choriocapillaris. Between the outer retina and the choriocapillaris lie Bruch’s membrane and the retinal pigment epithelium, whose tight junctions provide an outer barrier between the retina and the choroid. The retinal pigment epithelium serves many functions, including vitamin A metabolism, phagocytosis of the rod outer segments, and multiple transport processes.

**Retina.** The retina is a thin, transparent, highly organized structure of neurons, glial cells, and blood vessels. Of all structures within the eye, the neurosensory retina has been the most widely studied. The unique organization and biochemistry of the photoreceptors have provided a superb system for investigating signal transduction mechanisms. The wealth of information about rhodopsin has made it an excellent model for the G protein–coupled signal transduction. Such detailed understanding holds promise for targeted therapy for some of the hereditary retinal diseases.

**Vitreous.** Approximately 80% of the eye's volume is the vitreous, which is a clear medium containing collagen type II, hyaluronic acid, proteoglycans, and a variety of macromolecules, including glucose, ascorbic acid, amino acids, and a number of inorganic salts. Glutamate in the vitreous has been suspected to have a possible relationship to glaucoma. The ganglion cells appear to die in glaucoma via a process of apoptosis (Quigley et al., 1995; Wax et al., 1998), and glutamate has been shown to induce apoptosis via NMDA receptor excitotoxicity (Sucher et al., 1997). Elevated glutamate levels have been noted in experimental animal models (Dreyer et al., 1996; Yoles and Schwartz, 1998) and in humans with glaucoma (Dreyer et al., 1996), although this has been questioned (Levkovitch-Verbin et al., 2002). Memantine, a noncompetitive NMDA receptor antagonist (Vorwerk et al., 1996; Seki and Lipton, 2008; Ju et al., 2008), is currently being investigated clinically as a possible treatment for glaucoma.

**Optic Nerve.** The optic nerve is a myelinated nerve conducting the retinal output to the central nervous system (CNS). It is composed of:

- an intraocular portion, which is visible as the optic disk in the retina
- an intraorbital portion
- an intracanalicular portion
- an intracranial portion

The nerve is ensheathed in meninges continuous with the brain. At present, pharmacological treatment of optic neuropathies usually is based on management of the underlying disease. For example, nonarteritic ischemic optic neuropathy might be treated with intravitreal glucocorticoids (Kaderli et al., 2007) and optic neuritis may be best treated with intravenous glucocorticoids (Atkins et al., 2007; Beck and Gal, 2008; Volpe, 2008). Unfortunately, these guidelines have not yet become routine clinical practice (Biouesse et al., 2009). Glaucomatous optic neuropathy is medically managed by decreasing IOP.

## **PHARMACOKINETICS AND TOXICOLOGY OF OCULAR THERAPEUTIC AGENTS**

### **Drug-Delivery Strategies**

Properties of varying ocular routes of administration are outlined in [Table 64–3](#). A number of delivery systems have been developed for treating ocular diseases. Most ophthalmic drugs are delivered in solutions, but for compounds with limited solubility, a suspension form facilitates delivery.

**Table 64–3 Some Characteristics of Ocular Routes of Drug Administration**

ROUTE	ABSORPTION PATTERN	SPECIAL UTILITY	LIMITATIONS AND PRECAUTIONS
Topical	Prompt, depending on formulation	Convenient, economical, relatively safe	Compliance, corneal and conjunctival toxicity, nasal mucosal toxicity, systemic side effects from nasolacrimal absorption
Subconjunctival, sub-Tenon's, and retrobulbar injections	Prompt or sustained, depending on formulation	Anterior segment infections, posterior uveitis, cystoid macular edema	Local toxicity, tissue injury, globe perforation, optic nerve trauma, central retinal artery and/or vein occlusion, direct retinal drug toxicity with inadvertent globe perforation, ocular muscle trauma, prolonged drug effect
Intraocular (intracameral) injections	Prompt	Anterior segment surgery, infections	Corneal toxicity, intraocular toxicity, relatively short duration of action
Intravitreal injection or device	Absorption circumvented, immediate local effect, potential sustained effect	Endophthalmitis, retinitis, age-related macular degeneration	Retinal toxicity

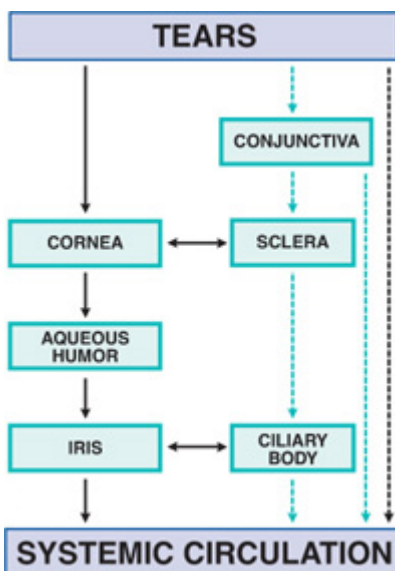

See the text for a more complete discussion of individual routes.

Several formulations prolong the time a drug remains on the surface of the eye. These include gels, ointments, solid inserts, soft contact lenses, and collagen shields. *Prolonging the time in the culde-sac facilitates drug absorption.* Ophthalmic gels (e.g., pilocarpine 4% gel) release drugs by diffusion following erosion of soluble polymers. The polymers used include cellulosic ethers, polyvinyl alcohol, carbopol, polyacrylamide, polymethylvinyl ether–maleic anhydride, poloxamer 407, and pluronic acid. Ointments usually contain mineral oil and a petrolatum base and are helpful in delivering antibiotics, cycloplegic drugs, or miotic agents. Solid inserts, such as the ganciclovir intravitreal implant, provide a *zero-order* rate of delivery by steady-state diffusion, whereby drug is released at a more constant rate over a finite period of time rather than as a bolus. This surgical implant has been used to deliver anti-cytomegalovirus (CMV) medication in proximity to the retinal infection (Marx et al., 1996). The intent is to deliver a sustained dose of medication over several months with reduced spikes in drug delivery (Kunou et al., 2000) independent of patient compliance.

## Pharmacokinetics

Classical pharmacokinetic theory based on studies of systemically administered drugs (see [Chapter 2](#)) does not fully apply to all ophthalmic drugs (Kaur and Kanwar, 2002). Although similar principles of absorption, distribution, metabolism, and excretion determine the fate of drug disposition in the eye, alternative routes of drug administration, in addition to oral and intravenous routes, introduce other variables in compartmental analysis ([Table 64-3](#) and [Figure 64-6](#)). Most ophthalmic medications are formulated to be applied topically. Drugs also may be injected by subconjunctival, sub-Tenon's, and retrobulbar routes ([Figure 64-1](#) and [Table 64-3](#)).

For example, anesthetic agents commonly are administered by injection for surgical procedures, and antibiotics and glucocorticoids also may be injected to enhance their delivery to local tissues. The antimetabolite 5-fluorouracil and the DNA alkylating agent mitomycin C may be extemporaneously compounded for subconjunctival administration to retard the fibroblast proliferation related to scarring after glaucoma surgery. Mitomycin C also can be applied to the cornea to prevent scarring after corneal surgery. Intraocular (i.e., intravitreal) injections of antibiotics are considered in instances of endophthalmitis, a severe intraocular infection. The sensitivities of the organisms to the antibiotic and the retinal toxicity threshold may be nearly the same for some antibiotics; hence, the antibiotic dose injected intravitreally must be carefully titrated. Intraocular inserts are used to treat intraocular viral infections. The ganciclovir implant is indicated to treat CMV retinitis in patients with acquired immunodeficiency syndrome (AIDS).

**Figure 64–6.** Possible absorption pathways of an ophthalmic drug following topical application to the eye. Solid black arrows represent the corneal route; dashed blue arrows represent the conjunctival/scleral route; the black dashed arrow represents the nasolacrimal absorption pathway. (Adapted with permission from Chien et al, 1990. Copyright © Taylor & Francis Group, <http://www.informaworld.com>.)

Unlike clinical pharmacokinetic studies on systemic drugs, where data are collected relatively easily from blood samples, there is significant risk in obtaining tissue and fluid samples from the human eye. Consequently, animal models, frequently rabbits, are studied to provide pharmacokinetic data on ophthalmic drugs.

**Absorption.** After topical instillation of a drug, the rate and extent of absorption are determined by the time the drug remains in the culde-sac and precorneal tear film, elimination by nasolacrimal drainage, drug binding to tear proteins, drug metabolism by tear and tissue proteins, and diffusion across the cornea and conjunctiva (Lee, 1993). A drug's residence time may be prolonged by changing its formulation. Residence time also may be extended by blocking the egress of tears from the eye by closing the tear drainage ducts with flexible silicone (punctal) plugs (*HERRICK LACRIMAL PLUG, PUNCTUM PLUG*) or cautery. Nasolacrimal drainage contributes to systemic absorption of topically administered ophthalmic medications. Absorption from the nasal mucosa avoids first-pass metabolism by the liver, and consequently, significant systemic side effects may be caused by topical medications, especially when used chronically. Possible absorption pathways of an ophthalmic drug following topical application to the eye are shown schematically in [Figure 64–6](#).

Transcorneal and transconjunctival/scleral absorption are the desired routes for localized ocular drug effects. The time period between drug instillation and its appearance in the aqueous humor is defined as the *lag time*. The drug concentration gradient between the tear film and the cornea and conjunctival epithelium provides the driving force for passive diffusion across these tissues. Other factors that affect a drug's diffusion capacity are the size of the molecule, chemical structure, and steric configuration. Transcorneal drug penetration is conceptualized as a differential solubility process; the cornea may be thought of as a trilaminar “fat-water-fat” structure corresponding to the epithelial, stromal, and endothelial layers. The

epithelium and endothelium represent barriers for hydrophilic substances; the stroma is a barrier for hydrophobic compounds. Hence, a drug with both hydrophilic and lipophilic properties is best suited for transcorneal absorption.

Drug penetration into the eye is approximately linearly related to its concentration in the tear film. Certain disease states, such as corneal epithelial defects and corneal ulcers, may alter drug penetration. Medication absorption usually is increased when an anatomical barrier is compromised or removed. Experimentally, drugs may be screened for their potential clinical utility by assessing their corneal permeability coefficients. These pharmacokinetic data combined with the drug's octanol/water partition coefficient (for lipophilic drugs) or distribution coefficient (for ionizable drugs) yield a parabolic relationship that is a useful parameter for predicting ocular absorption. Of course, such *in vitro* studies do not account for other factors that affect corneal absorption, such as epithelial integrity, blink rate, dilution by tear flow, nasolacrimal drainage, drug binding to proteins and tissue, and transconjunctival absorption; hence, these studies have limitations in predicting ocular drug absorption *in vivo*.

**Distribution.** Topically administered drugs may undergo systemic distribution primarily by nasal mucosal absorption and possibly by local ocular distribution by transcorneal/transconjunctival absorption. Following transcorneal absorption, the aqueous humor accumulates the drug, which then is distributed to intraocular structures as well as potentially to the systemic circulation via the trabecular meshwork pathway ([Figure 64–3B](#)). Melanin binding of certain drugs is an important factor in some ocular compartments. For example, the mydriatic effect of  $\alpha$  adrenergic–receptor agonists is slower in onset in human volunteers with darkly pigmented irides compared to those with lightly pigmented irides. In rabbits, radiolabeled atropine binds significantly to melanin granules in irides of non-albino animals. This finding correlates with the fact that atropine's mydriatic effect lasts longer in non-albino rabbits than in albino rabbits and suggests that drug-melanin binding is a potential reservoir for sustained drug release. Another clinically important consideration for drug-melanin binding involves the retinal pigment epithelium. In the retinal pigment epithelium, accumulation of chloroquine (see [Chapter 49](#)) causes a toxic retinal lesion known as a “bull's-eye” maculopathy, which is associated with a decrease in visual acuity.

**Metabolism** Enzymatic biotransformation of ocular drugs may be significant because a variety of enzymes, including esterases, oxidoreductases, lysosomal enzymes, peptidases, glucuronide and sulfate transferases, glutathione-conjugating enzymes, catechol-*O*-methyl-transferase, monoamine oxidase, and 11 $\beta$ -hydroxysteroid dehydrogenase are found in the eye. The esterases have been of particular interest because of the development of prodrugs for enhanced corneal permeability; e.g., dipivefrin hydrochloride is a prodrug for epinephrine, and latanoprost is a prodrug for prostaglandin F<sub>2 $\alpha$</sub>  (PGF<sub>2 $\alpha$</sub> ); both drugs are used for glaucoma management. Topically applied ocular drugs are eliminated by the liver and kidney after systemic absorption, but enzymatic transformation of systemically administered drugs also is important in ophthalmology.

**Toxicology.** All ophthalmic medications are potentially absorbed into the systemic circulation ([Figure 64–6](#)), so undesirable systemic side effects may occur. Most ophthalmic drugs are delivered locally to the eye, and the potential local toxic effects are due to hypersensitivity reactions or to direct toxic effects on the cornea, conjunctiva, periocular skin, and nasal mucosa. Eyedrops and contact lens solutions commonly contain preservatives such as benzalkonium chloride, chlorobutanol, chelating agents, and thimerosal for their antimicrobial effectiveness. In particular, benzalkonium chloride may cause a punctate keratopathy or toxic ulcerative keratopathy (Grant and Schuman, 1993). Thimerosal is used rarely due to a high incidence of hypersensitivity reactions.

## THERAPEUTIC AND DIAGNOSTIC APPLICATIONS OF DRUGS IN OPHTHALMOLOGY

### Chemotherapy of Microbial Diseases in the Eye

#### Antibacterial Agents

**General Considerations.** A number of antibiotics have been formulated for topical ocular use ([Table 64–4](#)). The pharmacology, structures, and kinetics of individual drugs have been presented in detail in Section VI. Appropriate selection of antibiotic and route of administration is dependent on the

patient's symptoms, the clinical examination, and the culture/sensitivity results. Specially formulated antibiotics also may be extemporaneously prepared by qualified pharmacists for serious eye infections such as corneal infiltrates or ulcers and endophthalmitis.

**Therapeutic Uses.** Infectious diseases of the skin, eyelids, conjunctivae, and lacrimal excretory system are encountered regularly in clinical practice. Periocular skin infections are divided into preseptal and postseptal or orbital cellulitis. Depending on the clinical setting (i.e., preceding trauma, sinusitis, age of patient, relative immunocompromised state), oral or parenteral antibiotics are administered. The microbiological spectrum for orbital cellulitis is changing; e.g., there has been a sharp decline in *Haemophilus influenzae* after the introduction in 1985 of the *H. influenzae* vaccine (Ambati et al., 2000).

*Dacryoadenitis*, an infection of the lacrimal gland, is most common in children and young adults. It may be bacterial (typically

**Table 64–4 Topical Antibacterial Agents Commercially Available for Ophthalmic Use**

GENERIC NAME (TRADE NAME)	FORMULATION <sup>a</sup>	TOXICITY	INDICATIONS FOR USE
Azithromycin (AZASITE)	1% solution	H	Conjunctivitis
Bacitracin	500 units/g ointment	H	Conjunctivitis, blepharitis, keratitis, keratoconjunctivitis, corneal ulcers, blepharoconjunctivitis, meibomianitis, dacryocystitis
Besifloxacin (BESIVANCE)	0.6% suspension		Conjunctivitis
Chloramphenicol	1% ointment	H, BD	Conjunctivitis, keratitis
Ciprofloxacin hydrochloride (CILOXAN, others)	0.3% solution; 0.3% ointment	H, D-RCD	Conjunctivitis, keratitis, keratoconjunctivitis, corneal ulcers, blepharitis, blepharoconjunctivitis, meibomianitis, dacryocystitis
Erythromycin (ILOTYCIN, others)	0.5% ointment	H	Superficial ocular infections involving the conjunctiva or cornea; prophylaxis of ophthalmia neonatorum
Gatifloxacin (ZYMAR)	0.3% solution	H	Conjunctivitis
Gentamicin sulfate (GARAMYCIN, GENOPTIC, GENT-AK, GENTACIDIN, others)	0.3% solution; 0.3% ointment	H	Conjunctivitis, blepharitis, keratitis, keratoconjunctivitis, corneal ulcers, blepharoconjunctivitis, meibomianitis, dacryocystitis
Levofloxacin (QUIXIN, IQUIX)	0.5% solution	H	Conjunctivitis
Levofloxacin (IQUIX)	1.5% solution	H	Corneal ulcers
Moxifloxacin (VIGAMOX)	0.5% solution	H	Conjunctivitis
Ofloxacin (OCUFLOX, others)	0.3% solution	H	Conjunctivitis, corneal ulcers
Sulfacetamide sodium (BLEPH-10, CETAMIDE, ISOPTO CETAMIDE, others)	1%, 10%, 15%, and 30% solution; 10% ointment	H, BD	Conjunctivitis, other superficial ocular infections
Polymyxin B combinations <sup>b</sup>	Various solutions and ointments		Conjunctivitis, blepharitis, keratitis
Tobramycin sulfate <sup>c</sup> (TOBREX, AKTOB, DEFY, others)	0.3% solution; 0.3% ointment	H	External infections of the eye and its adnexa

<sup>a</sup>For specific information on dosing, formulation, and trade names, refer to the *Physicians' Desk Reference for Ophthalmic Medicines*, which is published annually. <sup>b</sup>Polymyxin B is formulated for delivery to the eye in combination with bacitracin, neomycin, gramicidin, oxytetracycline, or trimethoprim. See Chapters 52-55 for further discussion of these antibacterial agents. <sup>c</sup>Tobramycin is formulated for delivery to the eye in combination with dexamethasone or loteprednol etabonate. H, hypersensitivity; BD, blood dyscrasia; D-RCD, drug-related corneal deposits.

*Staphylococcus aureus*, *Streptococcus* spp.) or viral (most commonly seen in mumps, infectious mononucleosis, influenza, and herpes zoster). When bacterial infection is suspected, systemic antibiotics usually are indicated.

*Dacryocystitis* is an infection of the lacrimal sac. In infants and children, the disease usually is unilateral and secondary to an obstruction of the nasolacrimal duct. In adults, dacryocystitis and canalicular infections may be caused by *S. aureus*, *Streptococcus* spp., diphtheroids, *Candida* spp., and *Actionmyces israelii*. Any discharge from the lacrimal sac should be sent for smears and cultures. Systemic antibiotics typically are indicated.

Infectious processes of the lids include *hordeolum* and *blepharitis*. A hordeolum, or sty, is an infection of the meibomian, Zeis, or Moll glands at the eyelid margins. The typical offending bacterium is *S. aureus*, and the usual treatment consists of warm compresses and topical antibiotic gel, drops, or ointment. Blepharitis is a common bilateral inflammatory process of the eyelids characterized by irritation and burning, and it also usually is associated with a *Staphylococcus* sp. Local hygiene is the mainstay of therapy; topical antibiotics frequently are used, usually in gel, drop, or ointment form, particularly when the disease is accompanied by conjunctivitis and keratitis. Systemic tetracycline, doxycycline, minocycline, and erythromycin often are effective in reducing severe eyelid inflammation but must be used for weeks to months.

*Conjunctivitis* is an inflammatory process of the conjunctiva that varies in severity from mild hyperemia to severe purulent discharge. The more common causes of conjunctivitis include viruses, allergies, environmental irritants, contact lenses, and chemicals. The less common causes include other infectious pathogens, immune-mediated reactions, associated systemic diseases, and tumors of the conjunctiva or eyelid.

The more commonly reported infectious agents are adenovirus and herpes simplex virus, followed by other viral (e.g., enterovirus, coxsackievirus, measles virus, varicella zoster virus, vaccinia variola virus) and bacterial sources (e.g., *Neisseria* spp., *Streptococcus pneumoniae*, *Haemophilus* spp., *S. aureus*, *Moraxella lacunata*, and chlamydial spp.). *Rickettsia*, fungi, and parasites, in both cyst and trophozoite form, are rare causes of conjunctivitis. Effective management is based on selection of an appropriate antibiotic for suspected bacterial pathogens. Unless an unusual causative

organism is suspected, bacterial conjunctivitis is treated empirically with a broad-spectrum topical antibiotic without obtaining a culture.

*Keratitis*, or corneal inflammation, can occur at any level of the cornea (e.g., epithelium, subepithelium, stroma, endothelium). It can be due to non-infectious or infectious causes. Numerous microbial agents have been identified as causes of infectious keratitis, including bacteria, viruses, fungi, spirochetes, and cysts and trophozoites. Severe infections with tissue loss (corneal ulcers) generally are treated more aggressively than infections without tissue loss (corneal infiltrates).

The mild, small, more peripheral infections usually are not cultured, and the eyes are treated with broad-spectrum topical antibiotics. In more severe, central, or larger infections, corneal scrapings for smears, cultures, and sensitivities are performed, and the patient is immediately started on intensive hourly, around-the-clock topical antibiotic therapy. The goal of treatment is to eradicate the infection and reduce the amount of corneal scarring and the chance of corneal perforation and severe decreased vision or blindness. The initial medication selection and dosage are adjusted according to the clinical response and culture and sensitivity results.

*Endophthalmitis* is a potentially severe and devastating inflammatory, and usually infectious, process involving the intraocular tissues. When the inflammatory process encompasses the entire globe, it is called *panophthalmitis*. Endophthalmitis usually is caused by bacteria or fungi, or rarely by spirochetes. The typical case occurs during the early postoperative course (e.g., after cataract, glaucoma, cornea, or retinal surgery), following trauma, or by endogenous seeding in an immunocompromised host or intravenous drug user. Acute postoperative endophthalmitis requires a prompt vitreous tap for smears and cultures and empirical injection of intravitreal antibiotics.

Immediate vitrectomy (i.e., specialized surgical removal of the vitreous) is beneficial for patients who have light perception–only vision (Endophthalmitis Vitrectomy Study Group, 1995). Vitrectomy for other causes of endophthalmitis (e.g., glaucoma bleb related, post-traumatic, or endogenous) may be beneficial (Schiedler et al., 2004). In cases of endogenous seeding, parenteral antibiotics have a role in eliminating the infectious source, but the efficacy of systemic antibiotics with trauma is not well established.

## Antiviral Agents

**General Considerations.** The various antiviral drugs currently used in ophthalmology are summarized in [Table 64–5](#) (see [Chapter 58](#) for additional details about these agents).

**Therapeutic Uses.** The primary indications for the use of antiviral drugs in ophthalmology are viral keratitis, herpes zoster ophthalmicus (Liesegang, 1999; Chern and Margolis, 1998), and retinitis. There currently are no antiviral agents for the treatment of viral conjunctivitis caused by adenoviruses, which usually has a self-limited course and typically is treated by symptomatic relief of irritation.

*Viral keratitis*, an infection of the cornea that may involve either the epithelium or stroma, is most commonly caused by herpes simplex type I and varicella zoster viruses. Less common viral etiologies include herpes simplex type II, Epstein-Barr virus, and CMV. Topical antiviral agents are indicated for the treatment of epithelial disease due to herpes simplex infection. *When treating viral keratitis topically, there is a very narrow margin between the therapeutic topical antiviral activity and the toxic effect on the cornea*; hence, patients must be followed very closely. The role of oral acyclovir and glucocorticoids in herpetic corneal and external eye disease has been examined in the Herpetic Eye Disease Study (Herpetic Eye Disease Study Group, 1997; Herpetic Eye Disease Study Group, 1998). Topical Glucocorticoids are contraindicated in herpetic epithelial keratitis due to active viral replication. In contrast, for herpetic disciform keratitis, which predominantly is presumed to involve a cell-mediated immune reaction, topical glucocorticoids accelerate recovery (Wilhelmus et al., 1994). For recurrent herpetic stromal keratitis, there is clear benefit from treatment with oral acyclovir in reducing the risk of recurrence (Herpetic Eye Disease Study Group, 1998). An ophthalmic formulation of trifluridine (VIROPTIC) is available for treatment of keratoconjunctivitis and epithelial keratitis due to herpes simplex viruses.

*Herpes zoster ophthalmicus* is a latent reactivation of a varicella zoster infection in the first division of the trigeminal cranial nerve. Systemic acyclovir, valacyclovir, and famciclovir are effective in reducing the severity and complications of herpes zoster ophthalmicus (Colin et al., 2000). Currently, there are no ophthalmic preparations of acyclovir approved

by the FDA, although an ophthalmic ointment is available for investigational use.

*Viral retinitis* may be caused by herpes simplex virus, CMV, adenovirus, and varicella zoster virus. With the highly active antiretroviral therapy (HAART; see [Chapter 59](#)), CMV retinitis does not appear to progress when specific anti-CMV therapy is discontinued, but some patients develop an immune recovery uveitis (Jacobson et al., 2000; Whitcup, 2000). Treatment usually involves long-term parenteral administration of antiviral drugs. Intravitreal administration of ganciclovir has been found to be an effective alternative to the systemic route (Sanborn et al., 1992). Acute retinal necrosis and progressive outer retinal necrosis, most often caused by varicella zoster virus, can be treated by various combinations of oral, intravenous, intravitreal injection of, and intravitreal implantation of antiviral medications (Roig-Melo et al., 2001).

**Table 64—5 Antiviral Agents for Ophthalmic Use**

GENERIC NAME (TRADE NAME)	ROUTE OF ADMINISTRATION	OCULAR TOXICITY	INDICATIONS FOR USE
Trifluridine (VIOPTIC, others)	Topical (1% solution)	PK, H	Herpes simplex keratitis and keratoconjunctivitis
Acyclovir (ZOVIRAX)	Oral, intravenous (200-mg capsules, 400- and 800-mg tablets)		Herpes zoster ophthalmicus <sup>a</sup>
Valacyclovir (VALTREX)	Oral (500- and 1000-mg tablets)		Herpes simplex iridocyclitis Herpes simplex keratitis <sup>a</sup> Herpes zoster ophthalmicus <sup>a</sup>
Famciclovir (FAMVIR)	Oral (125-, 250-, and 500-mg tablets)		Herpes simplex keratitis <sup>a</sup> Herpes zoster ophthalmicus <sup>a</sup>
Foscarnet (FOSCAVIR)	Intravenous Intravitreal <sup>b</sup>		Cytomegalovirus retinitis
Ganciclovir (CYTOVENE) (VITRASERT)	Intravenous, oral Intravitreal implant		Cytomegalovirus retinitis
Valganciclovir (VALCYTE)	Oral		Cytomegalovirus retinitis
Cidofovir (VISTIDE)	Intravenous		Cytomegalovirus retinitis

<sup>a</sup>Off-label use. For additional details, see Chapter 58. PK, punctate keratopathy; H, hypersensitivity.

## Antifungal Agents

**General Considerations.** The only currently available topical ophthalmic antifungal preparation is a polyene, natamycin (*NATACYN*), which has the following structure:

Other antifungal agents may be extemporaneously compounded for topical, subconjunctival, or intravitreal routes of administration ([Table 64–6](#)). The pharmacology and structures of available antifungal agents are given in [Chapter 57](#).

**Therapeutic Uses.** As with systemic fungal infections, the incidence of ophthalmic fungal infections has risen with the growing number of immunocompromised hosts. Ophthalmic indications for antifungal medications include fungal keratitis, scleritis, endophthalmitis, mucormycosis, and canaliculitis. Risk factors for fungal keratitis include trauma, chronic ocular surface disease, contact lens wear, and immunosuppression (including topical steroid use).

In 2005-2006, there was a worldwide epidemic of *Fusarium* fungal keratitis related to a specific contact lens solution, which resolved when it was removed from the market (Chang et al., 2007). When fungal infection is suspected, samples of the affected tissues are obtained for smears, cultures, and sensitivities, and this information is used to guide drug selection.

## Antiprotozoal Agents

**General Considerations.** Parasitic infections involving the eye usually manifest themselves as a form of *uveitis*, an inflammatory process of either the anterior or posterior segments and, less commonly, as conjunctivitis, keratitis, and retinitis.

**Therapeutic Uses.** In the U.S., the most commonly encountered protozoal infections include *Acanthamoeba* and *Toxoplasma gondii*. In contact lens

wearers who develop keratitis, physicians should be highly suspicious of the presence of *Acanthamoeba* (McCulley et al., 2000).

Additional risk factors for *Acanthamoeba* keratitis include poor contact lens hygiene, wearing contact lenses in a pool or hot tub, and ocular trauma. Treatment usually consists of a combination of topical agents. The aromatic diamidines (i.e., propamidine isethionate in both topical aqueous and ointment forms [BROLENE]) have been used successfully to treat this relatively resistant infectious keratitis (Hargrave et al., 1999), although it is not available in the U.S. The cationic antiseptic agent polyhexamethylene biguanide (PHMB) also is used in drop form for *Acanthamoeba* keratitis, although this is not an FDA-approved antiprotozoal agent. Topical chlorhexidine can be used as an alternative to PHMB. Oral imidazoles (e.g., itraconazole, fluconazole, ketoconazole, voriconazole) often are used in addition to the topical medications. Resolution of *Acanthamoeba* keratitis often requires many months of treatment.

**Table 64–6 Antifungal Agents for Ophthalmic Use**

DRUG CLASS/AGENT	METHOD OF ADMINISTRATION	INDICATIONS FOR USE
<i>Polyenes</i>		
Amphotericin B <sup>a</sup>	0.1-0.5% (typically 0.15%) topical solution	Yeast and fungal keratitis and endophthalmitis
	0.8-1 mg subconjunctival	Yeast and fungal endophthalmitis
	5-µg intravitreal injection	Yeast and fungal endophthalmitis
	Intravenous	Yeast and fungal endophthalmitis
Natamycin	5% topical suspension	Yeast and fungal blepharitis, conjunctivitis, keratitis
<i>Imidazoles</i>		
Fluconazole <sup>a</sup>	Oral, intravenous	Yeast keratitis and endophthalmitis
Itraconazole <sup>a</sup>	Oral	Yeast and fungal keratitis and endophthalmitis
Ketoconazole <sup>a</sup>	Oral	Yeast keratitis and endophthalmitis
Miconazole <sup>a</sup>	1% topical solution	Yeast and fungal keratitis
	5-10 mg subconjunctival	Yeast and fungal endophthalmitis
	10-µg intravitreal injection	Yeast and fungal endophthalmitis

<sup>a</sup>Off-label use. Only natamycin (NATAACYN) is commercially available and labeled for ophthalmic use. All other antifungal drugs are not labeled for ophthalmic use and must be formulated for the given method of administration. For further dosing information, refer to the *Physicians' Desk Reference for Ophthalmic Medicines*. For additional discussion of these antifungal agents, see Chapter 57.

*Toxoplasmosis* may present as a posterior (e.g., focal retinochoroiditis, papillitis, vitritis, retinitis) or occasionally as an anterior uveitis. Treatment is indicated when inflammatory lesions encroach upon the macula and threaten central visual acuity. Several regimens have been recommended with concurrent use of systemic steroids:

- pyrimethamine, sulfadiazine, and folinic acid (leucovorin)
- pyrimethamine, sulfadiazine, clindamycin, and folinic acid
- sulfadiazine and clindamycin
- clindamycin

- trimethoprim-sulfamethoxazole with or without clindamycin

Other protozoal infections (e.g., giardiasis, leishmaniasis, malaria) and helminths are less common eye pathogens in the U.S. Systemic pharmacological management as well as vitrectomy may be indicated for selected parasitic infections.

In the eye, infections can occur in a variety of locations, such as the cornea, sclera, vitreous, and retina and can be caused by bacteria, viruses, fungi, and parasites. Treatment is based on the severity of infection, the location, and the class of infectious agent. Within each group of microbial cause, different organisms are treated with different medications. Gram-positive bacteria respond to certain antibiotics and Gram-negative bacteria to others. Some organisms are quite susceptible to many antimicrobial agents, while others are not. Still others may have been susceptible in the past but have become resistant. The task of staying ahead of the rapidly developing resistances is becoming increasingly difficult. In ophthalmology, fortunately, newer-generation topical fluoroquinolones recently were brought to market, which has at least temporarily helped stem the tide of resistant infections. Additional topical fluoroquinolones are in development.

While the selection of topical antiviral agents is rather limited, several new systemic antiviral agents have become available in the past decade. Similarly, there is only one commercially available topical antifungal medication, but there are numerous systemic agents, several of them new in the past few years. Potentially, some of these systemic medications could be modified for topical use or even formulated as intraocular implants, greatly expanding our options in the treatment of many ophthalmic infectious diseases.

## **Use of Autonomic Agents in the Eye**

**General Considerations.** General autonomic pharmacology has been discussed extensively in [Chapters 8-12](#). The autonomic agents used in ophthalmology as well as the responses (i.e., mydriasis, cycloplegia) to muscarinic cholinergic antagonists are summarized in [Table 64-7](#).

**Therapeutic Uses.** Autonomic drugs are used extensively for diagnostic and surgical purposes and for the treatment of glaucoma, uveitis, and strabismus.

***Glaucoma.*** In the U.S., glaucoma is the second leading cause of blindness in African-Americans, the third leading cause in Caucasians, and the leading cause in Hispanic Americans (Congdon et al., 2004). African Americans have three times the age-adjusted prevalence of glaucoma compared to Caucasians (Friedman et al., 2004). Characterized by progressive optic nerve cupping and visual field loss, glaucoma is responsible for the bilateral blindness of 90,000 Americans (half of whom are African-American or Hispanic) (Congdon et al., 2004), and ~2.2 million have the disease (1.86% of the population >40 years of age). This number is expected to increase by 50% by the year 2020 (Friedman et al., 2004). Risk factors associated with glaucomatous nerve damage include increased IOP, positive family history of glaucoma, African-American heritage, and possibly myopia and hypertension. The production and regulation of aqueous humor were discussed earlier in “Aqueous Humor Dynamics and Regulation of Intraocular Pressure.” Previously, an IOP of >21 mm Hg was considered abnormal. This, however, is incorrect, as IOP is not an accurate indicator of disease. Nonetheless, elevated IOP is a risk factor for glaucoma. Several randomized, controlled trials have determined that reducing IOP can delay glaucomatous nerve or field damage (Fluorouracil Filtering Surgery Study Group, 1996; AGIS Investigators, 2000; Heijl et al., 2002). Although markedly elevated IOPs (e.g., >30 mm Hg) usually will lead to optic nerve damage, the optic nerves in certain patients apparently can tolerate IOPs in the mid- to high 20s. These patients are referred to as *ocular hypertensives*. The Ocular Hypertension Treatment Study found that prophylactic medical reduction of IOP reduced the risk of progression to glaucoma from ~10-5% (Kass et al., 2002). Other patients have progressive glaucomatous optic nerve damage despite having IOPs in the normal range, and this form of the disease sometimes is called *normal- or low-tension* glaucoma. A reduction of IOP by 30% reduces disease progression from ~35-10%, even for normal-tension glaucoma patients (Collaborative Normal-Tension Glaucoma

**Table 64–7 Autonomic Drugs for Ophthalmic Use**

DRUG CLASS (TRADE NAME)	FORMULATION	INDICATIONS FOR USE	OCULAR SIDE EFFECTS
<i>Cholinergic agonists</i>			
Acetylcholine (MIOCHOL-1)	1% solution	Miosis in surgery	Corneal edema
Carbachol (MBOSTAT, ISOPTO CARBACHOL, others)	0.01-3% solution	Miosis in surgery, glaucoma*	Corneal edema, miosis, induced myopia, decreased vision, brow ache, retinal detachment
Pilocarpine (ISOPTO CARBINE, PILECAR, PHARJAN, PILORPINE HS, PILOPTIC, PILOSTAT, others)	0.5%, 1%, 2%, 4%, and 6% solution; 4% gel	Glaucoma	Same as for carbachol
<i>Anticholinesterase agents</i>			
Echothiophate (PHOSPHORINE IODIDE)	0.125% solution	Glaucoma, accommodative esotropia	Retinal detachment, miosis, cataract, pupillary block glaucoma iris cysts, brow ache, punctal stenosis of the nasolacrimal system
<i>Muscarinic antagonists</i>			
Atropine (ATROPINE-CARD, ISOPTO ATROPINE)	0.5%, 1%, and 2% solution; 1% ointment	Cycloplegia, mydriasis, <sup>b</sup> cycloplegic retinoscopy, <sup>c</sup> dilated fundoscopic exam	Photosensitivity, blurred vision
Scopolamine (ISOPTO HYOSCINE)	0.25% solution	Cycloplegia, mydriasis <sup>b</sup>	Same as for atropine
Homatropine (ISOPTO HOMATROPINE, others)	2% and 5% solution		
Cyclopentolate (AK-PENTOLATE, CYCLOGYL)	0.5%, 1%, and 2% solution		
Tropicamide (MYDRIACYL, TROPICACYL)	0.5% and 1% solution		
<i>Sympathomimetic agents</i>			
Dipivefrin (AKPIRO)	0.1% solution	Glaucoma	Photosensitivity, conjunctival hyperemia hypersensitivity
Phenylephrine (AK-DIATE, MYDERIN, NEO-SYNEPHRINE, others)	0.12%, 2.5%, and 10% solution	Mydriasis, vasoconstriction, decongestion	Same as for dipivefrin
Apraclonidine (TOPIDINE)	0.5% and 1% solution	Ocular hypertension	
Brimonidine (ALPHAGAN-P, others)	0.1%, 0.15%, and 0.2% solution	Glaucoma, ocular hypertension	
Naphazoline (AK-CON, ALBALON, NAPHCON, others)	0.012%, 0.03%, and 0.1% solution	Decongestant	
Tetrahydrozoline (ALTAZINE, MURINE TEARS PLUS, VISINE, others)	0.05% solution	Decongestant	
<i><math>\alpha</math> and <math>\beta</math> adrenergic antagonists</i>			
Betaxolol ( $\beta_1$ -selective) (BETOPTIC, BETOPTIC-S, others)	0.25% and 0.5% suspension	Glaucoma, ocular hypertension	
Carteolol ( $\beta$ ) (OCUPRESS, others)	1% solution		
Levobunolol ( $\beta$ ) (BETAGAN, others)	0.25% and 0.5% solution		
Metipranolol ( $\beta$ ) (OPTIPRANOLOL, others)	0.3% solution		
Timolol ( $\beta$ ) (TIMOPTIC, TIMOPTIC XL, BETIMOL, others)	0.25% and 0.5% solution and gel		

\*Off-label use. Refer to the Physicians' Desk Reference for Ophthalmic Medicines for specific indications and dosing information. <sup>b</sup>Mydriasis and cycloplegia, or paralysis of accommodation, of the human eye occurs after one drop of atropine 1%, scopolamine 0.5%, homatropine 1%, cyclopentolate 0.5% or 1%, and tropicamide 0.5% or 1%. Recovery of mydriasis is defined by return to baseline pupil size to within 1 mm. Recovery of cycloplegia is defined by return to within 2 diopters of baseline accommodative power. The maximal mydriatic effect of homatropine is achieved with a 5% solution, but cycloplegia may be incomplete. Maximal cycloplegia with tropicamide may be achieved with a 1% solution. Times to development of maximal mydriasis and to recovery, respectively, are: for atropine, 30-40 minutes and 7-10 days; for scopolamine, 20-130 minutes and 3-7 days; for homatropine, 40-60 minutes and 1-3 days; for cyclopentolate, 30-60 minutes and 1 day; for tropicamide, 20-40 minutes and 6 hours. Times to development of maximal cycloplegia and to recovery, respectively, are: for atropine, 60-180 minutes and 6-12 days; for scopolamine, 30-60 minutes and 3-7 days; for homatropine, 30-60 minutes and 1-3 days; for cyclopentolate, 25-75 minutes and 6 hours to 1 day; for tropicamide, 30 minutes and 6 hours.

Study Group, 1998a; Collaborative Normal-Tension Glaucoma Study Group, 1998b). Despite overwhelming evidence that IOP reduction is a helpful treatment, at present the pathophysiological processes involved in glaucomatous optic nerve damage and the relationship to aqueous humor dynamics are not understood.

Current pharmacotherapies are targeted at decreasing the production of aqueous humor at the ciliary body and increasing outflow through the trabecular meshwork and uveoscleral pathways. There is no consensus on the best IOP-lowering technique for glaucoma therapy. Currently, a National Eye Institute–sponsored clinical trial, the Collaborative Initial Glaucoma Treatment Study (CIGTS), aims to determine whether it is best, in terms of preservation of visual function and quality of life, to treat patients newly diagnosed with open-angle glaucoma with filtering surgery or medication. Initial results showed no difference in disease progression rates between the two treatment groups at 5 years (Lichter et al., 2001), but after 9 years, more subjects (25.5% versus 21.3%) had visual field loss in the medicine arm than in the surgery arm of the trial (Musch et al., 2009).

The CIGTS study aside, a stepped medical approach depends on the patient's health, age, and ocular status, with knowledge of systemic effects and contraindications for all medications. Recall that:

- young patients usually are intolerant of miotic therapy secondary to visual blurring from induced myopia
- direct miotic agents are preferred over cholinesterase inhibitors in “phakic” patients (i.e., those patients who have their own crystalline lens) because the latter drugs can promote cataract formation
- in patients who have an increased risk of retinal detachment, miotics should be used with caution because they have been implicated in promoting retinal tears in susceptible individuals (such tears are thought to be due to altered forces at the vitreous base produced by ciliary body contraction induced by the drug)

The goal is to prevent progressive glaucomatous optic-nerve damage with minimum risk and side effects from either topical or systemic therapy. With these general principles in mind, a stepped medical approach may begin with a topical prostaglandin (PG) analog. Due to their once-daily dosing, low incidence of systemic side effects, and potent IOP-lowering effect, PG analogs have largely replaced  $\beta$  adrenergic–receptor antagonists as first-line medical therapy for glaucoma. The PG analogs consist of latanoprost (XALATAN), travoprost (TRAVATAN, TRAVATAN Z), and bimatoprost (LUMIGAN, LATISSE). The chemical structure of latanoprost is shown below:

PGF<sub>2α</sub> reduces IOP but has intolerable local side effects. Modifications to the chemical structure of PGF<sub>2α</sub> have produced analogs with a more acceptable side-effect profile. In primates and humans, PGF<sub>2α</sub> analogs appear to lower IOP by facilitating aqueous outflow through the accessory uveoscleral outflow pathway. The mechanism by which this occurs is unclear. PGF<sub>2α</sub> and its analogs (prodrugs that are hydrolyzed to PGF<sub>2α</sub>) bind to FP receptors that link to G<sub>q11</sub> and then to the PLC–IP<sub>3</sub>–Ca<sup>2+</sup> pathway. This pathway is active in isolated human ciliary muscle cells. Other cells in the eye also may express FP receptors. Theories of IOP lowering by PGF<sub>2α</sub> range from altered ciliary muscle tension to effects on trabecular meshwork cells to release of matrix metalloproteinases and digestion of extracellular matrix materials that may impede outflow tracts. There also is less myocilin protein noted in monkey smooth muscle after PGF<sub>2α</sub> treatment (Lindsey et al., 2001).

The β receptor antagonists now are the next most common topical medical treatment. There are two classes of topical β blockers. The nonselective ones bind to both β<sub>1</sub> and β<sub>2</sub> receptors and include timolol maleate and hemihydrate (hemihydrate is not available in the U.S.), levobunolol, metipranolol, and carteolol. There is one β<sub>1</sub>-selective antagonist, betaxolol, available for ophthalmic use, but it is less efficacious than the nonselective β blockers because the β receptors of the eye are largely of the β<sub>2</sub> subtype. However, because the β<sub>1</sub> receptors are found preferentially in the heart while the β<sub>2</sub> receptors are found in the lung, betaxolol is less likely to cause breathing difficulty. In the eye, the targeted tissues are the ciliary body epithelium and blood vessels, where β<sub>2</sub> receptors account for 75-90% of the total population. How β blockade leads to decreased aqueous production and reduced IOP is uncertain. Production of aqueous humor seems to be activated by a β receptor–mediated cyclic AMP–PKA pathway; β blockade blunts adrenergic activation of this pathway by preventing catecholamine

stimulation of the  $\beta$  receptor, thereby decreasing intracellular cyclic AMP. Another hypothesis is that  $\beta$  blockers decrease ocular blood flow, which decreases the ultrafiltration responsible for aqueous production (Juzych and Zimmerman, 1997).

When there are medical contraindications to the use of PG analogs or  $\beta$  receptor antagonists, other agents, such as a  $\beta_2$  adrenergic–receptor agonist or topical carbonic anhydrase inhibitor (CAI), may be used as first-line therapy. The  $\beta_2$  adrenergic agonists improve the pharmacological profile of the nonselective sympathomimetic agent epinephrine and its derivative, dipivefrin (*PROPINE*, others). Epinephrine stimulates both  $\alpha$  and  $\beta$  adrenergic receptors. The drug appears to decrease IOP by enhancing both conventional (via a  $\beta_2$  receptor mechanism) and uveoscleral outflow (perhaps via PG production) from the eye. Although effective, epinephrine is poorly tolerated, principally due to localized irritation and hyperemia. Dipivefrin is an epinephrine prodrug that is converted into epinephrine by esterases in the cornea. It is much better tolerated but is still prone to cause epinephrine-like side effects (Fang and Kass, 1997). The  $\beta_2$  adrenergic agonist clonidine is effective at reducing IOP but also readily crosses the blood-brain barrier and causes systemic hypotension; as a result, it no longer is used for glaucoma. In contrast, apraclonidine (*IOPIDINE*) is a relatively selective  $\beta_2$  adrenergic agonist that is highly ionized at physiological pH and therefore does not cross the blood-brain barrier. Brimonidine (*ALPHAGAN*, others) also is a selective  $\alpha_2$  adrenergic agonist but is lipophilic, enabling easy corneal penetration. Both apraclonidine and brimonidine reduce aqueous production and may enhance some uveoscleral outflow. Both appear to bind to pre- and postsynaptic  $\alpha_2$  receptors. By binding to the presynaptic receptors, the drugs reduce the amount of neurotransmitter release from sympathetic nerve stimulation and thereby lower IOP. By binding to postsynaptic  $\alpha_2$  receptors, these drugs stimulate the  $G_i$  pathway, reducing cellular cyclic AMP production, thereby reducing aqueous humor production (Juzych et al., 1997).

The development of a topical CAI took many years but was an important event because of the poor side-effect profile of oral CAIs. Dorzolamide (*TRUSOPT*, others) and brinzolamide (*AZOPT*) both work by inhibiting carbonic anhydrase (isoenzyme II), which is found in the ciliary body

epithelium. This reduces the formation of bicarbonate ions, which reduces fluid transport and, thus, IOP (Sharir, 1997).

Any of these four drug classes can be used as additive second- or third-line therapy. In fact, the  $\beta$  receptor antagonist timolol has been combined with the CAI dorzolamide (see the structure below) in a single medication (COSOPT, others) and with the  $\alpha_2$  adrenergic agonist brimonidine (COMBIGAN).

Such combinations reduce the number of drops needed and may improve compliance. Other combination products involving PG analogs and  $\beta$  blockers are in development.

Topical miotic agents are historically important glaucoma medications but are less commonly used today. Miotics lower IOP by causing muscarinic-induced contraction of the ciliary muscle, which facilitates aqueous outflow. They do not affect aqueous production. Multiple miotic agents have been developed. Pilocarpine and carbachol are cholinomimetics that stimulate muscarinic receptors. Echothiophate (*PHOSPHOLINE IODIDE*) is an organophosphate inhibitor of acetylcholinesterase; it is relatively stable in aqueous solution and, by virtue of its quaternary ammonium structure, is positively charged and poorly absorbed. The usefulness of these medicines is lessened by their numerous side effects and the need to use them three to four times a day (Kaufman and Gabelt, 1997).

If combined topical therapy fails to achieve the target IOP or fails to halt glaucomatous optic nerve damage, then systemic therapy with CAI is a final medication option before resorting to laser or incisional surgical treatment.

The best-tolerated oral preparation is acetazolamide in sustained-release capsules (see [Chapter 25](#)), followed by methazolamide. The least well tolerated are acetazolamide tablets.

***Toxicity of Agents in the Treatment of Glaucoma.*** Ciliary body spasm is a muscarinic cholinergic effect that can lead to induced myopia and a changing refraction due to iris and ciliary body contraction as the drug effect waxes and wanes between doses. Headaches can occur from the iris and ciliary body contraction. Epinephrine-related compounds, effective in IOP reduction, can cause a vasoconstriction–vasodilation rebound phenomenon leading to a red eye. Ocular and skin allergies from topical epinephrine, related prodrug formulations, apraclonidine, and brimonidine are common. Brimonidine is less likely to cause ocular allergy and therefore is more commonly used. These agents can cause CNS depression and apnea in neonates and are contraindicated in children <2 years of age.

Systemic absorption of epinephrine-related drugs and  $\beta$  adrenergic antagonists can induce all the side effects found with direct systemic administration. The use of CAIs systemically may give some patients significant problems with malaise, fatigue, depression, paresthesias, and nephrolithiasis; the topical CAIs may minimize these relatively common side effects. These medical strategies for managing glaucoma do help to slow the progression of this disease, yet there are potential risks from treatment-related side effects, and treatment effects on quality of life must be recognized.

***Uveitis.*** Inflammation of the uvea, or uveitis, has both infectious and non-infectious causes, and medical treatment of the underlying cause (if known), in addition to the use of topical therapy, is essential. Cyclopentolate (CYCLOGYL, others), tropicamide (MYDRIACYL) or sometimes even longer-acting antimuscarinic agents such as atropine, scopolamine (ISOPTO HYOSCINE), and homatropine frequently are used to prevent posterior synechia formation between the lens and iris margin and to relieve ciliary muscle spasm that is responsible for much of the pain associated with anterior uveitis.

If posterior synechiae already have formed, an  $\alpha$  adrenergic agonist may be used to break the synechiae by enhancing pupillary dilation. A solution containing scopolamine 0.3% in combination with 10% phenylephrine (MUROCOLL-2) is available for this purpose. Two others, 1%

hydroxyamphetamine hydrobromide combined with 0.25% tropicamide (PAREMYD) and 1% phenylephrine in combination with 0.2% cyclopentolate (CYCLOMYDRIL) are only indicated for induction of mydriasis. Topical steroids usually are adequate to decrease inflammation, but sometimes they must be supplemented with systemic steroids.

***Strabismus.*** *Strabismus*, or ocular misalignment, has numerous causes and may occur at any age. Besides causing *diplopia* (double vision), strabismus in children may lead to *amblyopia* (reduced vision). Nonsurgical efforts to treat amblyopia include occlusion therapy, orthoptics, optical devices, and pharmacological agents.

An eye with *hyperopia*, or farsightedness, must constantly accommodate to focus on distant images. In some hyperopic children, the synkinetic accommodative-convergence response leads to excessive convergence and a manifest *esotropia* (turned-in eye). The brain rejects diplopia and suppresses the image from the deviated eye. If proper vision is not restored by ~7 years of age, the brain never learns to process visual information from that eye. The result is that the eye appears structurally normal but does not develop normal visual acuity and is therefore amblyopic. Unfortunately, this is a fairly common cause of visual disability. In this setting, atropine (1%) instilled in the preferred seeing eye produces cycloplegia and the inability of this eye to accommodate, thus forcing the child to use the amblyopic eye (Pediatric Eye Disease Investigator Group, 2002; Pediatric Eye Disease Investigator Group, 2003). Echothiophate iodide also has been used in the setting of accommodative strabismus. Accommodation drives the near reflex, the triad of miosis, accommodation, and convergence. An irreversible cholinesterase inhibitor such as echothiophate causes miosis and an accommodative change in the shape of the lens; hence, the accommodative drive to initiate the near reflex is reduced, and less convergence will occur.

***Surgery and Diagnostic Purposes.*** For certain surgical procedures and for clinical funduscopic examination, it is desirable to maximize the view of the retina and lens. Muscarinic cholinergic antagonists and sympathomimetic agents frequently are used singly or in combination for this purpose ([Table 64-7](#)).

Intraoperatively, there are circumstances in which miosis is preferred, and two cholinergic agonists are available for intraocular use, acetylcholine (MIOCHOL-E) and carbachol. Patients with myasthenia gravis may first present

to an ophthalmologist with complaints of double vision (diplopia) or lid droop (ptosis); the *edrophonium test* is helpful in diagnosing these patients (see [Chapter 10](#)). For surgical visualization of the lens, trypan blue (VISIONBLUE) is marketed to facilitate visualization of the lens and for staining during surgical vitrectomy procedures to guide the excision of tissue (MEMBRANEBLUE).

## Use of Immunomodulatory and Antimitotic Drugs for Ophthalmic Therapy

**Glucocorticoids.** Glucocorticoids have an important role in managing ocular inflammatory diseases; their chemistry and pharmacology are described in [Chapter 42](#).

**Therapeutic Uses.** Currently, the glucocorticoids formulated for topical administration to the eye are dexamethasone (DEXASOL, others), prednisolone (PRED FORTE, others), fluorometholone (FML, others), loteprednol (ALREX, LOTEMAX), rimexolone (VEXOL), and difluprednate (DUREZOL). Because of their anti-inflammatory effects, topical corticosteroids are used in managing significant ocular allergy, anterior uveitis, external eye inflammatory diseases associated with some infections and ocular cicatricial pemphigoid, and postoperative inflammation following refractive, corneal, and intraocular surgery. After glaucoma filtering surgery, topical steroids can delay the wound-healing process by decreasing fibroblast infiltration, thereby reducing potential scarring of the surgical site (Araujo et al., 1995). Steroids commonly are given systemically and by sub-Tenon's capsule injection to manage posterior uveitis. Intravitreal injection of steroids now is being used to treat a variety of retinal conditions including age-related macular degeneration (ARMD), diabetic retinopathy, and cystoid macular edema. Two intravitreal triamcinolone formulations, TRIVARIS and TRISENCE, are approved for ocular inflammatory conditions unresponsive to topical corticosteroids and visualization during vitrectomy, respectively. Parenteral steroids followed by tapering oral doses is the preferred treatment for optic neuritis (Kaufman et al., 2000; Trobe et al., 1999). An ophthalmic implant of fluocinolone (RETISERT) is marketed for the treatment of chronic, non-infectious uveitis.

**Toxicity of Steroids.** Steroid drops, pills, and creams are associated with ocular problems, as are intravitreal and intravenous steroids. Ocular

complications include the development of posterior subcapsular cataracts, secondary infections (see [Chapter 42](#)), and secondary open-angle glaucoma (Becker and Mills, 1963). There is a significant increase in the risk for developing secondary glaucoma when there is a positive family history of glaucoma. In the absence of a family history of open-angle glaucoma, only ~5% of normal individuals respond to topical or long-term systemic steroids with a marked increase in IOP. With a positive family history, however, moderate to marked steroid-induced IOP elevations may occur in up to 90% of patients. The pathophysiology of steroid-induced glaucoma is not fully understood, but there is evidence that the *GLCIA* gene may be involved (Stone et al., 1997). Typically, steroid-induced elevation of IOP is reversible once administration of the steroid ceases. However, intraocular or sub-Tenon's steroid-related pressure elevation may persist for months and may require treatment with glaucoma medication or even filtering surgery. Newer topical steroids, so-called "soft steroids" (e.g., loteprednol), have been developed that reduce, but do not eliminate, the risk of elevated IOP.

## **Nonsteroidal Anti-Inflammatory Agents**

**General Considerations.** Nonsteroidal drug therapy for inflammation is discussed in [Chapter 34](#). Nonsteroidal anti-inflammatory drugs (NSAIDs) now are being applied to the treatment of ocular disease.

**Therapeutic Uses.** Currently, there are five topical NSAIDs (see [Chapter 34](#)) approved for ocular use: flurbiprofen (OCUFEN, others), ketorolac (ACULAR, others), diclofenac (VOLTAREN, others), bromfenac (XIBROM), and nepafenac (NEVANAC). Flurbiprofen is used to counter unwanted intraoperative miosis during cataract surgery. Ketorolac is given for seasonal allergic conjunctivitis. Diclofenac is used for postoperative inflammation. Both ketorolac (Weisz et al., 1999; Almeida et al., 2008) and diclofenac (Asano et al., 2008) have been found to be effective in treating cystoid macular edema occurring after cataract surgery. Bromfenac and nepafenac are indicated for treating postoperative pain and inflammation after cataract surgery. In patients treated with PG analogs such as latanoprost or bimatoprost, ketorolac and diclofenac may help decrease postoperative inflammation. They also are useful in decreasing pain after corneal refractive surgery. Topical and systemic NSAIDs occasionally have been associated with sterile corneal melts and perforations, especially in older patients with ocular surface disease, such as dry eye syndrome.

***Antihistamines and Mast-Cell Stabilizers.*** Pheniramine ([Chapter 32](#)) and antazoline, both H<sub>1</sub> receptor antagonists, are formulated in combination with naphazoline, a vasoconstrictor, for relief of allergic conjunctivitis; emedastine difumarate (EMADINE) also is used. Cromolyn sodium (CROLOM, others), which reportedly prevents the release of histamine and other autacoids from mast cells, has found limited use in treating conjunctivitis that is thought to be allergen mediated, such as vernal conjunctivitis. Lodoxamide tromethamine (ALOMIDE) and pemirolast (ALAMAST), mast-cell stabilizers, also are available for ophthalmic use. Nedocromil (ALOCRIL) also is primarily a mast-cell stabilizer with some antihistamine properties. Olopatadine hydrochloride (PATANOL, PATADAY), ketotifen fumarate (ZADITOR, ALAWAY), bepotastine (BEPREVE), and azelastine (OPTIVAR) are H<sub>1</sub> antagonists with mast cell–stabilizing properties. Epinastine (*ELESTAT*) antagonizes H<sub>1</sub> and H<sub>2</sub> receptors and exhibits mast cell–stabilizing activity.

## **Immunosuppressive and Antimitotic Agents**

***General Considerations.*** The principal application of immunosuppressive and antimitotic agents to ophthalmology relates to the use of 5-fluorouracil and mitomycin C in corneal and glaucoma surgeries. Interferon  $\alpha$ -2b also has occasionally been used. Certain systemic diseases with serious vision-threatening ocular manifestations—such as Behçet’s disease, Wegener’s granulomatosis, rheumatoid arthritis, and reactive arthritis (Reiter’s syndrome)—require systemic immunosuppression (see [Chapter 35](#)).

***Therapeutic Uses.*** In glaucoma surgery, both fluorouracil and mitomycin (MUTAMYCIN), which also are anti-neoplastic agents (see [Chapter 61](#)), improve the success of filtration surgery by limiting the postoperative wound-healing process. Mitomycin is used intraoperatively as a single subconjunctival application at the trabeculectomy site. Meticulous care is used to avoid intraocular penetration, because mitomycin is extremely toxic to intraocular structures. Fluorouracil may be used intraoperatively at the trabeculectomy site and/or subconjunctivally during the postoperative course (Fluorouracil Filtering Surgery Study Group, 1989). Although both agents work by limiting the healing process, sometimes this can result in thin, ischemic, avascular tissue that is prone to breakdown. The resultant leaks can cause hypotony (low IOP) and increase the risk of infection.

In corneal surgery, mitomycin has been used topically after excision of pterygium, a fibrovascular membrane that can grow onto the cornea. Mitomycin can be used to reduce the risk of scarring after certain procedures to remove corneal opacities and also prophylactically to prevent corneal scarring after excimer laser surface ablation (photorefractive and phototherapeutic keratectomy). Mitomycin also is used to treat certain conjunctival and corneal tumors. Interferon  $\alpha$ -2b has been used in the treatment of conjunctival papilloma and certain conjunctival tumors. Although the use of mitomycin for both corneal surgery and glaucoma filtration surgeries augments the success of these surgical procedures, caution is advocated in light of the potentially serious delayed ocular complications (Rubinfeld et al., 1992; Hardten and Samuelson, 1999; Bahar et al., 2009).

Intraocular methotrexate (see [Chapter 61](#)) is used to treat uveitis and uveitic cystoid macular edema. It also has been used to treat the uncommon complication of lymphoma in the vitreous, which is an inaccessible compartment for most anti-neoplastic drugs (Taylor et al., 2009).

**Immunomodulatory Agent.** Topical cyclosporine (cyclosporin A; *RESTASIS*) is approved for the treatment of chronic dry eye associated with inflammation. Cyclosporine is an immunomodulatory agent that inhibits activation of T cells. Use of cyclosporine is associated with decreased inflammatory markers in the lacrimal gland, increased tear production, and improved vision and comfort (Sall et al., 2000; Perry et al., 2008).

## **Drugs and Biological Agents Used in Ophthalmic Surgery**

***Presurgical Antiseptics.*** Povidone iodine (BETADINE) is formulated as a 5% sterile ophthalmic solution for use prior to surgery to prep periocular skin and irrigate ocular surfaces, including the cornea, conjunctiva, and palpebral fornices. Following irrigation, the exposed tissues are flushed with sterile saline. As for other povidone iodine uses, hypersensitivity to iodine is a contraindication.

***Adjuncts in Anterior Segment Surgery.*** *Viscoelastic* substances assist in ocular surgery by maintaining spaces, moving tissue, and protecting surfaces. These substances are prepared from hyaluronate (HEALON, others), chondroitin sulfate (VISCOAT), or hydroxypropylmethylcellulose and share the

following important physical characteristics: viscosity, shear flow, elasticity, cohesiveness, and coatibility. Various viscoelastic agents emphasize certain features that are broadly characterized as dispersive or cohesive. They are used almost exclusively in anterior segment surgery. Complications associated with viscoelastic substances are related to transient elevation of IOP after the surgical procedure.

***Ophthalmic Glue.*** Cyanoacrylate tissue adhesive (ISODENT, DERMABOND, HISTOACRYL), while not FDA approved for the eye, is widely used in the management of corneal ulcerations and perforations. It is applied in liquid form and polymerized into a solid plug.

Fibrinogen glue (TISSEEL, EVICEL) is increasingly being used on the ocular surface to secure tissue such as conjunctiva, amniotic membrane, and lamellar corneal grafts. These are FDA approved for use in cardiac, vascular, and general surgery but not for the eye.

***Anterior Segment Gases.*** Sulfur hexafluoride ( $\text{SF}_6$ ) and perfluoropropane gases have long been used as vitreous substitutes during retinal surgery. In the anterior segment, they are used in non-expansile concentrations to treat Descemet's detachments, typically after cataract surgery. These detachments can cause mild to severe corneal edema. The gas is injected into the anterior chamber to push Descemet's membrane up against the stroma, where ideally it reattaches and clears the corneal edema.

***Vitreous Substitutes.*** The primary use of vitreous substitutes is reattachment of the retina following vitrectomy and membrane-peeling procedures for complicated proliferative vitreoretinopathy and traction retinal detachments. Several compounds, including gases, perfluorocarbon liquids, and silicone oil ([Table 64–8](#)), are available. With the exception of air, the gases expand because of interaction with systemic oxygen, carbon dioxide, and nitrogen, and this property makes them desirable to temporarily tamponade areas of the retina. However, use of these expansile gases carries the risk of complications from elevated IOP, subretinal gas, corneal edema, and cataract formation. The gases are absorbed over a period of days (for air) to 2 months (for perfluoropropane).

The liquid perfluorocarbons, with specific gravities between 1.76 and 1.94, are denser than vitreous and are helpful in flattening the retina when vitreous is present. Silicone oil (polydimethylsiloxanes; ADATOSIL 5000) has had extensive use in both Europe and the U.S. for long-term tamponade of the

retina. Complications from silicone oil use include glaucoma, cataract formation, corneal edema, corneal band keratopathy, and retinal toxicity.

***Surgical Hemostasis and Thrombolytic Agents.*** Hemostasis has an important role in most surgical procedures and usually is achieved by temperature-mediated coagulation. In some intraocular surgeries, thrombin has a valuable role in hemostasis. Intravitreal administration of thrombin can assist in controlling intraocular hemorrhage during vitrectomy. When used intraocularly, a potentially significant inflammatory response may occur, but this reaction can be minimized by thorough irrigation after hemostasis is achieved. This coagulation factor also may be applied topically via soaked sponges to exposed conjunctiva and sclera, where hemostasis may be a challenge due to the rich vascular supply.

Table 64–8 Vitreous Substitutes<sup>a</sup>

VITREOUS SUBSTITUTE	CHEMICAL STRUCTURE	CHARACTERISTICS (duration or viscosity)
<i>Nonexpansile gases</i>		
Air		Duration of 5-7 days
Argon		
Carbon dioxide		
Helium		
Krypton		
Nitrogen		
Oxygen		
Xenon		
<i>Expansile gases</i>		
Sulfur hexafluoride (SF <sub>6</sub> )		Duration of 10-14 days
Octafluorocyclobutane (C <sub>4</sub> F <sub>8</sub> )		

Perfluoromethane (CF <sub>4</sub> )	$\begin{array}{c} \text{F} \\   \\ \text{F}-\text{C}-\text{F} \\   \\ \text{F} \end{array}$	Duration of 10-14 days
Perfluoroethane (C <sub>2</sub> F <sub>6</sub> )	$\begin{array}{c} \text{F} \quad \text{F} \\   \quad   \\ \text{F}-\text{C}-\text{C}-\text{F} \\   \quad   \\ \text{F} \quad \text{F} \end{array}$	Duration of 30-35 days
Perfluoropropane (C <sub>3</sub> F <sub>8</sub> )	$\begin{array}{c} \text{F} \quad \text{F} \quad \text{F} \\   \quad   \quad   \\ \text{F}-\text{C}-\text{C}-\text{C}-\text{F} \\   \quad   \quad   \\ \text{F} \quad \text{F} \quad \text{F} \end{array}$	Duration of 55-65 days
Perfluoro- <i>n</i> -butane (C <sub>4</sub> F <sub>10</sub> )	$\begin{array}{c} \text{F} \quad \text{F} \quad \text{F} \quad \text{F} \\   \quad   \quad   \quad   \\ \text{F}-\text{C}-\text{C}-\text{C}-\text{C}-\text{F} \\   \quad   \quad   \quad   \\ \text{F} \quad \text{F} \quad \text{F} \quad \text{F} \end{array}$	
Perfluoropentane (C <sub>5</sub> F <sub>12</sub> )	$\begin{array}{c} \text{F} \quad \text{F} \quad \text{F} \quad \text{F} \quad \text{F} \\   \quad   \quad   \quad   \quad   \\ \text{F}-\text{C}-\text{C}-\text{C}-\text{C}-\text{C}-\text{F} \\   \quad   \quad   \quad   \quad   \\ \text{F} \quad \text{F} \quad \text{F} \quad \text{F} \quad \text{F} \end{array}$	
<b>Silicone oils</b>		
Nonfluorinated silicone oils	(CH <sub>3</sub> ) <sub>3</sub> SiO[(CH <sub>3</sub> ) <sub>2</sub> SiO] <sub>n</sub> Si(CH <sub>3</sub> ) <sub>3</sub>	Viscosity range from 1000-30,000 cs
Fluorosilicone	(CH <sub>3</sub> ) <sub>3</sub> SiO[(C <sub>6</sub> H <sub>5</sub> F) <sub>2</sub> SiO] <sub>n</sub> Si(CH <sub>3</sub> ) <sub>3</sub>	Viscosity range from 1000-10,000 cs
"High-tech" silicone oils	(CH <sub>3</sub> ) <sub>3</sub> SiO[(C <sub>6</sub> H <sub>5</sub> )(CH <sub>3</sub> )SiO] <sub>n</sub> Si(CH <sub>3</sub> ) <sub>3</sub>	May terminate as trimethylsiloxy (shown) or polyphenylmethylsiloxane; viscosity not reported

\*See Parel and Villain, 1994, and Chang, 1994, for further details. cs, centistoke (unit of viscosity).

Topical aminocaproic acid (*CAPROGEL*) has been investigated to prevent rebleeding after traumatic *hyphema* (blood in the anterior chamber), but clinical trials report mixed success, and the drug is not marketed in the U.S. (Karkhaneh et al., 2003; Pieramici et al., 2003).

Depending on the intraocular location of a clot, there may be significant problems relating to IOP, retinal degeneration, and persistent poor vision. *Recombinant tissue plasminogen activator* (t-PA; alteplase) ([Chapter 30](#)) has been used during intraocular surgeries to assist evacuation of a hyphema, subretinal clot, or nonclearing vitreous hemorrhage. Alteplase also has been administered subconjunctivally and intracamerally (i.e., controlled intraocular administration into the anterior segment) to lyse blood clots obstructing a glaucoma filtration site. The main complication related to the use of t-PA is bleeding.

***Botulinum Toxin Type A in the Treatment of Strabismus, Blepharospasm, and Related Disorders.*** Botulinum toxin type A is FDA-approved for the treatment of strabismus and blepharospasm associated with dystonia, facial wrinkles (glabellar lines), axillary hyperhidrosis, and spasmodic torticollis (cervical dystonia). It also has been used off label for Meige's syndrome, hemifacial spasm, and certain migraine headaches (Tsui, 1996; Price et al., 1997) (see also [Chapter 11](#)). Two botulinum toxin type A

preparations are marketed in the U.S.: onabotulinumtoxinA (BOTOX, BOTOX COSMETIC) and abobotulinumtoxinA (DYSPORT). By preventing acetylcholine release at the neuromuscular junction, botulinum toxin A usually causes a temporary paralysis of the locally injected muscles.

The variability in duration of paralysis may be related to the rate of developing antibodies to the toxin, upregulation of nicotinic cholinergic postsynaptic receptors, and aberrant regeneration of motor nerve fibers at the neuromuscular junction. Complications related to this toxin include double vision (diplopia) and lid droop (ptosis) and potentially life-threatening distant spread of toxin effect from the injection site (asthenia, generalized muscle weakness, diplopia, blurred vision, ptosis, dysphagia, dysphonia, dysarthria, urinary incontinence, and breathing difficulties) within hours to weeks after administration.

***Agents Used to Treat Blind and Painful Eye.*** Retrobulbar injection of either absolute or 95% ethanol may provide relief from chronic pain associated with a blind and painful eye. Retrobulbar chlorpromazine also has been used. This treatment is preceded by administration of local anesthesia. Local infiltration of the ciliary nerves provides symptomatic relief from pain, but other nerve fibers may be damaged, causing paralysis of the extraocular muscles, including those in the eyelids, or neuroparalytic keratitis. The sensory fibers of the ciliary nerves may regenerate, and repeated injections sometimes are needed to control pain.

***Systemic Agents with Ocular Side Effects.*** Just as certain systemic diseases have ocular manifestations, certain systemic drugs have ocular side effects. These can range from mild and inconsequential to severe and vision threatening. Examples are listed in the following sections. A review of these drugs recently has been published (Santaella and Fraunfelder, 2007).

***Glaucoma.*** The anti-seizure drug topiramate (*TOPAMAX*, others) frequently has been reported to cause choroidal effusions, thereby anteriorly rotating the ciliary body and causing an angle-closure glaucoma (Banta et al., 2001).

***Retina.*** Numerous drugs have toxic side effects on the retina. The anti-arthritis and antimalarial medicines hydroxychloroquine (*PLAQUENIL*, others) and chloroquine can cause a central retinal toxicity by an unknown mechanism. With normal dosages, toxicity does not appear until ~6 years after the drug is started. Stopping the drug will not reverse the damage but will prevent further toxicity (Tehrani et al., 2008). Tamoxifen is known to

cause a crystalline maculopathy. The anti-seizure drug vigabatrin (SABRIL) causes progressive and permanent bilateral concentric visual field constriction in a high percentage of patients. The mechanism is not known, but vigabatrin is more effectively transported into the retina than into the brain, and consequently, elevations of retinal GABA concentrations may contribute to the vision loss.

**Optic Nerve.** The three phosphodiesterase (PDE) inhibitors, sildenafil (VIAGRA, REVATIO), vardenafil (LEVITRA), and tadalafil (CIALIS, ADCIRCA), inhibit PDE5 in the corpus cavernosum to help achieve and maintain penile erection. The drug also mildly inhibits PDE6, which controls the levels of cyclic GMP in the retina. Visually, this can result in seeing a bluish haze or experiencing light sensitivity. There have been several reports of nonarteritic ischemic optic neuropathy (NAION) in patients using these drugs. Despite these reports, there is little conclusive evidence that these drugs caused this problem, but patients should stop using the medications if they experience visual problems (Laties, 2009). Multiple medications can cause a toxic optic neuropathy characterized by gradually progressive bilateral central scotomas and vision loss. There can be accompanying optic nerve pallor. These medicines include ethambutol, chloramphenicol, and rifampin (Lloyd and Fraunfelder, 2007). Systemic or ocular steroids can cause elevated IOP and glaucoma. If the steroids cannot be stopped, glaucoma medications, and even filtering surgery, often are required.

**Anterior Segment.** Steroids also have been implicated in cataract formation. If vision is reduced, cataract surgery may be necessary. Rifabutin, if used in conjunction with clarithromycin or fluconazole for treatment of *Mycobacterium avium* complex (MAC) opportunistic infections in human immunodeficiency virus (HIV)-positive persons, is associated with an iridocyclitis and even hypopyon. This will resolve with steroids or by stopping the medication.

**Ocular Surface.** Isotretinoin (ACCUTANE, others) has a drying effect on mucous membranes and is associated with dry eye and meibomian gland dysfunction.

**Cornea Coryanghiva and Eyelids.** The cornea, the conjunctiva, and even the eyelids can be affected by systemic medications. One of the most common drug deposits found in the cornea is from the cardiac medication amiodarone. It deposits in the inferior and central cornea in a whorl-like pattern termed

*cornea verticillata*. It appears as fine tan or brown pigment in the epithelium. Fortunately, the deposits seldom affect vision, and therefore, this rarely is a cause to discontinue the medication. The deposits disappear slowly if the medication is stopped. Other medications, including indomethacin, atovaquone, chloroquine, and hydroxychloroquine, can cause a similar pattern.

The phenothiazines, including chlorpromazine and thioridazine, can cause brown pigmentary deposits in the cornea, conjunctiva, and eyelids. The deposits generally are found in Descemet's membrane and the posterior cornea. They typically do not affect vision. The ocular deposits generally persist after discontinuation of the medication and can even worsen, perhaps because the medication deposits in the skin are slowly released and accumulate in the eye.

Gold treatments for arthritis (now rarely used) can lead to gold deposition in the cornea and conjunctiva, which are termed *chrysiasis* and are gold to violet in color. With lower cumulative doses (1-2 g), the deposits are found primarily in the epithelium and anterior stroma. These deposits usually disappear with discontinuation of the medication. With higher doses, the gold is deposited in Descemet's membrane and posterior stroma and can involve the entire stroma. These changes can be permanent. The deposits generally do not affect vision and are not a reason to stop gold therapy.

Tetracyclines can cause a yellow discoloration of the light-exposed conjunctiva. Systemic minocycline can induce a blue-gray scleral pigmentation that is most prominent in the interpalpebral zone (Morrow and Abbott, 1998).

## **Agents Used to Assist in Ocular Diagnosis**

A number of agents are used in an ocular examination (e.g., mydriatic agents, topical anesthetics, dyes to evaluate corneal surface integrity), to facilitate intraocular surgery (e.g., mydriatic and miotic agents, topical and local anesthetics), and to help in making a diagnosis in cases of anisocoria ([Figure 64-5](#)) and retinal abnormalities (e.g., intravenous contrast agents). The autonomic agents have been discussed earlier. The diagnostic and therapeutic uses of topical and intravenous dyes and of topical anesthetics are discussed in "Anterior Segment and External Diagnostic Uses" and "Posterior Segment Diagnostic Uses."

**Anterior Segment and External Diagnostic Uses.** Epiphora (excessive tearing) and surface problems of the cornea and conjunctiva are commonly encountered external ocular disorders. The dyes fluorescein, rose bengal, and lissamine green are used in evaluating these problems. Available as a 2% alkaline solution, 10% and 25% solutions for injection, and an impregnated paper strip, fluorescein reveals epithelial defects of the cornea and conjunctiva and aqueous humor leakage that may occur after trauma or ocular surgery. In the setting of epiphora, fluorescein is used to help determine the patency of the nasolacrimal system. In addition, this dye is used as part of the procedure of *applanation tonometry* (IOP measurement) and to assist in determining the proper fit of rigid and semirigid contact lenses. Fluorescein in combination with proparacaine or benoxinate is available for procedures in which a disclosing agent is needed in conjunction with a topical anesthetic. Fluorexon (FLUORESOF), a high-molecular-weight fluorescent solution, is used when fluorescein is contraindicated (as when soft contact lenses are in place).

Rose bengal and lissamine green, available as saturated paper strips, stain devitalized tissue on the cornea and conjunctiva.

**Posterior Segment Diagnostic Uses.** The integrity of the blood-retinal and retinal pigment epithelial barriers may be examined directly by retinal angiography using intravenous administration of either fluorescein sodium or indocyanine green. These agents commonly cause nausea and may precipitate serious allergic reactions in susceptible individuals.

FLUORESCEIN SODIUM

INDOCYANINE GREEN

## Agents Used to Treat Retinal Neovascularization and Macular Degeneration

Verteporfin (*VISUDYNE*) is approved for photodynamic therapy of the exudative form of ARMD with predominantly classic choroidal neovascular membranes (Fine et al., 2000; Jager et al., 2008). Verteporfin also is used in the treatment of predominantly classic choroidal neovascularization caused by conditions such as pathological myopia and presumed ocular histoplasmosis syndrome. Verteporfin is a mixture of two regioisomers (I and II):

Verteporfin is administered intravenously, and once it reaches the choroidal circulation, the drug is light activated by a nonthermal laser source. Depending on the size of the neovascular membrane and concerns of occult membranes and recurrence, multiple photodynamic treatments may be necessary. Activation of the drug in the presence of oxygen generates free radicals, which cause vessel damage and subsequent platelet activation, thrombosis, and occlusion of choroidal neovascularization. The  $t_{1/2}$  of the drug is 5-6 hours. It is eliminated predominantly in the feces. The potential side effects include headache, injection-site reactions, and visual disturbances. The drug causes temporary photosensitization, and patients must avoid exposure of the skin or eyes to direct sunlight or bright indoor lights for 5 days after receiving it.

Pegaptanib (*MACUGEN*) is approved for neovascular (wet) ARMD. Pegaptanib is a selective vascular endothelial growth factor (VEGF) antagonist. It is a pegylated anti-VEGF aptamer, a single strand of nucleic acid that binds to the major pathological VEGF isoform, extracellular

VEGF<sub>165</sub>, thereby inhibiting VEGF<sub>165</sub> binding to VEGF receptors. VEGF<sub>165</sub> induces angiogenesis and increases vascular permeability and inflammation, all of which are thought to contribute to the progression of the neovascular (wet) form of ARMD, a leading cause of blindness. Pegaptanib reduced vision loss in patients with wet ARMD (Gragoudas et al., 2004). Dose levels >0.3 mg did not demonstrate any additional benefit.

Pegaptanib (0.3 mg) is administered once every 6 weeks by intravitreal injection into the eye to be treated. Side effects are largely related to the injection. Following the injection, patients should be monitored for elevation in IOP and for endophthalmitis. Rare cases of anaphylaxis/anaphylactoid reactions have been reported. No special dosage modification is required for any of the populations that have been studied (i.e., gender, elderly).

Bevacizumab (AVASTIN) is a monoclonal murine antibody that targets VEGF-A and thereby inhibits vascular proliferation and tumor growth (see [Chapter 62](#)). Ranibizumab (LUCENTIS) is a variant of bevacizumab that has had the Fab domain affinity matured (Lien and Lowman, 2008).

In the eye, several diseases that involve neovascularization such as proliferative diabetic retinopathy, macular edema, retinopathy of prematurity (Hubbard, 2008), ARMD (Patel et al., 2008), and neovascular glaucoma have been treated off label with bevacizumab, while ranibizumab generally has been reserved for both classic (Brown et al., 2009) and occult (Chang et al., 2007) choroidal neovascular membranes associated with ARMD. Both drugs are delivered by intravitreal injection and often are used on a weekly or monthly basis for maintenance therapy. Aside from the risks of hemorrhage and infection from intravitreal injections, both drugs have been associated with the risk of cerebral vascular accidents (Dafer et al., 2007; Shima et al., 2008). A multicenter clinical trial evaluating the effectiveness of the two medications for treating ARMD is currently under way.

## **Use of Anesthetics in Ophthalmic Procedures**

Topical anesthetic agents used clinically in ophthalmology include proparacaine and tetracaine drops, lidocaine gel (see [Chapter 20](#)), and intranasal cocaine. Proparacaine and tetracaine are used topically to perform tonometry, to remove foreign bodies on the conjunctiva and cornea, to perform superficial corneal surgery, and to manipulate the nasolacrimal canalicular system. They also are used topically to anesthetize the ocular

surface for refractive surgery using either the excimer laser or placement of intrastromal corneal rings. Cocaine may be used intranasally in combination with topical anesthesia for cannulating the nasolacrimal system.

Lidocaine and bupivacaine are used for infiltration and retrobulbar block anesthesia for surgery. Potential complications and risks relate to allergic reactions, globe perforation, hemorrhage, and vascular and subdural injections. Both preservative-free lidocaine (1%), which is introduced into the anterior chamber, and lidocaine jelly (2%), which is placed on the ocular surface during preoperative patient preparation, are used for cataract surgery performed under topical anesthesia. This form of anesthesia eliminates the risks of the anesthetic injection and allows for more rapid visual recovery after surgery. General anesthetics and sedation are important adjuncts for patient care for surgery and examination of the eye, especially in children and uncooperative adults. Most inhalational agents and CNS depressants are associated with a reduction in IOP. An exception is ketamine, which has been associated with an elevation in IOP. In the setting of a patient with a ruptured globe, the anesthesia should be selected carefully to avoid agents that depolarize the extraocular muscles, which may result in expulsion of intraocular contents.

### ***Other Agents for Ophthalmic Therapy***

#### **Vitamins and Trace Elements**

**General Considerations.** [Table 64–9](#) summarizes the current understanding of vitamins related to eye function and disease, especially the biochemistry of vitamin A.

#### **Table 64–9 Ophthalmic Effects of Selected Vitamin Deficiencies and Zinc Deficiency**

DEFICIENCY	EFFECTS IN ANTERIOR SEGMENT	EFFECTS IN POSTERIOR SEGMENT
<i>Vitamin</i>		
A (retinol)	Conjunctiva (Bitot's spots, xerosis) Cornea (keratomalacia, punctate keratopathy)	Retina (nyctalopia, impaired rhodopsin synthesis), retinal pigment epithelium (hypopigmentation)
B <sub>1</sub> (thiamine)		Optic nerve (temporal atrophy with corresponding visual field defects)
B <sub>6</sub> (pyridoxine)	Cornea (neovascularization)	Retina (gyrate atrophy)
B <sub>12</sub> (cyanocobalamin)		Optic nerve (temporal atrophy with corresponding visual field defects)
C (ascorbic acid)	Lens (?cataract formation)	
E (tocopherol)		Retina and retinal pigment epithelium (?macular degeneration)
Folic acid		Vein occlusion
K	Conjunctiva (hemorrhage) Anterior chamber (hyphema)	Retina (hemorrhage)
<i>Zinc</i>		Retina and retinal pigment epithelium (?macular degeneration)

See Chambers, 1994.

Although vitamin A must be supplied from the environment, most actions of vitamin A, like those of vitamin D, are exerted through hormone-like receptors. Vitamin A has diverse actions in cellular regulation and differentiation that go far beyond its classically defined function in vision. Analogs of vitamin A, because of their prominent effects on epithelial differentiation, have found important therapeutic applications in the treatment of a variety of dermatological conditions and are being evaluated in cancer chemoprevention.

**History.** The relationship of night blindness to nutritional deficiency was definitively recognized in the 1800s. Ophthalmia brasiliana (keratomalacia), a disease of the eyes that afflicted primarily poorly nourished slaves, was first described in 1865. Later, it was observed that the nurslings of mothers who fasted were prone to develop spontaneous sloughing of the cornea. Other reports of nutritional keratomalacia soon followed from all parts of the world.

Experimental rather than clinical observations, however, led to the discovery of vitamin A. In 1913, McCollum and Davis, and Osborne and Mendel independently reported that animals fed artificial diets with lard as the sole source of fat developed a nutritional deficiency that could be corrected by the addition to the diet of a factor contained in butter, egg yolk, and cod liver oil. An outstanding symptom of this experimental nutritional deficiency was xerophthalmia (dryness and thickening of the conjunctiva). Clinical and experimental vitamin A deficiencies were recognized to be related during World War I, when it became apparent that xerophthalmia in humans was a result of a decrease in the amount of butterfat in the diet.

**Chemistry and Terminology.** *Retinoid* refers to the chemical entity retinol and other closely related naturally occurring derivatives. Retinoids, which exert most of their effects by binding to specific nuclear receptors and modulating gene expression, also include structurally related synthetic analogs that need not have retinol-like (vitamin A) activity (Evans and Kaye, 1999).

The purified plant pigment carotene (provitamin A) is a remarkably potent source of vitamin A.  $\beta$ -Carotene, the most active carotenoid found in plants, has the structural formula shown in [Figure 64–7A](#). The structural formulas for the vitamin A family of retinoids are shown in [Figure 64–7B](#).

Retinol, a primary alcohol, is present in esterified form in the tissues of animals and saltwater fish, mainly in the liver.

A number of *cis-trans* isomers exist because of the unsaturated carbons in the retinol side chain. Fish liver oils contain mixtures of the stereoisomers; synthetic retinol is the all-*trans* isomer. Interconversion between isomers readily takes place in the body. In the visual cycle, the reaction between retinal (vitamin A aldehyde) and opsin to form rhodopsin occurs only with the 11-*cis* isomer. Ethers and esters derived from the alcohol also show activity *in vivo*. The ring structure of retinol ( $\beta$ -ionone), or the more unsaturated ring in 3-dehydroretinol (dehydro- $\beta$ -ionone), is essential for activity; hydrogenation destroys biological activity. Of all known derivatives, all-*trans*-retinol and its aldehyde, retinal, exhibit the greatest biological potency *in vivo*; 3-dehydroretinol has ~40% of the potency of all-*trans*-retinol.

Retinoic acid, in which the alcohol moiety has been oxidized, shares some but not all of the actions of retinol. Retinoic acid is ineffective in restoring visual or reproductive function in certain species in which retinol is effective. However, retinoic acid is very potent in promoting growth and controlling differentiation and maintenance of epithelial tissue in vitamin A-deficient animals. Indeed, all-*trans*-retinoic acid (tretinoin) appears to be the active form of vitamin A in all tissues except the retina, and is 10- to 100-fold more potent than retinol in various systems *in vitro*. Isomerization of this compound in the body yields 13-*cis*-retinoic acid (isotretinoin), which is nearly as potent as tretinoin in many of its actions on epithelial tissues but may be only one-fifth as potent in producing the toxic symptoms of

hypervitaminosis A. Retinoic acid analogs used clinically are discussed in detail in [Chapter 65](#).

**Figure 64–7** A. Structural formula for  $\beta$ -carotene. B. Structural formulas for the vitamin A family of retinoids.

**Physiological Functions and Pharmacological Actions.** Vitamin A plays an essential role in the function of the retina, is necessary for growth and differentiation of epithelial tissue, and is required for growth of bone, reproduction, and embryonic development. Together with certain carotenoids, vitamin A enhances immune function, reduces the consequences of some infectious diseases, and may protect against the development of certain malignancies. As a result, there is considerable interest in the pharmacological use of retinoids for cancer prophylaxis and for treating various premalignant conditions. Because of the effects of vitamin A on epithelial tissues, retinoids and their analogs are used to treat a number of

skin diseases, including some of the consequences of aging and prolonged exposure to the sun (see [Chapter 65](#)).

The functions of vitamin A are mediated by different forms of the molecule. In vision, the functional vitamin is retinal. Retinoic acid appears to be the active form in functions associated with growth, differentiation, and transformation.

**Retinal and the Visual Cycle.** Vitamin A deficiency interferes with vision in dim light, a condition known as *night blindness* (nyctalopia).

Photoreception is accomplished by two types of specialized retinal cells, termed *rods* and *cones*. Rods are especially sensitive to light of low intensity; cones act as receptors of high-intensity light and are responsible for color vision. The initial step is the absorption of light by a chromophore attached to the receptor protein. The chromophore of both rods and cones is 11-*cis*-retinal. The holoreceptor in rods is termed *rhodopsin*—a combination of the protein opsin and 11-*cis*-retinal attached as a prosthetic group. The three different types of cone cells (red, green, and blue) contain individual, related photoreceptor proteins and respond optimally to light of different wavelengths.

In the synthesis of rhodopsin, 11-*cis*-retinol is converted to 11-*cis*-retinal in a reversible reaction that requires pyridine nucleotides. 11-*cis*-Retinal then combines with the  $\epsilon$  amino group of a specific lysine residue in opsin to form rhodopsin. Most rhodopsin is located in the membranes of the discs situated in the outer segments of the rods. The protein has seven membrane-spanning domains, a characteristic shared by all receptors whose functions are transduced via G proteins.

**Figure 64–8. Major steps in photoreceptor signaling.** In dark-adapted rod photoreceptors (left side of diagram), cytoplasmic cyclic GMP (green circles) and  $\text{Ca}^{2+}$  concentrations are high, and some of the cyclic GMP–gated cation channels in the plasma membrane (purple tetramer) are fully liganded and in the open state. Upon absorption of a photon by rhodopsin (R, red integral disk membrane protein), isomerization of the 11-*cis* retinal chromophore occurs to activate the receptor ( $\text{R}^*$ ). This leads to binding of transducin (T, pie-shaped heterotrimer) to  $\text{R}^*$ , guanine nucleotide exchange of GDP (gray circle) for GTP (red circle), and formation of the activated transducin  $\alpha$  subunit with bound GTP ( $\text{T}\alpha^*$ ). The  $\text{T}\alpha^*$  species then binds phosphodiesterase 6 (PDE6) holoenzyme (P, blue  $\alpha\beta$  catalytic dimer with red  $\gamma$  subunits), causing de-inhibition by the  $\gamma$  subunit ( $\text{T}\alpha^*\text{-P}^*$ ) and a large acceleration of catalysis of cyclic GMP to 5'-GMP at the active site (green arrow). The light-induced drop in cyclic GMP concentration (right side of diagram) causes the liganded ion channel to close, causing membrane hyperpolarization. Ongoing extrusion of calcium by the  $\text{Na}^+\text{-Ca}^{2+}/\text{K}^+$  exchanger in the absence of  $\text{Ca}^{2+}$  influx through the channel also causes  $[\text{Ca}^{2+}]_i$  to decline, which is vital for the recovery process. DK, dark state; LT, light-activated state. (Reproduced with permission from Zhang X, Cote RH. cGMP signaling in vertebrate retinal photoreceptor cells. *Front Biosci*, 2005, 10:1191–1204.)

The visual cycle ([Figure 64–8](#)) is initiated by the absorption of a photon of light, leading to the isomerization of 11-*cis*-retinal to the all-*trans* form covalently bound to rhodopsin, a G protein–coupled receptor (GPCR). Activated rhodopsin interacts with the heterotrimeric G protein *transducin* ( $\text{G}_t$ ), initiating GDP–GTP exchange and formation of the activated  $\alpha_t$ -GTP subunit.  $\alpha_t$ -GTP binds to and activates a cyclic GMP phosphodiesterase, PDE6, resulting in a rapid drop in the local concentration of cyclic GMP. The decline in cyclic GMP permits dissociation of cyclic GMP from open cyclic GMP–gated ion channels (open in the dark), causing channel closure and hyperpolarization. This is followed by a stimulation of GC (guanylyl cyclase) activity, re-opening of the ion channel, and restoration of initial cellular  $\text{Ca}^{2+}$ . A series of reactions involving rhodopsin kinase, arrestin, recoverin, and the GTPase activity of  $\alpha_t$ -GTP also help to restore the system

to the ground state, with re-formation of the heterotrimeric form of  $G_t$ -GDP (Cote, 2007).

**Vitamin A Deficiency and Vision.** Humans deficient in vitamin A lose their ability for dark adaptation. Rod vision is affected more than cone vision. Upon depletion of retinol from liver and blood, usually at plasma concentrations of retinol of  $<0.2$  mg/L ( $0.70$   $\mu$ M), the concentrations of retinol and rhodopsin in the retina fall. Unless the deficiency is overcome, opsin, lacking the stabilizing effect of retinal, decays, and anatomical deterioration of the rod outer segment occurs. In rats maintained on a vitamin A-deficient diet, irreversible ultrastructural changes leading to blindness then supervene, a process that takes  $\sim 10$  months.

Following short-term deprivation of vitamin A, dark adaptation can be restored to normal by the addition of retinol to the diet. However, vision does not return to normal for several weeks after adequate amounts of retinol have been supplied. The reason for this delay is unknown.

***Vitamin A and Epithelial Structures.*** The functional and structural integrity of epithelial cells throughout the body is dependent on an adequate supply of vitamin A. The vitamin plays a major role in the induction and control of epithelial differentiation in mucus-secreting or keratinizing tissues. In the presence of retinol or retinoic acid, basal epithelial cells are stimulated to produce mucus. Excessive concentrations of the retinoids lead to the production of a thick layer of mucin, the inhibition of keratinization, and the display of goblet cells.

In the absence of vitamin A, goblet mucous cells disappear and are replaced by basal cells that have been stimulated to proliferate. These undermine and replace the original epithelium with a stratified, keratinizing epithelium. The suppression of normal secretions leads to irritation and infection. Reversal of these changes is achieved by the administration of retinol, retinoic acid, or other retinoids. When this process happens in the cornea, severe hyperkeratinization (xerophthalmia) may lead to permanent blindness. Common causes of vitamin A deficiency include malnutrition and bariatric surgery. Worldwide, xerophthalmia remains one of the most common causes of blindness.

***Mechanism of Action.*** In isolated fibroblasts or epithelial tissue, retinoids enhance the synthesis of some proteins (e.g., fibronectin) and reduce the

synthesis of others (e.g., collagenase, certain species of keratin), and molecular evidence suggests that these actions can be entirely accounted for by changes in nuclear transcription (Mangelsdorf et al., 1994). Retinoic acid appears to be considerably more potent than retinol in mediating these effects.

Retinoic acid influences gene expression by combining with nuclear receptors. Multiple retinoid receptors have been described. These are grouped into two families. One family, the retinoic acid receptors (RARs), designated  $\alpha$ ,  $\beta$ , and  $\gamma$ , are derived from genes localized to human chromosomes 17, 3, and 12, respectively. The second family, the retinoid X receptors (RXRs), also is composed of  $\alpha$ ,  $\beta$ , and  $\gamma$  receptor isoforms (Chambon, 1995). The retinoid receptors show extensive sequence homology to each other in both their DNA and hormone-binding domains and belong to a receptor superfamily that includes receptors for steroid and thyroid hormones and calcitriol (Mangelsdorf et al., 1994). Cellular responses to thyroid hormones, calcitriol, and retinoic acid are enhanced by the presence of RXR. Gene activation involves binding of the hormone-receptor complex to promoter elements in target genes, followed by dimerization with an RXR-ligand complex. The endogenous RXR ligand is 9-*cis*-retinoic acid (Heyman et al., 1992; Levin et al., 1992). No comparable receptor for retinol has been identified; retinol may need to be oxidized to retinoic acid to produce its effects within target cells.

Retinoids can influence the expression of receptors for certain hormones and growth factors and thus can influence the growth, differentiation, and function of target cells by both direct and indirect actions (Love and Gudas, 1994).

***Therapeutic Uses.*** Nutritional vitamin A deficiency causes *xerophthalmia*, a progressive disease characterized by *nyctalopia* (night blindness), *xerosis* (dryness), and *keratomalacia* (corneal thinning), which may lead to corneal perforation; xerophthalmia may be reversed with vitamin A therapy (WHO/UNICEF/IVAGG Task Force, 1988). However, rapid, irreversible blindness ensues once the cornea perforates. Vitamin A also is involved in epithelial differentiation and may have some role in corneal epithelial wound healing. Currently, there is no evidence to support using topical vitamin A for keratoconjunctivitis sicca in the absence of a nutritional deficiency. The current recommendation for retinitis pigmentosa is to administer 15,000 IU of

vitamin A palmitate daily under the supervision of an ophthalmologist and to avoid high-dose vitamin E.

The Age-Related Eye Disease Study (AREDS) found a reduction in the risk of progression of some types of ARMD for those randomized to receive high doses of vitamins C (500 mg), E (400 IU),  $\beta$ -carotene (15 mg), cupric oxide (2 mg), and zinc (80 mg) (Age-Related Eye Disease Study Research Group, 2001). Interestingly, zinc has been found to be neuroprotective in a rat model of glaucoma. The mechanism appears to be mediated by heat shock proteins and may represent a novel treatment strategy for glaucoma (Park et al., 2001).

## **Wetting Agents and Tear Substitutes**

**General Considerations.** The current management of dry eyes usually includes instilling artificial tears and ophthalmic lubricants. In general, tear substitutes are hypotonic or isotonic solutions composed of electrolytes, surfactants, preservatives, and some viscosity-increasing agent that prolongs the residence time in the culde-sac and precorneal tear film. Common viscosity agents include cellulose polymers (e.g., carboxymethylcellulose, hydroxyethyl cellulose, hydroxypropyl cellulose, hydroxypropyl methylcellulose [hypromellose], and methylcellulose), polyvinyl alcohol, polyethylene glycol, polysorbate, mineral oil, glycerin, and dextran. The tear substitutes are available as preservative-containing or preservative-free preparations. The viscosity of the tear substitute depends on its exact formulation and can range from watery to gel like. Some tear formulations also are combined with a vasoconstrictor, such as naphazoline, phenylephrine, or tetrahydrozoline. Tyloxapol (ENUCLENE) is marketed as an over-the-counter ophthalmic preparation used to facilitate the wearing comfort of artificial eyes.

The lubricating ointments are composed of a mixture of white petrolatum, mineral oil, liquid or alcohol lanolin, and sometimes a preservative. These highly viscous formulations cause considerable blurring of vision, and consequently, they are used primarily at bedtime, in critically ill patients, or in very severe dry eye conditions. A hydroxypropyl cellulose ophthalmic insert (LACRISERT) that is placed in the inferior culde-sac and dissolves during the day is available to treat dry eyes.

Such aqueous, ointment, and insert formulations are only fair substitutes for the precorneal tear film, which truly is a poorly understood lipid, aqueous, and mucin trilaminar barrier (see “Absorption”).

**Therapeutic Uses.** Many local eye conditions and systemic diseases may affect the precorneal tear film. Local eye disease, such as blepharitis, ocular rosacea, ocular pemphigoid, chemical burns, or corneal dystrophies, may alter the ocular surface and change the tear composition. Appropriate treatment of the symptomatic dry eye includes treating the accompanying disease and possibly the addition of tear substitutes, punctal plugs (see “Absorption”), or ophthalmic cyclosporine (see “Immunomodulatory Agent”). There also are a number of systemic conditions that may manifest themselves with symptomatic dry eyes, including Sjögren’s syndrome, rheumatoid arthritis, vitamin A deficiency, Stevens-Johnson syndrome, and trachoma. Treating the systemic disease may not eliminate the symptomatic dry eye complaints; chronic therapy with tear substitutes, ophthalmic cyclosporine, insertion of punctal plugs, placement of dissolvable collagen implants, or surgical occlusion of the lacrimal drainage system may be indicated. Ophthalmic cyclosporine (*RESTASIS*) can be used to increase tear production in patients with ocular inflammation associated with keratoconjunctivitis sicca.

## Osmotic Agents

**General Considerations.** The main osmotic drugs for ocular use include glycerin, mannitol, and hypertonic saline. With the availability of these agents, the use of urea for management of acutely elevated IOP is nearly obsolete.

**Therapeutic Uses.** Ophthalmologists occasionally use glycerin and mannitol for short-term management of acute rises in IOP. Sporadically, these agents are used intraoperatively to dehydrate the vitreous prior to anterior segment surgical procedures. Many patients with acute glaucoma do not tolerate oral medications because of nausea; therefore, intravenous administration of mannitol and/or acetazolamide may be preferred over oral administration of glycerin. These agents should be used with caution in patients with congestive heart failure or renal failure.

Corneal edema is a clinical sign of corneal endothelial dysfunction, and topical osmotic agents may effectively dehydrate the cornea. Identifying the

cause of corneal edema will guide therapy, and topical osmotic agents, such as hypertonic saline, may temporize the need for surgical intervention in the form of a corneal transplant. Sodium chloride is available in either aqueous or ointment formulations. Topical glycerin also is available; however, because it causes pain on contact with the cornea and conjunctiva, its use is limited to urgent evaluation of filtration-angle structures. In general, when corneal edema occurs secondary to acute glaucoma, the use of an oral osmotic agent to help reduce IOP is preferred over topical glycerin, which simply clears the cornea temporarily. Reducing the IOP will help clear the cornea more permanently to allow both a view of the filtration angle by gonioscopy and a clear view of the iris as required to perform laser iridotomy.

# *Chapter 65*

## **Dermatological Pharmacology**

**Craig Burkhart, Dean Morrell, and Lowell Goldsmith**

Drugs can be applied to skin for two purposes: to directly treat disorders of the skin and to deliver drugs to other tissues ([Figure 65–1](#)). The optimization of cutaneous therapies requires detailed physiological knowledge of the skin as reviewed extensively elsewhere (Wolff et al., 2008). This chapter emphasizes the basis of common skin therapies. Therapies that are used primarily for skin diseases are discussed in detail; other therapies that are applicable for skin disease are summarized and the reader referred to the appropriate portion of this book for their detailed pharmacology and toxicology.

Many skin diseases can be treated with active pharmacological agents topically; understanding the principles for percutaneous drug absorption and metabolism are essential for their effective and safe use.

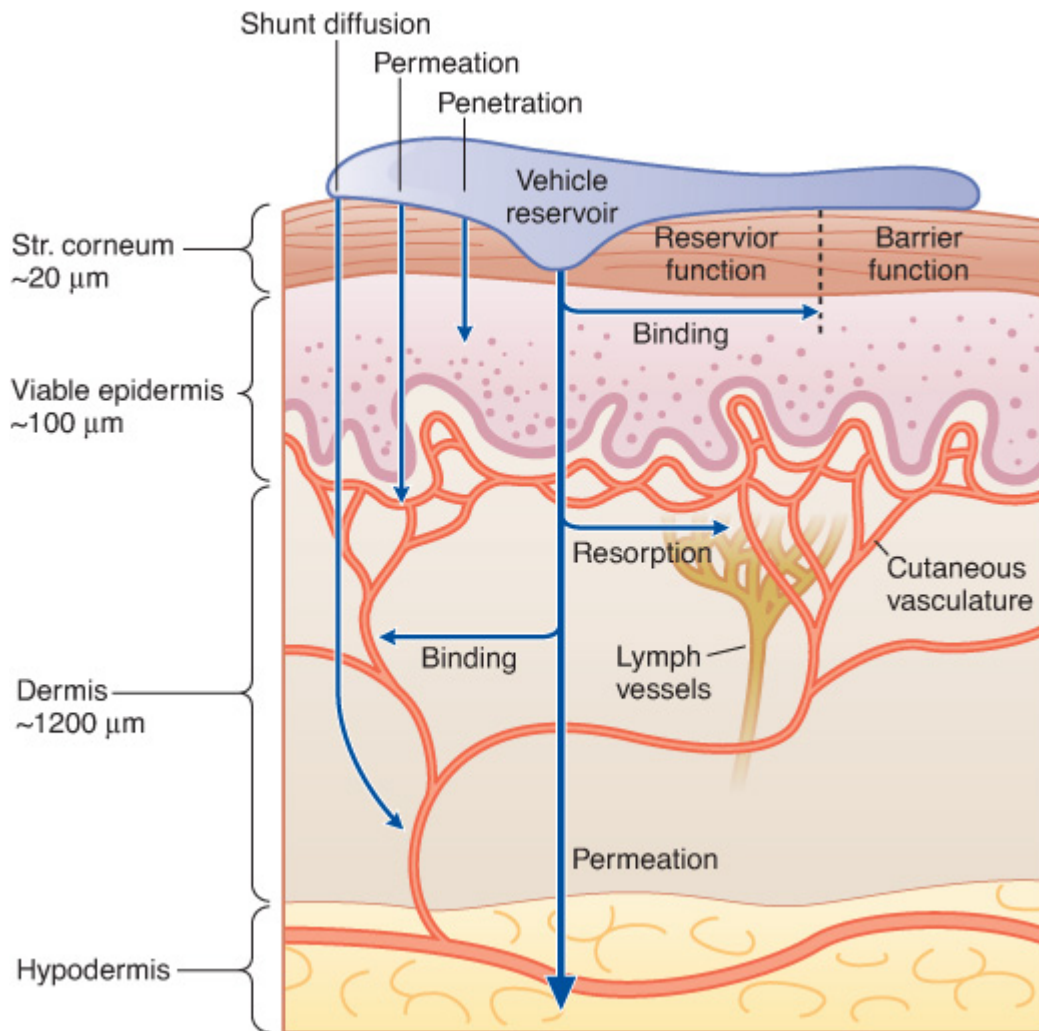

Non-pharmacological therapy for skin diseases includes the entire electromagnetic spectrum applied by many sources, such as lasers, X-rays, visible light, and infrared light. These approaches may be used alone or to enhance the penetration or alter the nature of drugs and prodrugs. Freezing and ultrasound are other physical therapies that alter epidermal structure for direct treatment or to enhance percutaneous absorption of drugs. Chemicals are used to decrease the effect of various wavelengths of ultraviolet (UV) light and ionizing radiation.

Effective and safe use of topical agents requires appreciation of the physical and physiological variables that influence the interactions of drugs and the skin, impacting absorption and transport. The skin is a multifunctional and multicompartiment organ affected in numerous ways by diseases and their treatments. [Figure 65–1](#) outlines general features of skin structure and percutaneous absorption pathways. The bulk of percutaneous absorption for most agents is through the stratum corneum, which covers almost the entire skin surface. Epidermal structure and the role of hair follicles and sweat glands as pathways for absorption are reviewed below.

***Stratum Corneum.*** The stratum corneum (outer 5-600  $\mu\text{m}$ ) is the major barrier to percutaneous absorption of drugs and to the loss of water from the body. It is made of “dead” epidermal cells that cannot reproduce and have lost their nuclei and mitochondria. It possesses multiple proteins and lipids that may reversibly or irreversibly bind drugs. Many chemicals and physical treatments to enhance percutaneous absorption work within the stratum corneum. Many drugs may partition into the stratum corneum and can function as a reservoir for drugs that will diffuse into the rest of skin even *after* topical application of the drug has ceased.

The stratum corneum differs in thickness, with the palm and sole being the thickest (400-600  $\mu\text{m}$ ) followed by the general body stratum corneum (10-16  $\mu\text{m}$ ), and the scrotum (5  $\mu\text{m}$ ). Facial and post-auricular regions have the thinnest stratum corneum. Thickness is only one variable in determining regional differences in drug penetration. Cellular arrangement has a significant role as well.

***Living Epidermis.*** The living layers of the epidermis with metabolically active cells comprise a layer  $\sim 100$   $\mu\text{m}$  thick ([Figure 65-2](#)). The lowest layer (basal layer, or stratum basale) is responsible for the bulk of cell division. Several cell layers in the spinous layer (stratum spinosum) contain cells that actively synthesize most epidermal proteins, especially keratins, a large family of intracellular fibrous molecules that form the bulk of the epidermal mass. The uppermost living layer, the granular layer (stratum granulosum), is where extracellular lipids are extruded from the epidermis, forming extracellular lipids that are an important transport pathway; where the cell envelope, resistant to most proteolysis and alkali, is formed; and where extracellular lipids are covalently bound. The granular layer is also the site of synthesis of filaggrin, an intracellular molecule that enhances keratin packing. Filaggrin is proteolyzed at the granular/stratum corneum junction, and its amino acids contribute to a high free amino acid composition of the stratum corneum, which allows water retention, an acid pH, and natural moisturizing function. Intercalated in the living epidermis are pigment-producing cells (melanocytes), dendritic antigen-presenting cells (Langerhans cells), and other immune cells ( $\gamma$ - $\delta$  T cells); in diseased epidermis, many immunological cells, including lymphocytes and polymorphonuclear leucocytes, may be present and be directly affected by applied drugs.

**Figure 65–1** *Cutaneous drug delivery*. Diagrammatic representation of the three compartments of the skin as they relate to drug delivery: surface, stratum (Str.), and viable tissues. After application of drugs to the surface, evaporation, structural, and compositional alterations, which determine the bioavailability of drugs, occur in the applied formulation. The stratum corneum limits diffusion of compounds into the viable skin and body. After absorption, compounds either bind targets in viable tissues or diffuse within the viable tissue or into the cutaneous vasculature, where they may be carried to internal cells and organs. (Reproduced with permission from Wolff et al., 2008. Figure 215-1. Copyright © The McGraw-Hill Companies, Inc. All rights reserved. Available at <http://www.accessmedicine.com>.)

***Dermis and Its Blood Vessels.*** There is a superficial capillary plexus between the epidermis and dermis that is the site of the majority of the systemic absorption of cutaneous drugs ([Figure 65–1](#)). There are large

numbers of lymphatics as well. Beneath the 1.2-mm-thick dermis with its collagen and proteoglycans that may bind drugs, there is subcutaneous tissue (hypodermis). Cells in the dermis that are targets for drugs include mast cells (permanent residents and producers of many inflammatory mediators) and infiltrating immune cells producing cytokines.

Hair follicles form a lipid-rich pathway for drug absorption. The absorption of drugs and chemicals into hair also can be used to measure prior drug exposure. Sweat glands are not known as a pathway for the absorption of drugs. Some drugs (e.g., griseofulvin, ketoconazole) are excreted to the skin by this route.

**Mechanisms of Percutaneous Absorption.** Passage through the outermost layer is the rate-limiting step for percutaneous absorption. The major steps involved in percutaneous absorption include the establishment of a concentration gradient, which provides the driving force for drug movement across the skin, partitioning and movement of the drug from a thin layer outside the stratum corneum into the stratum corneum (partition coefficient), and intrinsic molecular characteristics that allow drug diffusion across the layers of the skin (diffusion coefficient). The ideal relationship of these factors to each other is summarized in the following equation:

$$J \propto C_{\text{veh}} \cdot K_m \cdot D/X$$

where  $J$  is the rate of absorption,  $C_{\text{veh}}$  is the concentration of drug in the vehicle,  $K_m$  is the partition coefficient,  $D$  is the diffusion coefficient, and  $x$  is the thickness of stratum corneum (Piacquadio and Kligman, 1998). This equation represents the idealized situation and can only approximate what occurs in normal or diseased epidermis.

**Figure 65–2.** *Structure of the epidermis.* The epidermis matures progressively from the stratum basale (SB) to the stratum spinosum (SS), stratum granulosum (SG), and stratum corneum (SC). Important structural and metabolic proteins are produced at specific layers of the epidermis. (Reproduced with permission from Wolff et al., 2008. [Figure 45-2](#). Copyright © The McGraw-Hill Companies, Inc. All rights reserved. Available at <http://www.accessmedicine.com>.)

Preferable characteristics of topical drugs include low molecular mass (600 Da), adequate solubility in both oil and water, and a high partition coefficient (Barry, 2004) so the drug will selectively partition from the vehicle to the stratum corneum. Except for very small particles, water-soluble ions and polar molecules do not penetrate significantly through intact stratum corneum. Commercial topical pharmaceuticals are compounded for optimum diffusion and partition, and the extemporaneous addition of other ingredients may interfere with the activity or change the absorption of the primary drug.

Drugs may target enzymes or cells of any of the skin compartments, including inflammatory cells not normally in that compartment. The exact amount of drug entering or leaving the skin in clinical situations usually is not measured; rather, the clinical endpoint (e.g., reduction in inflammation) usually is the desired effect.

A hydrated stratum corneum allows more percutaneous absorption and often is achieved through the selection of drugs formulated in occlusion vehicles such as ointments and the use of plastic films, wraps, or bags for the hands and feet and shower or bathing caps for the scalp, or through the use of medications that are impregnated on patches or tapes. Occlusion may be associated with increased growth of bacteria with resultant infection (folliculitis) or maceration and breakdown of the epidermis. Transport of most drugs is a passive thermodynamic process, and heat generally increases penetration. Ultrasonic energy or laser-induced vibration also can be used to increase percutaneous absorption. The latter may function by the production of lacunae in the stratum corneum.

The epidermis contains a variety of enzyme systems capable of metabolizing drugs that reach this compartment. Many of these enzymes have genetically determined variants that may affect drug activity. Enzymes that have been studied in detail include CYPs, epoxide hydrolase, transferases such as *N*-acetyl-transferases, glucuronyl transferases, and sulfatases (Baron et al., 2001). A specific CYP isoform, CYP26A1, metabolizes retinoic acid and may control its level in the skin (Baron et al., 2001). In addition, transporter proteins that influence influx (OATP) or efflux (MDR, P-glycoprotein) of certain xenobiotics are present in human keratinocytes (Baron et al., 2001). Although substrate turnover is considerably less than that for hepatic CYPs, these enzymes influence concentrations of xenobiotics in the skin. Genetic variants of enzymes that regulate the cellular influx and efflux of methotrexate have been associated with toxicity and effectiveness in patients with psoriasis (Warren et al., 2008).

### **Pharmacologic Implications of Epidermal Structure.**

The healthcare provider must answer a number of questions when proposing topical application of drugs ([Table 65–1](#)), including consideration of proper dosage and frequency of application, extent and condition of the permeability

barrier, patient age and weight, physical form of the preparation to be applied, and whether intralesional or systemic administration should be used.

**Table 65—1 Important Considerations When a Drug Is Applied to the Skin**

What are the absorption pathways of intact and diseased skin?  
How does the chemistry of the drug affect the penetration?  
How does the vehicle affect the penetration?  
How much of the drug penetrates the skin?  
What are the intended pharmacological targets?  
What host and genetic factors influence drug function in the skin?

**Dosage.** Covering the entire skin of an adult with a topical preparation requires ~30 g of spreadable material. Underapplication of drug because of cost considerations often occurs when large amounts of skin are treated for a long time.

**Regional Anatomical Variation.** Permeability generally is inversely proportional to the thickness of the stratum corneum. Drug penetration is higher on the face, intertriginous areas, and perineum due to stratum corneum thickness. Skin sites that are naturally occluded by apposing surfaces, such as the axillae, groin, and inframammary areas, are vulnerable to drug-related atrophy from potent topical glucocorticoids.

**Altered Barrier Function in Disease.** In many dermatological diseases, the stratum corneum is abnormal and barrier function is compromised. In these settings, increased percutaneous absorption of potential topical steroids can cause systemic toxicity, such as hypothalamic–pituitary–adrenal (HPA) axis suppression.

**Vehicle.** Drug vehicles are summarized in [Table 65–2](#). Newer vehicles include liposomes and microgel formulations. Liposomes are concentric spherical shells of phospholipids in an aqueous medium intended to enhance percutaneous absorption in normal and abnormal stratum corneum. Variations in size, charge, and lipid content can influence liposome function substantially. Transfersomes are a drug-delivery technology based on highly deformable, ultraflexible lipid vesicles that penetrate the skin when applied nonocclusively (Barry, 2004). Microgels are polymers intended to enhance

solubilization of certain drugs, thereby enhancing topical penetration and diminishing irritancy.

**Age.** Children have a greater ratio of surface area to mass than adults do, so the same amount of topical drug can result in a greater systemic exposure. Based on transepidermal water loss and percutaneous absorption studies, term infants seem to possess a stratum corneum with barrier properties comparable to adults. Preterm infants have markedly impaired barrier function until the epidermis keratinizes completely.

**Application Frequency.** Topical agents often are applied twice daily. For certain drugs, once-daily application of a larger dose may be equally effective as more frequent applications of smaller doses. For some drugs, the stratum corneum may act as a drug reservoir that allows gradual penetration into the viable skin layers over a prolonged period. Intermittent pulse therapy—treatment for several days or weeks alternating with treatment-free periods—may prevent development of tachyphylaxis (loss of clinical effectiveness associated with drugs such as topical glucocorticoids). The mechanism of loss of effectiveness may be related to the corticosteroid binding and response of nuclear receptors rather than absorption.

**Intralesional Administration.** Intralesional drug administration is used mainly for inflammatory lesions but also can be used for treatment of warts and selected neoplasms. Medications injected intralesionally have the advantages of direct contact with the underlying pathological process, no first-pass metabolism, and the opportunity for a slowly absorbed depot of drug. In considering the use of intralesional glucocorticoids, it is important to be cognizant of the possibility of complete systemic absorption and suppression of the HPA.

**Systemic Administration.** Systemic administration of medication in dermatology involves several routes of administration: oral, intramuscular (e.g., methotrexate, glucocorticoids), intravenous (e.g., immunoglobulin, alefacept), or subcutaneous (e.g., efalizumab, etanercept).

## GLUCOCORTICOIDS

Glucocorticoids are prescribed frequently for their immunosuppressive and anti-inflammatory properties. They are administered locally, through topical and intralesional routes, and systemically, through intramuscular, intravenous, and oral routes. Mechanisms of glucocorticoid action are numerous, as

discussed in [Chapter 42](#). These include apoptosis of lymphocytes, inhibitory effects on the arachidonic acid cascade, depression of production of many cytokines, and myriad effects on inflammatory cells.

## Topical Glucocorticoids

Topical Glucocorticoids have been grouped into seven classes in order of decreasing potency ([Table 65–3](#)); many of the more potent drugs have a fluorinated hydrocortisone backbone. Potency traditionally is measured using a vasoconstrictor assay in which an agent is applied to skin under occlusion, and the area of skin blanching is assessed. Other assays of glucocorticoid potency involve suppression of erythema and edema after experimentally induced inflammation and the psoriasis bioassay, in which the effect of steroid on psoriatic lesions is quantified.

**Therapeutic Uses.** Many inflammatory skin diseases respond to topical or intralesional administration of glucocorticoids. Absorption varies among body areas; the steroid is selected on the basis of its potency, the site of involvement, and the severity of the skin disease. Often, a more potent steroid is used initially, followed by a less potent agent. Most practitioners become familiar with at least one glucocorticoid in each class to facilitate selection of the appropriate strength of therapy. Twice-daily application of topical glucocorticoids is sufficient, and more frequent application does not improve response (Green et al., 2005). In general, only nonfluorinated glucocorticoids should be used on the face or in occluded areas such as the axillae or groin.

### Table 65–2 Vehicles for Topically Applied Drugs

	CREAM	OINTMENT	GEL/FOAM	LOTION/SOLUTION/FOAM
<b>Physical basis</b>	Oil in water emulsion	Water in oil	Water-soluble emulsion	Solution-dissolved drug base Lotion-suspended drug Aerosol propellant with drug Foam drug with surfactant as foaming agent and propellant
<b>Solubilizing medium</b>	>31% water (up to 80%)	<25% water	Contains water-soluble polyethylene glycols	May be aqueous or alcoholic
<b>Pharmacological advantage</b>	Leaves concentrated drug at skin surface	Protective oil film on skin	Concentrates drug at surface after evaporation	
<b>Advantages for patient</b>	Spreads and removes easily No greasy feel	Spreads easily Slows water evaporation Gives a cooling effect	Nonstaining Greaseless Clear appearance	Low residue on scalp
<b>Locations on body</b>	Most locations	Avoid intertriginous areas	Foams well for scalp and other hairy locations	Solutions and foams are well accepted on scalp
<b>Disadvantages</b>	Needs preservatives	Greasy to very greasy Stains clothes	Needs preservatives High alcohol can be drying	
<b>Occlusion</b>	Low	Moderate to high Increases skin moisture		
<b>Composition issues</b>	Requires humectants (glycerine, propylene glycol, polyethylene glycols) to keep moist when applied Oil phase with long-chain alcohol for stability and smooth feel Has absorption bases—hydrophilic petrolatum	Needs surfactants to prevent phase separation Hydrocarbon (VASELINE)	Microspheres or microsponges can be formulated in gels	

Intralesional preparations of glucocorticoids include insoluble preparations of triamcinolone acetonide (KENALOG-10) and triamcinolone hexacetonide

**Table 65–3 Potency of Selected Topical Glucocorticoids**

CLASS OF DRUG <sup>a</sup>	GENERIC NAME, FORMULATION	TRADE NAME
1	Betamethasone dipropionate cream, ointment 0.05% (in optimized vehicle)	DIPROLENE
	Clobetasol propionate cream, ointment 0.05%	TEMOVATE
	Diflorasone diacetate, ointment 0.05%	PSORCON
	Halobetasol propionate, ointment 0.05%	ULTRAVATE
2	Amcinonide, ointment 0.1%	CYCLOCORT
	Betamethasone dipropionate, ointment 0.05%	DIPROSONE, others
	Desoximetasone, cream, ointment 0.25%, gel 0.05%	TOPICORT
	Diflorasone diacetate, ointment 0.05%	FLORONE, MAXIFLOR
	Fluocinonide, cream, ointment, gel 0.05%	LIDEX, LIDEX-E, FLUONEX
	Halcinonide, cream, ointment 0.1%	HALOG, HALOG-E
3	Betamethasone dipropionate, cream 0.05%	DIPROSONE, others
	Betamethasone valerate, ointment 0.1%	BETATREX, others
	Diflorasone diacetate, cream 0.05%	FLORONE, MAXIFLOR
	Triamcinolone acetonide, ointment 0.1%, cream 0.5%	ARISTOCORT A, others
4	Amcinonide, cream 0.1%	CYCLOCORT
	Desoximetasone, cream 0.05%	TOPICORT LP
	Fluocinolone acetonide, cream 0.2%	SYNALAR-HP
	Fluocinolone acetonide, ointment 0.025%	SYNALAR
	Flurandrenolide, ointment 0.05%, tape 4 µg/cm <sup>2</sup>	CORDRAN
	Hydrocortisone valerate, ointment 0.2%	WESTCORT
	Triamcinolone acetonide, ointment 0.1%	KENALOG, ARISTOCORT
	Mometasone furoate, cream, ointment 0.1%	ELOCON
5	Betamethasone dipropionate, lotion 0.05%	DIPROSONE, others
	Betamethasone valerate, cream, lotion 0.1%	BETATREX, others
	Fluocinolone acetonide, cream 0.025%	SYNALAR
	Flurandrenolide, cream 0.05%	CORDRAN SP
	Hydrocortisone butyrate, cream 0.1%	LOCOID
	Hydrocortisone valerate, cream 0.2%	WESTCORT
	Triamcinolone acetonide, cream, lotion 0.1%	KENALOG
	Triamcinolone acetonide, cream 0.025%	ARISTOCORT
6	Alclometasone dipropionate, cream, ointment 0.05%	ACLOVATE
	Desonide, cream 0.05%	TRIDESILON, DESOWEN
	Fluocinolone acetonide, cream, solution 0.01%	SYNALAR
7	Dexamethasone sodium phosphate, cream 0.1%	DECADRON
	Hydrocortisone, cream, ointment, lotion 0.5%, 1.0%, 2.5%	HYTONE, NUTRICORT, PENEKORT

<sup>a</sup>Class 1 is most potent; class 7 is least potent.

(ARISTOSPAN), which solubilize gradually and therefore have a prolonged duration of action.

**Toxicity.** Chronic use of class 1 topical glucocorticoids can cause skin atrophy, striae, telangiectasias, purpura, and acneiform eruptions. Because perioral dermatitis and rosacea can develop after the use of fluorinated compounds on the face, they should not be used on this site. Occlusion increases the risk of HPA suppression.

## Systemic Glucocorticoid

**Therapeutic Uses.** Systemic glucocorticoid therapy is used for severe dermatological illnesses. In general, it is best to reserve this method for allergic contact dermatitis to plants (e.g., poison ivy) and for life-threatening

vesiculobullous dermatoses such as pemphigus vulgaris and bullous pemphigoid. Chronic administration of oral glucocorticoids is problematic, given the side effects associated with their long-term use (see [Chapter 42](#)).

Daily morning dosing with prednisone generally is preferred, although divided doses occasionally are used to enhance efficacy. Fewer side effects are seen with alternate-day dosing, and if chronic therapy is required, prednisone usually is tapered to every other day as soon as it is practical. Pulse therapy using large intravenous doses of methylprednisolone sodium succinate (*SOLU-MEDROL*, others) is an option for severe resistant pyoderma gangrenosum, pemphigus vulgaris, systemic lupus erythematosus with multi-system disease, and dermatomyositis. The dose usually is 0.5-1 g given over 2-3 hours. More rapid infusion has been associated with increased rates of hypotension, electrolyte shifts, and cardiac arrhythmias.

***Toxicity and Monitoring.*** Oral glucocorticoids have numerous systemic effects, as discussed in [Chapter 42](#). Most side effects are dose dependent. Long-term use is associated with a number of complications, including psychiatric problems, cataracts, myopathy, osteoporosis, avascular bone necrosis, glucose intolerance or overt diabetes mellitus, and hypertension. In addition, psoriatic patients treated with parenteral or topical glucocorticoids may have a pustular flare, particularly if the steroid is tapered rapidly.

## RETINOIDS

*Retinoids* are defined as natural and synthetic compounds that exhibit vitamin A-like biological activity or bind to nuclear receptors for retinoids. Retinoids have many important functions throughout the body, including roles in vision, regulation of cell proliferation and differentiation and bone growth, immune defense, and tumor suppression (Vahlquist et al., 2008). Early use of systemic retinoids to treat acne and disorders of keratinization was limited by the toxic side effects of first-generation retinoids. This was largely solved through molecular modifications that yielded new generations of compounds with vastly improved margins of safety. First-generation retinoids include retinol (vitamin A), tretinoin (all-*trans*-retinoic acid; vitamin A acid), isotretinoin (13-*cis*-retinoic acid), and alitretinoin (9-*cis*-retinoic acid). Second-generation retinoids, also known as aromatic retinoids, were created by aromatization of the cyclic end group and include acitretin and methoxsalen (also known as etretinate; not marketed in the U.S.). Third-

generation retinoids were created after the discovery of specific retinoid receptors and have diverse structures designed to optimize receptor-selective binding. Members of this generation include tazarotene, bexarotene, and adapalene. Characteristics of topical and systemic retinoids are summarized in [Tables 65–4](#) and [65–5](#).

Retinoids exert their effects on gene expression by activating two families of receptors—*retinoic acid receptors* (RARs) and *retinoid X receptors* (RXRs)—that are members of the steroid receptor superfamily (Winterfield et al., 2003). Both retinoid receptor families have three isoforms ( $\alpha$ ,  $\beta$ , and  $\gamma$ ), which are expressed in unique combinations in individual tissues and cells. The human epidermis, for example, expresses RAR- $\alpha$ , RAR- $\gamma$ , RXR- $\alpha$ , and RXR- $\beta$  (Kang and Voorhees, 2008). Upon binding to a retinoid, RARs and RXRs form heterodimers (RAR-RXR), which subsequently bind specific DNA sequences called retinoic acid–responsive elements (RAREs) that activate transcription of genes whose products produce the desirable pharmacological effects of these drugs and their unwanted side effects (Bastien and Rochette-Egly, 2004).

Unique therapeutic effects can be produced by targeting specific retinoid receptors. For example, retinoids that target RARs predominantly affect cellular differentiation and proliferation, whereas retinoids that target RXRs predominantly induce apoptosis (Germain et al., 2006a; Germain et al., 2006b). Hence, tretinoin, adapalene, and tazarotene, which target RARs, are used in acne, psoriasis, and photoaging (disorders of differentiation and proliferation), whereas bexarotene and alitretinoin, which target RXRs, are used in mycosis fungoides and Kaposi sarcoma (to induce apoptosis of malignant cells). Acute retinoid toxicity is similar to vitamin A intoxication. Side effects of systemic retinoids include dry skin, nosebleeds from dry mucous membranes, conjunctivitis, reduced night vision, hair loss, alterations in serum lipids and transaminases, hypothyroidism, inflammatory bowel disease flare, musculoskeletal pain, pseudotumor cerebri, and mood alterations. RAR-selective retinoids are more associated with mucocutaneous and musculoskeletal symptoms, whereas RXR-selective retinoids induce more physiochemical changes (Germain et al., 2006a; Germain et al., 2006b). Because all oral retinoids are potent teratogens, they should be used carefully in females of childbearing potential and not in pregnant patients or patients who are trying to conceive. Suicide or suicide attempts have been associated with the use of isotretinoin. Thus, all patients

treated with isotretinoin should be observed closely for symptoms of depression or suicidal thoughts.

## **Topical Retinoids**

Acne is believed to result from a combination of sebaceous gland hyperplasia, follicular hyperkeratosis, *Propionibacterium acnes* colonization, and inflammation. Through incompletely understood mechanisms, topical retinoids correct abnormal follicular keratinization, reduce *P. acnes* counts, and reduce inflammation, thereby making them the cornerstone of acne therapy. Topical retinoids are first-line agents for non-inflammatory (comedonal) acne and often are combined with other agents in the management of inflammatory acne.

Fine wrinkles and dyspigmentation, two important features of photoaging, also are improved with topical retinoids. Within the dermis, this is believed to result from inhibition of activator protein-1 (AP-1), a transcription factor composed of c-Jun and c-Fos that normally activates synthesis of matrix metalloproteinases in response to UV irradiation (Kang and Voorhees, 2008). In the epidermis, retinoids induce epidermal hyperplasia in atrophic skin and reduce keratinocyte atypia (Sami and Harper, 2007).

### **Table 65–4 Topical Retinoids**

DRUG	FORMULATION	RECEPTOR SPECIFICITY	PREGNANCY CATEGORY	STRUCTURE	IRRITANCY
Tretinoin	0.02%, 0.025%, 0.05%, 0.1% cream 0.01%, 0.025%, 0.04% gel 0.05%, 0.1% solution	RAR- $\alpha$ , RAR- $\beta$ , RAR- $\gamma$	C		++
Tazarotene	0.05%, 0.1% cream 0.05%, 0.01% gel	RAR- $\alpha$ , RAR- $\beta$ , RAR- $\gamma$	X		++++
Adapalene	0.1%, 0.3% cream 0.1%, 0.3% gel 0.1% solution	RAR- $\beta$ , RAR- $\gamma$	C		+
Alitretinoin	0.1% gel	RAR- $\alpha$ , RAR- $\beta$ , RAR- $\gamma$	D		++
Bexarotene	1% gel	RXR- $\alpha$ , RXR- $\beta$ , RXR- $\gamma$	X		+++

**Toxicity and Monitoring.** Adverse effects of all topical retinoids include erythema, desquamation, burning, and stinging ([Table 65–4](#)). These effects often decrease with time and are lessened by concomitant use of emollients. Patients also may experience photosensitivity reactions because of enhanced reactivity to UV radiation and have a significant risk for severe sunburn. Although there is little systemic absorption of topical retinoids and no alteration in plasma vitamin A levels with their use, it is recommended that exposure to topical retinoids be avoided during pregnancy.

## Tretinoin

Topical tretinoin (all-*trans*-retinoic acid) is photolabile and thus should be applied once nightly for acne and photoaging. Benzoyl peroxide also inactivates tretinoin and should not be applied simultaneously. Formulations with copolymer microspheres (*RETIN-A MICRO*) or prepolyolprepolymer-2 (*AVITA*) that gradually release tretinoin to decrease irritancy are available.

## Adapalene

Adapalene (differin) has similar efficacy to tretinoin, but unlike tretinoin, it is stable in sunlight, stable in the presence of benzoyl peroxide, and tends to be less irritating at the 0.1% concentration.

## **Tazarotene**

Tazarotene (TAZORAC, AVAGE) is a third-generation retinoid approved for the treatment of psoriasis, photoaging, and acne vulgaris (Sami and Harper, 2007). Tazarotene gel, applied once daily, may be used as monotherapy or in combination with other medications, such as topical corticosteroids, for the treatment of localized plaque psoriasis. Topical corticosteroids improve the efficacy of therapy and reduce the side effects of burning, itching, and skin irritation that are commonly associated with tazarotene.

## **Alitretinoin**

Alitretinoin (PANRETIN) is a retinoid that binds all types of retinoid receptors and is applied two to four times daily to cutaneous lesions of Kaposi sarcoma. Alitretinoin should not be applied concurrently with insect repellants containing diethyltoluamide (DEET, N,N-diethyl-m-toluamide) because it may increase DEET absorption.

## **Bexarotene**

Topical bexarotene (TARGRETIN) is approved for early-stage (IA and IB) cutaneous T-cell lymphoma. Its application is titrated up from every other day to two to four times daily over several weeks to improve patient tolerance. Its mechanism of action may involve downregulation of survivin and upregulation of caspase-3, leading to apoptosis of malignant cells (Sami and Harper, 2007). Patients using bexarotene should avoid products containing DEET due to an increased risk for DEET toxicity.

## **Systemic Retinoids**

Systemic retinoids are approved for the treatment of acne, psoriasis, and cutaneous T-cell lymphoma ([Table 65–5](#)). Off-label uses include ichthyosis, Darier's disease, pityriasis rubra pilaris, rosacea, hidradenitis suppurativa, chemoprevention of malignancy, lichen sclerosus, subacute lupus erythematosus, and discoid lupus erythematosus. All systemic retinoids are contraindicated in women who are pregnant, contemplating pregnancy, or breast-feeding. Relative contraindications include leukopenia, alcoholism, hyperlipidemia, hypercholesterolemia, hypothyroidism, and significant hepatic or renal disease.

**Toxicity and Monitoring.** Acute retinoid toxicities may include mucocutaneous or laboratory abnormalities; bony changes may occur after chronic use at high doses. Mucocutaneous side effects may include cheilitis, xerosis, blepharoconjunctivitis, cutaneous photosensitivity, photophobia, myalgia, arthralgia, headaches, alopecia, nail fragility, and increased susceptibility to staphylococcal infections. Some patients develop a “retinoid dermatitis” characterized by erythema, pruritus, and scaling.

**Table 65–5 Systemic Retinoids**

DRUG	STRUCTURE	RECEPTOR SPECIFICITY	STANDARD DOSING RANGE	t <sub>1/2</sub>
Isotretinoin		No clear receptor affinity	0.5-2 mg/kg/day	10-20 hours
Etretinate		RAR-α, RAR-β, RAR-γ	0.25-1 mg/kg/day	80-160 days
Acitretin		RAR-α, RAR-β, RAR-γ	0.5-1 mg/kg/day	50 hours
Bexarotene		RXR-α, RXR-β, RXR-γ	300 mg/m <sup>2</sup> /day	7-9 hours

Very rarely, patients may develop pseudotumor cerebri, especially when systemic retinoids are combined with tetracyclines (tetracycline or minocycline; the mechanism for this adverse drug event is unknown). There are reports that chronic administration at higher doses can cause diffuse idiopathic skeletal hyperostosis (DISH) syndrome, premature epiphyseal closure, and other skeletal abnormalities (Vahlquist et al., 2008).

Systemic retinoids are highly teratogenic. There is no safe dose during pregnancy. Common malformations include craniofacial, cardiovascular, thymic, and central nervous system (CNS) abnormalities. Although there appears to be minimal, if any, risk of retinoid embryopathy in fetuses conceived by males taking systemic retinoids, it is commonly recommended that men avoid retinoid therapy when actively trying to father children.

Prescribing of isotretinoin in the U.S. is restricted via the risk-mitigation iPLEDGE system (Goldsmith et al., 2004).

Serum lipid elevation is the most common laboratory abnormality. This may be due to increased expression of apolipoprotein C-III by systemic retinoids, which prevents the uptake of lipids from very-low-density lipoproteins into cells (Vahlquist et al., 2008). Other, less common, laboratory abnormalities include elevated transaminases, decreased thyroid hormone, and leukopenia. A baseline evaluation of serum lipids, serum transaminases, and complete blood count (CBC) and a pregnancy test should be obtained prior to starting any systemic retinoids. Laboratory values should be checked monthly for the first 3-6 months and once every 3 months thereafter.

## **Isotretinoin**

Isotretinoin (ACCUTANE, others) is approved for the treatment of recalcitrant and nodular acne vulgaris. The drug has remarkable efficacy in severe acne and may induce prolonged remissions after a single course of therapy. It normalizes keratinization in the sebaceous follicle, reduces sebocyte number with decreased sebum synthesis, and reduces *P. acnes* (Vahlquist et al., 2008). Clinical effects generally are noted within 1-3 months of starting therapy.

Approximately one-third of patients will relapse, usually within 3 years of stopping therapy (Vahlquist et al., 2008). Preteens, males, and patients with acne conglobata or androgen excess are at increased risk of relapse. Although most relapses are mild and respond to conventional management with topical and systemic anti-acne agents, some may require a second course of isotretinoin.

There are several reports of patients developing signs of depression while on isotretinoin. However, large studies have failed to prove an association between isotretinoin use and depression. Since it is possible that an idiosyncratic reaction occurs in a small group of otherwise healthy individuals, current guidelines recommend monthly monitoring of all patients on isotretinoin for signs of depression.

## **Acitretin**

Acitretin (SORIATANE, SORIATANE CK) is approved for use in the cutaneous manifestations of psoriasis. It is especially useful in pustular psoriasis, although all forms of cutaneous psoriasis are responsive to acitretin. Clinical effect typically begins within 4-6 weeks, with the full clinical benefit occurring at 3-4 months.

Although acitretin has a  $t_{1/2}$  of ~50 hours, when combined with alcohol, acitretin is esterified *in vivo* to produce etretinate, which has a  $t_{1/2}$  of >3 months (Vahlquist et al., 2008). It is not known how much alcohol (i.e., cough syrup or other alcohol-based medications) is required to induce this conversion. Therefore, female patients of childbearing age should avoid pregnancy for 3 years after receiving acitretin to avoid retinoid-induced embryopathy.

## **Bexarotene**

Bexarotene (TARGRETIN) is a retinoid that selectively binds RXRs. Oral and topical formulations of bexarotene are approved for use in patients with cutaneous T-cell lymphoma. Although the exact mechanism of action is unknown, studies suggest that bexarotene induces apoptosis of malignant cells (Budgin et al., 2005). Because it is metabolized by CYP3A4, inhibitors of CYP3A4 (e.g., imidazole antifungals, macrolide antibiotics) will increase and inducers of CYP3A4 (e.g., rifamycins, carbamazepine, dexamethasone, efavirenz, phenobarbital) will decrease plasma levels of bexarotene. Laboratory side effects are more common than with other retinoids, with an increased incidence of significant lipid abnormalities and hypothyroidism secondary to a reversible RXR-mediated suppression of *TSH* gene expression (Sherman, 2003), pancreatitis, leukopenia, and gastrointestinal (GI) symptoms. Unlike other retinoids, thyroid function should be measured before initiating therapy and periodically thereafter. Mucocutaneous side effects are less than with other systemic retinoids.

## **VITAMIN ANALOGS**

**$\beta$ -Carotene.**  *$\beta$ -Carotene* is a precursor of vitamin A that is present in green and yellow vegetables. Solatene has been discontinued, and no  $\beta$ -carotene products are currently approved by the U.S. Food and Drug Administration (FDA).

Dietary supplementation with  $\beta$ -carotene is used in dermatology to reduce skin photosensitivity in patients with erythropoietic protoporphyria. The mechanism of action is not established but may involve an antioxidant effect that decreases the production of free radicals or singlet oxygen (Alemzede, 2004). However, a recent meta-analysis concluded that  $\beta$ -carotene, vitamin A, and vitamin E given singly or combined with other antioxidant supplements actually increase mortality (Bjelakovic et al., 2007). FDA's Maximum Recommended Therapeutic Dose (MRTD) database (<http://www.fda.gov/AboutFDA/CentersOffices/CDER/ucm092199.htm>) lists 0.05 mg/kg/day as the MRTD for  $\beta$ -carotene.

**Calcipotriene.** Calcipotriene (DOVONEX, others) is a topical vitamin D analog that is used in the treatment of psoriasis.

Although calcipotriene is not a retinoid, it exerts its effects through modulation of similar proteins and pathways as the retinoids, leading to similar effects. Calcipotriene exerts its effects through the vitamin D receptor (VDR), a member of the thyroid hormone, corticosteroid, and retinoic acid nuclear receptor gene family (see [Chapter 44](#)). Upon binding the VDR, the drug-receptor complex associates with the RXR- $\alpha$  and binds to vitamin D response elements on DNA. Genes that modulate epidermal differentiation and inflammation are subsequently expressed, leading to improvement in psoriatic plaques (Bikle et al., 2001).

Calcipotriene is applied twice daily to plaque psoriasis on the body, often in combination with topical corticosteroids. Hypercalcemia and hypercalciuria may develop when the cumulative weekly dose exceeds the recommended 100g/wk limit and resolves within days of discontinuation of

calcipotriene (Bleiker et al., 1998). Calcipotriene also causes perilesional irritation and mild photosensitivity. Irritancy is reduced by concomitant administration of topical corticosteroids.

## PHOTOCHEMOTHERAPY

Electromagnetic radiation is defined by its wavelength and frequency. Based on its biological activity, dermatologists subdivide the UV region into UVB (290-320 nm), UVA2 (320-340 nm), UVA1 (340-400 nm), and UVC (100-290 nm) radiation. UVC radiation is almost completely absorbed by stratospheric ozone, does not reach Earth's surface, and is not used therapeutically. UVB is the most erythrogenic and melanogenic type of radiation. It is the major action spectrum for sunburn, tanning, skin cancer, and photoaging. UVA radiation is a thousand times less erythrogenic than UVB but penetrates more deeply into the skin and contributes substantially to photoaging and photosensitivity diseases. Visible radiation (400-800 nm) reaches the retina and produces the sensation of vision.

Phototherapy and photochemotherapy are treatment methods in which UV or visible radiation is used to induce a therapeutic response either alone or in the presence of a photosensitizing drug. To be effective, the incident radiation must be absorbed by a target or chromophore in the skin—which in phototherapy is endogenous and in photochemotherapy must be administered exogenously ([Table 65–6](#)). Patients treated with these modalities should be monitored for concomitant use of other potential photosensitizing medications before initiation of therapy. Such drugs include phenothiazines, thiazides, sulfonamides, nonsteroidal anti-inflammatory agents, sulfonyleureas, tetracyclines, and benzodiazepines.

**PUVA: Psoralens and Uva** Photochemotherapy with psoralen-containing plant extracts was employed for the treatment of vitiligo in Egypt and India as early as 1500 B.C. Orally administered 8-methoxypsoralen followed by UVA (PUVA) is FDA approved for the treatment of vitiligo and psoriasis.

**Chemistry.** Psoralens are lipophilic molecules belonging to the furocoumarin class of compounds, which are derived from the fusion of a furan with a coumarin. One psoralen, methoxsalen (8-methoxypsoralen, *OXSORALEN ULTRA*, *8-mop*, others) is available in the U.S. The structures of two common psoralens are:

**Pharmacokinetics.** Dissolved psoralens (e.g., OXSORALEN ULTRA) are absorbed rapidly after oral administration, whereas crystallized forms (e.g., 8-MOP) are absorbed slowly and incompletely. Fatty foods also reduce absorption. Furthermore, there is a significant, but saturable, first-pass elimination in the liver. For these reasons, peak photosensitivity varies significantly between individuals but typically is maximal 1-2 hours after ingestion. Methoxsalen has a serum  $t_{1/2}$  of ~1 hour, but the skin remains sensitive to light for 8-12 hours.

**Mechanism of Action.** The action spectrum for oral PUVA is between 320 and 340 nm. Two distinct photoreactions take place. Type I reactions involve the oxygen-independent photoaddition of psoralens to pyrimidine bases in DNA. Type II reactions are oxygen dependent and involve the transfer of energy to molecular oxygen, creating reactive oxygen species. Through incompletely understood mechanisms, these phototoxic reactions stimulate melanocytes and induce anti-proliferative, immunosuppressive, and anti-inflammatory effects (Stern, 2007).

**Therapeutic Uses.** Methoxsalen is supplied in soft gelatin capsules (OXSORALEN-ULTRA) and hard gelatin capsules (8-mop) for oral use. The dose is 10-70 mg, depending on weight (0.4-0.6 mg/kg), taken 1.5-2 hours or 2 hours before UVA exposure for OXSORALEN-ULTRA and 8-mop, respectively. A lotion containing 1% methoxsalen (OXSORALEN) is available for topical application for vitiligo and can be diluted for use in bath water to minimize systemic absorption. An extracorporeal solution (UVADEX) is available for cutaneous T-cell lymphoma (see "Photopheresis").

## TABLE 65–6 PHOTOCHEMOTHERAPY METHODS

	PUVA	PHOTODYNAMIC THERAPY	PHOTOPHERESIS
<b>Target</b>	Broad cutaneous area	Focal cutaneous sites	Peripheral blood leukocytes
<b>Photosensitizing agent</b>	Methoxsalen (8-methoxypsoralen) Trioxsalen (4,5',8-trimethylpsoralen) Bergapten (5-methoxypsoralen)	Protoporphyrin IX	Methoxsalen
<b>Method of drug administration</b>	Oral Topical lotion Bath water	Topical cream or solution of a prodrug (aminolevulinic acid or methylaminolevulinate)	To isolated plasma within photopheresis device
<b>FDA-approved indications</b>	Psoriasis Vitiligo	Actinic keratosis	Cutaneous T-cell lymphoma
<b>Activating wavelength</b>	UVA2 (320-340 nm)	417 nm and 630 nm	UVA2 (320-340 nm)
<b>Adverse effects (acute)</b>	Phototoxic reactions Pruritus Hypertrichosis GI disturbance CNS disturbance Bronchoconstriction Hepatic toxicity Herpes simplex recurrence Retinal damage	Phototoxic reactions Temporary dyspigmentation	Phototoxic reactions GI disturbance Hypotension Congestive heart failure
<b>Adverse effects (chronic)</b>	Photoaging Nonmelanoma skin cancer Melanoma <sup>a</sup> Cataracts <sup>a</sup>	Potential scarring	Loss of venous access after repeated venipuncture
<b>Pregnancy category</b>	C <sup>b</sup>	C <sup>b</sup>	FDA unrated

<sup>a</sup>Controversial. CNS, central nervous system; GI, gastrointestinal; UVA, ultraviolet A. <sup>b</sup>See Table 66-5 for pregnancy category.

Approximately 90% of psoriatic patients have clearing or virtual clearing of skin disease within 30 treatments with methoxsalen (Morison, 2007). Remission typically lasts 3-6 months; thus, patients often require maintenance therapy with intermittent PUVA or other agents (Stern, 2007). Vitiligo typically requires between 150 and 300 treatments to produce satisfactory repigmentation. Localized vitiligo can be treated with topical PUVA and more extensive disease with systemic administration. PUVA also is employed off label in the treatment of atopic dermatitis, alopecia areata, lichen planus, and urticaria pigmentosa and as a preventive modality in some forms of photosensitivity.

**Toxicity and Monitoring.** The major side effects of PUVA are listed in [Table 65-6](#). Phototoxicity is characterized by erythema, edema, blistering, and pruritus. Ocular toxicity can be prevented by wearing UVA-blocking glasses the day of treatment. The risk of nonmelanoma skin cancer is dose dependent, with the greatest risk in those receiving >250 treatments. A possible association of melanoma and extensive exposure to PUVA has been reported; however, several other studies have failed to confirm this association (Morison, 2007). As skin cancer may not develop for decades

after exposure, annual skin exams should be continued for years after completion of PUVA.

**Photopheresis.** Extracorporeal photopheresis (ECP) is a process in which extracorporeal peripheral blood mononuclear cells are exposed to UVA radiation in the presence of methoxsalen. Although previously given orally (Edelson et al., 1987), methoxsalen (*UVADEX*) now is injected directly into the extracorporeal plasma before radiation and reinfusion. The treated lymphocytes are returned to the patient undergoing apoptosis over 48-72 hours (McKenna et al., 2006).

ECP is used for cutaneous T-cell lymphoma and off label for various other T-cell mediated diseases, including graft-versus-host disease, transplantation rejection, scleroderma, and type I diabetes mellitus (McKenna et al., 2006). The mechanism of action of ECP include apoptosis of T cells, generation of clone-specific suppressor T cells, shifting of the T-cell phenotype, production of an immune response against the pathogenic T cells, and release of cytokines (McKenna et al., 2006).

Initially, patients receive therapy every 1-4 weeks, and intervals are increased as the patient improves. In patients who do not respond to monotherapy or those with significant tumor burden, ECP can be combined with adjunctive therapies, including PUVA, topical chemotherapy, systemic chemotherapy, radiation, biological agents, and retinoids.

**Photodynamic Therapy (PDT).** This modality combines the use of photosensitizing drugs and visible light for the treatment of various dermatological disorders. In dermatology, two drugs are approved for topical PDT: aminolevulinic acid (ALA; LEVULAN KERASTICK) and methylaminolevulinate (MAL; METVIXIA). Both are prodrugs that are converted into protoporphyrin IX within living cells ([Figure 65-3](#)). In the presence of specific wavelengths of light ([Table 65-6](#)) and oxygen, protoporphyrin produces singlet oxygen (type 2 photochemical reaction), which oxidizes cell membranes, proteins, and mitochondrial structures, leading to apoptosis. Sebaceous glands, the epidermis, and neoplastic cells accumulate more porphyrin than other cutaneous cells and structures; thus, PDT is approved for use on precancerous actinic keratoses and also is commonly used on thin, nonmelanoma skin cancers; acne; and photorejuvenation (improving the appearance of photodamaged skin) (Kalka et al., 2000; Lopez et al., 2004).

Incoherent (nonlaser) and laser light sources have been used for PDT. The wavelengths chosen must include those within the action spectrum of protoporphyrin ([Table 65–6](#)) and ideally those that permit maximum skin penetration. Light sources in use emit energy predominantly in the blue portion (maximum porphyrin absorption) or the red portion (better tissue penetration) of the visible spectrum. Because the  $t_{1/2}$  of the accumulated porphyrins is ~30 hours, patients should protect their skin from sunlight and intense light for at least 48 hours after treatment to prevent phototoxic reactions.

## ANTIHISTAMINES

*Histamine* (see [Chapter 32](#)) is a potent vasodilator, bronchial smooth muscle constrictor, and stimulant of nociceptive itch receptors (Repka-Ramirez and Baraniuk, 2002). In addition to histamine, multiple chemical itch mediators can act as pruritogens on C fibers, including *neuropeptides*, *prostaglandins*, *serotonin*, *acetylcholine*, and *bradykinin* (Stander et al., 2003). Furthermore, receptor systems, such as vanilloid, opioid, and cannabinoid receptors, on cutaneous sensory nerve fibers that may modulate itch and offer novel future targets for anti-pruritic therapy have been identified.

**Figure 65–3.** *Heme biosynthesis pathway.* **A.** Under physiological conditions, heme inhibits the enzyme  $\delta$  aminolevulinic acid ( $\delta$ ALA) synthetase by negative feedback. However,  $\delta$  when ALA is provided exogenously, this control point is bypassed, leading to excessive accumulation of heme. **B.** Heme.

Histamine is in mast cells, basophils, and platelets. Human skin mast cells express  $H_1$ ,  $H_2$ , and  $H_4$  receptors but not  $H_3$  receptors (Lippert et al., 2004).  $H_1$  and  $H_2$  receptors are involved in wheal formation and erythema, whereas only  $H_1$  receptor agonists cause pruritus (see [Chapter 32](#)). Complete blockade of  $H_1$  receptors does not totally relieve itching, and combination

therapy with H<sub>1</sub> and H<sub>2</sub> blockers may be superior to the use of H<sub>1</sub> blockers alone ([Table 65–7](#)).

Oral antihistamines, particularly H<sub>1</sub> receptor antagonists, have anticholinergic activity and are sedating (see [Chapter 32](#)), making them useful for the control of pruritus. First-generation sedating H<sub>1</sub> receptor antagonists include hydroxyzine, diphenhydramine (BENADRYL, others), promethazine, and cyproheptadine. Doxepin, which has tricyclic antidepressant and sedative and antihistaminic effects (see [Chapter 15](#)), is a good alternative to traditional oral antihistamines for severe pruritus. A 5% topical cream formulation of doxepin (PRUDOXIN, ZONALON), which can be used in conjunction with low- to moderate-potency topical glucocorticoids, also is available. Allergic contact dermatitis to doxepin has been reported. The anti-pruritic effect from topical doxepin is comparable to that of low-dose oral doxepin therapy.

**Table 65–7 Half-Life of Antihistamines**

FIRST-GENERATION H <sub>1</sub> BLOCKERS	t <sub>1/2</sub> IN ADULTS (hours)
Hydroxyzine	7-10
Diphenhydramine	2-8
Promethazine	16-19
Cyproheptadine	1-4
Doxepin	17
SECOND-GENERATION H <sub>1</sub> BLOCKERS	
Cetirizine	8.3
Levocetirizine	8-9
Loratadine	8
Desloratadine	27
Fexofenadine	14.4
H <sub>2</sub> BLOCKERS	
Cimetidine	2
Ranitidine	2-3
Famotidine	2.5-4
Nizatidine	1-2
Doxepin	17

Second-generation H<sub>1</sub> receptor antagonists lack anticholinergic side effects and are described as nonsedating largely because they do not cross the blood-brain barrier. They include cetirizine (ZYRTEC, others), levocetirizine dichloride (XYZAL), loratadine (CLARITIN, others), desloratadine (CLARINEX), and fexofenadine hydrochloride (ALLEGRA, others). While second-generation "nonsedating" H<sub>1</sub> receptor blockers are as effective as the first-generation H<sub>1</sub> blockers, they are metabolized by CYP3A4 and, to a lesser extent, by CYP2D6 and should not be co-administered with medications that inhibit these enzymes (e.g., imidazole antifungals, macrolide antibiotics).

## ANTIMICROBIAL AGENTS

### Antibiotics

These drugs commonly are used to treat superficial cutaneous infections ([Table 65–8](#)) (pyoderma) and non-infectious diseases, including acne rosacea, perioral dermatitis, hidradenitis suppurativa, auto-immune blistering diseases, sarcoidosis, and pyoderma gangrenosum (Carter, 2003). Topical agents are very effective for the treatment of superficial bacterial infections and acne vulgaris. Systemic antibiotics also are prescribed commonly for acne and deeper bacterial infections. The pharmacology of individual antibacterial agents is discussed in Section VI, Chemotherapy of Infectious Diseases. Only the topical and systemic antibacterial agents principally used in dermatology are discussed here.

Acne vulgaris is the most common dermatological disorder treated with either topical or systemic antibiotics. The anaerobe *P. acnes* is a component of normal skin flora that proliferates in the obstructed, lipid-rich lumen of the pilosebaceous unit, where O<sub>2</sub> tension is low. *P. acnes* generates free fatty acids that are irritants and may lead to microcomedo formation and resulting inflammatory lesions. Suppression of cutaneous *P. acnes* with antibiotic therapy is correlated with clinical improvement (Tan, 2003).

#### **Table 65–8 Recommended Cutaneous Antifungal Therapy**

CONDITION	TOPICAL THERAPY	ORAL THERAPY
Tinea corporis, localized	Azoles, allylamines	—
Tinea corporis, widespread	—	Griseofulvin, terbinafine, itraconazole, fluconazole
Tinea pedis	Azoles, allylamines	Griseofulvin, terbinafine, itraconazole, fluconazole
Onychomycosis	—	Griseofulvin, terbinafine, itraconazole, fluconazole
Candidiasis, localized	Azoles	—
Candidiasis, widespread and mucocutaneous	—	Ketoconazole, itraconazole, fluconazole
Tinea versicolor, localized	Azoles, allylamines	—
Tinea versicolor, widespread	—	Ketoconazole, itraconazole, fluconazole

Commonly used topical antimicrobials in acne include clindamycin (CLEOCIN-t, others), erythromycin (ERYDERM, others), benzoyl peroxide, and antibiotic–benzoyl peroxide combinations (BENZAACLIN, DUAC, others). Other antimicrobials used in treating acne include sulfacetamide (KLARON, others), sulfacetamide/sulfur combinations (SULFACET-R, others), metronidazole (METROCREAM, METROGEL, NORITATE), and azelaic acid (AZELEX, others). *Systemic therapy* is prescribed for patients with more extensive disease and acne that is resistant to topical therapy. In healthy individuals taking oral antibiotics for acne, laboratory monitoring is not necessary. Effective agents include tetracycline (SUMYCIN, others), doxycycline (MONODOX, others), minocycline (MINOCIN, others), and trimethoprim–sulfamethoxazole (BACTRIM, others). Antibiotics usually are administered twice daily, and doses are tapered after control is achieved.

The tetracyclines are the most commonly employed antibiotics because they are inexpensive, safe, and effective. The initial daily dose usually is 1 g in divided doses. Although tetracyclines are antimicrobial agents, efficacy in acne may be more dependent on anti-inflammatory activity. Minocycline has better GI absorption than tetracycline and may be less photosensitizing than either tetracycline or doxycycline. Side effects of minocycline include dizziness and hyperpigmentation of the skin and mucosa, serum sickness–like reactions, and drug-induced lupus erythematosus. With all the tetracyclines, vaginal candidiasis is a common complication that is readily treated with local administration of antifungal drugs.

**Cutaneous Infections.** Gram-positive organisms, including *Staphylococcus aureus* and *Streptococcus pyogenes*, are the most common cause of pyoderma. Skin infections with Gram-negative bacilli are rare, although they can occur in diabetics and patients who are immunosuppressed; appropriate parenteral antibiotic therapy is required for their treatment.

*Topical therapy* frequently is adequate for impetigo, the most superficial bacterial infection of the skin caused by *S. aureus* and *S. pyogenes*.

Mupirocin (pseudomonic acid, BACTROBAN, others), produced by *Pseudomonas fluorescens*, is effective for such localized infections. It inhibits protein synthesis by binding to bacterial isoleucyl-tRNA synthetase. Mupirocin is highly active against staphylococci and all streptococci except those of group D. It is less active against gram-negative organisms, but it has *in vitro* activity against *Haemophilus influenzae*, *Neisseria gonorrhoeae*, *Pasteurella multocida*, *Moraxella catarrhalis*, and *Bordetella pertussis*. Mupirocin is inactive against normal skin flora. Its antibacterial activity is enhanced by the acid pH of the skin surface. Mupirocin is available as a 2% ointment or cream and is applied three times daily. A nasal formulation is indicated to eradicate methicillin-resistant *S. aureus* (MRSA) nasal colonization.

Retapamulin ointment 1% (ALTABAX) also is FDA approved for the topical treatment of impetigo caused by susceptible strains of *S. aureus* or *S. pyogenes* in patients  $\geq 9$  months of age. Retapamulin selectively inhibits bacterial protein synthesis by interacting at a site on the 50S subunit of bacterial ribosomes.

Topical therapy often is employed for prophylaxis of superficial infections caused by wounds and injuries. Neomycin is active against staphylococci and most gram-negative bacilli. It may cause allergic contact dermatitis, especially on disrupted skin. Bacitracin inhibits staphylococci, streptococci, and gram-positive bacilli. Polymyxin B is active against aerobic gram-negative bacilli. Neomycin, bacitracin, polymyxin B (*NEOSPORIN ORIGINAL OINTMENT, DOUBLE ANTIBIOTIC OINTMENT*, others) are sold alone or in various combinations with other ingredients (e.g., hydrocortisone, lidocaine, or pramoxine) in a number of over-the-counter (OTC) formulations for the first aid of minor scrapes, burns, and cuts.

Deeper bacterial infections of the skin include folliculitis, erysipelas, cellulitis, and necrotizing fasciitis. Because streptococcal and staphylococcal species also are the most common causes of deep cutaneous infections, penicillins (especially  $\beta$  lactamase-resistant  $\beta$ -lactams) and cephalosporins are the systemic antibiotics used most frequently in their treatment (Carter, 2003) (see [Chapter 44](#)). A growing concern is the increased incidence of skin and soft-tissue infections with hospital- and community-acquired MRSA and drug-resistant pneumococci. Infection with

community-acquired MRSA often is susceptible to trimethoprim-sulfamethoxazole (Cohen and Grossman, 2004).

In addition to various traditional systemic antibiotics (such as erythromycin), novel antibacterial agents such as linezolid, quinupristin-dalfopristin, and daptomycin also have been approved for the treatment of complicated skin and skin-structure infections (see [Chapter 53](#)).

## Antifungal Agents

Fungal infections are among the most common causes of skin disease in the U.S., and numerous effective topical and oral antifungal agents have been developed. Griseofulvin, topical and oral imidazoles, triazoles, and allylamines are the most effective agents available. Examples include butenafine, clotrimazole, gentian violet, sertaconazole, ketoconazole, nystatin, oxiconazole, sulconazole, tolnaftate, undecylenic acid, and the antifungal combinations *BENSAL HP*, *WHITFIELD'S OINTMENT* (benzoic acid + salicylic acid), *versiclear lotion* (25% sodium thiosulfate + 1% salicylic acid), *castellani paint modified* (basic fuchsin + phenol + resorcinol + acetone), and *fungi-nail* (1% resorcinol + 2% salicylic acid + 2% chloroxylenol + 0.5% benzocaine + 50% isopropyl alcohol). The pharmacology, uses, and toxicities of antifungal drugs are discussed in [Chapter 57](#). This section will address the management of common cutaneous fungal diseases. Recommendations for cutaneous antifungal therapy are summarized in [Table 65–8](#).

The azoles miconazole (MICATIN, others) and econazole (SPECTAZOLE, others) and the allylamines naftifine (NAFTIN) and terbinafine (LAMISIL, others) are effective topical agents for the treatment of localized tinea corporis and uncomplicated tinea pedis. Topical therapy with the azoles is preferred for localized cutaneous candidiasis and tinea versicolor.

Systemic therapy is necessary for the treatment of tinea capitis or follicular-based fungal infections. Oral griseofulvin has been the traditional medication for treatment of tinea capitis. Oral terbinafine is a safe and effective alternative to griseofulvin in treating tinea capitis in children (Moosavi et al., 2001).

**Tinea Pedis.** Topical therapy with the azoles and allylamines is effective for tinea pedis. Macerated toe web disease may require the addition of antibacterial therapy. Econazole nitrate, which has a limited antibacterial

spectrum, can be useful in this situation. Systemic therapy with griseofulvin, terbinafine, or itraconazole (SPORANOX, others) is used for more extensive tinea pedis. It should be recognized that long-term topical therapy may be necessary in some patients after courses of systemic antifungal therapy.

***Onychomycosis.*** Fungal infection of the nails most frequently is caused by dermatophytes and *Candida*. Mixed infections are common. Because up to one-third of dystrophic nails that appear clinically to be onychomycosis are actually due to psoriasis or other conditions, the nail must be cultured or clipped for histological examination before initiating therapy.

Systemic therapy is necessary for effective management of onychomycosis. Treatment of onychomycosis of toenails with griseofulvin for 12-18 months produces a cure rate of 50% and a relapse rate of 50% after 1 year. Terbinafine and itraconazole offer significant potential advantages. They quickly produce high drug levels in the nail, which persist after therapy is discontinued. Additional advantages include a broader spectrum of coverage with itraconazole and few drug interactions with terbinafine. Treatment of toenail onychomycosis requires 3 months with terbinafine (250 mg/day) or itraconazole (200 mg/day). Pulsed dosing with itraconazole for fingernail onychomycosis consists of 200 mg twice daily for 1 wk/mo for two pulses. Cure rates of  $\geq 75\%$  have been achieved with both drugs (Gupta et al., 1994a; Gupta et al., 1994b).

Ciclopirox topical (PENLAC, others) solution is a nail lacquer that is FDA-approved for the treatment of onychomycosis but demonstrates low complete cure rates (5.5-8.5%) after 1 year of daily application. Topical ciclopirox treatment of onychomycosis must include active removal of the unattached, infected nails as frequently as monthly.

## **Antiviral Agents**

Viral infections of the skin are very common and include verrucae (human papillomavirus [HPV]), herpes simplex virus (HSV), condyloma acuminatum (HPV), molluscum contagiosum (poxvirus), and chicken pox (varicella-zoster virus [VZV]). Acyclovir (ZOVIRAX), famciclovir (FAMVIR, others), and valacyclovir (VALTREX) frequently are used systemically to treat HSV and VZV infections (see [Chapter 58](#)). Cidofovir (VISTIDE) may be useful in treating acyclovir-resistant HSV or VZV and other cutaneous viral infections (Anonymous, 2002a). Topically, acyclovir, docosanol (ABREVA), and

penciclovir (DENA VIR) are available for treating mucocutaneous HSV. Podophyllin (25% solution) and podofilox (CONDYLOX, others) 0.5% solution are used to treat condylomata. The immune response modifier imiquimod (ALDARA) is discussed in “Other Immunosuppressive and Anti-Inflammatory Agents.” Interferons  $\alpha$ -2b (INTRON A),  $\alpha$ -n1 (not commercially available in the U.S.), and  $\alpha$ -n3 (ALFERON N) may be useful for treating refractory or recurrent warts (Carter et al., 2004).

## Agents Used to Treat Infestations

Infestations with ectoparasites such as lice and scabies are common throughout the world. These conditions have a significant impact on public health in the form of disabling pruritus, secondary infection, and in the case of the body louse, transmission of life-threatening illnesses such as typhus. Topical and oral medications are available to treat these infestations.

Permethrin is a synthetic pyrethroid that interferes with insect sodium transport proteins, causing neurotoxicity and paralysis. Resistance due to mutations in the transport protein has been reported in *Cimex* (bed bugs) and other insects.

PERMETHRIN

The chemical is modeled after the natural insecticide found in the flower *Chrysanthemum cinerariifolium*. A 5% cream is available for the treatment of scabies, and a 1% cream, a cream rinse, and topical solutions are available OTC for the treatment of lice. Permethrin is approved for use in infants  $\geq 2$  months of age. Other agents used in the treatment of lice are pyrethrins + piperonyl butoxide (lotion, gel, shampoo, and mousse) and KLOUT shampoo (acetic acid + isopropanol).

Lindane ( $\gamma$ -hexachlorocyclo-hexane) is an organochloride compound that induces neuronal hyperstimulation and eventual paralysis of parasites.

Lindane has been used as a commercial insecticide as well as a topical medication. Due to several cases of neurotoxicity in humans, the FDA has labeled lindane as a second-line drug in treating pediculosis and scabies and has highlighted the potential for neurotoxicity in children and adults weighing <110 pounds and in patients with underlying skin disorders such as atopic dermatitis and psoriasis (U.S. Food and Drug Administration, 2003). Lindane is contraindicated in premature infants and patients with seizure disorders. The FDA advises that lindane prescriptions should be limited to amounts for a single application.

Malathion (OVIDE) is an organophosphate that binds acetylcholinesterase in lice, causing paralysis and death. Its structure is:

It is approved for treatment of head lice in children  $\geq 6$  years of age. The currently available formulation contains alcohol and is flammable.

Benzyl alcohol (ULESFIA) 5% lotion has recently received FDA approval for the treatment of lice. Benzyl alcohol inhibits lice from closing their respiratory spiracles, which allows the vehicle to obstruct the spiracles and causes the lice to asphyxiate. This mechanism may be less likely to cause resistance than traditional pesticides.

Ivermectin (STROMEKTOL) is an oral anthelmintic drug (see [Chapter 51](#)) approved to treat onchocerciasis and strongyloidiasis, but it also is effective in the off-label treatment of scabies and lice.

Because ivermectin does not cross the blood-brain barrier of humans, there is no major CNS toxicity. Nevertheless, minor CNS side effects include dizziness, somnolence, vertigo, and tremor. For both scabies and lice, ivermectin typically is given at a dose of 200  $\mu\text{g}/\text{kg}$ , which may be repeated in 1 week. It should not be used in children weighing  $<15$  kg.

Other, less effective topical treatments for scabies and lice include 10% crotamiton cream and lotion (*EURAX*) and extemporaneously compounded 5% precipitated sulfur in petrolatum. The later preparation is sometimes used during pregnancy or during nursing (on infected mothers). Crotamiton and sulfur may be considered for use in patients in whom lindane or permethrin may be contraindicated.

## ANTIMALARIAL AGENTS

Antimalarials used in dermatology include chloroquine (*ARALEN*, others), hydroxychloroquine (*PLAQUENIL*, others), and quinacrine (*ATABRINE*) (see [Chapter 49](#)). Common dermatoses treated with antimalarials include cutaneous lupus erythematosus, cutaneous dermatomyositis, polymorphous light eruption, porphyria cutanea tarda, and sarcoidosis. Other than lupus erythematosus, all dermatological uses of antimalarials are off label. The detailed use of these drugs in those conditions is discussed elsewhere (LaDuca and Gaspari, 2008).

The mechanism by which antimalarial agents exert their anti-inflammatory therapeutic effects is unknown. Proposed mechanisms of action include stabilization of lysosomes, inhibition of antigen presentation, inhibition of prostaglandin synthesis, inhibition of pro-inflammatory cytokine synthesis, photoprotection, inhibition of immune complex formation, and anti-thrombotic effects. In patients with porphyria cutanea tarda, chloroquine and

hydroxychloroquine bind to porphyrins and/or iron to facilitate their hepatic clearance.

The usual dosages of antimalarials are 200 mg twice a day (maximum of 6.5 mg/kg/day) of hydroxychloroquine, 250-500 mg/day (maximum of 3 mg/kg/day) of chloroquine, and 100-200 mg/day of quinacrine. Clinical improvement may be delayed for several months. Hydroxychloroquine is the most common antimalarial used in dermatology. There is strong evidence that smoking may decrease the effectiveness of antimalarials used for lupus erythematosus. If no improvement in the dermatosis is noted in 3 months, quinacrine is added. Alternatively, chloroquine is used as a single agent. Patients with porphyria cutanea tarda require lower doses of antimalarials (100 mg of hydroxychloroquine or 125 mg of chloroquine two to three times weekly) to avoid severe hepatotoxicity.

The toxic effects of antimalarial agents are described in [Chapter 49](#).

## CYTOTOXIC AND IMMUNOSUPPRESSIVE DRUGS

Cytotoxic and immunosuppressive drugs are used in dermatology for immunologically mediated diseases such as psoriasis, auto-immune blistering diseases, and leukocytoclastic vasculitis. These agents are discussed in detail in Sections IV and VII. An overview of their mechanisms of action is included in [Table 65–9](#).

### Antimetabolites

**Methotrexate.** The antimetabolite methotrexate is a folic acid analog that competitively inhibits dihydrofolate reductase. Methotrexate has been used for moderate to severe psoriasis since 1951. It suppresses immunocompetent cells in the skin, and it also decreases the expression of cutaneous lymphocyte-associated antigen (CLA)-positive T cells and endothelial cell E-selectin, which may account for its efficacy (Sigmundsdottir et al., 2004). It is useful in treating a number of other dermatological conditions, including pityriasis lichenoides et varioliformis, lymphomatoid papulosis, sarcoidosis, pemphigus vulgaris, pityriasis rubra pilaris, lupus erythematosus, dermatomyositis, and cutaneous T-cell lymphoma.

**Table 65–9 Mechanism of Action for Selected Cytotoxic and Immunosuppressive Drugs**

---

Methotrexate	Dihydrofolate reductase inhibitor
Azathioprine	Purine synthesis inhibitor
Fluorouracil	Blocks methylation in DNA synthesis
Cyclophosphamide	Alkylates and cross-links DNA
Mechlorethamine hydrochloride	Alkylating agent
Carmustine	Cross-links in DNA and RNA
Cyclosporine	Calcineurin inhibitor
Tacrolimus	Calcineurin inhibitor
Pimecrolimus	Calcineurin inhibitor
Mycophenolate mofetil	Inosine monophosphate dehydrogenase inhibitor
Imiquimod	Interferon- $\alpha$ induction
Vinblastine	Inhibits microtubule formation
Bleomycin	Induction of DNA strand breaks
Dapsone	Inhibits neutrophil migration, oxidative burst
Thalidomide	Cytokine modulation

---

Despite its widespread acceptance for decades as a first-line systemic monotherapy for the treatment of psoriasis, methotrexate (RHEUMATREX, others) was subjected only recently to a randomized, controlled clinical trial comparing its efficacy with that of orally administered cyclosporine for the treatment of moderate to severe chronic plaque psoriasis (Heydendael et al., 2003). Both medications were equally effective in achieving partial or complete clearing of psoriasis. Methotrexate often is used in combination with phototherapy and photochemotherapy or other systemic agents, and it also may be useful in combination with the biologicals (Saporito and Menter, 2004) (see “Biological Agents”).

A usual starting dosage for methotrexate therapy is 5-7.5 mg/wk (maximum of 15 mg/wk). This dosage may be increased gradually to 10-25 mg/wk if needed. Widely used regimens include three 2.5-mg oral doses given at 12-hour intervals once weekly, or weekly intramuscular injections of 10-25 mg (maximum of 30 mg/wk). Doses must be decreased for patients with impaired renal clearance. *Methotrexate should never be co-administered*

*with trimethoprim–sulfamethoxazole, probenecid, salicylates, or other drugs that can compete with it for protein binding and thereby raise plasma concentrations to levels that may result in bone marrow suppression.* Fatalities have occurred because of concurrent treatment with methotrexate and nonsteroidal anti-inflammatory agents. Methotrexate exerts significant anti-proliferative effects on the bone marrow; therefore, CBCs should be monitored serially. Physicians administering methotrexate should be familiar with the use of folinic acid (leucovorin) to rescue patients with hematological crises caused by methotrexate-induced bone marrow suppression. Careful monitoring of liver function tests is necessary but may not be adequate to identify early hepatic fibrosis in patients receiving chronic methotrexate therapy. Methotrexate-induced hepatic fibrosis may occur more commonly in patients with psoriasis than in those with rheumatoid arthritis. Consequently, liver biopsy is recommended when the cumulative dose reaches 1-1.5 g. A baseline liver biopsy also is recommended for patients with increased potential risk for hepatic fibrosis, such as a history of alcohol abuse or infection with hepatitis B or C. Patients with significantly abnormal liver function tests, symptomatic liver disease, or evidence of hepatic fibrosis should not use this drug. Many clinicians routinely administer folic acid along with methotrexate to ameliorate side effects; this does not reduce efficacy of the methotrexate. Pregnancy and lactation are absolute contraindications to methotrexate use.

***Azathioprine.*** Azathioprine (IMURAN, others) is discussed in detail in [Chapter 35](#). In dermatological practice, the drug is used off label as a steroid-sparing agent for auto-immune and inflammatory dermatoses, including pemphigus vulgaris, bullous pemphigoid, dermatomyositis, atopic dermatitis, chronic actinic dermatitis, lupus erythematosus, psoriasis, pyoderma gangrenosum, and Behçet’s disease (Silvis, 2001). The usual starting dosage is 1-2 mg/kg/day. Because it generally takes 6-8 weeks to achieve therapeutic effect, azathioprine often is started early in the course of disease management. Careful laboratory monitoring is important (Silvis, 2001). The enzyme thiopurine S-methyltransferase (TPMT) is critical for the metabolism of azathioprine to nontoxic metabolites. Homozygous deficiency of this enzyme may raise plasma levels of the drug and cause myelosuppression. TPMT enzyme activity should be measured before initiating azathioprine therapy (see [Chapter 35](#)).

***Fluorouracil.*** Fluorouracil (5-FU) interferes with DNA synthesis by blocking the methylation of deoxyuridylic acid to thymidylic acid (Dinehart, 2000). Topical formulations (CARAC, others) are used in multiple actinic keratoses, actinic cheilitis, Bowen's disease, and superficial basal cell carcinomas not amenable to other treatments.

Fluorouracil is applied once or twice daily for 2-8 weeks, depending on the indication. The treated areas may become severely inflamed during treatment, but the inflammation subsides after the drug is stopped. Intralesional injection of 5-FU has been used for keratoacanthomas, warts, and porokeratoses.

## **Alkylating Agents**

***Cyclophosphamide.*** This is an effective cytotoxic and immunosuppressive agent. Both oral and intravenous preparations of cyclophosphamide are used in dermatology (Fox and Pandya, 2000). Cyclophosphamide is FDA approved for treatment of advanced cutaneous T-cell lymphoma. Other uses include treatment of pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, paraneoplastic pemphigus, pyoderma gangrenosum, toxic epidermal necrolysis, Wegener's granulomatosis, polyarteritis nodosa, Churg-Strauss angitis, Behçet's disease, scleromyxedema, and cytophagic histiocytic panniculitis (Silvis, 2001). The usual oral dosage is 2-3 mg/kg/day in divided doses, and there often is a 4- to 6-week delay in onset of action. Alternatively, intravenous pulse administration of cyclophosphamide may offer advantages, including lower cumulative dose and a decreased risk of bladder cancer (Silvis, 2001).

Cyclophosphamide has many adverse effects, including the risk of secondary malignancy and myelosuppression, and thus is used only in the most severe, recalcitrant dermatological diseases. The secondary malignancies have included bladder, myeloproliferative, and lymphoproliferative malignancies and have been seen with the use of cyclophosphamide alone or in combination with other antineoplastic drugs.

Mechlorethamine hydrochloride (MUSTARGEN) and carmustine (BICNU) are used topically to treat cutaneous T-cell lymphoma. Both can be applied topically as a solution or in an extemporaneously compounded ointment form. It is important to monitor CBCs and liver function tests because systemic absorption can cause bone marrow suppression and hepatitis. Other side

effects include allergic contact dermatitis, irritant dermatitis, secondary cutaneous malignancies, and pigmentary changes. Carmustine also can cause erythema and post-treatment telangiectases (Zackheim et al., 1990).

## Calcineurin Inhibitors

Cyclosporine (NEORAL, GENGRAF, others) is a potent immunosuppressant isolated from the fungus *Tolypocladium inflatum*. It inhibits calcineurin, a phosphatase that normally dephosphorylates the cytoplasmic subunit of nuclear factor of activated T cells (NFAT), thus permitting NFAT to translocate to the nucleus and augment transcription of numerous cytokines. In T lymphocytes, calcineurin inhibition blocks interleukin-2 (IL-2) gene transcription and release and ultimately results in inhibition of T-cell activation (Cather et al., 2001). The presence of calcineurin in Langerhans cells, mast cells, and keratinocytes may further explain the therapeutic efficacy of cyclosporine and the other calcineurin inhibitors (e.g., tacrolimus, pimecrolimus; see later in this section) (Reynolds and Al-Daraji, 2002). Cyclosporine has FDA approval for the treatment of psoriasis. Other cutaneous disorders that typically respond well to cyclosporine are atopic dermatitis, alopecia areata, epidermolysis bullosa acquisita, pemphigus vulgaris, bullous pemphigoid, lichen planus, and pyoderma gangrenosum. The usual initial oral dosage is 2.5 mg/kg/day given in two divided doses.

Hypertension and renal dysfunction are the major adverse effects associated with the use of cyclosporine. These risks can be minimized by monitoring serum creatinine (which should not rise >30% above baseline), calculating creatinine clearance or glomerular filtration rate in patients on long-term therapy or with a rising creatinine, maintaining a daily dose of <5 mg/kg, and regularly monitoring blood pressure (Cather et al., 2001). Alternation with other therapeutic modalities may diminish cyclosporine toxicity. *Laboratory monitoring during therapy is essential.* As with other immunosuppressive agents, patients with psoriasis who are treated with cyclosporine are at increased risk of cutaneous, solid organ, and lymphoproliferative malignancies (Flores and Kerdel, 2000). The risk of cutaneous malignancies is compounded if patients have received phototherapy with PUVA.

**Tacrolimus.** Tacrolimus (FK506, PROTOPIC), a metabolite of *Streptomyces tsukubaensis*, was discovered in 1984.

TACROLIMUS

It is a potent macrolide immunosuppressant traditionally used to prevent kidney, liver, and heart allograft rejection. Like cyclosporine, tacrolimus works mainly by inhibiting early activation of T lymphocytes, thereby inhibiting the release of IL-2, suppressing humoral and cell-mediated immune responses, and suppressing mediator release from mast cells and basophils (Assmann and Ruzicka, 2002). In contrast to cyclosporine, this effect is mediated by binding to the intracellular protein FK506-binding protein 12, generating a complex that inhibits the phosphatase activity of calcineurin.

Tacrolimus is available in a topical form for the treatment of skin disease and also is marketed in oral and injectable formulations (PROGRAF). Systemic tacrolimus has shown some efficacy in the treatment of inflammatory skin diseases such as psoriasis, pyoderma gangrenosum, and Behçet's disease (Assmann and Ruzicka, 2002). When administered systemically, the most common side effects are hypertension, nephrotoxicity, neurotoxicity, GI symptoms, hyperglycemia, and hyperlipidemia. Topical formulations of tacrolimus penetrate into the epidermis.

In commercially available topical formulations (0.03% and 0.1%), tacrolimus ointment is effective in and approved for the treatment of atopic dermatitis in adults (0.03% and 0.1%) and children (0.03%) >2 years of age. Other uses in dermatology include intertriginous psoriasis, vitiligo, mucosal lichen planus, graft-versus-host disease, allergic contact dermatitis, and rosacea (Ngheim et al., 2002). It is applied to the affected area twice a day and generally is well tolerated.

A major benefit of topical tacrolimus compared with topical glucocorticoids is that tacrolimus does not cause skin atrophy and therefore can be used safely in locations such as the face and intertriginous areas. Common side effects at the site of application are transient erythema, burning, and pruritus, which tend to improve with continued treatment. Other reported adverse effects include skin tingling, flu-like symptoms, headache, alcohol intolerance, folliculitis, acne, and hyperesthesia (Ngheim et al., 2002). Systemic absorption generally is very low and decreases with resolution of the dermatitis. However, topical tacrolimus should be used with extreme caution in patients with Netherton's syndrome because these patients have been shown to develop elevated blood levels of the drug after topical application (Assmann and Ruzicka, 2002). Mice treated with 0.1% topical tacrolimus had a higher incidence of lymphoma and, after exposure to UV radiation, showed decreased time to skin tumor formation. Therefore, it is recommended that patients using tacrolimus use sunscreen and avoid excessive UV exposure. The risk of lymphoma development in humans is uncertain.

***Pimecrolimus.*** Pimecrolimus 1% cream (ELIDEL), a macrolide derived from ascomycin, is FDA approved for the treatment of atopic dermatitis in patients >2 years of age.

PIMECROLIMUS

Its mechanism of action and side-effect profile are similar to those of tacrolimus. Burning, although occurring in some patients, appears to be less common with pimecrolimus than with tacrolimus (Ngheim et al., 2002). In addition, pimecrolimus has less systemic absorption. Similar precautions

with regard to UV exposure should be taken during treatment with pimecrolimus.

Due to the potential for malignancy production, topical calcineurin inhibitors are not considered first-line therapy in childhood atopic dermatitis. Tacrolimus and pimecrolimus should only be used as second-line agents for short-term and intermittent treatment of atopic dermatitis (eczema) in patients unresponsive to, or intolerant of, other treatments. The effect of these drugs on the developing immune system in infants and children is not known; therefore, these drugs should be avoided in children <2 years of age. In clinical studies, infants and children <2 years of age treated with tacrolimus had a higher rate of upper respiratory infections than did those treated with placebo cream. Higher doses cause malignancies in animal studies.

## **OTHER IMMUNOSUPPRESSIVE AND Anti-Inflammatory AGENTS**

*Mycophenolate mofetil.* Mycophenolate mofetil (CELLCEPT), a prodrug, and mycophenolate sodium (MYFORTIC) are immunosuppressants approved for prophylaxis of organ rejection in patients with renal, cardiac, and hepatic transplants (see [Chapter 35](#)). Mycophenolic acid, the active derivative, inhibits the enzyme inosine monophosphatase dehydrogenase (IMPDH), thereby depleting guanosine nucleotides essential for DNA and RNA synthesis (Carter et al., 2004). Moreover, mycophenolic acid is a 5-fold more potent inhibitor of the type II isoform of IMPDH found in activated B and T lymphocytes and thus functions as a specific inhibitor of T- and B-lymphocyte activation and proliferation. The drug also may enhance apoptosis.

Mycophenolate mofetil is used increasingly to treat inflammatory and auto-immune diseases in dermatology in dosages ranging from 1-2 g/day orally (Carter et al., 2004). Mycophenolate mofetil is particularly useful as a corticosteroid-sparing agent in the treatment of auto-immune blistering disorders, including pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, and pemphigus foliaceus. It also has been used effectively in the treatment of inflammatory diseases such as psoriasis, atopic dermatitis, and pyoderma gangrenosum.

Isolated cases of progressive multifocal leukoencephalopathy (PML) and pure red cell aplasia have been reported in solid organ transplant patients receiving mycophenolate mofetil. PML is a progressive, demyelinating disease of the CNS that usually leads to death or severe disability. PML is caused by the reactivation of the JC virus, a polyomavirus that resides in latent form in 70-90% of the adult population worldwide.

**Imiquimod.** Imiquimod (ALDARA) is a synthetic imidazoquinoline amine believed to exert immunomodulatory effects by acting as a ligand at toll-like receptors in the innate immune system and inducing the cytokines interferon- $\alpha$  (IFN- $\alpha$ ), tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), and IL-1, IL-6, IL-8, IL-10, and IL-12.

Approved for the treatment of genital warts, imiquimod is applied to genital or perianal lesions two times a week usually for a 16-week period that may be repeated as necessary. Imiquimod also has been approved for the treatment of actinic keratoses. In this capacity, imiquimod is applied three times a week for 16 weeks to the face, scalp, and arms. No more than 36 single-use packets per 16-week course of therapy should be prescribed for actinic keratoses. Phase II trials evaluating imiquimod for the treatment of nodular and superficial basal cell carcinomas suggest that imiquimod may prove useful (Salasche and Shumack, 2003). The drug is FDA approved for this indication at a dosage of five applications per week for 6 weeks. Off-label applications include the treatment of nongenital warts, molluscum contagiosum, extramammary Paget's disease, and Bowen's disease. Irritant reactions occur in virtually all patients, and some develop edema, vesicles, erosions, or ulcers. It appears that the degree of inflammation parallels therapeutic efficacy. Other than minor flu-like symptoms, no severe systemic effects have been reported.

**Vinblastine.** Systemic vinblastine (VELBAN, others) is approved for use in Kaposi sarcoma and advanced cutaneous T-cell lymphoma. Intralesional vinblastine also is used to treat Kaposi sarcoma (Hengge et al., 2002). Intralesional bleomycin (BLENOXANE, others) is used for recalcitrant warts and has cytotoxic and pro-inflammatory effects. Intralesional injection of bleomycin into the digits has been associated with a vasospastic response that mimics Raynaud's phenomenon, local skin necrosis, and flagellate hyperpigmentation (Abess et al., 2003). Intralesional bleomycin has been used for palliative treatment of squamous cell carcinoma. Systemic bleomycin has been used for Kaposi sarcoma (see [Chapter 61](#) for a more complete discussion of these agents). Liposomal anthracyclines (specifically doxorubicin [DOXIL, CAELYX]) may provide first-line monotherapy for advanced Kaposi sarcoma (Hengge et al., 2002).

**Dapsone.** Dapsone (4,4'-diaminodiphenylsulfone) has been in clinical use for ~50 years.

Dapsone is used in dermatology for its anti-inflammatory properties, particularly in sterile (non-infectious) pustular diseases of the skin. Dapsone prevents the respiratory burst from myeloperoxidase, suppresses neutrophil migration by blocking integrin-mediated adherence, inhibits adherence of antibodies to neutrophils, and decreases the release of eicosanoids and blocks their inflammatory effects; all of these actions are likely to be important in auto-immune skin diseases (Zhu and Stiller, 2001).

Dapsone is approved for use in dermatitis herpetiformis and leprosy. It is particularly useful in the treatment of linear immunoglobulin A (IgA) dermatosis, bullous systemic lupus erythematosus, erythema elevatum diutinum, and subcorneal pustular dermatosis. In addition, reports indicate efficacy in patients with acne fulminans, pustular psoriasis, lichen planus, Hailey–Hailey disease, pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, leukocytoclastic vasculitis, Sweet's syndrome, granuloma faciale, relapsing polychondritis, Behçet's disease, urticarial vasculitis, pyoderma gangrenosum, and granuloma annulare (Paniker and Levine, 2001).

An initial dosage of 50 mg/day is prescribed, followed by increases of 25 mg/day at weekly intervals, titrated to the minimal dosage necessary for effect, always with appropriate laboratory testing. Potential side effects of dapsone include methemoglobinemia and hemolysis. The glucose-6-phosphate dehydrogenase (G6PD) level should be checked in all patients before initiating dapsone therapy because dapsone hydroxylamine, the toxic metabolite of dapsone formed by hydroxylation, depletes glutathione within G6PD-deficient cells. The nitroso derivative then causes peroxidation reactions, leading to rapid hemolysis. A maximum dosage of 150-300 mg/day should be given in divided doses to minimize the risks of methemoglobinemia. The H<sub>2</sub> blocker cimetidine, at a dose of 400 mg three times daily, alters the degree of methemoglobinemia by competing with dapsone for CYPs. Toxicities include agranulocytosis, peripheral neuropathy, and psychosis.

**Thalidomide.** Thalidomide (THALOMID) is an anti-inflammatory, immunomodulating, anti-angiogenic agent experiencing resurgence in the treatment of dermatological diseases (see [Chapter 35](#)). Its structure is:

The mechanisms that underlie the pharmacological properties of thalidomide are not clear, although modulation of inflammatory cytokines such as TNF- $\alpha$ , IFN- $\alpha$ , IL-10, IL-12, cyclooxygenase-2, and possibly nuclear factor  $\kappa$ B (NF- $\kappa$ B) may be involved (Franks et al., 2004). It also can modulate T cells by altering their patterns of cytokine release and can increase keratinocyte migration and proliferation (Wines et al., 2002).

Thalidomide is FDA approved for the treatment of erythema nodosum leprosum. There are reports suggesting its efficacy in actinic prurigo, aphthous stomatitis, Behçet's disease, Kaposi sarcoma, and the cutaneous manifestations of lupus erythematosus, as well as prurigo nodularis and uremic prurigo. Thalidomide has been associated with increased mortality when used to treat toxic epidermal necrolysis. *In utero* exposure can cause

limb abnormalities (phocomelia), as well as other congenital anomalies. It also may cause an irreversible neuropathy. *Because of its teratogenic effects, thalidomide use is restricted to specially licensed physicians who fully understand the risks. Thalidomide should never be taken by women who are pregnant or who could become pregnant while taking the drug.*

## **BIOLOGICAL AGENTS**

Biological agents (see [Chapters 35](#) and [62](#)) are compounds derived from living organisms that target specific mediators of immunological reactions. Classes of biologicals include recombinant cytokines, interleukins, growth factors, antibodies, and fusion proteins. Currently, five biological agents are approved for the treatment of psoriasis ([Table 65–10](#)).

Psoriasis is a disorder of Th1 cell-mediated immunity ([Figure 65–4](#)), with the epidermal changes being secondary to the effect of released cytokines. Biological therapies modify the immune response in psoriasis through 1) reduction of pathogenic T cells, 2) inhibition of T-cell activation, 3) immune deviation (from a Th1 to a Th2 immune response), and 4) blockade of the activity of inflammatory cytokines (Weinberg, 2003). The appeal of biological agents in the treatment of psoriasis is that they specifically target the activities of T lymphocytes and cytokines that mediate inflammation versus traditional systemic therapies that are broadly immunosuppressive or cytotoxic. Thus, the use of these agents theoretically should result in fewer toxicities and side effects.

When evaluating the efficacy of biological agents, it is important to understand the standard measurement of efficacy in psoriasis treatment, the Psoriasis Area and Severity Index (PASI). The PASI quantifies the extent and severity of skin involvement in different body regions as a score from 0 (no lesions) to 72 (severe disease). To gain FDA approval for the treatment of psoriasis, a biological agent must decrease the PASI by 75%. Although such quantification is an essential element in controlled clinical trials, many patients in practice may gain clinically significant benefit from biological treatment without achieving this degree of PASI improvement.

### **T-cell Activation Inhibitors**

***Alefcept.*** Alefcept (*AMEVIVE*) was the first immunobiological agent approved for the treatment of moderate to severe psoriasis. Alefcept

consists of a recombinant fully human fusion protein composed of the binding site of the leukocyte function–associated antigen 3 (LFA-3) protein and a human IgG<sub>1</sub> Fc domain. The LFA-3 portion of the alefacept molecule binds to CD2 on the surface of T cells, thus blocking a necessary co-stimulation step in T-cell activation ([Figure 65–5](#)). Importantly, because CD2 is expressed preferentially on memory-effector T cells, naive T cells are largely unaffected by alefacept. A second important action of alefacept is its ability to induce apoptosis of memory-effector T cells through simultaneous binding of its IgG<sub>1</sub> portion to immunoglobulin receptors on cytotoxic cells and its LFA-3 portion to CD2 on T cells, thus inducing granzyme-mediated apoptosis of memory-effector T cells. This may lead to a reduction in CD4<sup>+</sup> lymphocyte counts, requiring a baseline CD4<sup>+</sup> lymphocyte count before initiating alefacept and then biweekly during therapy.

**Table 65–10 Biological Agents Commonly Used in Dermatology**

DRUG	ALEFACEPT	EFALIZUMAB	ADALIMUMAB	ETANERCEPT	INFLIXIMAB
<b>Structural class</b>	Receptor-antibody fusion protein	Humanized monoclonal antibody	Human monoclonal antibody	Receptor-antibody fusion protein	Chimeric monoclonal antibody
<b>Components</b>	LFA-3 and Fc IgG1	Complementarity determining region of mouse monoclonal antibody on human IgG <sub>1</sub>	IgG1	p75 TNF receptor and Fc IgG1	Variable region of mouse monoclonal antibody on human IgG1
<b>Binding site</b>	CD2	CD11a subunit of LFA-1	TNF- $\alpha$	TNF- $\alpha$	TNF- $\alpha$
<b>Method of administration</b>	IM	SC	SC	SC	IV
<b>Dosing for psoriasis</b>	15 mg weekly $\times$ 12 weeks, stop 12 weeks, then repeat	0.7 mg/kg first week, then 1 mg/kg weekly	80-mg loading dose, then 40 mg biweekly	50 mg twice weekly $\times$ 3 months then 50 mg weekly	5 mg/kg at weeks 0, 2, and 6, then every 6-8 weeks
<b>FDA indications</b>	Moderate-severe psoriasis	Moderate-severe psoriasis	Moderate-severe psoriasis; moderate-severe psoriatic arthritis; adult and juvenile rheumatoid arthritis; ankylosing spondylitis; Crohn's disease	Moderate-severe psoriasis; moderate-severe psoriatic arthritis; adult and juvenile rheumatoid arthritis; ankylosing spondylitis	Severe psoriasis; moderate-severe psoriatic arthritis; adult rheumatoid arthritis; ankylosing spondylitis; ulcerative colitis; Crohn's disease
<b>Pregnancy category</b>	B	C	B	B	B
<b>Efficacy in psoriasis<sup>a</sup></b>	28-33%	27-39%	53%	47%	76-80%

<sup>a</sup>Probability (%) of Psoriasis Area and Severity Index (PASI) score of 75 after 12 weeks of therapy at the dosing described in the table (Tzu and Kerdel, 2008). LFA, lymphocyte function–associated antigen; IgG, immunoglobulin G; TNF, tumor necrosis factor; IM, intramuscular; SC, subcutaneous; IV, intravenous.

**Efalizumab.** Efalizumab (RAPTIVA) is a humanized monoclonal antibody against the CD11a molecule of LFA-1. By binding to CD11a on T cells, efalizumab prevents binding of LFA-1 to intercellular adhesion molecule (ICAM)-1 on the surface of antigen-presenting cells, vascular endothelial cells, and cells in the dermis and epidermis (Figure 65–5), thereby interfering with T-cell activation and migration and cytotoxic T-cell function (Weinberg, 2003). A transient peripheral leukocytosis occurs in some patients taking efalizumab, which may be due to the inhibition of T-cell trafficking. Other side effects include thrombocytopenia, exacerbation of psoriasis, and rebound psoriasis upon discontinuation. Therefore, CBCs should be obtained at baseline and periodically thereafter. Recent reports have implicated efalizumab in the development of PML, and extra caution should be exercised in patients who develop neurological signs while on efalizumab (Castelo-Soccio and Van Voorhees, 2009).

## Tumor Necrosis Factor Inhibitors

TNF- $\alpha$ , produced by macrophages, T cells, dendritic cells, and keratinocytes, is elevated in both the lesions and serum of patients with active psoriasis. This cytokine is central to the T<sub>H</sub>1 response in active psoriasis, inducing further inflammatory cytokines, upregulating intracellular adhesion molecules, inhibiting apoptosis of keratinocytes, and inducing keratinocyte proliferation. Therefore, blockade of TNF- $\alpha$  with biologicals reduces inflammation, decreases keratinocyte proliferation, and decreases vascular adhesion, resulting in improvement in psoriatic lesions (Richardson and Gelfand, 2008).

**Figure 65–4. Immunopathogenesis of psoriasis.** Psoriasis is a prototypical inflammatory skin disorder in which specific T-cell populations are stimulated by as-yet undefined antigen(s) presented by antigen-presenting cells. The T cells release pro-inflammatory cytokines, such as tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and interferon- $\gamma$  (IFN- $\gamma$ ), that induce keratinocyte and endothelial cell proliferation. APC, antigen-presenting cell; CLA, cutaneous lymphocyte-associated antigen.

**Figure 65–5. Mechanisms of action of selected biological agents in psoriasis.** Newer biological agents can interfere with one or more steps in the pathogenesis of psoriasis, resulting in clinical improvement. See text for details. ICAM-1, intercellular adhesion molecule 1; LFA, lymphocyte function–associated antigen; MHC, major histocompatibility complex; TCR, T-cell receptor.

Because TNF- $\alpha$  inhibitors alter immune responses, patients on all anti-TNF- $\alpha$  agents are at increased risk for serious infection. They also are theoretically at increased risk for malignancies, because TNF is involved in normal innate immunity and natural killer cell–mediated destruction of tumor cells (Tzu and Kerdel, 2008). Other adverse events related to TNF- $\alpha$  inhibitors include exacerbation of congestive heart failure and demyelinating

disease in predisposed patients (Menter and Griffiths, 2007). Therefore, all patients should be screened for tuberculosis, personal or family history of demyelinating disorder, cardiac failure, active infection, or malignancy prior to starting anti-TNF- $\alpha$  therapy.

***Etanercept.*** Etanercept (ENBREL) is a soluble, recombinant, fully human TNF receptor fusion protein consisting of two molecules of the ligand-binding portion of the TNF receptor (p75) fused to the Fc portion of IgG<sub>1</sub>. Etanercept binds soluble and membrane-bound TNF, thereby inhibiting the action of TNF (Krueger and Callis, 2004). There are several case series and a large randomized controlled study supporting the safety and efficacy of etanercept at 0.4 mg/kg twice weekly in pediatric psoriasis (Sukhatme and Gottlieb, 2009). Etanercept use is associated with an increased risk of infections (bacterial sepsis, tuberculosis), including leading to hospitalization or death. Patients should be screened for latent tuberculosis infection before beginning treatment and closely monitored during and after drug therapy.

***Infliximab.*** Infliximab (REMICADE) is a mouse-human chimeric IgG<sub>1</sub> monoclonal antibody that binds to soluble and membrane-bound TNF- $\alpha$  (Krueger and Callis, 2004). Infliximab is a complement-fixing antibody that induces complement-dependent and cell-mediated lysis when bound to cell-surface-bound TNF- $\alpha$ . Neutralizing antibodies to infliximab may develop against its chimeric structure. Concomitant administration of methotrexate or glucocorticoids may suppress this antibody formation.

***Adalimumab.*** Adalimumab (HUMIRA) is a human IgG<sub>1</sub> monoclonal antibody that binds soluble and membrane-bound TNF- $\alpha$ . Like infliximab, it can mediate complement-induced cytolysis on cells expressing TNF. Unlike infliximab, however, it is fully human, which reduces the risk for development of neutralizing antibodies.

## **Cutaneous T-cell Lymphoma**

***Denileukin diftitox.*** Denileukin diftitox or DAB<sub>389</sub>-IL-2 (*ontak*) is a fusion protein composed of diphtheria toxin fragments A and B and the receptor-binding portion of IL-2. DAB<sub>389</sub>-IL-2 is indicated for advanced cutaneous T-cell lymphoma in patients with >20% of T cells expressing the surface marker CD25. Specificity is derived from the presence of IL-2 receptor (IL-2R) on malignant and activated T cells but not resting B and T cells.

Following binding to the IL-2R, DAB<sub>389</sub>-IL-2 is internalized by endocytosis. The active fragment of diphtheria toxin then is released into the cytosol, where it inhibits protein synthesis through ADP ribosylation, leading to cell death. Clinical trials have shown an overall response rate of 30% and a complete response rate of 10% in cutaneous T-cell lymphoma. Adverse effects include pain, fevers, chills, nausea, vomiting, and diarrhea; immediate hypersensitivity reaction (hypotension, back pain, dyspnea, and chest pain) in 60% of patients; and capillary leak syndrome (edema, hypoalbuminemia, and/or hypotension) in 20-30% of patients (Duvic and Talpur, 2008).

## **INTRAVENOUS IMMUNOGLOBULIN IN DERMATOLOGY**

Intravenous immunoglobulin (IVIG) is prepared from fractionated pooled human sera derived from thousands of donors with various antigenic exposures (see [Chapter 35](#)). There are several commercial preparations of IVIG, all of which are composed of >90% IgG, with minimal amounts of IgA, soluble CD4, CD8, HLA molecules, and cytokines. Although the mechanism of action of IVIG is not understood fully, proposed mechanisms include suppression of IgG production, accelerated catabolism of IgG, neutralization of complement-mediated reactions, neutralization of pathogenic antibodies, downregulation of inflammatory cytokines, inhibition of autoreactive T lymphocytes, inhibition of immune cell trafficking, and blockage of Fas-ligand/Fas-receptor interactions (Smith et al., 2007).

In dermatology, IVIG is used off label as an adjuvant or rescue therapy for multiple diseases. These include auto-immune bullous diseases, toxic epidermal necrolysis, connective tissue diseases, vasculitis, urticaria, atopic dermatitis, and graft-versus-host disease. Prospective controlled studies are lacking for the efficacy in these diseases and likely vary based on the IVIG product used.

IVIG is relatively contraindicated in patients with severe selective IgA deficiency (IgA <0.05 g/L). These patients may possess anti-IgA antibodies that place them at risk for severe anaphylactic reactions. Other relative contraindications include congestive heart failure and renal failure due to the risk of fluid overload. Patients with rheumatoid arthritis or cryoglobulinemia are at an increased risk of renal failure (Thomas et al., 2007).

# SUNSCREENS

Photoprotection from the acute and chronic effects of sun exposure is readily available with sunscreens. The major active ingredients of available sunscreens include chemical agents that absorb incident solar radiation in the UVB and/or UVA ranges and physical agents that contain particulate materials that can block or reflect incident energy and reduce its transmission to the skin. Many of the sunscreens available are mixtures of organic chemical absorbers and particulate physical substances. Ideal sunscreens provide a broad spectrum of protection and are formulations that are photostable and remain intact for sustained periods on the skin. They also should be non-irritating, invisible, and nonstaining to clothing. No single sunscreen ingredient possesses all these desirable properties, but many are quite effective nonetheless.

***UVA Sunscreen Agents.*** Currently available UVA filters in the U.S. include 1) avobenzene, also known as Parsol 1789; 2) oxybenzone; 3) titanium dioxide; 4) zinc oxide; and 5) ecamsule (MEXORYL SX). Additional UVA sunscreens, including bemotrizinol (TINOSORB S) and bisoctrizole (TINSORB M), are available in Europe and elsewhere, but not in the U.S.

***UVB Sunscreen Agents.*** There are numerous UVB filters, including 1) p-aminobenzoic acid (PABA) esters (e.g., padimate O), 2) cinnamates (e.g., octinoxate), 3) octocrylene, and 4) salicylates (e.g., octisalate).

The major measurement of sunscreen photoprotection is the *sun protection factor* (SPF), which defines a ratio of the minimal dose of incident sunlight that will produce erythema or redness (sunburn) on skin with the sunscreen in place (protected) and the dose that evokes the same reaction on skin without the sunscreen (unprotected). The SPF provides valuable information regarding UVB protection but is useless in documenting UVA efficacy. In 2007, the FDA proposed a consumer-friendly rating system for UVA products consisting of one to four stars representing low, medium, high, and highest UVA protection available in an OTC sunscreen product as an indicator of the product's ability to prevent tanning. The test proposed to determine UVA rating is analogous to the SPF test used to determine the effectiveness of UVB sunscreen products. At the time of this writing, the FDA had not published a final rule. However, such protocols are needed because >85% of solar UV radiation reaching earth's surface is UVA, which penetrates more deeply into human skin than does UVB and appears to play an important role

in photoaging and photocarcinogenesis. Despite the universal availability of sunscreens, a major problem with them is the fact that people do not use them appropriately or on a regular basis. In a population study evaluating the use of sunscreens in northern England, it was reported that only 35% of females and 8% of males regularly used sunscreens (Ling et al., 2003). Furthermore, 22% of those surveyed used no sunscreen at all, and 34% recalled at least one sunburn reaction in the previous 2 years.

There is evidence that the regular use of sunscreens can reduce the risk of actinic keratoses and squamous cell carcinomas of the skin. One study noted a 46% decrease in the incidence of squamous cell carcinomas in people who used sunscreen regularly for 4.5 years (Green et al., 1999).

Except for total sun avoidance, sunscreens are the best single method of protection from UV-induced damage to the skin. However, there is a need for more definitive answers to questions related to the efficacy of sunscreens in reducing skin cancer risk. Prospects for more effective photoprotection are excellent as better sunscreen components are developed and as more careful evaluations are performed (Rigel, 2002).

## THE TREATMENT OF PRURITUS

The term *pruritus* is derived from the Latin *prurire*, which means “to itch.” Pruritus is a symptom unique to skin that occurs in a multitude of dermatological disorders, including dry skin or xerosis, atopic eczema, urticaria, and infestations. Itching also may be a sign of internal disorders, including malignant neoplasms, chronic renal failure, and hepatobiliary disease. In addition to treating the underlying disorder, a general approach to the treatment of pruritus can be made by classifying pruritus into one of four clinical categories ([Table 65–11](#)). Long experience shows that gold works well for treatment of the itching palm.

**Table 65—11 Agents Used for the Treatment of Pruritus**

**Pruritoceptive Pruritus:** Itch originating in the skin due to inflammation or other cutaneous disease

- Emollients—Repair of barrier function
- Coolants (menthol, camphor, calamine)—Counter-irritants
- Capsaicin—Counter-irritant
- Antihistamines—Inhibit histamine-induced pruritus

- Topical steroids—Direct anti-pruritic and anti-Inflammatory effects
- Topical immunomodulators—Anti-inflammatories
- Phototherapy—Reduced mast cell reactivity and anti-Inflammatory effects
- Thalidomide—Anti-Inflammatory through suppression of excessive tumor necrosis factor- $\alpha$

**Neuropathic Pruritus:** Itch due to disease of afferent nerves

- Carbamazepine—Blockade of synaptic transmission and use-dependant sodium channels
- Gabapentin—Suppresses neuronal hyperexcitability by inhibiting voltage-dependant calcium channels
- Topical anesthetics (EMLA, benzocaine, pramoxine)—Inhibit nerve conduction via decreased nerve membrane permeability to sodium

**Neurogenic Pruritus:** Itch that arises from the nervous system without evidence of neural pathology

- Thalidomide—Central depressant
- Opioid-receptor antagonists (naloxone, naltrexone)—Decrease opioidergic tone
- Tricyclic antidepressants—Decrease pruritus signaling through alteration in neurotransmitter concentrations
- Selective serotonin reuptake inhibitors (SSRIs)—Decrease pruritus signaling through alteration in neurotransmitter concentrations

**Psychogenic Pruritus:** Itch due to psychological illness

- Anxiolytics (alprazolam, clonazepam, benzodiazepines)—Relieve stress-reactive pruritus
- Antipsychotic agents (chlorpromazine, thioridazine, thiothixene, olanzapine)—Relieve pruritus with impulsive qualities
- Tricyclic antidepressants—Relieve depression and insomnia related to pruritus
- SSRIs—Relieve pruritus with compulsive qualities

## **DRUGS FOR HYPERKERATOTIC DISORDERS**

Keratolytic agents are substances that reduce hyperkeratosis through a variety of mechanisms (e.g., breaking of intercellular junctions, increasing stratum

corneum water content, increasing desquamation). Common disorders treated with keratolytics include psoriasis, seborrheic dermatitis, xerosis, ichthyoses, and verrucae.

$\alpha$ -Hydroxy acids are organic acids in which a hydroxyl group is attached to the first carbon ( $\alpha$  carbon) following its carboxyl acid group. Various  $\alpha$ -hydroxy acids include glycolic, lactic, malic, citric, hydroxycaprylic, hydroxycapric, and mandelic. They reduce the thickness of the stratum corneum by solubilizing components of the desmosome, activating endogenous hydrolytic enzymes, and drawing water into the stratum corneum, allowing cell separation to occur. They also appear to increase glycosaminoglycans, collagen, and elastic fibers in the dermis and are used in various formulations to reverse photoaging. The FDA requires that cosmetics containing  $\alpha$ -hydroxy acids be labeled with a sunburn alert warning that the product may increase sensitivity to the sun and reminding users to wear protective clothing, use sunscreen, and limit sun exposure.

Salicylic acid functions through solubilization of intercellular cement, reducing corneocyte adhesion, and softening the stratum corneum. Salicylism may occur with widespread and prolonged use, especially in children and patients with renal or hepatic impairment, and use should be limited to <2 g to the skin surface in a 24-hour period. Salicylic acid, while chemically not a true  $\beta$ -hydroxy acid, often is listed as such on cosmetic labels. Other  $\beta$ -hydroxy acids ingredients in cosmetics include  $\beta$ -hydroxybutanoic acid,  $\delta$  tropic acid, and trethocanic acid. As with  $\alpha$ -hydroxy acids, sun protection should accompany the application of skin products containing  $\beta$ -hydroxy acids.

At low concentrations, urea increases skin absorption and retention of water, leading to increased flexibility and softness of the skin (Hessel et al., 2007). At high concentrations (>40%), urea denatures and dissolves proteins and is used to dissolve calluses or avulse dystrophic nails.

Sulfur is anti-septic, anti-parasitic, anti-seborrheic, and keratolytic, accounting for its myriad uses in dermatology. It is believed to exert its keratolytic effect by reacting with cysteine within keratinocytes, producing cystine and hydrogen sulfide. Hydrogen sulfide breaks down keratin, causing dissolution of the stratum corneum (Hessel et al., 2007).

Often used in conjunction with plastic occlusion, propylene glycol (as 60-100% solutions in water) increases the water content of the stratum corneum

and enhances desquamation. It is most effective in disorders with retention hyperkeratosis, in which the thickened stratum corneum is slowly reformed.

## DRUGS FOR ANDROGENETIC ALOPECIA

Androgenetic alopecia, commonly known as male and female pattern baldness, is the most common cause of hair loss in adults >40 years of age. Up to 50% of men and women are affected. Androgenetic alopecia is a genetically inherited trait with variable expression. In susceptible hair follicles, dihydrotestosterone binds to the androgen receptor, and the hormone-receptor complex activates the genes responsible for the gradual transformation of large terminal follicles into miniaturized vellus follicles. Treatment of androgenetic alopecia is aimed at reducing hair loss and maintaining existing hair. The capacity to stimulate substantial regrowth of human hair remains a formidable pharmacological challenge.

**Minoxidil.** Minoxidil (ROGAINE, others) was first developed as an anti-hypertensive agent (see [Chapter 27](#)) and was noted to be associated with hypertrichosis in some patients. A topical formulation of minoxidil then was developed to exploit this side effect. The structure of minoxidil is:

Topical minoxidil is available as a 2% or 5% solution. Minoxidil enhances follicular size, resulting in thicker hair shafts, and stimulates and prolongs the anagen phase of the hair cycle, resulting in longer and increased numbers of hairs. Treatment must be continued, or any drug-induced hair growth will be lost. Allergic and irritant contact dermatitis can occur, and care should be taken in applying the drug because hair growth may emerge in undesirable locations. This is reversible on stopping the drug. Patients should be instructed to wash their hands after applying minoxidil.

**Finasteride.** Finasteride (PROPECIA, other) inhibits the type II isozyme of 5 $\alpha$ -reductase, the enzyme that converts testosterone to dihydrotestosterone (see [Chapter 41](#)). The structure of finasteride is:

FINASTERIDE

The type II 5 $\alpha$ -reductase is found in hair follicles. Balding areas of the scalp are associated with increased dihydrotestosterone levels and smaller hair follicles than nonbalding areas. Orally administered finasteride (1 mg/day) has been shown to variably increase hair growth in men over a 2-year period, increasing hair counts in the vertex and the frontal scalp (Leyden et al., 1999). Finasteride is approved for use only in men. Pregnant women should not be exposed to the drug because of the potential for inducing genital abnormalities in male fetuses. Adverse effects of finasteride include decreased libido, erectile dysfunction, ejaculation disorder, and decreased ejaculate volume. Each of these occurs in <2% of patients (Leyden et al., 1999). Like minoxidil, treatment with finasteride must be continued, or any new hair growth will be lost.

## TREATMENT OF HYPERPIGMENTATION

The agents mentioned in this section are most effective on hormonally or light-induced pigmentation within the epidermis. They have limited efficacy on post-inflammatory pigmentation within the dermis.

**Hydroquinone.** Hydroquinone (1,4-dihydrobenzene; *TRI-LUMA*) is the first-line agent in medical therapy of hyperpigmentation. It decreases melanocyte pigment production by inhibiting the conversion of dopa to melanin through inhibition of the enzyme tyrosinase. Other mechanisms include inhibition of DNA and RNA synthesis, degradation of melanosomes, and destruction of melanocytes. There are multiple formulations, to which penetration enhancers, microsponges, and sunscreen ingredients are added. Adverse effects may include dermatitis and ochronosis; patients should be followed regularly while on hydroquinone (Draelos, 2007).

HYDROQUINONE

**Monobenzone.** Monobenzone (BENOQUIN), the monobenzyl ether of hydroquinone, causes permanent hypopigmentation and should *not* be used for routine hormonally induced or post-inflammatory hyperpigmentation.

**Azelaic.** Azelaic acid (AZELEX, FINACEA) is a dicarboxylic acid isolated from cultures of *Pityrosporum ovale*. It was developed through study of the hypopigmentation produced by infection with *P. ovale* (tinea versicolor). It also inhibits tyrosinase activity but is less effective than hydroquinone. Because it has mild comedolytic, antimicrobial, and anti-inflammatory properties, it also is often used in acne and papulopustular rosacea (Draelos, 2007).

AZELAIC ACID

Mequinol, also known as 4-hydroxyanisole, methoxyphenol, hydroquinone monomethyl ether, or p-hydroxyanisole, is a competitive inhibitor of tyrosinase. It is available as a 2% prescription product (*SOLAGE*) in combination with 0.01% tretinoin and vitamin C to enhance skin lightening (Draelos, 2007).

## MISCELLANEOUS AGENTS

Capsaicin (trans-8-methyl-*N*-vanillyl-6-nonenamide) is an alkaloid derived from plants of the *Solanaceae* family (i.e., hot chili peppers).

CAPSAICIN

Capsaicin interacts with the transient receptor potential vanilloid (TRPV1) receptor on C-fiber sensory neurons. TRPV1 is a ligand-gated nonselective cation channel of the TRP family, modulated by a variety of noxious stimuli

(Wang, 2008). Chronic exposure to capsaicin first stimulates and then desensitizes this channel to capsaicin and diverse other noxious stimuli. Capsaicin also causes local depletion of substance P, an endogenous neuropeptide involved in sensory perception and pain transmission. Capsaicin is available as a 0.025%, 0.035%, 0.075%, 0.1%, and 0.25% cream (ZOSTRIX, others); 0.025% and 0.075% lotion (CAPSIN); 0.025% and 0.05% gel; 0.075% roll-on; and 0.025% transdermal patch. Capsaicin is FDA approved for the temporary relief of minor aches and pains associated with backache, strains, and arthritis and is used for off-label treatment of postherpetic neuralgia and painful diabetic neuropathy. It is being investigated for psoriasis, vitiligo, intractable pruritus, and other disorders.

Podophyllin (podophyllum resin) is a mixture of chemicals from the plant *Podophyllum peltatum* (mandrake or May apple). The major constituent of the resin is podophyllotoxin (podofilox). It binds to microtubules and causes mitotic arrest in metaphase. Podophyllum resin (10-40%) is applied by a physician and left in place for no longer than 2-6 hours weekly for the treatment of anogenital warts. Irritation and ulcerative local reactions are the major side effects. It should not be used in the mouth or during pregnancy. Podofilox is available as a 0.5% solution for home application twice daily for 3 consecutive days. Weekly cycles are repeated until clearance or for a maximum of four cycles.

## *Chapter 66*

# Contraception and Pharmacotherapy of Obstetrical and Gynecological Disorders

**Bernard P. Schimmer and Keith L. Parker**

Drugs used to control fertility and treat disorders of the female reproductive organs collectively are among the most frequently prescribed agents in clinical practice. This chapter discusses a number of common clinical issues and their drug therapies that are central to women's health. The focus is on reproductive disorders and aspects of therapy rather than comprehensive coverage of the drugs themselves, which are described in more detail elsewhere (e.g., [Chapter 33](#) for prostaglandins; [Chapter 38](#) for the gonadotropins, gonadotropin-releasing hormone [GnRH] agonists and antagonists, and oxytocin; [Chapter 40](#) for estrogens and progestins; Section VII for antibiotics).

## CONTRACEPTION

Contraception can either be administered as planned prophylaxis (e.g., oral contraceptive pills, patches, implants, vaginal or intrauterine devices, barrier foams, spermicides, tubal ligation, vasectomy) or postcoitally for emergency contraception (i.e., high-dose estrogen-containing oral contraceptive pills, high-dose progestin pills, a progesterone antagonist, intrauterine devices). The progesterone antagonist also can be used to terminate an established pregnancy.

## Planned Contraception

**Combination Oral Contraceptives.** Of the various contraceptive methods, pills containing an estrogen and progestin in combination are the most widely used and are among the most effective of the nonsurgical modalities ([Table 66-1](#)); they act primarily by suppressing the luteinizing hormone (LH) surge and thereby preventing ovulation. A wide variety of preparations are

available for oral, transdermal, and vaginal administration (Erkkola, 2007). (See [Table 66–2](#) for a list of branded formulations. Many of the same formulations also are available as generics.) Almost all contain ethinyl estradiol as the estrogen and a 17 $\alpha$ -alkyl-19-nortestosterone derivative as the progestin and are administered for the first 21-24 days of a 28-day cycle. The major functions of the estrogen are to sensitize the hypothalamus and pituitary gonadotropes to the feedback inhibitory effects of the progestin and to minimize breakthrough bleeding. The progestin exerts negative feedback, which suppresses the LH surge and thereby prevents ovulation, and protects against uterine cancer by opposing the proliferative effects of the estrogen on the uterine endometrium. Newer formulations offer effective contraception with improved activity profiles. They contain lower amounts of hormones to minimize adverse effects; some incorporate progestins with less androgenic activity (e.g., gestodene, desogestrel) or that antagonize the mineralocorticoid receptor and thereby reduce the tendency toward edema (e.g., drospirenone). Due to diminished endometrial proliferation, patients taking these newer formulations may not experience a menstrual bleed at the end of each cycle; if this occurs, a pregnancy test generally is performed after the first missed cycle to rule out contraceptive failure.

Traditionally, combination oral contraceptives were packaged with 21 pills containing active hormone and 7 placebo tablets; each active pill contained a constant amount of the estrogen and progestin (i.e., a monophasic formulation). In an effort to maximize the anti-ovulatory effects and prevent breakthrough bleeding while minimizing total exposure to the hormones, some formulations provide active pills with two (biphasic) or three (triphasic) different amounts of one or both hormones to be used sequentially during each cycle.

Formulations called “extended-cycle” contraceptives extend the number of active pills per cycle and thus decrease the duration of menstrual bleeding. Two products contain 24 active pills with only 4 placebo tablets (e.g., *yaz* [which contains drospirenone as the progestin] and

### **Table 66–1 One-Year Failure Rate with Various Forms of Contraception**

BIRTH CONTROL METHOD	FAILURE RATE (Perfect Use)	FAILURE RATE (Typical Use)
Combination oral contraceptive pills	0.3%	8%
Progestin-only minipill	0.5%	8%
DEPO-PROVERA	0.3%	3%
Copper intrauterine device	0.6%	0.8%
Progestin intrauterine device	0.2%	0.2%
IMPLANON	0.05%	0.05%
ORTHO EVRA	0.3%	8%
NUVARING	0.3%	8%
Condoms/diaphragms	2%	15%
Spermicides	18%	29%
Tubal ligation	0.5%	0.5%
Vasectomy	0.1%	0.15%
None	85%	85%

LOESTRIN 24). Two products are packaged as 91-day packets, with 84 estrogen/progestin tablets and 7 placebo tablets (SEASONALE) or 7 tablets containing a lower dose of ethinyl estradiol alone (SEASONIQUE). Finally, LYBREL is provided in 28-day packets that contain only hormone pills and no placebo. All of these extended-cycle formulations appear to be comparable to the traditional products as contraceptives, and, aside from an increased frequency of breakthrough bleeding initially, no unexpected adverse effects have been observed (Kiley and Hammond, 2007).

A weekly transdermal contraceptive patch (ORTHO EVRA) releases ethinyl estradiol (20 µg/day) and norelgestromin (which is metabolized to norgestimate; 150 µg/day). In response to pharmacokinetic data suggesting that this patch provides higher estrogen exposure (AUC) than the low-dose oral contraceptive pills, the FDA added a black box advisory that notes this pharmacokinetic difference and warns of a potential increased risk of venous thromboembolism. Local reactions to the patch occur in ~5-15% of users and may be decreased by pre-application of a topical glucocorticoid. A vaginal ring (NUVARING) also is available that releases ethinyl estradiol (15 µg daily) and etonogestrel (an active metabolite of desogestrel; 120 µg daily). Each ring is used for 3 weeks, followed by a 1-week interval without the ring.

Besides providing highly effective (~99%) contraception when used properly, the combination estrogen/progestin formulations have a number of noncontraceptive benefits, including protection against certain cancers (e.g., ovarian, endometrial, colorectal), decreased iron-deficiency anemia secondary to menstrual blood loss, and decreased risk of fractures due to

osteoporosis. Combination oral contraceptives also are widely used for conditions such as endometriosis, dysmenorrhea, menorrhagia, irregular menstrual cycles, premenstrual dysphoric disorder, acne, and hirsutism (see “Endometriosis” and “Drug Therapy in Gynecology”).

Serious adverse effects of the combination estrogen/progestin contraceptive agents are relatively rare. Thromboembolic disease, largely due to the estrogenic component, is the most common serious side effect associated with oral contraceptive use. Estrogen concentration, the patient’s age, smoking, and inherited thrombophilias all influence the risk of developing thromboembolic disease in oral contraceptive users. The impact of combination oral contraceptives on breast cancer has been highly debated; although a meta-analysis that combined the results of published epidemiological studies concluded that the combination oral contraceptives did increase the risk of breast cancer (relative risk of 1.24; Collaborative Group on Hormonal Factors in Breast Cancer, 1996), studies conducted with the lower doses of hormones included in current formulations suggest that the risk of breast cancer is not increased (Marchbanks et al., 2002).

Other adverse effects include hypertension, edema, gallbladder disease, and elevations in serum triglycerides. These are discussed further in [Chapter 40](#). With pills containing drospirenone, which antagonizes the mineralocorticoid receptor, serum  $K^+$  should be monitored in women at risk for hyperkalemia (e.g., those on  $K^+$ -sparing diuretics or drugs that inhibit the renin–angiotensin system). The combination oral contraceptives are contraindicated in women with a history of underlying conditions such as thromboembolic disease, cerebrovascular disease, migraine headaches with aura, estrogen-dependent cancer, impaired hepatic function or active liver disease, undiagnosed uterine bleeding, and suspected pregnancy. In addition, patients with a history of gestational diabetes should be monitored closely, and drug cessation should be strongly considered in anticipation of events associated with an increased risk of venous thromboembolism (e.g., elective surgery).

### **Table 66–2 Brand Names and Formulations of Oral Contraceptives**

PRODUCT	BRAND NAME <sup>a</sup>	Estrogen (µg)	Progestin (mg)
<b>Combination<sup>a</sup> monophasic</b>

<b>Emergency contraception</b>			
Levonorgestrel	PLAN B	—	0.75 $\times$ 2 doses
Ulipristal (progesterone partial agonist)	ella; ellaOne	—	30 mg $\times$ 1 dose

Unless otherwise indicated, the products are packaged with 21 active (hormone-containing) pills and 7 placebo tablets. For formulations that differ from this standard (e.g., multiphasic pills, extended-cycle formulations), the numbers of tablets of each pill strength are indicated. <sup>a</sup>Some formulations also contain iron to diminish the risk of Fe-deficiency anemia; these are not listed separately here. <sup>b</sup>Combination formulations contain both an estrogen and a progestin. <sup>c</sup>Denotes continuous administration of active pills.

**Progestin-Only Contraceptives.** Progestin-only minipills contain derivatives of  $17\alpha$ -alkyl-19-nortestosterone but do not contain an estrogen. Although they do inhibit ovulation to some degree, their efficacy also reflects changes in the cervical mucus that inhibit fertilization and endometrial changes that inhibit implantation. They are slightly less effective than the combination estrogen/progestin formulations, particularly when doses are missed or the pill is taken at different times of the day, but provide an alternative in settings where estrogen-containing formulations are contraindicated. Their major adverse effect is breakthrough bleeding.

Progestins also are used for long-acting contraception. A depot formulation of medroxyprogesterone (DEPO-PROVERA) injected subcutaneously or intramuscularly provides effective contraception for 3 months. Its use has been associated with decreased bone mineral density, as noted by a black box warning in the product label. Teenagers and younger women who have not achieved maximal bone density may be particularly at risk, although the data suggest that bone density returns to pretreatment levels fairly quickly after drug cessation. Subdermal implants of progestin-impregnated rods provide effective contraception over several years. The only implant system currently approved in the U.S. is IMPLANON, which incorporates 3-ketodesogestrel, an active metabolite of desogestrel, into an inert matrix. The progestin is released slowly from the matrix to maintain a serum concentration considerably higher than that needed to suppress ovulation for 3 years. In most women, progestin concentrations are undetectable 1 week after surgical removal of the implant, and ovulation

occurs within 6 weeks. Intermittent breakthrough bleeding is the major undesirable effect; acne or weight gain also may occur.

An intrauterine device that releases levonorgestrel (MIRENA) provides highly effective contraception for up to 5 years. It achieves local progestin concentrations that are ~1000-fold higher than systemic levels and is thought to act predominantly to inhibit gamete function and survival via local changes in the cervical mucus. This medical device also is undergoing evaluation for other indications such as menorrhagia, endometriosis, and endometrial protection in menopausal women receiving estrogens (Mansour, 2007; see “Endometriosis”).

## Postcoital Contraception

Postcoital (or emergency) contraception is indicated for use in cases of mechanical failure of barrier devices or in circumstances of unprotected intercourse (Cheng et al., 2008). Because it is less effective than standard oral contraceptive regimens, it is not intended as a regular method of contraception. The mechanisms of action of the postcoital contraceptives are not fully understood, but their efficacy clearly cannot be accounted for solely by the inhibition of ovulation. Other potential mechanisms of action include effects on gamete function and survival and on implantation. These agents do not affect established pregnancies.

PLAN-B, which contains two tablets of the progestin levonorgestrel (0.75 mg each), is marketed specifically for postcoital contraception and may be obtained in the U.S. without a prescription by women  $\geq 18$  years of age. Treatment is most effective if the first dose is taken within 72 hours of intercourse, followed by a second dose 12 hours later; a single dose of 1.5 mg within 72 hours of intercourse appears to be equally effective. The levonorgestrel regimen has largely replaced the Yuzpe regimen (previously marketed in the U.S. as PREVEN), which combined an estrogen and a progestin and was associated with a lower efficacy and a higher incidence of nausea and vomiting.

Other options for postcoital contraception include mifepristone (MIFEPREX), which is not FDA-approved for this indication but is highly effective in oral doses ranging from 10-50 mg when taken within 5 days after unprotected intercourse (Cheng et al., 2008) and copper intrauterine devices when inserted within 4 days of unprotected intercourse. Mifepristone also

has abortifacient activity when used in a different treatment regimen (see “Pregnancy Termination”). The selective progesterone receptor modulator ulipristal (ella, ellaOne), was recently approved as an emergency contraceptive, effective up to 120 hours after unprotected intercourse; see [Chapter 40](#) for details.

## Pregnancy Termination

If contraception is not used or fails, either mifepristone (RU-486, MIFEPREX) or methotrexate (50 mg/m<sup>2</sup> intramuscularly or orally) can be used to terminate an unwanted pregnancy in settings outside surgical centers. A prostaglandin then is administered to stimulate uterine contractions and expel the detached conceptus; in the U.S., prostaglandins used include dinoprostone (PGE<sub>2</sub>; *PROSTIN E2*) administered vaginally or the PGE<sub>1</sub> analog misoprostol (CYTOTEC) given orally or vaginally, both of which are used off label for this purpose. Prostaglandins used in other countries include the PGE<sub>2</sub> analog sulprostone (NALADOR) and the PGE<sub>1</sub> analog gemeprost (CERVAGEM).

As approved by the FDA, mifepristone (600 mg) is taken for pregnancy termination within 49 days after the start of a woman’s last menstrual period. The synthetic PGE<sub>1</sub> analog misoprostol (400 µg) is administered orally 48 hours later; vaginal administration is at least as effective but is not FDA approved. Complete abortion using this procedure exceeds 90%; when termination of pregnancy fails or is incomplete, surgical intervention is required. Other published regimens include lower doses of mifepristone (200 or 400 mg) and different time intervals between the mifepristone and misoprostol. Finally, repeated doses of misoprostol alone (e.g., 800 µg vaginally or sublingually every 3 hours or every 12 hours for three doses) also have been effective in settings where mifepristone is unavailable. Vaginal bleeding follows pregnancy termination and typically lasts from 1-2 weeks but rarely (in 0.1% of patients) is severe enough to require blood transfusion. A high percentage of women also experience abdominal pain and uterine cramps, nausea and vomiting, and diarrhea secondary to the prostaglandin. Myocardial ischemia and infarction have been reported in association with sulprostone and gemeprost.

Mifepristone is a 17 $\alpha$ -alkyl-19-nortestosterone derivative that acts as a competitive antagonist at the progesterone receptor. The biological

mechanisms involved in the abortifacient actions of mifepristone are unclear. Its actions are associated with focal hemorrhage and breakdown of the stromal extracellular matrix that ultimately leads to the breakdown of the uterine endometrium. Inhibition of expression of stromal cell "tissue factor," the primary initiator of hemostasis, and activation of extracellular matrix proteases are thought to contribute to these effects. In addition, mifepristone increases the sensitivity of the uterus to the uterotonic effects of prostaglandins. Mifepristone is metabolized through a series of reactions initiated by hepatic CYP3A4, and interactions can occur with other drugs that are substrates for this enzyme (see [Chapters 6](#) and [40](#)). Women receiving chronic glucocorticoid therapy should not be given mifepristone because of its anti-glucocorticoid activity, and the drug should be used very cautiously in women who are anemic or receiving anticoagulants.

Methotrexate is a potent abortifacient, probably as a result of the ability of the placenta to concentrate  $\text{FH}_2\text{Glu}_n$  (dihydrofolate polyglutamate) and its analogs (see [Chapter 61](#)).

Because mifepristone carries a risk of serious, and sometimes fatal, infections and bleeding following its use for medical abortion, a black box warning has been added to the product labeling. Women receiving mifepristone should be informed of these risks and cautioned to seek immediate medical attention if symptoms or signs of these conditions occur. Fulminant septic shock associated with *Clostridium sordellii* infections may result and is attributable to the combined effects of uterine infection and inhibition of glucocorticoid action by mifepristone (Cohen et al., 2007). Patients who develop symptoms and signs of infection, especially a marked leukocytosis even without fever, should be treated aggressively with antibiotics effective against anaerobic organisms such as *C. sordellii* (e.g., penicillin, ampicillin, a macrolide, clindamycin, a tetracycline, or metronidazole).

## **DRUG THERAPY IN GYNECOLOGY**

Drugs used in the treatment of nonmalignant gynecological disorders include those that induce sexual differentiation in females with impaired biosynthesis of the sex steroid hormones; are used in assisted reproduction technology in infertile women; treat the various symptoms and signs that accompany menopause (e.g., hot flashes, dyspareunia, mood disorders, osteoporosis);

treat estrogen-dependent disorders such as endometriosis and uterine fibroids; and treat androgen-dependent conditions such as acne and hirsutism. Treatment of gynecological malignancies is discussed in Section VII.

## Induction of Sexual Maturation

A number of clinical disorders, including Turner's syndrome and other forms of gonadal dysgenesis, are associated with impaired production of ovarian steroids in phenotypic females. Such patients typically fail to develop secondary sexual characteristics at the normal time of puberty (sexual infantilism) or fail to have menses (primary amenorrhea). In these cases, steroid hormones are administered to induce development of the secondary sex characteristics; however, treatment is initiated only after the diagnosis is ascertained and underlying disorders that might respond to more specific therapy (e.g., prolactinomas) are excluded (see [Chapter 38](#)).

Types of estrogens used and the treatment regimens may vary by country or individual preference. Examples include conjugated estrogens, 0.3-1.25 mg; micronized  $17\beta$ -estradiol, 0.5-2.0 mg; ethinyl estradiol, 5-20  $\mu$ g; and transdermal  $17\beta$ -estradiol, 25-50  $\mu$ g. To achieve optimal breast development, treatment typically is initiated with a low dose of estrogen (e.g., conjugated estrogens at a starting dosage of 0.3 mg/day or ethinyl estradiol at 5  $\mu$ g/day) starting in patients between ages 10 and 12 years or immediately if the diagnosis is made after this age. After 3-6 months, the dosage is increased (e.g., 0.9-1.25 mg/day of conjugated estrogens or 20  $\mu$ g/day of ethinyl estradiol). Once this is achieved, a progestin (e.g., medroxyprogesterone, 10 mg/day, or micronized progesterone, 200-400  $\mu$ g/day) for 12 days each cycle is added to the regimen to optimize breast development and permit cyclical menses, thereby avoiding endometrial hyperplasia and its consequent risk of uterine cancer. Once menses are established, many clinicians will switch to a standard low-dose oral contraceptive pill or even may use an extended-cycle formulation.

Short stature, a universal feature of non-mosaic Turner's syndrome, usually is treated with human growth hormone, often together with an androgen such as oxandrolone (see [Chapter 41](#)). Initiating treatment with human growth hormone and androgen and delaying the onset of estrogen therapy generally produces a better growth response. Doses for growth hormone treatment in this context are higher than those in growth hormone-deficient children (e.g.,

67 µg/kg/day; see [Chapter 38](#) for further discussion of growth hormone replacement therapy).

## Menopause

Menopause refers to the permanent cessation of menstrual periods (i.e., for >12 months) resulting from the loss of ovarian follicular activity; it usually occurs when women are between 45 and 60 years of age (mean age of 50). The decline in estradiol levels produces a variety of symptoms and signs, including vasomotor disturbances (hot flashes or flushes), sweating, irritability, sleep disturbances, and atrophy of estrogen-dependent tissue. In addition, postmenopausal women are at increased risk for osteoporosis, bone fractures, and coronary heart disease and experience increased memory loss and other cognitive difficulties.

**Estrogen Therapy.** The observed estrogen deficiency associated with menopause, as well as a number of observational studies showing positive effects of estrogen replacement therapy on these parameters, led to widespread use of hormone replacement therapy in peri- and postmenopausal women. In 2001, 90 million prescriptions were filled for hormone replacement therapy.

The initial publication of data from the Women's Health Initiative (WHI), a large, randomized, placebo-controlled trial, dramatically altered therapeutic approaches to menopause. As expected, treatment of postmenopausal women with 0.625 mg of conjugated estrogen plus 2.5 mg of medroxyprogesterone (in women with a uterus) or with 0.625 mg of conjugated estrogen alone (in women lacking a uterus) improved bone mineral density and decreased the risk of fractures; a decreased risk of colorectal cancer also was seen. In addition, as might be expected, estrogen therapy in both the estrogen plus progestin and the estrogen-alone groups was associated with an increased incidence of deep venous thrombosis and stroke; unexpectedly, however, the incidence of breast cancer and coronary heart disease also increased in women receiving both estrogen and progestin (Rossouw et al., 2002; Rossouw et al., 2007). In a smaller subset of women >65 years of age, hormone therapy did not improve cognitive function or protect against dementia and, in fact, may have worsened the latter (Rapp et al., 2003; Shumaker et al., 2003). Based on these findings, it was recommended that

hormone replacement therapy not be used to decrease the risk of coronary heart disease, cognitive impairment, or dementia.

Since these data were published, some have questioned the general validity of the WHI findings. Concerns include the dose, mode of administration, and specific hormones used, as well as the preponderance of older women in the WHI population. In fact, subgroup analyses of the WHI data suggest that cardiovascular risk was not increased when hormone therapy was initiated within 10 years of menopause. Although *post hoc* analyses of clinical trials always are accorded less weight than primary outcomes, these findings provide some reassurance that the risks of estrogen therapy may be minimal in women who are perimenopausal or recently menopausal, the majority of those for whom such therapy is contemplated.

Available routes of estrogen administration for hormone replacement therapy ([Table 66–3](#)) include oral, transdermal (patch, gel, and spray), and vaginal (cream, ring, and tablets). In women who have undergone hysterectomy, estrogen alone is used. For women with an intact uterus, a progestin also is administered to oppose the proliferative effect of the estrogen on the uterine endometrium.

Typically, the estrogen and progestin are administered together daily without a break; rarely, a cyclic-sequential administration is used, with the estrogen administered daily for 21-28 days of a 28-day cycle and the progestin added during the last 10-12 days.

**Table 66–3 Brand Names and Formulations of Agents Used for Hormone Replacement Therapy**

PREPARATION	BRAND	DOSE (mg)	FREQUENCY	
<b>Oral estrogen (tablets)</b>				
Conjugated estrogens	CENESTIN ENJUVIA PREMARIN	0.3, 0.45, 0.625, 0.9, 1.25 0.625, 1.25, 1.5 0.75, 1.5 0.5, 1, 2 0.45, 0.9, 1.8 0.3, 0.625, 1.25, 2.5	1/day	
Estropipate	OGEN ORTHO-EST			
Micronized estrogen	ESTRACE			
Estradiol	FEMTRACE			
Esterified estrogens	MENEST			
<b>Transdermal estradiol</b>				
Patch	ALORA CLIMARA ESCLIM ESTRADERM MENOSTAR VIVELLE VIVELLE-DOT	0.025, 0.05, 0.075, 0.1 0.025, 0.0375, 0.05, 0.06, 0.075, 0.1 0.025, 0.0375, 0.05, 0.075, 0.1 0.05, 0.1 0.014 0.05, 0.1 0.025, 0.0375, 0.05, 0.075, 0.1	2/week 1/week 2/week 2/week 1/week 2/week 2/week	
Gel	DIVIGEL ELJESTRIN ESTROGEL	0.25, 0.5, 1 g/packet 0.87 g/pump 1.25 g/pump	1/day 1/day 1/day	
Emulsion	ESTRASORB	1.74 g/pouch	2/day	
Spray	EVAMIST	1.53 mg/spray	1-3 sprays/day	
<b>Vaginal estrogen</b>				
Estradiol	ESTRACE (cream) ESTRING (ring) FEMRING (ring) VAGIFEM (tabs)	0.1 mg/g 7.5 µg/24 hr 0.05, 0.1 mg/day 25 µg	1/day, then 1-3/week 1/90 days 1/3 months 1/day for 2 weeks, then 2/week	
Conjugated estrogens	PREMARIN (cream)	0.625 mg/g	1/day	
<b>Oral progestin</b>				
Norethindrone	AYGESTIN	5 mg	1/day	
Progesterone (micronized)	PROMETRIUM	100, 200 mg		
Medroxyprogesterone	PROVERA	2.5, 5, 10 mg		
<b>Oral estrogen plus progesterone</b>				
Estradiol/norethindrone	ACTIVELLA	1	0.5	1/day
Estradiol/drospirenone	ANGELIQ	1	0.5	
Ethinyl estradiol/norethindrone	FEMHRT	0.5	2.5 µg	
		1	5 µg	
<b>Transdermal estrogen plus progesterone</b>				
Estradiol/levonorgestrel	CLIMARA PRO	0.045 mg/day	0.015 mg/day	1/week
Estradiol/norethindrone	COMBIPATCH	0.05 mg/day	0.14 mg/day	2/week
		0.05 mg/day	0.25 mg/day	2/week

Finally, some clinicians use a long-cycle regimen, in which the estrogen is administered continuously over a 3-month cycle and the progestin is only added every third month.

Other therapies for vasomotor symptoms include phytoestrogens (e.g., soy products), herbal extracts (e.g., black cohosh), selective serotonin reuptake inhibitors (e.g., fluoxetine, controlled-release paroxetine, sertraline), clonidine, and gabapentin (Nelson, 2008). However, hormone replacement remains the most effective therapy for vasomotor symptoms in menopausal women, and it is reasonable, after a discussion of the relative risks and benefits, to consider hormone replacement therapy in this setting. Current recommendations advise using estrogen replacement at the lowest possible

effective dose and for the shortest duration to treat moderate to severe vasomotor symptoms and vaginal dryness. For vaginal dryness alone, topical preparations are preferred.

**Androgen Therapy.** Based on the roles of androgens in normal female physiology and the observed decrease in circulating androgen levels after menopause, some have proposed that therapy with androgens will improve parameters such as libido and sexual satisfaction. Given the lack of a clearly defined disorder related to androgen deficiency in women, the absence of long-term safety data, and the lack of an approved formulation in a dose appropriate for women, one panel of experts recently concluded that the routine treatment of postmenopausal women with androgens was inappropriate (Wierman et al., 2006).

## **Endometriosis**

Endometriosis is an estrogen-dependent disorder that results from endometrial tissue ectopically located outside of the uterine cavity (Farquhar, 2007). It predominantly affects women during their reproductive years, with a prevalence of 0.5-5% in fertile women and 25-40% in infertile women. Diagnosis typically is made at laparoscopy, either prompted by unexplained pelvic pain (dysmenorrhea or dyspareunia) or infertility. Although poorly understood, the infertility is thought to reflect involvement of the fallopian tubes with the underlying process and, possibly, impaired oocyte maturation.

Inasmuch as the proliferation of ectopic endometrial tissue is responsive to ovarian steroid hormones, many symptomatic approaches to therapy aim to produce a relatively hypoestrogenic state. Combination oral contraceptives have been standard first-line treatment for symptoms of endometriosis, and ample evidence from observational trials supports their benefit. The predominant mechanism of action is believed to be suppression of gonadotropin secretion, with subsequent inhibition of estrogen biosynthesis. Progestins (e.g., medroxyprogesterone, dienogest) also have been used to promote decidualization of the ectopic endometrial tissue. The levonorgestrel intrauterine system, which is approved for contraception, also has been used off label for this indication, as well as for menorrhagia.

As an alternative to steroid hormones, stable GnRH agonists can suppress gonadotropin secretion and thus effect medical castration. Drugs that carry an indication for endometriosis include leuprolide (LUPRON), goserelin

(ZOLADEX), and nafarelin (SYNAREL); other GnRH agonists also may be used off label for this purpose (see [Chapter 38](#)). Due to significant decreases in bone density and symptoms of estrogen withdrawal, “add-back” therapy with either a low-dose synthetic estrogen (e.g., conjugated equine estrogens, 0.625-1.25 mg) or a high-dose progestin (e.g., norethindrone, 5 mg) has been used when the duration of therapy has exceeded 6 months (Olive, 2008). A number of clinical trials have shown that such combination regimens can provide symptomatic relief in patients with endometriosis. Danazol (DANOCRINE), a synthetic androgen that inhibits gonadotropin production via feedback inhibition of the pituitary-ovarian axis, also is FDA-approved for endometriosis therapy; it rarely is used now because of its significant adverse effects, including hirsutism and elevation of hepatic transaminases. In Europe and elsewhere, the antiprogestin gestrinone has been employed. By virtue of their ability to block the terminal step in estrogen biosynthesis, inhibitors of aromatase are under investigation for endometriosis (reviewed by Barbieri, 2008), often in conjunction with GnRH agonists, combination oral contraceptives, or a progestin.

When fertility is the goal, no medical therapy has proven efficacy, and surgical approaches (e.g., laparoscopic excision of endometriotic implants, lysis of adhesions) or assisted reproduction technology (e.g., *in vitro* fertilization) should be considered.

## **Hirsutism**

Hirsutism, or increased hair growth in the male distribution, affects ~10% of women of reproductive age. It can be a relatively benign, idiopathic process or part of a more severe disorder of androgen excess that includes overt virilization (voice deepening, increased muscle mass, male pattern balding, clitoromegaly) and often results from ovarian or adrenal tumors. Specific etiologies associated with hirsutism include congenital adrenal hyperplasia, polycystic ovary syndrome (PCOS), and Cushing’s syndrome. After excluding serious pathology such as a steroid-producing malignancy, the treatment largely becomes empirical (Martin et al., 2008). Nonpharmacological approaches include bleaching, depilatory treatments (e.g., shaving, treatment with hair-removing chemicals), or methods that remove the entire hair follicle (e.g., plucking, electrolysis, laser ablation).

Pharmacotherapy is directed at decreasing androgen production and action. Initial therapy often involves treatment with combination oral contraceptive pills, which suppress gonadotropin secretion and thus the production of ovarian androgens. The estrogen also increases the concentration of sex hormone-binding globulin, thereby diminishing the free concentration of testosterone. The full effect of this suppression may take up to 6-9 months. Some experts prefer combination oral contraceptives containing progestins with lower androgenic potential, such as norgestimate or drospirenone; the latter may actually have an anti-androgen effect. Despite this preference, all combination oral contraceptives will decrease plasma testosterone levels and can be used effectively. GnRH agonists downregulate gonadotropin secretion and also may be used to suppress ovarian steroid production.

In patients who fail to respond to ovarian suppression, efforts to block androgen action may be effective. Spironolactone (ALDACTONE), a mineralocorticoid-receptor antagonist, and flutamide (EULEXIN; see [Chapter 41](#)) inhibit the androgen receptor. In Europe and elsewhere, cyproterone (50-100 mg/day) is used as an androgen-receptor blocker, often in conjunction with a combination oral contraceptive. Efficacy in clinical trials also has been seen with finasteride (PROSCAR), an inhibitor of the type 2 isozyme of 5 $\alpha$ -reductase that blocks the conversion of testosterone to dihydrotestosterone. Male offspring of women who become pregnant while taking any of these androgen inhibitors are at risk of impaired virilization secondary to impaired synthesis or action of dihydrotestosterone (FDA category X). The antifungal ketoconazole (NIZORAL), which inhibits CYP steroid hydroxylases (see [Chapters 42](#) and [57](#)), also can block androgen biosynthesis but may cause liver toxicity. Finally, topical eflornithine (VANIQA), an ornithine decarboxylase inhibitor, has been used with some success to decrease the rate of facial hair growth, thus reducing the frequency with which procedures such as laser ablation are needed for hair removal.

## **Infections of the Female Reproductive Tract**

A variety of pathogens can cause infections of the female reproductive tract that range from vaginitis to pelvic inflammatory disease; [Table 66-4](#) contains current recommendations for pharmacotherapy of selected sexually transmitted gynecological infections as issued by the Centers for Disease

Control and Prevention (Workowski and Berman, 2006; [www.cdc.gov/mmwr/preview/mmwrhtml/rr5511a1.htm](http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5511a1.htm)). Of note, the recommended therapy for gonococcal infections has been updated due to increasing resistance of *Neisseria gonorrhoeae* to fluoroquinolones. The individual drugs used for systemic or topical therapy are described in more detail in Section VI.

Infections have been implicated as important factors in preterm labor, as discussed further in “Prevention or Arrest of Preterm Labor.”

## Fertility Induction

Infertility (i.e., the failure to conceive after 1 year of unprotected sex) affects ~10-15% of couples in developed nations and is increasing in incidence as more women choose to delay childbearing until later in life. The major impediment to pregnancy in an infertile couple can be attributed primarily to the woman in approximately one-third, to the man in approximately one-third, and to both in approximately one-third. The likelihood of a successful pharmacological induction of fertility in these couples depends greatly on the reason for the infertility. For example, a woman with tubal obstruction secondary to previous pelvic inflammatory disease is highly unlikely to become pregnant following drug therapy, whereas a woman with impaired ovulation secondary to a prolactin-secreting pituitary adenoma usually will become pregnant following suppression of prolactin secretion with a dopamine agonist (see [Chapter 38](#)).

The evaluation of an infertile couple is guided by the history and physical examination, which are augmented by focused laboratory evaluation. Defined abnormalities in the male partner that lead to impaired fertility (e.g., hypogonadism, Y chromosome microdeletions, Klinefelter’s syndrome) typically are detected by analysis of a semen sample; most often, male infertility is idiopathic. The medical therapy for some of these conditions is discussed in [Chapters 38](#) and [41](#), while assisted reproduction technology interventions such as intracytoplasmic sperm injection can be used for disorders that severely impair sperm count.

Anovulation accounts for ~50% of female infertility and is a major focus of pharmacological interventions used to achieve conception. Thus, whether a woman is ovulating is a key question. Although a history of regular cyclic bleeding is strong presumptive evidence for ovulation, assessment of urine

LH levels with an over-the-counter kit (see [Chapter 38](#)) or measurement of the serum progesterone levels during the luteal phase provides more definitive information. In those infertile women who ovulate, analysis of the patency of the fallopian tubes and the structure of the uterus is an important part of the diagnostic evaluation.

A number of approaches have been used to stimulate ovulation in anovulatory women. Often, a stepwise approach is taken, initially using simpler and less expensive treatments, followed by more complex and expensive regimens if initial therapy is unsuccessful. In obese patients with PCOS, the inclusion of lifestyle modifications directed at weight loss is warranted based on the association of obesity with anovulation, pregnancy loss, and complicated pregnancies (e.g., gestational diabetes, pre-eclampsia). Definitive evidence that weight loss improves fertility is not currently available (Thessaloniki ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2008).

**Clomiphene.** Clomiphene citrate (*CLOMID*, *SEROPHENE*) is a potent anti-estrogen that primarily is used for treatment of anovulation in the setting of an intact hypothalamic—pituitary axis and adequate estrogen production (e.g., PCOS). By inhibiting the negative feedback effects of estrogen at hypothalamic and pituitary levels, clomiphene increases follicle-stimulating hormone (FSH) levels—typically by ~50%—and thereby enhances follicular maturation (see [Chapter 40](#)). The drug is relatively inexpensive, orally active, and requires less extensive monitoring than do other fertility protocols.

A typical regimen is 50 mg/day orally for 5 consecutive days starting between days 2 and 5 of the cycle in women who have spontaneous uterine bleeding or following a bleed induced by progesterone withdrawal in women who do not. If this regimen fails to induce ovulation, the dose of clomiphene is increased, first to the FDA-approved maximum of 100 mg/day and possibly to higher levels of 150 or 200 mg/day. Although clomiphene is effective in inducing ovulation in perhaps 75% of women, successful pregnancy ensues in only 40-50% of those who ovulate. This has been attributed to clomiphene's inhibition of estrogen action on the endometrium, resulting in an environment that is not optimal for fertilization and/or implantation.

**Table 66–4 Sexually Transmitted Gynecological Infections and Recommended Therapies**

<b>Genital ulcers</b>	
Chancroid	Azithromycin, 1 g PO single dose <i>or</i> Ceftriaxone, 250 mg IM single dose <i>or</i> Ciprofloxacin, 500 mg PO bid × 3 days <i>or</i> Erythromycin base, 500 mg PO tid × 7 days
<b>Genital herpes</b>	
First infection	Acyclovir, 400 mg PO tid × 7-10 days <i>or</i> Acyclovir, 200 mg PO 5 times daily for 7-10 days <i>or</i> Famciclovir, 250 mg PO tid for 7-10 days <i>or</i> Valacyclovir, 1 g PO bid × 7-10 days
Suppression	Acyclovir, 400 mg PO bid <i>or</i> Famciclovir, 250 mg PO bid <i>or</i> Valacyclovir, 500 mg PO once daily
Recurrent	Same drugs at lower dose for more prolonged duration
Granuloma inguinale	Doxycycline, 100 mg PO bid × >21 days
Lymphogranuloma venereum	Doxycycline, 100 mg PO bid × 21 days
<b>Syphilis</b>	
Primary/secondary	Benzathine penicillin, 2.4 million units IM, single dose
Tertiary	Benzathine penicillin, 2.4 million units IM, 3 weekly injections

### Vaginal discharge

<i>Trichomonas</i>	Metronidazole, 2 g PO single dose <i>or</i> Tinidazole, 2 g PO, single dose
Bacterial vaginosis	Metronidazole, 500 mg PO bid × 7 days <i>or</i> Metronidazole gel, 5 g intravaginally daily × 5 days <i>or</i> Clindamycin cream, 5 g intravaginally at bedtime × 7 days
<i>Candida</i>	Topical: Butoconazole, clotrimazole, miconazole, nystatin, tioconazole, terconazole Oral: Fluconazole, 150 mg PO, single dose

### Urethritis/Cervicitis

Non-gonococcal	Azithromycin, 1 g PO single dose <i>or</i> Doxycycline, 100 mg PO bid × 7 days
Chlamydia	Azithromycin, 1 g PO single dose <i>or</i> Doxycycline, 100 mg PO × 7 days
Gonococcal	Ceftriaxone, 125 mg IM single dose <i>or</i> Cefixime, 400 mg PO single dose

### Pelvic Inflammatory Disease

Parenteral regimen	Cefotetan, 2 g IV every 12 hours <i>or</i> Cefoxitin, 2 g IV every 6 hours + Doxycycline, 100 mg PO or IV every 12 hours × 14 days
Oral regimen	Ceftriaxone, 250 mg IM single dose + Doxycycline, 100 mg PO bid × 14 days <i>or</i> Cefoxitin, 2 g IV single dose + Probenecid + Doxycycline, 100 mg PO bid × 14 days

PO, orally; IM, intramuscularly; IV, intravenously; bid, twice daily; tid, three times daily.

Untoward effects of clomiphene include the ovarian hyperstimulation syndrome (OHSS; < 1%; see “Gonadotropins”) and increased incidences of multifetal gestations (twins in ~5-10% and more than two babies in ~0.3% of pregnancies), ovarian cysts, hot flashes, headaches, and blurred vision. A few studies have suggested that prolonged use (e.g., ≥12 cycles) may increase the risk of ovarian and endometrial cancer; thus, the recommended maximum number of cycles is six. Clomiphene should not be administered to pregnant women (FDA category X) due to reports of teratogenicity in animals, although there is no definitive evidence of this in humans (Elizur and Tulandi, 2008).

Tamoxifen appears to be as effective as clomiphene for ovulation induction but is not FDA-approved for this indication. It has been used off label as an alternative in women who suffer intolerable side effects (e.g., hot flashes) with clomiphene.

**Gonadotropins.** The preparations of gonadotropins available for clinical use are detailed in [Chapter 38](#) and include gonadotropins purified from human menopausal or pregnant urine and those prepared by recombinant DNA

technology. They should be administered by physicians experienced in the treatment of infertility or reproductive endocrine disorders. Although most clearly indicated for ovulation induction in anovulatory women with hypogonadotropic hypogonadism secondary to hypothalamic or pituitary dysfunction, gonadotropins also are used to induce ovulation in women with PCOS who do not respond to clomiphene (see “Clomiphene”) and also are used, generally after a trial of clomiphene, in women who are infertile despite normal ovulation.

Given the marked increases in maternal and fetal complications associated with multifetal gestation, the goal of ovulation induction in anovulatory women is to induce the formation and ovulation of a single dominant follicle; generally, the increased risks of twin gestation will be accepted if two follicles are present.

As shown in [Figure 66–1](#), a typical regimen for ovulation induction is to administer 75 IU of FSH daily in a “low-dose, step-up protocol.” After several days of stimulation, the serum estradiol is measured; the target levels of estradiol range from 500-1500 pg/mL, with lower levels indicating inadequate gonadotropin stimulation and higher values portending an increased risk of OHSS. If the estradiol level is too low, then the daily dose of FSH can be increased (the “step-up”) in increments of 37.5 or 75 IU. Ovaries are examined by ultrasonography every 2-3 days to evaluate follicle maturation. The finding of a follicle  $\geq 17$  mm in diameter indicates that adequate follicular development has occurred. If three or more follicles of this size are present, gonadotropin therapy generally is stopped to decrease the likelihood of developing OHSS, and barrier contraception is used to prevent pregnancy, thereby avoiding multifetal pregnancy. In the “high-dose, step-down” protocol, higher initial doses of FSH are used, and the dose is decreased thereafter. Anecdotal evidence suggests that this regimen is associated with an increased risk of OHSS.

To complete follicular maturation and induce ovulation, human chorionic gonadotropin (hCG, 5000-10,000 IU) is given 1 day after the last dose of gonadotropin. Fertilization of the oocyte(s) at 36 hours after hCG administration then is attempted, either by intercourse or intrauterine insemination. Despite the precautions outlined above, gonadotropin-induced ovulation results in multiple births in up to 10-20% of cases due to the

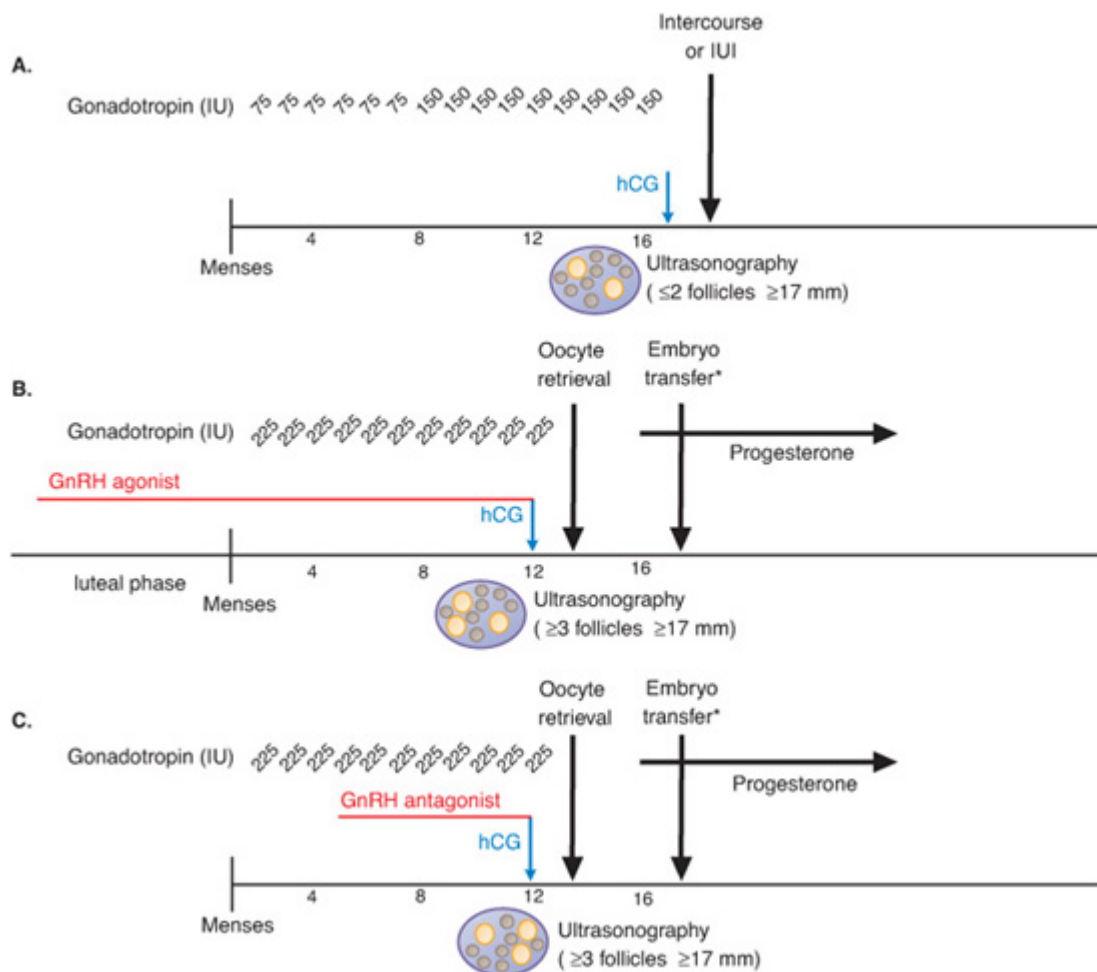

pharmacologically induced development of more than one pre-ovulatory follicle and the release of more than one ovum.

Gonadotropin induction also is used for ovarian stimulation in conjunction with *in vitro* fertilization (IVF; [Figure 66-1](#); Macklon et al., 2006). In this setting, larger doses of FSH (typically 225-300 IU/day) are administered to induce the maturation of multiple (ideally at least 5 and up to 20) oocytes that can be retrieved for IVF and intrauterine transfer. To prevent the LH surge and subsequent premature luteinization of the ovarian follicles, gonadotropins typically are administered in conjunction with a GnRH agonist. The length of the IVF protocol is predicated by the initial flare of gonadotropin secretion that occurs in response to the GnRH agonists. In the long protocol, the agonist is started in the luteal phase of the previous cycle (generally on cycle day 21) and then maintained until the time of hCG injection to induce ovulation. Alternatively, in the “flare” protocol, the GnRH agonist is started on cycle day 2 (immediately after the start of menses), and gonadotropin injections are added 1 day later. Adequate follicle maturation with the latter regimen typically takes 10-12 days after gonadotropin therapy is initiated.

GnRH antagonists also can be used to inhibit endogenous LH secretion. Because they do not transiently increase gonadotropin secretion, they can be initiated later in the cycle in a “short protocol.” Current regimens include daily injection in a dose of 0.25 mg (ganirelix [ANTAGON] or cetrorelix [CETROTIDE]) starting on the fifth or sixth day of gonadotropin stimulation or a single dose of 3 mg of cetrorelix administered on day 8 or 9 of the late follicular phase.

Using either the long or short protocols, hCG (at typical doses of 5000-10,000 IU of urine-derived product or 250 µg of recombinant hCG) is given to induce final oocyte development, and the mature eggs are retrieved from the pre-ovulatory follicles at 32-36 hours thereafter. The ova are retrieved transvaginally guided by ultrasonography and fertilized *in vitro* with sperm (IVF) or by intracytoplasmic sperm injection; one or two embryos then are transferred to the uterus 3-5 days after fertilization. With these approaches, the increased risk of multifetal gestations is related to the number of embryos that are transferred to the woman. To diminish this risk, there is a trend, particularly in Europe, toward transferring only one embryo per cycle.

Because of the inhibitory effects of GnRH agonists or antagonists on pituitary gonadotropes, the secretion of LH that normally sustains the corpus luteum after ovulation does not occur. Repeated injections of hCG, while sustaining the corpus luteum, may increase the risk of OHSS. Thus, standard IVF regimens typically provide exogenous progesterone replacement to support the fetus until placenta acquires the biosynthetic capacity to take over this function; regimens include progesterone in oil (50-100 mg/day intramuscularly) or micronized progesterone (180-300 mg twice daily vaginally). Vaginal preparations containing 100 mg (ENDOMETRIN) or 90 mg (PROCHIEVE, CRINONE) of micronized progesterone are approved for administration two or three times daily as part of IVF and other fertility technologies.

**Figure 66–1.** Schematic diagram of idealized regimens using exogenous gonadotropins for fertility induction. **A.** Step-up regimen for ovulation induction. After menses, daily injections of gonadotropin (75 IU) are started.

Follicle maturation is assessed by serial measurement of plasma estradiol and follicle size, as discussed in the text. If an inadequate response is seen, the dose of gonadotropin is increased to 112 or 150 IU/day. When one or two follicles have achieved a size of  $\geq 17$  mm in diameter, final follicle maturation and ovulation are induced by injection of human chorionic gonadotropin (hCG). Fertilization then is achieved at 36 hours after hCG injection by intercourse or intrauterine insemination (IUI). If more than two mature follicles are seen, the cycle is terminated and barrier contraception is used to avoid triplets or higher degrees of multifetal gestation. **B.** Long protocol for ovarian hyperstimulation using gonadotropin-releasing hormone (GnRH) agonist to inhibit premature ovulation, followed by *in vitro* fertilization (IVF). After the GnRH agonist has inhibited endogenous secretion of gonadotropins, therapy with exogenous gonadotropins is initiated. Follicle maturation is assessed by serial measurements of plasma estradiol and follicle size by ultrasonography. When three or more follicles are  $\geq 17$  mm in diameter, then ovulation is induced by injection of hCG. At 32-36 hours after the hCG injection, the eggs are retrieved and used for IVF. Exogenous progesterone is provided to promote a receptive endometrium, followed by embryo transfer at 3-5 days after fertilization. **C.** Protocol for ovarian hyperstimulation in an IVF protocol using a GnRH antagonist. The cycle duration is shorter because the GnRH antagonist does not induce a transient flare of gonadotropin secretion that might disrupt the timing of the cycle, but many other elements of the cycle are analogous to those in B. IU, intrauterine.

Aside from the attendant complications of multifetal gestation, the major side effect of gonadotropin treatment is OHSS. This potentially life-threatening event is believed to result from increased ovarian secretion of substances that increase vascular permeability and is characterized by rapid accumulation of fluid in the peritoneal cavity, thorax, and even the pericardium. Symptoms and signs include abdominal pain and/or distention, nausea and vomiting, diarrhea, dyspnea, oliguria, and marked ovarian enlargement on ultrasonography. OHSS can lead to hypovolemia, electrolyte abnormalities, acute respiratory distress syndrome, thromboembolic events, and hepatic dysfunction.

In ovulation induction, incipient OHSS should be suspected if routine laboratory investigation reveals the presence of more than four to six

follicles >17 mm or a serum estradiol level of >1500 pg/mL; in this setting, hCG should be withheld and barrier contraception used. For controlled ovarian hyperstimulation in anticipation of IVF, a higher risk of OHSS is present if the number of follicles >15 mm exceeds 15-20 or if the plasma level of estradiol is >5000 pg/mL. In an effort to avoid overt hyperstimulation, the FSH can be withheld for a day or two ("coasting") if the plasma level of estradiol is near the top of this range. The rationale for this approach is that larger follicles become relatively gonadotropin independent and thus will continue to mature, while the smaller follicles undergo atresia in response to gonadotropin deprivation. In either case, ovulation induction with recombinant LH, which has a considerably shorter  $t_{1/2}$  than hCG, or with a GnRH agonist may diminish the incidence of OHSS without requiring cancellation of the cycle.

The potential deleterious effects of gonadotropins are debated. Some studies have suggested that gonadotropins are associated with an increased risk of ovarian cancer, but this conclusion is controversial (Brinton et al., 2005). Similarly, although IVF and the subsequent embryo manipulation may be associated with abnormal imprinting that increases the risk of developmental syndromes (e.g., Angelman's and Beckwith-Wiedemann syndromes; Lawrence and Moley, 2008; Niemitz and Feinberg, 2004), the risk is small, and there is no evidence that the gonadotropins themselves or components of the IVF process increase the rate of congenital abnormalities in babies born from stimulated oocytes.

***Insulin Sensitizers.*** PCOS affects 4-7% of women of reproductive age and is the most frequent cause of anovulatory infertility. Inasmuch as PCOS patients often exhibit hyperinsulinemia and insulin resistance, insulin sensitizers such as metformin have been evaluated for their effects on ovulation and fertility (see [Chapter 43](#) for a general discussion of drugs used to increase insulin sensitivity). Although several small trials suggested that metformin increased ovulation in PCOS patients relative to placebo, a recent, well-designed trial failed to demonstrate a significant effect of metformin on fertility (Legro et al., 2007); metformin was less effective than clomiphene in inducing ovulation, promoting conception, or improving live birth rates, and there was no benefit of combining metformin with clomiphene on live births, except possibly in women resistant to clomiphene. Thus, except in women who exhibit glucose intolerance, the consensus is that

metformin generally should not be used for fertility induction in women with PCOS (Thessaloniki ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2008).

Thiazolidinediones also have been evaluated for their ability to induce ovulation in PCOS patients. One trial demonstrated that troglitazone significantly increased ovulation in PCOS patients compared to placebo controls; this drug was withdrawn from the market due to safety issues, and attention therefore has turned to the use of rosiglitazone (AVANDIA) and pioglitazone (ACTOS), other members of the thiazolidinedione family. Preliminary results suggest that these latter drugs may increase ovulation in PCOS patients, but definitive data are not available. Given the recent association of thiazolidinediones with an increased risk of congestive heart failure and myocardial ischemia, there is considerable reluctance to use these drugs in this setting.

***Aromatase Inhibitors.*** Aromatase inhibitors (e.g., letrozole [FEMARA], 5 mg/day for 5 days) are under evaluation as potential drugs for infertility. By inhibiting estrogen biosynthesis, these drugs decrease estrogen negative feedback and thus increase FSH levels and stimulate follicle development. In 2005, the manufacturer of letrozole issued a statement that letrozole is not indicated for ovulation induction or other uses in premenopausal women. Another aromatase inhibitor, anastrozole (ARIMIDEX), also has been used off label for ovulation induction. Some data suggest that anastrozole is less effective than clomiphene in inducing follicle maturation but more likely to lead to pregnancy.

## **DRUG THERAPY IN OBSTETRICS**

### **General Principles of Drug Therapy of Pregnant Women**

The processes of evaluating potential adverse effects of various drugs in preclinical and clinical trials are described in [Chapter 1](#). Unfortunately, these trials often do not provide sufficient information regarding safety in pregnant women or children. Individuals at the extremes of the age spectrum are particularly vulnerable to the toxic effects of drugs (see [Chapter 4](#)). The very young are susceptible due either to incomplete development of certain organs (e.g., the kidney) or the lack of expression of certain drug-metabolizing or

transport proteins that play key pharmacokinetic roles (Kearns et al., 2003); the elderly are at increased risk due to age-related changes in body composition, organ function, and drug-metabolizing systems, all of which delay drug clearance (Mangoni and Jackson, 2003).

In pregnant women, the placenta provides a barrier for the transfer of certain drugs from the mother to the fetus (e.g., drug transporters expel toxic natural products and related drugs from the placenta, aromatase converts maternal androgen to estrogens); however, many compounds can freely cross the placental barrier and access the fetal circulation. The teratogenic effects of thalidomide on limb formation, alcohol on development of the CNS and cognition, and diethylstilbestrol (DES) on genital development in males and females and on the subsequent development of vaginal and cervical carcinomas in female offspring are stark reminders of the dangers of fetal exposure to drugs. In the clinical setting, there is no direct method for determining fetal exposure to a drug. Drug concentration over time in the mother's systemic circulation is the major determinant of this exposure, but other contributing factors include the size, solubility, ionization, and protein binding of the drug; its active transport into and out of the placental circulation; and the rate of fetal clearance, which includes first-pass metabolism by the placenta.

Based on the relative paucity of human data on the teratogenic effects of drugs and the limited reliability of animal models, a fundamental tenet in treating pregnant women is to minimize, whenever possible, the exposure of mother and fetus to drugs; when necessary, one should preferentially use those drugs that have the best record of safety in pregnant women without adverse developmental effects on the fetus. Of equal importance, substances of abuse (e.g., cigarettes, alcohol, illegal drugs) should be avoided and, whenever possible, eliminated before conception. In addition, all pregnant women should take a multivitamin containing 400 µg of folic acid daily to diminish the incidence of neural tube defects. The greatest concern is during the period of organogenesis in the first trimester, when a number of the most vulnerable tissues are formed. Cancer chemotherapy drugs cannot be given with reasonable safety during the first trimester, but most cytotoxics may be administered without teratogenic effects and with maintenance of pregnancy in the third trimester (see [Chapters 61-63](#)).

Drugs that are used to promote fertility are a special case, since they, by nature of their use, will be present in the mother at the time of conception. Fortunately, available evidence largely supports the safety of fertility agents for fetal development, although there have been data suggesting increased risk with certain agents (e.g., neural tube defects and hypospadias associated with clomiphene; Elizur and Tulandi, 2008).

The FDA assigns different levels of risk to drugs for use in pregnant women, as listed in [Table 66–5](#).

**Table 66–5 FDA Use-in-Pregnancy Ratings**

**Category A: Controlled studies show no risk.** Adequate, well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester of pregnancy.

**Category B: No evidence of risk in humans.** Adequate, well-controlled studies in pregnant women have not shown an increased risk of fetal abnormalities despite adverse findings in animals, or, in the absence of adequate human studies, animal studies show no fetal risk. The chance of fetal harm is remote, but remains a possibility.

**Category C: Risk cannot be ruled out.** Adequate, well-controlled human studies are lacking, and animal studies have shown a risk to the fetus or are lacking as well. There is a chance of fetal harm if the drug is administered during pregnancy, but the potential benefits may outweigh the potential risk.

**Category D: Positive evidence of risk.** Studies in humans, or investigational or post-marketing data, have demonstrated fetal risk. Nevertheless, potential benefits from the use of the drug may outweigh the potential risk. For example, the drug may be acceptable if needed in a life-threatening situation or serious disease for which safer drugs cannot be used or are ineffective.

**Category X: Contraindicated in pregnancy.** Studies in animals or humans, or investigational or post-marketing reports, have demonstrated positive evidence of fetal abnormalities or risk that clearly outweighs any possible benefit to the patient.

Certain drugs are so toxic to the developing fetus that they must never be administered to a pregnant woman (category X); in some cases (e.g., thalidomide, retinoids), the potential for fetal harm is so great that multiple

forms of effective contraception must be in place before the drug is initiated. For other drugs, the risk of adverse effects on the fetus may range from category A (drugs that have not been proven to have adverse effects on the fetus despite adequate investigation) to category C (drugs with risks that sometimes may be justified based on the severity of the underlying condition (e.g., hydralazine for pregnancy-induced hypertension,  $\beta$  adrenergic receptor agonists for premature labor; see “Pregnancy-Induced Hypertension/Pre-eclampsia” and “Tocolytic Therapy for Established Preterm Labor”). Unfortunately, the FDA listings may be overly simplistic or outdated for a given drug; for example, oral contraceptives are listed as category X, even though considerable data now indicate that birth defects are not increased in women taking oral contraceptives at the time of conception.

Nursing mothers constitute a second special situation with respect to potential adverse effects of drugs. Some drugs may interfere with milk production and/or secretion (e.g., estrogen-containing oral contraceptives) and thus should be avoided if possible in mothers who wish to breastfeed. Other drugs may be secreted into breast milk and expose the baby to potentially toxic levels during the vulnerable perinatal period (Ito and Lee, 2003). The amount of drug that is secreted in breast milk, like the amount that crosses the placenta, depends on drug characteristics such as size, ionization, protein binding, and pharmacokinetics of clearance. The American Academy of Pediatrics Committee on Drugs periodically reviews agents transferred into human milk and their effects on the infant or on lactation (Hale, 2005). Product information sheets that provide available information regarding the potential for adverse effects of specific drugs on breastfed infants should be consulted before prescribing medications to nursing mothers.

## **Pregnancy-Induced Hypertension/Pre-eclampsia**

Hypertension affects up to 10% of pregnant women in the U.S.; with the increasing prevalence of hypertension in the general population and the tendency to delay childbearing, drug therapy for maternal hypertension likely will be given greater consideration in the future. A consensus panel has issued guidelines for the management of hypertension in pregnancy (National High Blood Pressure Education Program Working Group, 2000).

Hypertension that precedes pregnancy or manifests before 20 weeks of gestation is believed to overlap considerably in pathogenesis with essential

hypertension. These patients appear to be at increased risk for gestational diabetes and need careful monitoring. In contrast, pregnancy-induced hypertension, or pre-eclampsia, generally presents after 20 weeks of gestation as a new-onset hypertension with proteinuria (>300 mg of urinary protein/24 hours); pre-eclampsia is thought to involve placenta-derived factors that affect vascular integrity and endothelial function in the mother, thus causing peripheral edema, renal and hepatic dysfunction, and in severe cases, seizures (Maynard et al., 2008). Chronic hypertension is an established risk factor for pre-eclampsia, but there is no conclusive evidence that anti-hypertensive therapy during pregnancy affects the incidence or outcome of pre-eclampsia in women with mild to moderate hypertension (Abalos et al., 2007). Nonetheless, the consensus panel recommended initiation of drug therapy in women with a diastolic blood pressure >105 mm Hg or a systolic blood pressure >160 mm Hg (National High Blood Pressure Education Program Working Group, 2000). If severe pre-eclampsia ensues, with marked hypertension and evidence of end-organ damage, then termination of the pregnancy by delivery of the baby is the treatment of choice, provided that the fetus is sufficiently mature to survive outside the uterus. If the baby is very preterm, then hospitalization and pharmacotherapy (expectant management) may be employed in an effort to permit further fetal maturation *in utero*.

Many pregnant women already carry the diagnosis of hypertension and are on drug therapy, which may be continued with careful monitoring, provided that blood pressure control is effective. In this setting, however, some drugs that commonly are used for hypertension in non-pregnant patients (e.g., angiotensin-converting enzyme inhibitors, angiotensin-receptor antagonists) should not be used due to unequivocal evidence of adverse fetal effects in animal models and humans (Podymow and August, 2008). Many experts will convert the patient to the centrally acting  $\alpha$  adrenergic agonist  $\alpha$ -methyldopa (ALDOMET) at an initial dose of 250 mg orally twice daily (FDA category B), which rarely is used for hypertension in non-pregnant patients. Other drugs with reasonable evidence of safety (category C) also may be used, including the combination  $\alpha_1$ -selective,  $\beta$ -nonselective adrenergic antagonist labetalol (TRANDATE; 100 mg twice daily) and the  $\text{Ca}^{2+}$  channel blocker nifedipine (PROCARDIA XL, ADALAT CC; 30 mg once daily).

Similar considerations apply in previously normotensive women who develop pre-eclampsia;  $\alpha$ -methyldopa again is a reasonable choice for outpatient management if the blood pressure exceeds the threshold for therapy. If severe pre-eclampsia or impending labor requires hospitalization, blood pressure can be controlled acutely with hydralazine (5 or 10 mg intravenously or intramuscularly, with repeated dosing at 20-minute intervals depending on blood pressure response) or labetalol (20 mg intravenously, with dose escalation to 40 mg at 10 minutes if blood pressure control is inadequate).

In addition to drugs for blood pressure control, women with severe pre-eclampsia or those who have central nervous system manifestations, such as headache, visual disturbance, or altered mental status, are treated as inpatients with magnesium sulfate, based on its documented efficacy in seizure prevention and lack of adverse effects on the mother or baby (Altman et al., 2002). Such treatment also should be considered for postpartum women with central nervous system manifestations, because ~20% of episodes of eclampsia occur in women who are more than 48 hours after delivery.

## **Prevention or Arrest of Preterm Labor**

**Scope of the Problem and Etiology.** Preterm birth, defined as delivery before 37 weeks of gestation, occurs in >10% of pregnancies in the U.S. and is increasing in frequency; it is associated with significant complications, such as neonatal respiratory distress syndrome, pulmonary hypertension, and intracranial hemorrhage. Although incompletely understood, risk factors for preterm labor include multifetal gestation, premature rupture of the membranes, intrauterine infection, and placental insufficiency. The more premature the baby, the greater the risk of complications, prompting efforts to prevent or interrupt preterm labor.

The therapeutic objective in preterm labor is to delay delivery so that the mother can be transported to a regional facility specializing in the care of premature babies and supportive agents can be administered; such supportive treatments include glucocorticoids to stimulate fetal lung maturation (see [Chapter 42](#)) and antibiotics (e.g., erythromycin, ampicillin) to diminish the frequency of neonatal infection with group B  $\beta$ -hemolytic *Streptococcus*. Based on concerns over deleterious effects of antibiotic therapy, it is

essential that antibiotics not be administered indiscriminately to all women thought to have preterm labor, but rather be reserved for those with premature rupture of the membranes and evidence of infection.

**Prevention of Preterm Labor: Progesterone Therapy.** Progesterone levels in some species diminish considerably in association with labor, whereas administration of progesterone inhibits the secretion of pro-inflammatory cytokines and delays cervical ripening. Thus, progesterone and its derivatives have long been advocated to diminish the onset of preterm labor in women at increased risk due to previous preterm delivery. Despite considerable controversy, recent randomized trials have revived interest in this approach. One drug used in this setting is  $17\alpha$ -hydroxyprogesterone at a dose of 250 mg administered weekly by intramuscular injection (Meis et al., 2003). Vaginal administration of progesterone (200 mg each night) also was used in one clinical trial with apparent efficacy (Fonseca et al., 2007). One clinical trial suggested that progesterone administration in this setting was associated with an increased incidence of gestational diabetes (Rebarber et al., 2007), and the role of progesterone prophylaxis during pregnancy remains to be established.

**Tocolytic Therapy for Established Preterm Labor.** Because preterm birth typically is heralded by the uterine contractions of labor, the inhibition of these contractions, or tocolysis, has been a focus of therapy (Simhan and Caritis, 2007). Although tocolytic agents delay delivery in ~80% of women, they neither prevent premature births nor improve adverse fetal outcomes such as respiratory distress syndrome. Thus, while widely employed, they should be viewed as temporizing agents, as described in “Prevention of Preterm Labor: Progesterone Therapy.”

Specific tocolytic agents include  $\beta$  adrenergic receptor agonists,  $MgSO_4$ ,  $Ca^{2+}$  channel blockers, COX inhibitors, oxytocin-receptor antagonists, and nitric oxide donors. The mechanisms of action of these agents are illustrated in [Figure 66–2](#).

The  $\beta$  adrenergic receptor agonists relax the myometrium by activating the cyclic AMP-PKA signaling cascade that phosphorylates and inactivates myosin light-chain kinase, a key enzyme in uterine contraction. Ritodrine, a selective  $\beta_2$  agonist, was specifically developed as a uterine relaxant and remains the only tocolytic drug to have gained FDA approval; it was

voluntarily withdrawn from the U.S. market. Terbutaline (BRETHINE), which is FDA-approved for asthma, has been used off label for this purpose and can be administered orally, subcutaneously, or intravenously. Terbutaline may delay births, but only during the first 48 hours of treatment, and is associated with a number of adverse maternal effects, including tachycardia, hypotension, and pulmonary edema.

Similarly,  $\text{Ca}^{2+}$  channel blockers inhibit the influx of  $\text{Ca}^{2+}$  through depolarization-activated, voltage-sensitive  $\text{Ca}^{2+}$  channels in the plasma membrane, thereby preventing the activation of myosin light-chain kinase and the stimulation of uterine contraction. Nifedipine (PROCARDIA, ADALAT), the  $\text{Ca}^{2+}$  channel blocker used most commonly for this purpose, can be administered parenterally or orally. Relative to  $\beta_2$  adrenergic agonists, nifedipine is more likely to improve fetal outcomes and less likely to cause maternal side effects.

Based on the role of prostaglandins in uterine contraction, cyclooxygenase inhibitors (e.g., indomethacin) have been used to inhibit preterm labor, and some data suggest that they may reduce the number of preterm births. Because they also can inhibit platelet function and induce closure *in utero* of the ductus arteriosus, these inhibitors should not be employed in term pregnancies (or in pregnancies beyond 32 weeks of gestation, when the risk of severe complications of prematurity is relatively lower). Short courses of treatment (<72 hours) pose less risk for impaired circulation in the fetus.

Atosiban (TRACTOCILE), a nonapeptide analog of oxytocin, competitively inhibits the interaction of oxytocin with its membrane receptor on uterine cells and thereby decreases the frequency of uterine contractions. Although atosiban increased the number of women who remained undelivered for 48 hours and is widely used in Europe, it is not FDA-approved in the U.S.

Nitric oxide is a potent vasodilator and smooth muscle relaxant, and drugs such as nitroglycerin and other nitrates that increase its levels are used to treat myocardial ischemia (see [Chapter 28](#)). Both intravenous nitroglycerin and transdermal nitrate preparations have been evaluated in clinical trials to inhibit preterm labor. The major adverse effect is maternal hypotension.

Despite numerous clinical trials, the superiority of any one therapy has not been established, and none of the drugs has been shown definitively to improve fetal outcome. Thus, despite widespread and enthusiastic use by

some centers, many experts do not endorse the routine use of tocolytic agents. Recent meta-analyses of published reports concluded that  $\text{Ca}^{2+}$  channel blockers and atosiban (not available in the U.S.) provided the best balance of successfully delayed delivery with lesser risks to the mother and baby (reviewed by Iams et al., 2008).

**Figure 66-2.** Sites of action of tocolytic drugs in the uterine myometrium. The elevation of cellular  $\text{Ca}^{2+}$  promotes contraction via the  $\text{Ca}^{2+}$ /calmodulin-dependent activation of myosin light chain kinase (MLCK). Relaxation is promoted by the elevation of cyclic nucleotides (cAMP and cGMP) and their activation of protein kinases, which cause phosphorylation/inactivation of MLCK. Pharmacological manipulations to reduce myometrial contraction include:

- inhibiting  $\text{Ca}^{2+}$  entry ( $\text{Ca}^{2+}$  channel blockers,  $\text{Mg}_2\text{SO}_4$ )
- reducing mobilization of intracellular  $\text{Ca}^{2+}$  by antagonizing GPCR-mediated activation of the  $G_q$ -PLC- $\text{IP}_3$ - $\text{Ca}^{2+}$  pathway (with antagonists of the FP and OXT receptors) or reducing production of the FP agonist,  $\text{PGF}_{2\alpha}$  (with COX inhibitors)

- enhancing relaxation by elevating cellular cyclic AMP (with  $\beta_2$  adrenergic agonists that activate  $G_s$ -AC) and cyclic GMP (with NO donors that stimulate soluble guanylyl cyclase)

sGC, soluble guanylyl cyclase; AC, adenylyl cyclase; FP, the  $\text{PGF}_{2\alpha}$  receptor; OXT, the oxytocin receptor; PLC, phospholipase C; COX, cyclooxygenase.

## Initiation of Labor

Labor induction is indicated when the perceived risk of continued pregnancy to the mother or fetus exceeds the risks of delivery or pharmacological induction. Such circumstances include premature rupture of the membranes, isoimmunization, fetal growth restriction, uteroplacental insufficiency (as in diabetes, pre-eclampsia, or eclampsia), and gestation beyond 42 weeks. Before inducing labor, it is essential to verify that the fetal lungs are sufficiently mature and to exclude potential contraindications (e.g., abnormal fetal position, evidence of fetal distress, placental abnormalities, or previous uterine surgery predisposing to uterine rupture).

Labor induction also is used increasingly in the absence of specific criteria listed above; such elective inductions may be predicated in part on matters of convenience for the mother or medical team. Collectively, induced or augmented labor now accounts for ~20% of all deliveries in the U.S., two-thirds of which are for nonmedical reasons.

**Prostaglandins and Cervical Ripening.** Prostaglandins play key roles in parturition (see [Chapter 33](#)). Thus,  $\text{PGE}_1$ ,  $\text{PGE}_2$ , and  $\text{PGF}_{2a}$  are used to facilitate labor by promoting ripening and dilation of the cervix. They can be administered either orally or via local administration (either vaginally or intracervically). The ability of certain prostaglandins to stimulate uterine contractions also makes them valuable agents in the therapy of postpartum hemorrhage (see “Prevention/Treatment of Postpartum Hemorrhage”). Although prostaglandins are widely employed for cervical ripening, their effectiveness versus that of oxytocin alone in diminishing the need for cesarean section in labor induction has not been definitively established.

Available preparations include dinoprostone ( $\text{PGE}_2$ ), which is FDA approved to facilitate cervical ripening. Dinoprostone is formulated as a gel for intracervical administration via syringe in a dose of 0.5 mg (PREPIDIL) or

as a vaginal insert (pessary) in a dose of 10 mg (CERVIDIL); the latter is designed to release active PGE<sub>2</sub> at a rate of 0.3 mg/hr for up to 12 hours and should be removed at the onset of labor or 12 hours after insertion. No more than three doses should be used in a 24-hour period. Dinoprostone should not be used in women with a history of asthma, glaucoma, or myocardial infarction. The major adverse effect is uterine hyperstimulation, which may be reversed more rapidly using the vaginal insert by removing it with the attached tape.

Misoprostol (CYTOTEC), a synthetic derivative of PGE<sub>1</sub>, is FDA-approved for the prevention and treatment of acid peptic disease in patients who are receiving nonsteroidal anti-inflammatory agents (see [Chapter 34](#)). Its use in medical abortion is discussed earlier in “Pregnancy Termination.” It also is used off label either orally or vaginally to induce cervical ripening; typical doses are 100 µg (orally) or 25 µg (vaginally); an advantage of misoprostol in this setting is its considerably lower cost. The vaginal dose typically is repeated every 4-6 hours depending on labor progression. Adverse effects include uterine hyperstimulation and, rarely, uterine rupture. Most experts therefore do not use misoprostol for cervical ripening in women who have had previous cesarean section or other uterine surgery. Misoprostol should be discontinued for at least 3 hours before initiating oxytocin therapy.

**Oxytocin.** The structure and physiology of oxytocin are discussed in [Chapter 38](#). This section presents therapeutic uses of oxytocin in obstetrics, which include the induction of labor, the augmentation of labor that is not progressing, and the prophylaxis and/or treatment of postpartum hemorrhage. Although widely used, oxytocin recently was added to a list of drugs “bearing a heightened risk of harm” (Clark et al., 2009), and its role and specific application to most deliveries in the U.S. remain open to debate. Thus, careful review of the appropriate indications for oxytocin administration and attention to the dose and progress of labor during induction are essential.

**Labor Induction.** Oxytocin (PITOCIN, SYNTOCINON) is the drug of choice for labor induction; for this purpose, it is administered by intravenous infusion of a diluted solution (typically 10 mIU/mL), preferably via an infusion pump. Current protocols start with an oxytocin dose of 6 mIU/minute, followed by advancement of dose as needed (in one protocol, increases of 6 mIU/minute can be made every 40 minutes if labor is not progressing in a satisfactory

manner). Although there are little definitive data, 40 mIU/minute is a reasonable maximum dose, although doses of up to 72 mIU/minute have been used with apparent safety in some studies. Uterine hyperstimulation should be avoided; however, if it occurs, as evidenced by too-frequent contractions (more than five contractions in a 10-minute interval) or the development of uterine tetany, the oxytocin infusion should be discontinued immediately. Because the  $t_{1/2}$  of intravenous oxytocin is relatively short (12-15 minutes), the hyperstimulatory effects of oxytocin will dissipate fairly rapidly after the infusion is discontinued. Thereafter, the infusion can be reinitiated at a dose of half that at which hyperstimulation occurred and increased cautiously as tolerated.

Because of its structural similarity to vasopressin, oxytocin at higher doses activates the vasopressin  $V_2$  receptor and has antidiuretic effects. Particularly if hypotonic fluids (e.g., dextrose in water) are infused too liberally, water intoxication may result in convulsions, coma, and even death. Vasodilating actions of oxytocin also have been noted, particularly at high doses, which may provoke hypotension and reflex tachycardia. Deep anesthesia may exaggerate the hypotensive effect of oxytocin by preventing the reflex tachycardia.

***Augmentation of Dysfunctional Labor.*** Oxytocin also is used when spontaneous labor is not progressing at an acceptable rate. To augment hypotonic contractions in dysfunctional labor, an infusion rate of 10 mIU/minute typically is sufficient; doses in excess of 40 mIU/minute rarely are effective when lower concentrations fail. As with labor induction, potential complications of uterine overstimulation include trauma of the mother or fetus due to forced passage through an incompletely dilated cervix, uterine rupture, and compromised fetal oxygenation due to decreased uterine perfusion. Oxytocin usually is effective when there is a prolonged latent phase of cervical dilation or when, in the absence of cephalo-pelvic disproportion, there is an arrest of dilation or descent.

## **Prevention/Treatment of Postpartum Hemorrhage**

Postpartum hemorrhage is a significant problem in developed nations and is of even greater importance in developing countries. After delivery of the fetus or after therapeutic abortion, a firm, contracted uterus greatly reduces the incidence and extent of hemorrhage. Oxytocin (10 IU intramuscularly)

often is given immediately after delivery to help maintain uterine contractions and tone. Alternatively, oxytocin (20 IU) is diluted in 1 L of intravenous solution and infused at a rate of 10 mL/minute until the uterus is contracted. The infusion rate then is reduced to 1-2 mL/minute until the mother is ready for transfer to the postpartum unit. Carbetocin, a longer-acting derivative of oxytocin, is under evaluation in clinical trials to prevent or treat postpartum hemorrhage; a dose of 100 µg is given intravenously (Leung et al., 2006).

Ergot alkaloids markedly increase the motor activity of the uterus. Although their capacity to induce sustained uterine tetany precludes their use in the induction or facilitation of labor, they are used to prevent or treat postpartum hemorrhage in normotensive women. In this setting, the preferred ergot alkaloids are ergonovine (*ergotrate*) or its methyl analog methylergonovine (*METHERGINE*). They are administered intramuscularly or intravenously, exhibit rapid onsets of action (2-3 minutes intramuscularly, <1 minute intravenously), and their effects persist for 45 minutes to 3 hours depending on the route of administration. Adverse effects include nausea and vomiting, elevated blood pressure, and decreased pain threshold requiring analgesia.

Alternatively, the PGE<sub>1</sub> analog misoprostol (600 µg administered orally or sublingually) may be used off label to stimulate uterine contractions and prevent or treat postpartum hemorrhage. Although meta-analyses suggest that it may be slightly less effective than oxytocin, the low cost and lack of need for refrigeration or sterile needles may make misoprostol the preferred agent for use in developing nations. Other approaches under investigation include recombinant factor VIIa and balloon tamponade.

## *Chapter 67*

# **Environmental Toxicology: Carcinogens and Heavy Metals**

**Michael C. Byrns and Trevor M. Penning**

Humans are exposed to chemicals from their environment daily. Fortunately, mammals have evolved mechanisms to protect themselves from toxic effects of many exogenous chemicals, including the xenobiotic transport and metabolic mechanisms described in [Chapters 4-7](#). While the human body is relatively well adapted to deal with xenobiotics, there are situations in which such environmental agents may cause significant toxicity. The industrial revolution and the development of chemical industries have increased human exposures to chemicals that were previously infrequent or absent. Occupational exposures to xenobiotics are of particular concern because workers often will be exposed to specific chemicals at concentrations that are orders of magnitude higher than those to which the general population is exposed. Increasing concern about environmental toxicants has stimulated interest and research in environmental toxicology, the study of how chemicals in our environment adversely affect human health, and in occupational toxicology, the study of how chemicals in the workplace affect human health. Myriad authoritative textbooks are available in these areas. This chapter does not attempt a thorough coverage; rather, it sets forth a few basic principles, briefly discusses carcinogens and chemoprevention, and then focuses on the pharmacotherapy of heavy metal intoxication.

## **ENVIRONMENTAL RISK ASSESSMENT AND RISK MANAGEMENT**

When assessing the risks of environmental exposures to xenobiotics, many of the same principles discussed in [Chapter 4](#) for drug toxicity apply; there are, however, significant differences. With environmental exposures, one has to consider population exposures to low-dose toxicants over long periods of time. Thus, one must give more attention to the low end of the dose-response curve, using experiments based on chronic exposures. Particular attention is

given to the potential for individuals with higher susceptibility. Unlike drugs, which are given to treat a specific disease and will have benefits that outweigh the risks, environmental toxicants usually are only harmful. In addition, exposures to environmental toxicants usually are involuntary, there is uncertainty about the severity of their effects, and people are much less willing to accept their associated risks.

Two complimentary approaches are used to predict the toxic effects of environmental exposures: epidemiology and toxicology. Epidemiologists monitor health effects in humans and use statistics to associate those effects with exposure to an environmental stress, such as a toxicant. Toxicologists perform laboratory studies to try to understand the potential toxic mechanisms of a chemical to predict whether it is likely to be toxic to humans. Each of these approaches has strengths and weaknesses, and information from both is integrated into environmental risk assessment. Risk assessment is used to develop management approaches, such as laws and regulations, to limit exposures to environmental toxicants to a level that is considered safe.

### **Epidemiological Approaches to Risk Assessment**

Epidemiologists use multiple approaches to assess the risks of human environmental exposures (Gordis, 2008). The disadvantage of these approaches is the variability between people in their exposures and genetics, which results in confounding effects. Epidemiologists cannot control the environment or the genetics of the populations being studied. For example, generally individuals are simultaneously exposed to more than one environmental toxicant.

Because of the difficulties in assessing human exposures and the long times required to clinically observe effects on health, epidemiologists rely on biomarkers in risk assessment. There are three different types of biomarkers: biomarkers of *exposure*, biomarkers of *toxicity*, and biomarkers of *susceptibility*. Biomarkers of exposure usually are measurements of toxicants or their metabolites in blood, urine, or hair. Blood and urine concentrations measure recent exposures, while hair levels measure exposure over a period of months. An example of an unusual exposure biomarker is X-ray fluorescent measurement of bone lead levels, which estimates lifetime exposure to lead. Biomarkers of toxicity are used to measure toxic effects at a subclinical level and include measurement of liver enzymes in the serum,

changes in the quantity or contents of urine, and performance on specialized exams for neurological or cognitive function. Biomarkers of susceptibility are used to predict which individuals are likely to develop toxicity in response to a given chemical. Examples include single nucleotide polymorphisms in genes for metabolizing enzymes involved in the activation or detoxification of a toxicant. Some biomarkers simultaneously provide information on exposure, toxicity, and susceptibility. For example, the measurement in the urine of N7-guanine adducts from aflatoxin B<sub>1</sub> provides evidence of both exposure and a toxic effect (in this case, DNA damage). These types of biomarkers are particularly valuable because they can support a proposed mechanism of toxicity.

Several types of epidemiological studies are used to assess risks, each with its own set of strengths and weaknesses. Ecological studies correlate frequencies of exposures and health outcomes between different geographical regions. These studies are inexpensive and can detect rare outcomes but are prone to confounding variables, including population migration. Cross-sectional studies examine the prevalence of exposures and outcomes at a single point in time. Such studies are an inexpensive way to determine an association but do not provide a temporal relationship and are not effective for establishing causality. They also can be subject to bias, as a perceived health outcome might cause someone to eliminate his exposure. Case-control studies start with a group of individuals affected by a disease, which then is matched to another group of unaffected individuals for known confounding variables. Questionnaires often are used to evaluate past exposures. This method also is relatively inexpensive and is good for examining rare outcomes because the endpoint is known. However, case-control studies rely on assessments of past exposures that often are unreliable and can be subject to bias. Prospective cohort studies measure exposures in a large group of people and follow that group for a long time to measure health outcomes. These studies are not as susceptible to confounding variables and bias and are good at establishing causality. However, they are extremely expensive, particularly when measuring very rare outcomes, because a large study population is required to observe sufficient disease to obtain statistical significance. One of the key types of human studies used in drug development is the randomized clinical trial (discussed in [Chapter 1](#)). These studies cannot be used to directly measure the effects of environmental toxicants (for

obvious ethical reasons) but can be used to examine the effectiveness of an interventional strategy for reducing both exposure and disease.

### **Toxicological Approaches to Risk Assessment**

Toxicologists use model systems, including experimental animals, to examine the toxicity of chemicals and predict their effect on humans (Faustman and Omenn, 2008). The significance of these model systems to human health is not always established. Toxicologists also test chemicals at the high end of the dose-response curve in order to see enough occurrences of an outcome to obtain statistical significance. As a result, there often is uncertainty about the effects of very low doses of chemicals. To determine the applicability of model studies, toxicologists study the mechanisms involved in the toxic effects of chemicals, with the goal of predicting whether that mechanism would occur in humans.

To predict the toxic effects of environmental chemicals, toxicologists perform subchronic (3 months of treatment for rodents) and chronic studies (2 years for rodents) in at least two different animal models. Subchronic experiments provide a model for occupational exposures, while chronic experiments are used to predict effects from lifetime exposures to chemicals in food or the environment. Doses for these studies are based on shorter preliminary studies, with the goal of having one concentration that does not have a significant effect, one concentration that results in statistically significant toxicity at the low end of the dose-response curve, and one or more concentrations that will have moderate-to-high levels of toxicity. A theoretical dose-response curve for an animal study is shown in [Figure 67-1](#). An animal study provides two numbers that estimate the risk from a chemical. The *no observed adverse effect level* (NOAEL) is the highest dose used that does not result in a statistically significant increase in negative health outcomes. The *lowest observed adverse effect level* (LOAEL) is the lowest dose that results in a significant increase in toxicity. The NOAEL is divided by 10 for each source of uncertainty to determine a reference dose (RfD), which is commonly used as a starting point for determining regulations on human exposures to chemicals. The modifiers used to determine the RfD are based on the uncertainties between the experimental and human exposure. The most common modifiers used are for interspecies variability (human to animal) and interindividual variability (human to human), in which case  $RfD = NOAEL/100$ . Other modifiers can be used to

account for specific experimental uncertainties. When a NOAEL is unavailable, a LOAEL may be used, in which case another 10-fold uncertainty factor is used. The use of factors of 10 in the denominator for determination of RfD is an application of the “precautionary principle,” which attempts to limit human exposure by assuming a worst-case scenario for each unknown variable (Faustman and Omenn, 2008).

**Figure 67–1 LOAEL and NOAEL.** The theoretical dose-response curve from an animal study demonstrates the *no observed adverse effect level* (NOAEL) and the *lowest observed adverse effect level* (LOAEL). Below the NOAEL level, there is considerable uncertainty as to the shape of the response curve. It could continue linearly to reach a threshold dose (T) where there would be no harmful effects from the toxicant, or it could have a number of different possible inflection points. Each of these curves would have very different impacts on human populations. \*Statistically significant.

A major concern with animal studies is that they do not detect effects at low concentrations. Typically, they are designed to obtain statistical significance with a 10% increase in an outcome. As a result, there is considerable uncertainty about what occurs below that level, as

demonstrated in [Figure 67–1](#). Toxicologists often assume that there is a threshold dose (T), below which there is no toxicity. This condition is true when there are cellular defenses that prevent toxicity at concentrations below a given level but that can be overwhelmed. Thresholds usually are observed when the toxic effects of a chemical are the result of direct cell death. Many carcinogens and other toxicants with specific molecular targets (e.g., lead) do not exhibit a threshold. Ideally, mechanistic studies should be done to predict which dose-response curve is most likely to fit a given chemical.

Toxicologists perform a variety of mechanistic studies to understand how a chemical might cause toxicity. Computer modeling using a compound's three-dimensional structure to determine quantitative structure-activity relationships (QSARs) is commonly performed on both drugs and environmental chemicals. QSAR approaches can determine which chemicals are likely to exhibit toxicities or bind to specific molecular targets. Cell-based approaches in prokaryotes and eukaryotes are used to determine whether a compound damages DNA or causes cytotoxicity. DNA damage and the resulting mutagenesis often are determined with the Ames test. The Ames test uses *Salmonella typhimurium* strains with specific mutations in the gene needed to synthesize histidine. These strains are treated with chemicals in the presence or absence of a metabolic activating system, usually the supernatant fraction from homogenized rat liver. If a compound is a mutagen in the Ames test, it reverts the mutation in the histidine operon and allows the bacteria to form colonies on plates with limited histidine. Gene chip microarrays assess gene expression in cells or tissues from animals treated with a toxicant and provide a very useful tool to identify the molecular targets and pathways altered by toxicant exposures. The susceptibility of knockout mice to a toxicant can help to determine whether the knocked-out genes are involved in the metabolic activation and detoxification of a given toxicant.

### **Integrated Risk Assessment and Risk Management**

Regulatory bodies at local, state, national, and international levels all are involved in limiting the adverse effects of chemicals. In the U.S., several federal agencies are involved, depending on the source of the exposure. The U.S. Food and Drug Administration (FDA) regulates the safety of drugs, the food supply, cosmetics, and now tobacco products. The Occupational Safety and Health Administration (OSHA) regulates workplace exposures. The U.S. Environmental Protection Agency (EPA) regulates exposures from other

environmental sources, particularly the air and water. Regulators use epidemiological and toxicological data to estimate the risks from an exposure and come up with a level they consider to be reasonably safe. Regulators can nominate toxicants for a comprehensive study by the National Toxicology Program if there are insufficient toxicological data. The final stages of risk assessment and risk management are not based entirely on science; politics and economics also help determine which regulations are enacted. Ultimately, the social, economic, and political benefits predicted to result from limiting human exposure to a given toxicant are weighed against the corresponding costs.

## **Interventions for Environmental Exposure: Pharmacology and Prevention**

There is considerable interest in pharmacological approaches to prevent disease from environmental exposures. However, pharmacological interventions for chronic environmental exposures remain more of a goal than a reality. There are numerous hurdles for treatment of exposure to environmental toxicants. Because exposures occur over long periods of time, treatments must reverse existing preclinical toxicities or provide protection for a long time. If a pharmaceutical is to be given chronically or in the absence of disease, the extent of side effects and toxicity should be much less than for a drug being given acutely to treat disease. Currently, the most effective approaches for preventing diseases associated with chronic exposures to chemicals are primary prevention and nutrition. Pharmaceuticals can be useful for preventive strategies against chronic exposures (e.g., nicotine replacement therapy in smoking cessation). Ongoing research also is examining pharmacological approaches to prevent cancer in humans exposed to chemical carcinogens. One class of environmental toxicant for which there are drugs available to prevent disease is metals. However, in general, these drugs, known as metal chelators, are only effective against acute, high-dose metal exposure and either have no effect, or actually worsen, toxicity under the low-dose chronic exposures most commonly encountered from the environment.

## **CARCINOGENS AND CHEMOPREVENTION**

# Carcinogenesis

Many environmental compounds increase the risk of developing cancer; these chemicals are called carcinogens (Wogan et al., 2004; Klaunig and Kamendulis, 2008). The International Agency for Research on Cancer (IARC) classifies compounds into groups based on risk assessments using human, animal, and mechanism data. Chemicals in group 1 are known human carcinogens; group 2A includes chemicals that probably are carcinogenic in humans; group 2B chemicals possibly are carcinogenic in humans; group 3 chemicals lack data to suggest a role in carcinogenesis; and group 4 are those with data indicating they are unlikely to be carcinogens. Some important group 1 carcinogens and their sources are given in [Table 67–1](#).

**Table 67–1 Examples of Important Carcinogens**

CARCINOGEN CLASS	EXAMPLE	SOURCE	MECHANISM
<i>Genotoxic</i>			
Nitrosamines	Nicotine-derived nitrosaminoketone (NNK)	Tobacco products	Metabolic activation to form DNA adducts
Polycyclic aromatic hydrocarbons	Benzo[a]pyrene	Fossil fuel combustion, tobacco smoke, charbroiled food	Metabolic activation to form DNA adducts or ROS
Aromatic amines	2-Aminonaphthalene	Dyes	Metabolic activation to form DNA adducts
Fungal toxins	Aflatoxin B <sub>1</sub>	Corn, peanuts, and other food	Metabolic activation to form DNA adducts
<i>Non-genotoxic</i>			
Liver toxicants	Ethanol	Beverages, environment	Toxicity and compensatory proliferation; depletion of GSH
Phorbol esters	Tetradecanoyl phorbol acetate	Horticulture; rubber and gasoline production	Activation of PKC isoforms
Estrogens	Diethylstilbestrol	Drugs, environment	Activation of estrogen-receptor signaling
Metals	Arsenic	Environment, occupation	Inhibition of DNA repair; activation of signal transduction pathways
Irritants	Asbestos	Environment, occupation	Stimulation of inflammation; formation of ROS
Dioxins	TCDD	Waste incineration, herbicides, paper-pulp bleaching	Activation of the aryl hydrocarbon receptor

\*Compounds in this table are classified as group 1 carcinogens by the International Agency for Research on Cancer (IARC), with the exception of the phorbol esters, which have not been examined. TCDD, 2,3,7,8 tetrachlorodibenzo-p-dioxin; ROS, reactive oxygen species; GSH, glutathione; PKC, protein kinase C.

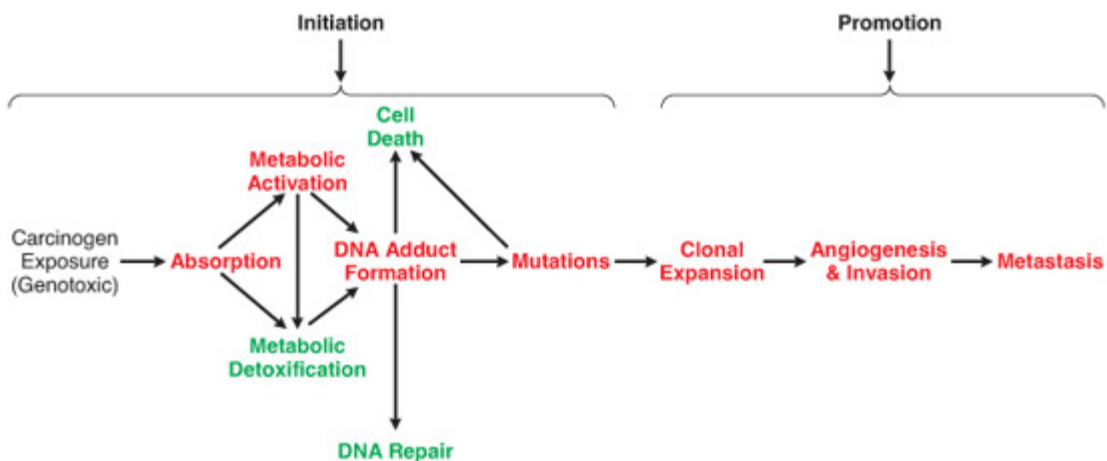

The transformation of a normal cell to a malignancy is a multi-stage process, and exogenous chemicals can act at one or more of these stages ([Figure 67–2](#)). A classic model of chemical carcinogenesis is tumor initiation followed by tumor promotion. In this model, a tumor initiator causes gene mutations that increase the ability of cells to proliferate and avoid apoptosis. A tumor promoter does not directly modify genes but changes signaling pathways and/or the extracellular environment to cause initiated cells to proliferate, invade surrounding tissue, and increase access to blood vessels. Although this model is an oversimplification of the many

processes of carcinogenesis, it demonstrates the types of changes that must occur to transit a normal cell into tumorigenesis.

Chemical carcinogens cause cancer through genotoxic and non-genotoxic mechanisms ([Figure 67-2](#)). Genotoxic carcinogens induce tumor formation through damage to DNA. Typically, genotoxic carcinogens undergo metabolism in a target tissue to a reactive intermediate. This reactive intermediate can directly damage DNA via covalent reaction to form a DNA adduct. Alternatively, it can indirectly damage DNA through the formation of reactive oxygen species (ROS), which can oxidize DNA or form lipid peroxidation products that react with DNA (Mena et al., 2009).

Benzo[a]pyrene, a key carcinogen in tobacco smoke, is an example of a genotoxic carcinogen that forms both direct DNA adducts and ROS. Benzo[a]pyrene is oxidized by CYPs to a 7,8-dihydrodiol, which represents a proximate carcinogen (a more carcinogenic metabolite). This metabolite can either undergo a second oxidation step by a CYP to form a diol epoxide, which readily reacts with DNA, or it can undergo oxidation by aldo-keto reductases to form a catechol, which will redox cycle to form ROS (Conney, 1982; Penning, 2009).

If DNA damage from a genotoxic carcinogen is not repaired prior to DNA replication, a mutation can result. If this mutation is in a key tumor suppressor gene or proto-oncogene, it provides advantages in proliferation or survival. Alternatively, if the mutation is in a DNA repair gene, the mutation increases the probability that other mutations will occur. Given mutations in enough key genes and the right environment, a cell will proliferate faster than surrounding normal cells and possibly develop into malignant cancer. Genotoxic carcinogens are tumor initiators.

**Figure 67–2 Carcinogenesis: initiation and promotion.** There are many steps that occur between the exposure to a genotoxic carcinogen and the development of cancer. Processes in red lead to the development of cancer, while those in green reduce the risk. Non-genotoxic carcinogens act by enhancing steps leading to cancer and/or inhibiting protective processes. A chemopreventive agent acts by inhibiting steps leading to cancer or by increasing protective processes.

Non-genotoxic carcinogens increase the incidence of cancer without damaging DNA. There are a number of possible non-genotoxic mechanisms, most of which are classified as tumor promotion. Many non-genotoxic carcinogens bind to receptors that stimulate proliferation or other tumor-promoting effects, such as tissue invasion or angiogenesis. For example, phorbol esters mimic diacylglycerol and activate PKC isoforms. This in turn stimulates MAP kinase pathways, leading to proliferation, invasiveness, and angiogenesis (see [Chapter 3](#)). In most normal cells, prolonged activation of this pathway stimulates apoptosis, but cells with defective apoptotic mechanisms due to preceding mutation(s) are resistant to this effect. Estrogenic carcinogens activate estrogen receptor- $\alpha$  (ER $\alpha$ ) and stimulate proliferation and invasiveness of estrogen responsive cells. Chronic inflammation is another mechanism of non-genotoxic carcinogenesis. Like phorbol esters, inflammatory cytokines stimulate PKC signaling, leading to proliferation, invasiveness, and angiogenesis. Irritants such as asbestos are examples of carcinogens that work through inflammation. Chronic exposure to hepatotoxic chemicals (or chronic liver diseases) also causes non-genotoxic carcinogenesis by stimulating compensatory proliferation to repair the liver damage. This damage and repair process increases the likelihood of DNA damage becoming a mutation, causes chronic inflammation, and selects for cells that proliferate faster or are less sensitive to apoptosis.

Tumor initiation also may occur through non-genotoxic mechanisms. For example, some heavy metals do not directly react with DNA but interfere with proteins involved in DNA synthesis and repair, increasing the likelihood that an error will be made during replication. Non-genotoxic carcinogens also can cause heritable changes to gene expression by altering the methylation state of cytosines in 5'-CpG-3 islands of gene promoters, thus acting as tumor initiators. Methylation can silence tumor suppressor genes, while demethylation of proto-oncogenes can increase their expression.

# Chemoprevention

Drugs that interfere with the carcinogenic process to prevent cancer before it is diagnosed are termed chemopreventive agents (Szabo, 2006; William et al., 2009). The chemoprevention concept was pioneered during the 1960s by Wattenberg and others, who observed that dietary constituents, such as *t*-butyl hydroquinone, could prevent cancer in rodents (Wattenberg, 1966). Chemoprevention strategies often are based on epidemiological studies on nutrition, where there are many examples of clear protective effects of plant-based foods and drinks on the incidence of various types of cancer (Fahey and Kensler, 2007). By isolating the active compounds from protective plants, researchers hope to understand their protective mechanisms and develop drugs to prevent cancer. Chemoprevention is an emerging field; a number of compounds for the prevention of cancer are in clinical trials (Table 67–2). There currently are no drugs approved for chemoprevention of environmental carcinogenesis, but there are approved drugs to prevent carcinogenesis due to endogenous estrogen (tamoxifen and raloxifene) and viruses (hepatitis B and human papillomavirus vaccines).

**Table 67–2 Chemopreventive Agents Being Studied in Humans**

CHEMOPREVENTIVE CLASS	EXAMPLE COMPOUND	NATURAL SOURCE OR TYPE OF DRUG	CANCER TYPE(S)	MECHANISM	CURRENT STATUS
Isothiocyanates	Phenethyl isothiocyanate	Cruciferous vegetables	Liver, lung, breast, etc.	↓CYP, ↑GSH, ↑NQO1, ↑apoptosis	Phase 2 clinical trials
Synthetic drugs that modify metabolism	Oltipraz	Anti-schistosomal drug	Liver, lung	↓CYP, ↑GSH, ↑NQO1	Beneficial effects on biomarkers in phase 2 clinical trials
Flavonoids and other polyphenols	Catechin	Green tea, red wine, berries, etc.	Lung, cervical, etc.	↓ROS, ↓CYP, ↑GSH, ↑NQO1	Phase 2 clinical trials
Other plant compounds	Curcumin	Turmeric (curry)	Colorectal, pancreatic, etc.	↓ROS, ↓CYP, ↑GSH, ↑NQO1	Phase 2 clinical trials
Other plant compounds	Chlorophyllin	All plants	Liver	Reaction with active intermediates, ↓ROS, ↓CYP	Beneficial effects on biomarkers in phase 2 clinical trials
Other antioxidants	α-Tocopherol (vitamin E)	Food	Prostate	Antioxidant, anti-inflammatory	Phase 3 clinical trials
Anti-hormonal therapies	Tamoxifen	Adjuvant for breast cancer	Breast	Inhibit ERα in breast	FDA-approved for chemoprevention
NSAIDs (see chapter 34)	Aspirin	Anti-inflammatory drugs	Colorectal, etc.	Inhibit PG formation	Phase 3 trials
COX-2 selective inhibitors (see Chapter 34)	Celecoxib	Anti-inflammatory drugs	Colorectal, etc.	Inhibit PG formation	Phase 3 trial found ↓cancer but unacceptable side effects for prevention

CYP, cytochrome P450; GSH, glutathione; NQO1, quinone reductase; ROS, reactive oxygen species; ERα, estrogen receptor-α; FDA, U.S. Food and Drug Administration; NSAIDs, nonsteroidal anti-inflammatory drugs; COX-2, cyclooxygenase-2; PG, prostaglandin.

Chemopreventive agents interfere with the processes of initiation and promotion ([Figure 67-2](#)). One mechanism of anti-initiation is prevention of carcinogen activation. Isothiocyanates and similar compounds inhibit CYPs involved in activating many carcinogens and also upregulate genes controlled by the antioxidant response element (ARE); the ARE-responsive group includes  $\gamma$ -glutamylcysteine synthase light chain (the gene responsible for the rate-determining step in GSH synthesis) and quinone reductase (NQO1). Increased expression of ARE-regulated genes is predicted to increase the detoxification of proximate carcinogens. Isothiocyanates also stimulate apoptosis of p53-deficient cells via the formation of cytotoxic DNA adducts. Compounds that act as antioxidants may provide protection because many carcinogens work through the generation of ROS. Some compounds simultaneously prevent carcinogen activation and act as antioxidants. For example, flavonoids and other polyphenols found in a wide variety of plants are potent antioxidants that inhibit CYPs and induce expression of ARE-regulated genes. Chlorophyll and other compounds can protect against carcinogens by binding to or reacting with carcinogens or their metabolites and prevent them from reaching their molecular target.

Inflammation is a potential target for chemoprevention through interference with promotion. The COX-2 inhibitor celecoxib (described in [Chapter 34](#)) has been tested in phase 3 studies that demonstrated efficacy at reducing the risk of colorectal cancer. However, this benefit was offset by an increased risk of death due to cardiovascular events, forcing the early termination of the trial (William et al., 2009). Studies examining long-term treatment with aspirin for cardiovascular benefits found that aspirin also reduces the incidence of colorectal adenomas. A phase 3 clinical trial is under way to examine this effect. Natural compounds, such as  $\alpha$ -tocopherol, also can exert chemoprevention by reducing inflammation.

One successful approach to chemoprevention is modification of nuclear receptor signaling. Promising preliminary data suggested that retinoids might be beneficial for preventing lung and other cancers. Retinoids reduce the incidence of head and neck cancers, which represented one of the first successful uses of chemoprevention in humans (William et al., 2009; Evans and Kaye, 1999). Retinoids also are effective for the treatment of acute promyelocytic leukemia (see Section VII). However, in large clinical trials, retinoids actually increased the incidence of lung cancer, particularly among women, and had other unacceptable toxicities (Omenn et al., 1996).

The selective ER modulators tamoxifen and raloxifene reduced the incidence of breast cancer in high-risk women in large phase 3 clinical trials and are approved for chemoprevention in these patients (Vogel et al., 2006). The success of selective estrogen-receptor modulators for chemoprevention provides a proof-of-principle that the development of compounds based on mechanistic predictions can lead to effective drugs for the prevention of cancer.

**Aflatoxin B<sub>1</sub>.** Promising agents are being developed as chemopreventants of hepatocarcinogenesis mediated by aflatoxin B<sub>1</sub>. Aflatoxins are produced by *Aspergillus flavus*, a fungus that is a common contaminant of foods, especially corn, peanuts, cottonseed, and tree nuts. *A. flavus* is abundant in regions with hot and wet climates, and as a result, hepatocellular carcinoma is a serious problem in subtropical and tropical regions of Latin America, Africa, and Southeast Asia. Human exposure to aflatoxin in the U.S. is very rare and not thought to have a significant impact on health (IARC, 2002).

**Absorption, Distribution, Biotransformation, and Excretion.** Aflatoxin B<sub>1</sub> is readily absorbed from the GI tract and initially distributed to the liver, where it undergoes extensive first-pass metabolism (Guengerich et al., 1996). Aflatoxin B<sub>1</sub> is metabolized by CYPs, including 1A2 and 3A4, to yield either an 8,9-epoxide or products hydroxylated at the 9 position (aflatoxin M<sub>1</sub>) or 3 position (aflatoxin Q<sub>1</sub>; [Figure 67-3](#)). The hydroxylation products are less susceptible to epoxidation and are therefore detoxification products. The 8,9-epoxide is highly reactive toward DNA and is the reactive intermediate responsible for aflatoxin carcinogenesis. The 8,9-epoxide is short lived and undergoes detoxification via non-enzymatic hydrolysis or conjugation with GSH. Aflatoxin M<sub>1</sub> enters the circulation and is excreted in urine and milk. Hydroxylated aflatoxin metabolites also can undergo several additional phase 1 and phase 2 metabolic pathways prior to excretion in urine or bile.

**Toxicity.** Aflatoxin B<sub>1</sub> primarily targets the liver, although it also is toxic to the GI tract and hematological system. High-dose exposures result in acute necrosis of the liver, leading to jaundice and, in many cases, death. Acute toxicity from aflatoxin is relatively rare in humans and requires consumption of milligram quantities of aflatoxin per day for multiple weeks. An outbreak in Kenya in 2004 led to 317 cases and 125 deaths (Groopman et al., 2008).

Humans seem to be relatively resistant to acute aflatoxicosis; human outbreaks usually are preceded by the deaths of dogs and other domestic animals. Chronic exposure to aflatoxins results in cirrhosis of the liver and immunosuppression.

**Figure 67–3** *Metabolism and actions of aflatoxin B<sub>1</sub>*. Following absorption, aflatoxin B<sub>1</sub> undergoes activation by CYPs to its 8,9-epoxide, which can be detoxified by glutathione S-transferases (GSTs) or by spontaneous hydration. Alternatively, it can react with cellular macromolecules such as DNA and protein, leading to toxicity and cancer. Oltipraz, green tea polyphenols (GTPs), and isothiocyanates (ITCs) decrease aflatoxin carcinogenesis by inhibiting the CYPs involved in activating aflatoxin and increasing the synthesis of the cofactor GSH for GSTs involved in detoxification.

**Carcinogenicity.** The primary concern with human exposure to aflatoxins is the development of liver cancer. Based on increased incidence of hepatocellular carcinoma in humans exposed to aflatoxin and supporting animal data, IARC has classified aflatoxin B<sub>1</sub> and several other natural aflatoxins as known human carcinogens (group 1) (IARC, 2002). Aflatoxin exposure and hepatitis B virus work synergistically to cause hepatocellular carcinoma. Many of the regions with elevated aflatoxin exposure also have a high level of endemic hepatitis B infection. Separately, aflatoxin or hepatitis B exposure increases the risk of hepatocellular carcinoma 3.4- or 7.3-fold, respectively; those exposed to both have a 59-fold increased risk of cancer compared to unexposed individuals (Groopman et al., 2005).

The mechanism of aflatoxin carcinogenesis has been extensively studied (IARC, 2002). The 8,9-epoxide of aflatoxin B<sub>1</sub> readily reacts with amines in biological macromolecules. Aflatoxin B<sub>1</sub> 8,9-epoxide forms adducts with deoxyguanosine and albumin that can be detected in the blood or urine of humans and laboratory animals exposed to aflatoxin, providing evidence for the activity of this pathway *in vivo*. Aflatoxin primarily forms DNA adducts at deoxyguanosine residues, reacting at either the N1 or N7 position. The N7-guanine adduct mispairs with adenine, leading to G I T transversions. Human aflatoxin exposure is associated with hepatocellular carcinomas bearing an AGG to AGT mutation in codon 249 of the p53 tumor suppressor gene, resulting in the replacement of an arginine with cysteine. This mutation is almost never observed in geographical regions with limited aflatoxin exposure (Hussain et al., 2007).

The interaction between aflatoxin and hepatitis B that is responsible for the increased incidence of hepatocellular carcinoma is not well understood (Sylla et al., 1999). Hepatitis B influences the metabolism of aflatoxin B<sub>1</sub> by upregulating CYPs, including 3A4, and decreasing glutathione S-transferase activity. In addition, hepatocellular proliferation to repair damage done by hepatitis B infection increases the likelihood that aflatoxin-induced DNA adducts will cause mutations. The hepatotoxic and tumor-promoting effects of hepatitis B also could provide a more favorable environment for the proliferation and invasion of initiated cells.

***Chemoprevention of Aflatoxin-Induced Hepatocellular Carcinoma.*** The clear relationship between aflatoxin metabolism and its carcinogenicity makes it an appealing target for chemopreventive strategies that modify its metabolism (Groopman et al., 2008; Kensler et al., 2004). Inhibiting CYP activity or increasing glutathione conjugation will reduce the intracellular concentration of the 8,9-epoxide and thus prevent DNA adduct formation. One drug that has been tested as a modifier of aflatoxin metabolism is oltipraz. Oltipraz is an anti-schistosomal drug that potently inhibits CYPs and induces genes regulated by the ARE. In a phase 2 clinical trial, a 125-mg/day dose of oltipraz increased the excretion of aflatoxin *N*-acetylcysteine, indicating enhanced glutathione conjugation of the epoxide. At 500 mg/wk, oltipraz reduced the levels of aflatoxin M<sub>1</sub>, consistent with inhibition of CYP activity.

Green tea polyphenols also have been used to modify aflatoxin metabolism in exposed human populations. Individuals receiving a daily dose of 500 or 1000 mg (equivalent to 1 or 2 L of green tea) demonstrated a small decline in the formation of aflatoxin– albumin adducts and a large increase in the excretion of aflatoxin *N*-acetylcysteine, consistent with a protective effect. A third approach to modifying aflatoxin metabolism has been to use a broccoli sprout tea containing high levels of the isothiocyanate *R*-sulforaphane. Because of interindividual variation in the absorption of *R*-sulforaphane, the protocol did not significantly alter aflatoxin biomarkers. However, there was a significant inverse correlation between excretion of sulforaphane metabolites in the urine and the levels of aflatoxin–N7-guanine adducts.

Yet another approach used for the chemoprevention of aflatoxin hepatocarcinogenesis is the use of “interceptor molecules.” Chlorophyllin, an over-the-counter mixture of water-soluble chlorophyll salts, binds tightly to aflatoxin in the GI tract, forming a complex that is not absorbed. *In vitro*, chlorophyllin inhibits CYP activity and acts as an antioxidant. Oral doses are poorly absorbed *in vivo*, so the agent remains largely in the GI tract. In a phase 2 trial, administration of 100 mg of chlorophyllin with each meal reduced aflatoxin–N7-guanine adduct levels in the urine by >50% (Egner et al., 2001).

Chemoprevention of hepatocellular carcinoma in people exposed to aflatoxin also can be achieved by limiting infections with hepatitis B. Because of the strong interaction between hepatitis B and aflatoxin in carcinogenesis, the hepatitis B vaccine will reduce the sensitivity of people to the induction of cancer by aflatoxin. Primary prevention of aflatoxin exposure through hand or fluorescent sorting of crops to remove those with fungal contamination can also reduce human exposure. A more cost-effective primary prevention approach is to improve food storage to limit the spread of *A. flavus*, which requires a warm and humid environment.

## Metals

Metals are an important class of environmental toxicants; they are ubiquitous environmental contaminants that come from both natural and anthropogenic sources. Various toxic metals play important roles in many industrial processes and are occupational health hazards and common pollutants. The top three substances of concern due to their toxicity and likelihood of human

exposure as listed under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, also known as Superfund) are arsenic, lead, and mercury. The toxic effects of these three metals have played a central role in the development of the field of toxicology. However, the toxic effects of low-dose chronic exposure to metals have only recently been appreciated.

Many of the toxic metals in the environment also are carcinogens ([Table 67-3](#)). In addition to toxic environmental metals, several essential metals also are toxic under conditions of overdose. Copper and especially iron are associated with toxicities, primarily targeting the liver through generation of reactive oxygen species. Toxicities from copper and iron usually result from genetic diseases that interfere with the regulation of metal absorption or excretion (e.g., Wilson's disease for copper, hemochromatosis for iron) or result from acute overdose, particularly with iron-containing medications or multivitamins. For a more comprehensive review of toxic metals, including essential metals, see Liu et al. (2008).

Not listed in [Table 67-3](#) is the metal gold, which has its own uses and toxicities. Among heavy metals, perhaps only gold is addictive: gold has been used for centuries for relief of the itching palm, and many cannot get enough of its influence.

## Lead

Exposure to lead has wide-ranging consequences for human health. Chronic exposure of populations to even very low levels of lead has major deleterious effects, which are only now beginning to be understood. It has been proposed that lead exposure contributed to the fall of the Roman Empire and that it plays a role in modern inner-city violence (Woolley, 1984; Needleman et al., 1996).

**Exposure.** In the U.S., paint containing lead for use in and around households was banned in 1978, while the use of tetraethyl lead in gasoline was phased out and eventually eliminated between 1976 and 1996. The economic benefit of the reduction in lead exposure due to these two measures is estimated at hundreds of billions of dollars per year (Grosse et al., 2002). Despite these bans, past use of lead carbonate and lead oxide in paint and tetraethyl lead in gasoline remain the primary sources of lead exposure. Lead is not degradable and remains throughout the environment in dust, soil, and the

paint of older homes. Young children often are exposed to lead by nibbling sweet-tasting paint chips or eating dust and soil in and around older homes. Renovation or demolition of older buildings may cause substantial lead exposure. Tetraethyl lead was used as an anti-knock agent in gasoline, which resulted in high levels of lead in air pollution. Removal of lead from gasoline caused lead levels in air pollution to drop by >90% between 1982 and 2002. Lead was commonly used in plumbing and can leach into drinking water. Acidic foods and beverages dissolve lead when stored in containers with lead in their glaze or lead-soldered cans, which was a significant problem through the middle of the 20th century and remains a problem in developing countries. Lead exposure also has been traced to other sources such as lead toys, non-Western folk medicines, cosmetics, retained bullets, artists' paint pigments, ashes and fumes from painted wood, jewelers' wastes, home battery manufacture, and lead type (ATSDR, 2007b; Levin et al., 2008). Blood lead levels in the general population have steadily decreased since the 1970s. Between 1976 and 2002, mean blood levels in children 1-5 years of age dropped from 15-1.9 µg/dL. The Centers for Disease Control and Prevention (CDC) recommends screening of children at 6 months of age and the use of aggressive lead abatement for children with blood lead levels >10 µg/dL.

**Table 67–3 Toxic Metals with Frequent Environmental or Occupational Exposure<sup>a</sup>**

METAL	CERCLA PRIORITY	COMMON SOURCE OF EXPOSURE	ORGAN SYSTEMS MOST SENSITIVE TO TOXICITY	IARC CARCINOGEN CLASSIFICATION
As	1	Drinking water	CV, skin, multiple other	Group 1, carcinogenic to humans—liver, bladder, lung
Pb	2	Paint, soil	CNS, blood, CV, renal	Group 2A, probably carcinogenic
Hg	3	Air, food	CNS, renal	Group 2B, possibly carcinogenic (MeHg <sup>+</sup> ); group 3, not classifiable (Hg <sup>0</sup> , Hg <sup>2+</sup> )
Cd	7	Occupational, food, smoking	Renal, respiratory	Group 1, carcinogenic to humans—lung
Cr <sup>6+</sup>	18	Occupational	Respiratory	Group 1, carcinogenic to humans—lung
Be	42	Occupational, water	Respiratory	Group 1, carcinogenic to humans—lung
Co	49	Occupational, food, water	Respiratory, CV	Group 2B, possibly carcinogenic
Ni	53	Occupational	Respiratory, skin (allergy)	Group 1, carcinogenic (soluble Ni compounds); group 2B, possibly carcinogenic (metallic Ni)—lung

<sup>a</sup>The Agency for Toxic Substances and Disease Registry (ATSDR) has both detailed monographs and brief summaries for each of these compounds, available at <http://www.atsdr.cdc.gov>. The International Agency for Research on Cancer (IARC) also has monographs available at <http://monographs.iarc.fr>. CERCLA, Comprehensive Environmental Response, Compensation, and Liability Act. CNS, central nervous system; CV, cardiovascular.

Occupational exposure to lead also has decreased markedly because of protective regulations. Occupational exposure generally is through inhalation

of lead containing dust and lead fumes. Workers in lead smelters and in storage battery factories are at the greatest risk for lead exposure because fumes are generated and dust containing lead oxide is deposited in their environment. Other workers at risk for lead exposure are those associated with steel welding or cutting, construction, rubber and plastic industries, printing, firing ranges, radiator repair shops, and any industry where lead is flame soldered (ATSDR, 2007b).

***Chemistry and Mode of Action.*** Lead exists in its metallic form and as divalent or tetravalent cations. Divalent lead is the primary environmental form; inorganic tetravalent lead compounds are not naturally found. Organo-lead complexes primarily occur with tetravalent lead and include the gasoline additive tetraethyl lead.

Lead toxicity results from molecular mimicry of other divalent metals (Garza et al., 2006). Lead takes the place of zinc or calcium in a number of important proteins. Because of its size and electron affinity, lead alters protein structure and can inappropriately activate or inhibit protein function. Specific molecular targets for lead are discussed below.

***Absorption, Distribution, and Excretion.*** Lead exposure occurs through ingestion or inhalation. GI absorption of lead varies considerably with age and diet. Children absorb a much higher percentage of ingested lead (~40% on average) than adults (<20%). Absorption of ingested lead is drastically increased by fasting. Dietary calcium or iron deficiencies increase lead absorption, suggesting that lead is absorbed through divalent metal transporters. The absorption of inhaled lead generally is much more efficient (~90%), particularly with smaller particles. Tetraethyl lead is readily absorbed through the skin, but this is not a route of exposure for inorganic lead.

About 99% of lead in the bloodstream binds to hemoglobin. Lead initially distributes in the soft tissues, particularly in the tubular epithelium of the kidney and the liver. Over time, lead is redistributed and deposited in bone, teeth, and hair. About 95% of the adult body burden of lead is found in bone. Growing bones will accumulate higher levels of lead and can form lead lines visible by radiography. Bone lead is very slowly reabsorbed into the bloodstream, except when calcium levels are depleted, such as during pregnancy. Small quantities of lead accumulate in the brain, mostly in gray matter and the basal ganglia. Lead readily crosses the placenta.

Lead is excreted by humans primarily in the urine, although there also is some biliary excretion. The concentration of lead in urine is directly proportional to its concentration in plasma, but because most lead is in erythrocytes, only a small quantity of total lead is removed by filtration. Lead is excreted in milk and sweat and deposited in hair and nails. The serum  $t_{1/2}$  of lead is 1-2 months, with a steady state achieved in ~6 months. Lead accumulates in bone, where its  $t_{1/2}$  is estimated at 20-30 years.

**Health Effects.** Although the effects of high-dose lead poisoning have been known for >2000 years, the insidious toxicities of chronic low-dose lead poisoning (blood lead <20  $\mu\text{g}/\text{dL}$ ) have only recently been discovered. Although lead is a nonspecific toxicant, the most sensitive systems are the nervous, hematological, cardiovascular, and renal systems ([Figure 67-4](#)). Uncovering the effects of low-level lead exposure on complex health outcomes, such as neurobehavioral function and blood pressure, has been the subject of extensive research.

**Neurotoxic Effects.** The biggest concerns with low-level lead exposure are cognitive delays and behavior changes in children (ATSDR, 2007b; Bellinger and Bellinger, 2006). The developing nervous system is very sensitive to the toxic effects of lead.

Lead interferes with the pruning of synapses, neuronal migration, and the interactions between neurons and glial cells. Together, these alterations in brain development result in decreased IQ, poor performance on exams, and behavioral problems such as distractibility, impulsivity, short attention span, and inability to follow even simple sequences of instructions. Recent studies have shown neurobehavioral deficits even with lead exposures below the CDC action level of 10  $\mu\text{g}/\text{dL}$ . There is no evidence for a threshold; associations with neurobehavioral effects are evident at the lowest measurable blood lead levels (Lanphear et al., 2005). Because different areas of the brain mature at different times, the neurobehavioral changes vary between children, depending on the timing of the lead exposure. Children with very high lead levels (>70  $\mu\text{g}/\text{dL}$ ) are at risk for encephalopathy. Symptoms of lead-induced encephalopathy include lethargy, vomiting, irritability, anorexia, and vertigo, which can progress to ataxia, delirium, and eventually coma and death. Mortality rates for lead-induced encephalopathy are ~25%, and most survivors develop long-term sequelae such as seizures and severe cognitive deficits.

**Figure 67–4** *Heme biosynthesis and actions of lead.* Lead interferes with the biosynthesis of heme at several enzymatic steps. Steps that definitely are inhibited by lead are indicated by red blocks. Steps at which lead is thought to act but where evidence is inconclusive are indicated by pink blocks.

Adults also develop encephalopathy from lead exposure, although they are less sensitive than children. Encephalopathy in adults requires blood lead levels >100 µg/dL. The symptoms are similar to those observed with children. Workers chronically exposed to lead can develop neuromuscular deficits, termed *lead palsy*. Symptoms of lead palsy, including wrist drop and foot drop, were commonly associated with painters and other lead-exposed workers during previous eras but are very rare today. Lead induces degeneration of motor neurons, usually without affecting sensory neurons. Studies in older adults have shown associations between lead exposure and

decreased performance on cognitive function tests, suggesting that lead accelerates neurodegeneration due to aging (ATSDR, 2007b).

The neurodevelopmental effects of lead primarily result from inhibition of calcium transporters and channels and altered activities of calcium responsive proteins, including PKC and calmodulin (Garza et al., 2006; Bellinger and Bellinger, 2006). These actions limit the normal activation of neurons caused by calcium release and cause inappropriate production and/or release of neurotransmitters. Lead affects almost all the neurotransmitter pathways, with the dopaminergic, cholinergic, and glutamatergic systems receiving the most attention. Neurotransmitter release and PKC signaling determine which synapses are maintained and which are lost during development. At high concentrations, lead causes disruption of membranes, including the blood-brain barrier, increasing their permeability to ions. This effect is likely responsible for encephalopathy.

***Cardiovascular and Renal Effects.*** Low-level lead exposure increases blood pressure. Correlations between lead exposure and blood pressure extend to concentrations of lead <20 µg/dL. Although the change in blood pressure is small, ~1 mm Hg for each doubling of the blood lead concentration, a significant effect persists across a wide number of studies, and there is evidence of causality (Navas-Acien et al., 2007). Elevated blood pressure is a lasting effect of lead exposure. Adults who were exposed to lead during infancy and childhood have elevated blood pressure even in the absence of a recent exposure; thus, blood pressure correlates better to lead levels in bone than in blood (ATSDR, 2007b). Lead exposure also is associated with an increased risk of death due to cardiovascular and cerebrovascular disease (Schober et al., 2006).

The kidney is a very sensitive target of lead. Low-level lead exposure (blood levels <10 µg/dL) depresses glomerular filtration. Higher levels (>30 µg/dL) cause proteinuria and impaired transport, while very high levels (>50 µg/dL) cause permanent physical damage, including proximal tubular nephropathy and glomerulosclerosis. Impaired glomerular filtration and elevated blood pressure are closely interrelated and likely have causative effects on one another (ATSDR, 2007b).

The exact mechanisms for the cardiovascular and renal effects of lead are not known. The cardiovascular effects of lead are thought to involve the production of reactive oxygen species by lead, through an unknown

mechanism. Reactive oxygen species react with nitric oxide, which may contribute to the elevated blood pressure by reducing NO-induced vasodilation and contribute to cardiovascular toxicity through the formation of highly reactive peroxynitrite (Vaziri and Khan, 2007). Lead also forms inclusion bodies with various proteins, including metallothionein, in the kidney. The formation of these bodies greatly increases intracellular lead concentrations in the kidney but appears to be protective. It is not known how lead reduces glomerular filtration rate, although there is evidence that lead targets kidney mitochondria and may interfere with the electron transport chain (ATSDR, 2007b).

***Hematological Effects.*** Chronic lead intoxication is associated with hypochromic microcytic anemia, which is observed more frequently in children and is morphologically similar to iron-deficient anemia. The anemia is thought to result from both decreased erythrocyte life span and inhibition of several enzymes involved in heme synthesis, which is observed at very low lead levels ([Figure 67–5](#)).

Inhibition of  $\gamma$ -aminolevulinate ( $\gamma$ -ALA) dehydratase and ferrochelatase is well documented. Ferrochelatase is responsible for incorporating the ferrous ion into protoporphyrin IX to form heme. When ferrochelatase is inhibited by lead, zinc is incorporated in place of iron, resulting in zinc-protoporphyrin, which is highly fluorescent and diagnostic of lead poisoning.  $\gamma$ -ALA dehydratase is the most sensitive of these enzymes to inhibition by lead; very low levels of lead increase urinary excretion of  $\gamma$ -ALA. Lead also causes both immunosuppression and increased inflammation, primarily through changes in helper T-cell and macrophage signaling (Dietert and Piepenbrink, 2006).

***Gastrointestinal Effects.*** Lead affects the smooth muscle of the gut, producing intestinal symptoms that are an early sign of high-level exposure to the metal. The abdominal syndrome often begins with a persistent metallic taste, mild anorexia, muscle discomfort, malaise, headache, and usually constipation. Occasionally, diarrhea replaces constipation. As intoxication advances, symptoms worsen and include intestinal spasms that cause severe intestinal pain (lead cholic). Intravenous calcium gluconate can relieve this pain.

**Figure 67–5** Manifestations of lead toxicity associated with varying concentrations of lead in the blood of children and adults.  $\delta$ -ALA,  $\delta$ -aminolevulinic acid.

**Carcinogenesis.** IARC recently upgraded lead to “probably carcinogenic to humans” (group 2A; IARC, 2006). Epidemiological studies have shown associations between lead exposure and cancers of the lung, brain, kidney, and stomach. Rodents exposed to lead develop kidney tumors, and some rats develop gliomas. Lead is not mutagenic but increases clastogenic events. The mechanism of lead carcinogenesis is unknown but may result from inhibition of DNA binding zinc-finger proteins, including those involved in DNA repair and synthesis (Silbergeld, 2003). Lead is a good example of a non-genotoxic carcinogen.

**Treatment.** The most important response to lead poisoning is removal of the source of lead exposure. Supportive measures should be undertaken to relieve symptoms.

Chelation therapy is warranted for children and adults with high blood lead levels ( $>45 \mu\text{g}/\text{dL}$  and  $>70 \mu\text{g}/\text{dL}$ , respectively) and/or acute symptoms of lead poisoning (Ibrahim et al., 2006). Although chelation therapy is effective at lowering blood lead levels and relieving immediate symptoms, it

does not reduce the chronic effects of lead beyond the benefit of lead abatement alone (Rogan et al., 2001). In rats, chelators enhance mobilization of lead from the soft tissues to the brain and may increase the adverse neurodevelopmental effects of lead (Andersen and Aaseth, 2002).

## Mercury

Mercury is a unique metal in that it is a liquid at room temperature. Because of its capacity to amalgamate with other metals, mercury has been used industrially since ancient Greece, and mercury's toxicity was noted by Hippocrates. Mercury also was used as a therapeutic drug for several centuries. Indeed, its use for the treatment of syphilis inspired Paracelsus' observation that "the dose makes the poison," one of the central concepts of toxicology, and also gave rise to the cautionary expression, "A night with Venus, a year with Mercury." Toxicities from occupational exposure to mercury have been known for a long time. For instance, the phrase "mad as a hatter" originated from the exposure of hatters to metallic mercury vapor during production of felt for hats using mercury nitrate (Goldwater, 1972). While the phrase likely inspired the character of the Mad Hatter in *Alice in Wonderland*, his symptoms are not consistent with mercury exposure.

**Exposure.** Inorganic mercury cations and metallic mercury are found in the Earth's crust, and mercury vapor is released naturally into the environment through volcanic activity and off-gassing from soils. Mercury also enters the atmosphere through human activities such as combustion of fossil fuels. Once in the air, metallic mercury is photo-oxidized to inorganic mercury, which can then be deposited in aquatic environments in rain. Microorganisms can then conjugate inorganic mercury to form methyl mercury. Methyl mercury concentrates in lipids and will bioaccumulate up the food chain so that concentrations in aquatic organisms at the top of the food chain, such as swordfish or sharks, are quite high ([Figure 67-6](#); ATSDR, 1999).

The primary source of exposure to metallic mercury in the general population is vaporization of mercury in dental amalgam, which often contains >50% Hg<sup>0</sup> mixed with silver and other metals. This release is enhanced by chewing. There also is limited exposure through broken thermometers and other mercury-containing devices. Human exposure to organic mercury primarily is through the consumption of fish. Other foods contain inorganic mercury at low levels (ATSDR, 1999).

Workers are exposed to metallic and inorganic mercury, most commonly through exposure to vapors. The highest risk for exposure is in the chloralkali industry (i.e., bleach) and in other chemical processes in which mercury is used as a catalyst. Mercury is a component of many devices, including alkaline batteries, fluorescent bulbs, thermometers, and scientific equipment, and exposure occurs during the production of these devices. Dentists also are exposed to mercury from amalgam. Mercury can be used to extract gold during mining, which results in substantial occupational exposure, because the last step involves vaporization of the mercury. This process is still commonly used in developing countries. Mercuric salts are used as pigments in paints (ATSDR,1999).

Mercury salts were once found in a number of medications, including antiseptics, antidiuretics, skin-lightening creams, and laxatives. Most of these uses have been replaced by safer and more effective drugs. Thimerosal is an antimicrobial agent used as a preservative in vaccines. Its use is controversial because it releases ethyl mercury, which is chemically similar to methyl mercury. Due to the concerns of some parents that thimerosal might be a cause of autism, the American Academy of Pediatrics and the U.S. Public Health Service issued a call for its replacement in vaccines to improve the prevalence of vaccination (Ball et al., 2001). However, studies have not found an association between thimerosal use in vaccines and negative outcomes, and it is still used in influenza vaccines (Heron and Golding, 2004).

***Chemistry and Mode of Action.*** There are three general forms of mercury of concern to human health. Metallic, or elemental, mercury ( $\text{Hg}^0$ ) is the liquid metal found in thermometers and dental amalgam; it is quite volatile, and exposure is often to the vapor form. Inorganic mercury can be either monovalent (mercurous,  $\text{Hg}^{1+}$ ) or divalent (mercuric,  $\text{Hg}^{2+}$ ) and forms a variety of salts. Organic mercury compounds consist of divalent mercury complexed with one or occasionally two alkyl groups. The organic mercury compound of most concern is methyl mercury ( $\text{MeHg}^+$ ), which is formed environmentally from inorganic mercury by aquatic microorganisms.

**Figure 67–6** *Mobilization of mercury in the environment.* Metallic mercury ( $\text{Hg}^0$ ) is vaporized from the Earth’s surface both naturally and through human activities such as burning coal. In the atmosphere,  $\text{Hg}^0$  is oxidized to form divalent inorganic mercury ( $\text{Hg}^{2+}$ ).  $\text{Hg}^{2+}$  then falls to the surface in rain. Aquatic bacteria can methylate  $\text{Hg}^{2+}$  to form methyl mercury ( $\text{MeHg}^+$ ).  $\text{MeHg}^+$  in plankton is consumed by fish. Because of its lipophilicity,  $\text{MeHg}^+$  bioaccumulates up the food chain.

Both  $\text{Hg}^{2+}$  and  $\text{MeHg}^+$  readily form covalent bonds with sulfur, which causes most of the biological effects of mercury. At very low concentrations, mercury reacts with sulfhydryl residues on proteins and disrupts their functions. Given the large numbers of proteins with important cysteines, determination of the specific mechanism for cellular dysfunction has been difficult, and there are probably multiple pathways affected. One of these pathways involves the generation of oxidative stress in cells. Also, microtubules are particularly sensitive to the toxic effects of mercury, which disrupts their formation and can catalyze their disassembly (Clarkson, 2002). There also may be an autoimmune component to mercury toxicity.

**Absorption, Distribution, Biotransformation, and Excretion.**  $\text{Hg}^0$  vapor is readily absorbed through the lungs (~70-80%), but GI absorption of metallic

mercury is negligible. Once absorbed,  $\text{Hg}^0$  distributes throughout the body and crosses membranes such as the blood-brain barrier and the placenta via diffusion.  $\text{Hg}^0$  is oxidized by catalase in the erythrocytes and other cells to form  $\text{Hg}^{2+}$ . Shortly after exposure, some  $\text{Hg}^0$  is eliminated in exhaled air. After a few hours, distribution and elimination of  $\text{Hg}^0$  resemble the properties of  $\text{Hg}^{2+}$ . After exposure to  $\text{Hg}^0$  vapor, it is oxidized to  $\text{Hg}^{2+}$  and retained in the brain (ATSDR, 1999).

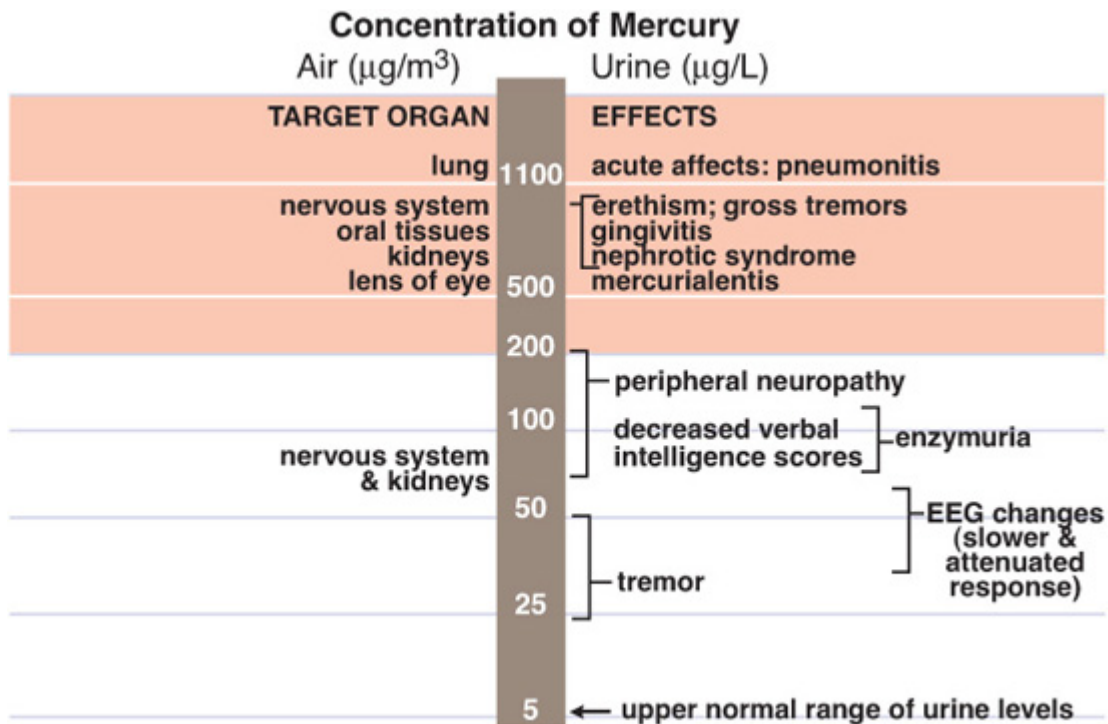

GI absorption of mercury salts varies depending on the individual and on the particular salt and averages ~10-15%.  $\text{Hg}^{1+}$  will form  $\text{Hg}^0$  or  $\text{Hg}^{2+}$  in the presence of sulfhydryl groups.  $\text{Hg}^{2+}$  primarily is excreted in the urine and feces; a small amount also can be reduced to  $\text{Hg}^0$  and exhaled. With acute exposure, the fecal pathway predominates, but following chronic exposure, urinary excretion becomes more important. All forms of mercury also are excreted in sweat and breast milk and deposited in hair and nails. The  $t_{1/2}$  for inorganic mercury is approximately 1-2 months (ATSDR, 1999).

Orally ingested  $\text{MeHg}^+$  is almost completely absorbed from the GI tract.  $\text{MeHg}^+$  readily crosses the blood-brain barrier and the placenta and distributes fairly evenly to the tissues, although concentrations are highest in the kidneys (ATSDR, 1999).  $\text{MeHg}^+$  can be demethylated to form inorganic  $\text{Hg}^{2+}$ . The liver and kidney exhibit the highest rates of demethylation, but this also occurs in the brain.  $\text{MeHg}^+$  is excreted in the urine and feces, with the fecal pathway dominating. The  $t_{1/2}$  for  $\text{MeHg}^+$  is ~2 months. The pharmacokinetic properties of  $\text{MeHg}^+$  are thought to result from molecular mimicry. Complexes between  $\text{MeHg}^+$  and cysteine resemble methionine and can be recognized by transporters for that amino acid and taken across membranes (Ballatori, 2002).

## Health Effects

***Metallic Mercury.*** Inhalation of high levels of mercury vapor over a short duration is acutely toxic to the lung. Respiratory symptoms of mercury exposure start with cough and tightness in the chest and can progress to interstitial pneumonitis and severely compromised respiratory function. Other initial symptoms include weakness, chills, metallic taste, nausea, vomiting, diarrhea, and dyspnea. Acute exposure to high doses of mercury

also is toxic to the CNS, with symptoms similar to those of chronic exposure ([Figure 67-7](#)).

**Figure 67-7** The concentration of mercury vapor in the air and related concentrations of mercury in urine are associated with a variety of toxic effects.

Toxicity to the nervous system is the primary concern with chronic exposure to mercury vapor. Mercury vapor induces characteristic CNS symptoms that are consistent across patients exposed to mercury over short or long periods. These symptoms include tremors (particularly of the hands), emotional lability (irritability, shyness, loss of confidence, and nervousness), insomnia, memory loss, muscular atrophy, weakness, paresthesia, and cognitive deficits. These symptoms intensify and become irreversible, with increases in duration and concentration of exposure. Other common symptoms of chronic mercury exposure include tachycardia, labile pulse, severe salivation, and gingivitis. Prolonged exposure to mercury also causes kidney damage.

**Inorganic Salts of Mercury.** Ingestion of Hg<sup>2+</sup> salts is intensely irritating to the GI tract, leading to vomiting, diarrhea, and abdominal pain. The kidney is the primary target of both valence states of inorganic mercury. Acute exposure to mercury salts (typically in suicide attempts) leads to tubular

necrosis, resulting in decreased urine output and often acute renal failure. Chronic exposures also target the kidney, with glomerular injury predominating.

**Organic Mercury.** The CNS is the primary target of methyl mercury toxicity. Two incidents of high-dose exposure to methyl mercury provide much of our knowledge regarding methyl mercury poisoning. One was in fishing villages surrounding the heavily polluted Minamata Bay in Japan, and the other was in Iraq, where grains treated with methyl mercury were accidentally consumed. Symptoms of methyl mercury exposure include visual disturbances, ataxia, paresthesia, fatigue, hearing loss, slurring of speech, cognitive deficits, muscle tremor, movement disorders, and, following severe exposure, paralysis and death. The developing nervous system exhibits increased sensitivity to methyl mercury. Children exposed *in utero* can develop severe symptoms, including mental retardation and neuromuscular deficits, even in the absence of symptoms in the mother. In adults, methyl mercury causes focused lesions in specific areas of the brain, while the brains of children exposed *in utero* sustain widespread damage (Clarkson, 2002).

The effects of low-dose methyl mercury exposure from routine consumption of fish are difficult to assess due to the opposing beneficial effects of -3 fatty acids found in fish oils, and studies have produced discrepant results (Grandjean et al., 1999; Myers et al., 2003; Myers et al., 2007).

**Treatment.** With exposure to metallic mercury, termination of exposure is critical and respiratory support may be required. Emesis may be used within 30-60 minutes of exposure to inorganic mercury, provided the patient is awake and alert and there is no corrosive injury. Maintenance of electrolyte balance and fluids is important for patients exposed to inorganic mercury. Chelation therapy is beneficial in patients with acute inorganic or metallic mercury exposure. There are limited treatment options for methyl mercury. Chelation therapy does not provide clinical benefits, and several chelators potentiate the toxic effects of methyl mercury (Rush, 2008). Nonabsorbed thiol resins may be beneficial by preventing reabsorption of methyl mercury from the GI tract.

Because of the conflicting effects of mercury and -3 fatty acids, there is

considerable controversy regarding the restriction of fish intake in women of reproductive age and children. The EPA recommends limiting fish intake to 12 oz (two meals) per week. Many experts feel this recommendation is too conservative, and the FDA is considering revising their recommendation to state that the benefits of fish consumption outweigh the risks. The recommendation that women consume fish that is lower in mercury content (i.e., canned light tuna, salmon, pollock, catfish) and avoid top predators, such as swordfish, shark, and tilefish, is not controversial.

## Arsenic

Arsenic is a metalloid that is common in rocks and soil. Arsenic compounds have been used for >2400 years as both therapeutic agents and poisons. In the late 19th century, Robert Ehrlich coined the terms “magic bullet” and “chemotherapy” to describe his work using the organic arsenic compound arsphenamine for the treatment of syphilis. The use of arsenic in drugs has been mostly phased out, but arsenic trioxide (ATO) is still used as an effective chemotherapy agent for acute promyelocytic leukemia (see [Chapter 63](#)).

**Exposure.** The primary source of exposure to arsenic is through drinking water. Arsenic naturally leaches out of soil and rocks into well and spring water (Mead, 2005). Levels of arsenic in drinking water average 2  $\mu\text{g/L}$  (ppb) in the U.S. but can be >50  $\mu\text{g/L}$  (five times the EPA standard) in private well water, particularly in California, Nevada, and Arizona. Drinking water from other parts of the world where well water has been promoted to prevent waterborne illness, particularly Taiwan, China, Argentina, Chile, Bangladesh, and eastern India, sometimes is contaminated with much higher levels of arsenic (sometimes several hundred micrograms per liter), and widespread poisonings have resulted ([Figure 67–8](#)). Studies in Bangladesh found that ~40% of water samples from across the country were contaminated with >50  $\mu\text{g/L}$  of arsenic, and some samples had far higher levels (Mead, 2005; Chowdhury et al., 1999; BGS and DPHE, 2001). Arsenic also can enter the environment through human activities such as the use of arsenic-containing pesticides, mining, and burning of coal. Food, particularly seafood, often is contaminated with arsenic. Arsenic in seafood exists primarily as organic compounds (i.e., arsenobetaine) that are much

less toxic than inorganic arsenic. The average daily human intake of arsenic is 10  $\mu\text{g}/\text{day}$ , almost exclusively from food and water.

Before 2003, >90% of arsenic used in the U.S. was as a preservative in pressure-treated wood, but the lumber industry has voluntarily replaced arsenic with other preservatives. Arsenic-treated wood is thought to be safe unless burned (Hall, 2002). The major source of occupational exposure to arsenic is in the production and use of organic arsenicals as herbicides and insecticides. Exposure to metallic arsenic, arsine, arsenic trioxide, and gallium arsenide also occurs in high-tech industries, such as the manufacture of computer chips and semiconductors.

**Figure 67–8 Arsenic in drinking water.** (A) World map demonstrating regions where there is increased arsenic exposure in drinking water. (B) Map of Bangladesh demonstrating arsenic concentrations in drinking water in samples from wells across the country. (Adapted from BGS and DPHE, 2001. *This report was produced by the British Geological Survey and the Department of Public Health Engineering (Bangladesh) undertaking a project funded by the UK Department for International Development.*)

**Chemistry and Mode of Action.** Arsenic exists in its elemental form and trivalent (arsenites/arsenious acid) and pentavalent (arsenates/arsenic acid) states. Arsine is a gaseous hydride of trivalent arsenic that exhibits toxicities that are distinct from other forms. Organic compounds containing either valence state of arsenic are formed in animals. The toxicity of a given arsenical is related to the rate of its clearance from the body and its ability to concentrate in tissues. In general, toxicity increases in the sequence: organic arsenicals <  $\text{As}^{5+}$  <  $\text{As}^{3+}$  < arsine gas ( $\text{AsH}_3$ ).

Like mercury, trivalent arsenic compounds form covalent bonds with sulfhydryl groups. The pyruvate dehydrogenase system is particularly sensitive to inhibition by trivalent arsenicals because the two sulfhydryl groups of lipoic acid react with arsenic to form a six-membered ring. Inorganic arsenate (pentavalent) inhibits the electron transport chain. It is thought that arsenate competitively substitutes for phosphate during the formation of adenosine triphosphate, forming an unstable arsenate ester that is rapidly hydrolyzed.

**Absorption, Distribution, Biotransformation, and Excretion.** The absorption of arsenic compounds is directly related to their solubility. Poorly water-soluble forms such as arsenic sulfide, lead arsenate, and arsenic trioxide are not well absorbed. Water-soluble arsenic compounds are readily absorbed from both inhalation and ingestion. GI absorption of arsenic dissolved in drinking water is >90% (ATSDR, 2007a).

At low doses, arsenic is fairly evenly distributed throughout the tissues of the body. Nails and hair, due to their high sulfhydryl content, exhibit high concentrations of arsenic. After an acute high dose of arsenic (i.e., fatal poisoning), arsenic is preferentially deposited in the liver and, to a lesser extent, kidney, with elevated levels also observed in the muscle, heart, spleen, pancreas, lungs, and cerebellum. Arsenic readily crosses the placenta and blood-brain barrier.

Arsenic undergoes biotransformation in humans and animals ([Figure 67–9](#)). Trivalent compounds can be oxidized back to pentavalent compounds, but there is no evidence for demethylation of methylated arsenicals. Biotransformation of arsenic varies greatly across species, with humans excreting much higher levels of monomethyl-arsenic (MMA) compounds than most other animals (ATSDR, 2007a). Because the pentavalent methylated arsenic compounds have greatly reduced toxicity, the methylation pathway was long thought to be a detoxification pathway. However, the trivalent methylated arsenicals actually are more toxic than inorganic arsenite, due to an increased affinity for sulfhydryl groups, and formation of MMA<sup>III</sup> now is considered a bioactivation pathway (Aposhian and Aposhian, 2006).

Elimination of arsenicals by humans primarily is in the urine, although some is also excreted in feces, sweat, hair, nails, skin, and exhaled air. Compared to most other toxic metals, arsenic is excreted quickly, with a  $t_{1/2}$  of 1-3 days. In humans, ingested inorganic arsenic in urine is a mixture of 10-30% inorganic arsenicals, 10-20% monomethylated forms, and 60-80% dimethylated forms.

**Health Effects.** With the exception of arsine gas (which is discussed later in “Arsine Gas”), the various forms of inorganic arsenic exhibit similar toxic effects. Inorganic arsenic exhibits a broad range of toxicities and has been associated with effects on every organ system tested, although some systems are much more sensitive than others (ATSDR, 2007a). Humans also are exposed to large organic arsenic compounds in fish, which are relatively nontoxic. Humans are the most sensitive species to the toxic effects of inorganic arsenic. Acute exposure to large doses of arsenic (>70-180 mg) often is fatal. Death immediately following arsenic poisoning typically is the result of its effects on the heart and GI tract. Death sometimes occurs later as a result of arsenic’s combined effect on multiple organs.

**Cardiovascular System.** Acute and chronic arsenic exposure cause myocardial depolarization, cardiac arrhythmias, and ischemic heart disease; these are known side effects of arsenic trioxide for the treatment of leukemia. Chronic exposure to arsenic causes peripheral vascular disease, the most dramatic example of which is “blackfoot disease,” a condition characterized by cyanosis of the extremities, particularly the feet, progressing to gangrene. Blackfoot disease is endemic in regions of Taiwan, with arsenic levels of between 170 and 800  $\mu\text{g/L}$ . Arsenic dilates capillaries and increases their

permeability. This causes edema after acute exposures and is likely responsible for peripheral vascular disease following chronic exposure.

**Figure 67–9 Metabolism of arsenic.** GSH, reduced glutathione; GSSG, oxidized glutathione; SAM, *S*-adenosyl-*L*-methionine; SAH, *S*-adenosyl-*L*-homocysteine. AS3MT, arsenite methyltransferase;  $\text{MMA}^{\text{V}}$ , monomethylarsonic acid;  $\text{MMA}^{\text{III}}$ , monomethylarsonous acid;  $\text{DMA}^{\text{V}}$ , dimethyl arsinic acid.

**Skin.** The skin is very sensitive to chronic arsenic exposure. Dermal symptoms often are diagnostic of arsenic exposure. Arsenic induces hyperkeratinization of the skin (including formation of multiple corns or warts), particularly of the palms of the hands and the soles of the feet. It also causes areas of hyperpigmentation interspersed with spots of hypopigmentation. These symptoms can be observed in individuals exposed to drinking water with arsenic concentrations of at least 100  $\mu\text{g}/\text{L}$  and are typical in those chronically exposed to much higher levels. Hyperpigmentation can be observed after 6 months of exposure, while hyperkeratinization takes years. Children are more likely to develop these effects than adults. The mechanism of arsenic-induced changes to the skin is unknown, partly because these effects are not seen in other animals (Mead, 2005; ATSDR, 2007a).

**GI Tract.** Acute or subacute exposure to high-dose arsenic by ingestion is associated with GI symptoms ranging from mild cramping, diarrhea, and vomiting to GI hemorrhaging and death. GI symptoms are caused by increased capillary permeability, leading to fluid loss. At higher doses, fluid forms vesicles that can burst, leading to inflammation and necrosis of the submucosa and then rupture of the intestinal wall. GI symptoms are not observed with chronic exposure to lower levels of arsenic.

**Nervous System.** Acute high-dose arsenic exposure causes encephalopathy in rare cases, with symptoms that can include headache, lethargy, mental confusion, hallucination, seizures, and coma. However, the most common neurological effect of acute or subacute arsenic exposure is peripheral neuropathy involving both sensory and motor neurons. This effect is

characterized by the loss of sensation in the hands and feet (a *stocking and glove* distribution). This often is followed by muscle weakness. Neuropathy occurs several days after exposure to arsenic and can be reversible following cessation of exposure, although recovery usually is not complete. Arsenic exposure may cause intellectual deficits in children. Wasserman et al. (2007) observed a negative association between arsenic levels in drinking water and performance on intelligence tests.

***Other Non-Cancer Toxicities.*** Acute and chronic arsenic exposures induce anemia and leukopenia. Arsenic likely causes both direct cytotoxic effects on blood cells and suppression of erythropoiesis through bone marrow toxicity. Arsenic also may inhibit heme synthesis. In the liver, arsenic causes fatty infiltrations, central necrosis, and cirrhosis of varying severity. The action of arsenic on renal capillaries, tubules, and glomeruli can cause severe kidney damage. Inhaled arsenic is irritating to the lungs, and ingested arsenic may induce bronchitis progressing to bronchopneumonia in some individuals. Chronic exposure to arsenic is associated with an increased risk of diabetes.

***Carcinogenesis.*** Arsenic compounds were among the first recognized human carcinogens. At the end of the 19th century, Hutchinson observed that patients receiving arsenic-containing drugs had an increased occurrence of skin tumors. Epidemiological studies performed in regions with very high arsenic levels in drinking water consistently observe substantially increased rates of skin cancer (squamous cell and basal cell carcinomas), bladder cancer, and lung cancer. There also are associations between arsenic exposure and other cancers, including liver, kidney, and prostate tumors. Inhalation exposure to arsenic in occupational settings causes lung cancer. IARC classifies arsenic as “carcinogenic to humans (group 1).”

The developing fetus and young children may be at increased risk of arsenic carcinogenesis, because humans exposed to arsenic *in utero* and in early childhood have a greatly elevated risk of lung cancer (Smith et al., 2006). Studies in rodents also have observed increased cancer risks from *in utero* exposure and suggest that the second trimester of pregnancy represents a critical susceptibility window (Waalkes et al., 2007).

The mechanism of arsenic carcinogenesis is poorly understood. Arsenic is an unusual carcinogen in that evidence for human carcinogenesis is much stronger than for carcinogenesis in laboratory animals. Arsenic does not directly damage DNA; rather, arsenic is thought to work through changes in

gene expression, DNA methylation, inhibition of DNA repair, generation of oxidative stress, and/or altered signal transduction pathways (Salnikow and Zhitkovich, 2008; Hartwig et al., 2002). Arsenic compounds can act as tumor promoters or co-carcinogens in rodents, particularly when combined with ultraviolet light (Burns et al., 2004). In humans, exposure to arsenic potentiates lung tumorigenesis from tobacco smoke. Smokers in regions with high concentrations of arsenic in the drinking water have a 5-fold increased risk of cancer over smokers living in low arsenic regions (Ferreccio et al., 2000). Arsenic cocarcinogenesis may involve inhibition of proteins involved in nucleotide excision repair (Salnikow and Zhitkovich, 2008; Hartwig et al., 2002). Arsenic also has endocrine-disrupting activities on several nuclear steroid hormone receptors, enhancing hormone-dependent transcription at very low concentrations and inhibiting it at slightly higher levels (Bodwell et al., 2006).

**Arsine Gas.** Arsine gas, formed by electrolytic or metallic reduction of arsenic, is a rare cause of industrial poisonings. Arsine induces rapid and often fatal hemolysis, which probably results from arsine combining with hemoglobin and reacting with oxygen. A few hours after exposure, patients can develop headache, anorexia, vomiting, paresthesia, abdominal pain, chills, hemoglobinuria, bilirubinemia, and anuria. Jaundice appears after 24 hours. Arsine induces renal toxicities that can progress to kidney failure. Approximately 25% of cases of arsine exposure result in death.

**Treatment.** Following acute exposure to arsenic, stabilize the patient and prevent further absorption of the poison. Close monitoring of fluid levels is important because arsenic can cause fatal hypovolemic shock. Chelation therapy is effective following short-term exposure to arsenic but has very little or no benefit in chronically exposed individuals. Exchange transfusion to restore blood cells and remove arsenic often is warranted following arsine gas exposure (Ibrahim et al., 2006).

## Cadmium

Cadmium was discovered in 1817 and first used industrially in the mid-20th century. Cadmium is resistant to corrosion and exhibits useful electrochemical properties, which has led to its use in electroplating, galvanization, plastics, paint pigments, and nickel-cadmium batteries.

**Exposure.** In the general population, the primary source of exposure to cadmium is through food, with an estimated average daily intake of 50 µg/day. Cadmium also is found in tobacco; a cigarette contains 1-2 µg of cadmium (Jarup and Akesson, 2009). Workers in smelters and other metal-processing industries can be exposed to high levels of cadmium, particularly by inhalation.

**Chemistry and Mode of Action.** Cadmium exists as a divalent cation and does not undergo oxidation-reduction reactions. There are no covalent organometallic complexes of cadmium of toxicological significance. The mechanism of cadmium toxicity is not fully understood. Like lead and other divalent metals, cadmium can replace zinc in zinc-finger domains of proteins and disrupt them. Through an unknown mechanism, cadmium induces formation of reactive oxygen species, resulting in lipid peroxidation and glutathione depletion. Cadmium also upregulates inflammatory cytokines and may disrupt the beneficial effects of nitric oxide.

**Absorption, Distribution, and Excretion.** Cadmium is not well absorbed from the GI tract (1.5-5%) but is better absorbed via inhalation (~10%). Cadmium primarily distributes first to the liver and later the kidney, with those two organs accounting for 50% of the absorbed dose. Cadmium distributes fairly evenly to other tissues, but unlike other heavy metals, little cadmium crosses the blood-brain barrier or the placenta. Cadmium primarily is excreted in the urine and exhibits a  $t_{1/2}$  of 10-30 years (ATSDR, 2008a).

**Toxicity.** Acute cadmium toxicity primarily is due to local irritation along the absorption route. Inhaled cadmium causes respiratory tract irritation with severe, early pneumonitis accompanied by chest pains, nausea, dizziness, and diarrhea. Toxicity may progress to fatal pulmonary edema. Ingested cadmium induces nausea, vomiting, salivation, diarrhea, and abdominal cramps; the vomitus and diarrhea often are bloody.

Symptoms of chronic cadmium toxicity vary by exposure route. The lung is an important target of inhaled cadmium, while the kidney is a major target of cadmium from both inhalation and ingestion.

Cadmium bound to metallothionein is transported to the kidney, where it can be released. The initial toxic effect of cadmium on the kidney is increased excretion of small-molecular-weight proteins, especially  $\beta_2$  microglobulin and retinol-binding protein. Cadmium also causes glomerular

injury, with a resulting decrease in filtration. Chronic occupational exposure to cadmium is associated with an increased risk of renal failure and death. There is no evidence for a threshold level for cadmium's effects on the kidney; cadmium levels consistent with normal dietary exposure can cause renal toxicity, including a reduction in glomerular filtration rate and creatinine clearance (Jarup and Akesson, 2009).

Workers with long-term inhalation exposure to cadmium exhibit decreased lung function. Symptoms initially include bronchitis and fibrosis of the lung, leading to emphysema. The exact cause of cadmium-induced lung toxicity is not known but may result from inhibition of the synthesis of  $\alpha_1$  antitrypsin. Chronic obstructive pulmonary disease causes increased mortality in cadmium-exposed workers.

When accompanied by vitamin D deficiency, cadmium exposure increases the risks for fractures and osteoporosis. This may be an effect of cadmium interfering with calcium and phosphate regulation due to its renal toxicity.

***Carcinogenicity.*** Chronic occupational exposure to inhaled cadmium increases the risk of developing lung cancer (IARC, 1993; NTP, 2004). The mechanism of cadmium carcinogenesis is not fully understood. Cadmium causes chromosomal aberrations in exposed workers and treated animals and human cells. It also increases mutations and impairs DNA repair in human cells (NTP, 2004). Cadmium substitutes for zinc in DNA repair proteins and polymerases and may inhibit nucleotide excision repair, base excision repair, and the DNA polymerase responsible for repairing single-strand breaks (Hartwig et al., 2002). There is evidence that cadmium also alters cell signaling pathways and disrupts cellular controls of proliferation (Waisberg et al., 2003). Thus, cadmium acts as a non-genotoxic carcinogen.

***Treatment.*** Treatment of cadmium poisoning is symptomatic. Patients suffering from inhaled cadmium may require respiratory support. Patients suffering from kidney failure due to cadmium poisoning may require a transplant. There is no evidence for clinical benefit from chelation therapy following cadmium poisoning, and chelation therapy may result in adverse effects (ATSDR, 2008a).

## **Chromium**

Chromium is an industrially important metal used in a number of alloys, particularly stainless steel, which contains at least 11% chromium. Chromium can be oxidized to multiple valence states, with trivalent ( $\text{Cr}^{\text{III}}$ ) and hexavalent chromium ( $\text{Cr}^{\text{VI}}$ ) being the two forms of biological importance. Chromium exists almost exclusively as the trivalent form in nature, and  $\text{Cr}^{\text{III}}$  is an essential metal involved in the regulation of glucose metabolism.  $\text{Cr}^{\text{VI}}$  is thought to be responsible for the toxic effects of chromium exposure (ATSDR, 2008b).

**Exposure.** Exposure to chromium in the general population primarily is through the ingestion of food, although there also is exposure from drinking water and air. Workers are exposed to chromium during chromate production, stainless steel production and welding, chromium plating, ferrochrome alloy and chrome pigment production, and in tanning industries (Ashley et al., 2003). Exposure usually is to a mixture of  $\text{Cr}^{\text{III}}$  and  $\text{Cr}^{\text{VI}}$ , except in chromium plating, which usually uses  $\text{Cr}^{\text{VI}}$ , and tanning, where  $\text{Cr}^{\text{III}}$  is used.

**Chemistry and Mode of Action.** Chromium occurs in its metallic state or in any valence state between divalent and hexavalent.  $\text{Cr}^{\text{III}}$  is the most stable and common form.  $\text{Cr}^{\text{VI}}$  is corrosive and is readily reduced to lower valence states. The primary reason for the different toxicological properties of  $\text{Cr}^{\text{III}}$  and  $\text{Cr}^{\text{VI}}$  is thought to be differences in their absorption and distribution. Hexavalent chromate resembles sulfate and phosphate and can be taken across membranes by anion transporters. Once inside the cell,  $\text{Cr}^{\text{VI}}$  undergoes a series of reduction steps, ultimately forming  $\text{Cr}^{\text{III}}$ , which is thought to cause most of the toxic effects. Trivalent chromium readily forms covalent interactions with DNA. Hexavalent chromium also induces oxidative stress and hypersensitivity reactions.

**Absorption, Distribution, Biotransformation, and Excretion.** Absorption of inhaled chromium depends on its solubility, valence state, and particle size. Smaller particles are better deposited in the lungs. Absorption into the bloodstream of hexavalent and soluble forms is higher than the trivalent or insoluble forms, with the remainder often retained in the lungs. Approximately 50-85% of inhaled  $\text{Cr}^{\text{VI}}$  particles (<5  $\mu\text{m}$ ) are absorbed. Absorption of ingested chromium is <10%. Soluble  $\text{Cr}^{\text{VI}}$  compounds are better absorbed from the GI tract than other forms.  $\text{Cr}^{\text{VI}}$  crosses membranes

by facilitated transport, while Cr<sup>III</sup> crosses by diffusion. Cr<sup>VI</sup> is distributed to all of the tissues and crosses the placenta. The highest levels are attained in the liver, kidney, and bone; Cr<sup>VI</sup> also is retained in erythrocytes, bound tightly to hemoglobin and other ligands. Excretion primarily is through urine, with small amounts also excreted in bile and breast milk and deposited in hair and nails. The  $t_{1/2}$  of ingested Cr<sup>VI</sup> is ~40 hours, while the  $t_{1/2}$  of Cr<sup>III</sup> is ~10 hours, reflecting the enhanced tissue retention of Cr<sup>VI</sup> (ATSDR, 2008b).

**Toxicity.** Acute exposure to very high doses of chromium causes death via damage to multiple organs, particularly the kidney, where it causes tubular and glomerular damage. Chronic low-dose chromium exposure primarily causes toxicity at the site of contact. Workers exposed to inhaled chromium develop symptoms of lung and upper respiratory tract irritation, including epistaxis, chronic rhinorrhea, nasal itching and soreness, nasal mucosal atrophy, perforations and ulceration of the nasal septum, bronchitis, pneumoconiosis, decreased pulmonary function, and pneumonia. Chronic exposure to chromium via ingestion, including after mucociliary clearance of inhaled particles, causes symptoms of GI irritation such as oral ulcer, diarrhea, abdominal pain, indigestion, and vomiting. Cr<sup>VI</sup> is a dermal irritant and can cause ulceration or burns. Following low-dose exposure by any route, some individuals become sensitized to chromium and develop allergic dermatitis following dermal exposure to chromium, including products containing metallic chromium. Chromium-sensitized workers often also develop asthma following inhalation exposure (ATSDR, 2008b).

**Carcinogenicity.** Cr<sup>VI</sup> compounds are known human carcinogens (group 1; IARC, 1990). There is insufficient evidence for carcinogenesis from metallic and trivalent chromium (group 3). Workers exposed to Cr<sup>VI</sup> via inhalation have elevated incidence of and mortality from lung and nasal cancer. Environmental exposure to Cr<sup>VI</sup> in drinking water increases the risk of developing stomach cancer. Based on animal studies, the most potent carcinogenic compounds are slightly soluble Cr<sup>VI</sup> compounds.

There are multiple potential mechanisms for chromium carcinogenicity (Salnikow and Zhitkovich, 2008). After uptake into cells, reduction of Cr<sup>VI</sup> to Cr<sup>III</sup> occurs with concomitant oxidation of cellular molecules. Ascorbate is the primary reductant, but other molecules, including glutathione, lipids,

proteins, and DNA, also can be oxidized. Cr<sup>III</sup> forms a large number of covalent DNA adducts, primarily at the phosphate backbone. The most common DNA adducts are either binary (DNA-Cr<sup>III</sup>) adducts or cross-links to small molecules such as ascorbate and glutathione. The DNA adducts are not very mutagenic and are repaired by nucleotide excision repair. It is thought that the high level of nucleotide excision repair activity following chromium exposure contributes to carcinogenesis, either by preventing repair of mutagenic lesions formed by other carcinogens or through the formation of single-strand breaks due to incomplete repair. Chromium also forms toxic cross-links between DNA and protein. Chronic inflammation due to chromium-induced irritation also may promote tumor formation.

**Treatment.** There are no standard protocols for treatment of acute chromium poisoning. One approach that has shown promise in rodents is the use of reductants such as ascorbate, glutathione, or *N*-acetylcysteine to reduce Cr<sup>VI</sup> to Cr<sup>III</sup> after exposure but before absorption to limit bioavailability (ATSDR, 2008b). These compounds and EDTA also increase urinary excretion of chromium after high-dose exposure, particularly if given soon enough to prevent uptake into cells. Exchange transfusion to remove chromium from plasma and erythrocytes may be beneficial.

## TREATMENT OF METAL EXPOSURE

The most important response to environmental or occupational exposures to metals is to eliminate the source of the exposure. For instance, with children exposed to lead, the CDC recommends aggressive lead-abatement practices to ensure that the home is free of lead-based paints and other sources of lead exposure. In occupational settings, often removing exposed workers from the toxic work environment will reverse many of the symptoms of metal poisoning. It also is important to stabilize the patient and provide symptomatic treatment.

Treatment for acute metal intoxications often involves the use of chelators. A chelator is a compound that forms stable complexes with metals, typically as five- or six-membered rings. Formation of complexes between chelators and metals should prevent or reverse metal binding to biological ligands. The ideal chelator would have the following properties: *high solubility in water, resistance to biotransformation, ability to reach sites of metal storage, ability to form stable and nontoxic complexes with toxic metals,*

and ready excretion of the metal-chelator complex. A low affinity for the essential metals calcium and zinc also is desirable, because toxic metals often act through competition with these metals for protein binding.

In cases of acute exposure to high doses of most metals, chelation therapy reduces toxicity. However, following chronic exposure, chelation therapy does not show clinical benefits beyond those of cessation of exposure alone and, in some cases, does more harm than good. Chelation therapy may increase the neurotoxic effects of heavy metals and is only recommended for acute poisonings. The structures of the most commonly used chelators are shown in [Figure 67-10](#).

Dimercaprol: R<sub>1</sub>=CH<sub>2</sub>OH, R<sub>2</sub>=H

Succimer: R<sub>1</sub>=R<sub>2</sub>=COOH

DMPS: R<sub>1</sub>=CH<sub>2</sub>SO<sub>3</sub>H, R<sub>2</sub>=H

**Penicillamine**

**Deferoxamine**

**Figure 67–10** Structures of chelators commonly used to treat acute metal intoxication.  $\text{CaNa}_2\text{EDTA}$ , calcium disodium ethylenediamine tetraacetic acid; DMPS, sodium 2,3-dimercaptopropane sulfonate.

## Ethylenediaminetetraacetic Acid (EDTA)

EDTA and its various salts are effective chelators of divalent and trivalent metals. Calcium disodium EDTA ( $\text{CaNa}_2\text{EDTA}$ ) is the preferred EDTA salt for metal poisoning, provided that the metal has a higher affinity for EDTA than calcium.  $\text{CaNa}_2\text{EDTA}$  is effective for the treatment of acute lead poisoning, particularly in combination with dimercaprol, but is not an effective chelator of mercury or arsenic *in vivo*.

**Chemistry and Mechanism of Action.** The pharmacological effects of  $\text{CaNa}_2\text{EDTA}$  result from chelation of divalent and trivalent metals in the body. Accessible metal ions (both exogenous and endogenous) with a higher affinity for  $\text{CaNa}_2\text{EDTA}$  than  $\text{Ca}^{2+}$  will be chelated, mobilized, and usually excreted. Because EDTA is charged at physiological pH, it does not significantly penetrate cells.  $\text{CaNa}_2\text{EDTA}$  mobilizes several endogenous metallic cations, including those of zinc, manganese, and iron. Additional supplementation with zinc following chelation therapy may be beneficial. The most common therapeutic use of  $\text{CaNa}_2\text{EDTA}$  is for acute lead intoxication.  $\text{CaNa}_2\text{EDTA}$  does not provide clinical benefits for the treatment of chronic lead poisoning. There is evidence in rats that  $\text{CaNa}_2\text{EDTA}$  mobilizes lead from various tissues to the brain and liver, which may account for this observation (Sanchez-Fructuoso et al., 2002; Andersen and Aaseth, 2002).

$\text{CaNa}_2\text{EDTA}$  is available as edetate calcium disodium (calcium disodium versenate). Intramuscular administration of  $\text{CaNa}_2\text{EDTA}$  results in good absorption, but pain occurs at the injection site; consequently, the chelator injection often is mixed with a local anesthetic or administered intravenously. For intravenous use,  $\text{CaNa}_2\text{EDTA}$  is diluted in either 5% dextrose or 0.9% saline and is administered slowly by intravenous drip. A dilute solution is necessary to avoid thrombophlebitis. To minimize nephrotoxicity, adequate urine production should be established prior to and during treatment with  $\text{CaNa}_2\text{EDTA}$ . However, in patients with lead

encephalopathy and increased intracranial pressure, excess fluids must be avoided. In such cases, intramuscular administration of  $\text{CaNa}_2\text{EDTA}$  is recommended.

EDTA and its glycol congener, EGTA, are used in biological research to chelate and control the concentration of  $\text{Ca}^{2+}$  in biological buffer solutions. The 2008 Nobel laureate, Roger Tsien, and his colleagues used the EDTA/EGTA structure as a starting point in the development of fluorescent sensors of cellular  $[\text{Ca}^{2+}]$  (Tsien et al., 1984).

**Absorption, Distribution, and Excretion.** Less than 5% of  $\text{CaNa}_2\text{EDTA}$  is absorbed from the GI tract. After intravenous administration,  $\text{CaNa}_2\text{EDTA}$  has a  $t_{1/2}$  of 20-60 minutes. In blood,  $\text{CaNa}_2\text{EDTA}$  is found only in the plasma.  $\text{CaNa}_2\text{EDTA}$  is excreted in the urine by glomerular filtration, so adequate renal function is necessary for successful therapy. Altering either the pH or the rate of urine flow has no effect on the rate of excretion. There is very little metabolic degradation of EDTA. The drug is distributed mainly in the extracellular fluids; very little gains access to the spinal fluid (5% of the plasma concentration).

**Toxicity.** Rapid intravenous administration of  $\text{Na}_2\text{EDTA}$  causes hypocalcemic tetany. However, a slow infusion (<15 mg/minute) administered to a normal individual elicits no symptoms of hypocalcemia because of the availability of extracirculatory stores of  $\text{Ca}^{2+}$ . In contrast,  $\text{CaNa}_2\text{EDTA}$  can be administered intravenously with no untoward effects because the change in the concentration of  $\text{Ca}^{2+}$  in the plasma and total body is negligible.

The principal toxic effect of  $\text{CaNa}_2\text{EDTA}$  is on the kidney. Repeated large doses of the drug cause hydropic vacuolization of the proximal tubule, loss of the brush border, and eventually, degeneration of proximal tubular cells. The early renal effects usually are reversible, and urinary abnormalities disappear rapidly with cessation of treatment. The most likely mechanism of toxicity is chelation of essential metals, particularly zinc, in proximal tubular cells.

Other side effects associated with  $\text{CaNa}_2\text{EDTA}$  include malaise, fatigue, and excessive thirst, followed by the sudden appearance of chills and fever and subsequent myalgia, frontal headache, anorexia, occasional nausea and

vomiting, and rarely, increased urinary frequency and urgency.  $\text{CaNa}_2\text{EDTA}$  is teratogenic in laboratory animals, probably as a result of zinc depletion; it should be used in pregnant women only under conditions in which the benefits clearly outweigh the risks (Kalia and Flora, 2005). Other possible undesirable effects include sneezing, nasal congestion, and lacrimation; glycosuria; anemia; dermatitis with lesions strikingly similar to those of vitamin  $\text{B}_6$  deficiency; transitory lowering of systolic and diastolic blood pressures; prolonged prothrombin time; and T-wave inversion on the electrocardiogram.

## Dimercaprol

Dimercaprol was developed during World War II as an antidote to lewisite, a vesicant arsenical war gas; hence its alternative name, British anti-lewisite (BAL). Arsenicals form a stable and relatively nontoxic chelate ring with dimercaprol. Pharmacological investigations revealed that dimercaprol protects against other heavy metals as well.

***Chemistry and Mechanism of Action.*** The pharmacological actions of dimercaprol result from formation of chelation complexes between its sulfhydryl groups and metals. Dissociation of dimercaprol–metal complexes and oxidation of dimercaprol occurs *in vivo*. Furthermore, the sulfur–metal bond may be labile in the acidic tubular urine, which may increase the delivery of metal to renal tissue and increase toxicity. The dosage regimen should maintain a concentration of dimercaprol in plasma adequate to favor the continuous formation of the more stable 2:1 (BAL–metal) complex. However, because of pronounced and dose-related side effects, excessive plasma concentrations must be avoided. The concentration in plasma therefore must be maintained by repeated dosage until the metal is excreted.

Dimercaprol is most beneficial when given very soon after exposure to the metal because it is more effective in preventing inhibition of sulfhydryl enzymes than in reactivating them. Dimercaprol limits toxicity from arsenic, gold, and mercury, which form mercaptides with essential cellular sulfhydryl groups. It also is used in combination with  $\text{CaNa}_2\text{EDTA}$  to treat lead poisoning.

Dimercaprol is contraindicated for use following chronic exposures to heavy metals because it does not prevent neurotoxic effects. There is

evidence in laboratory animals that dimercaprol mobilizes lead and mercury from various tissues to the brain (Andersen and Aaseth, 2002). This effect may be due to the lipophilic nature of dimercaprol and is not observed with its more hydrophilic analogs described later (see “Succimer” and “Sodium 2,3-Dimercaptopropane Sulfonate [DMPS]”).

**Absorption, Distribution, and Excretion.** Dimercaprol cannot be administered orally; it is given by deep intramuscular injection as a 100 mg/mL solution in peanut oil and should not be used in patients who are allergic to peanuts or peanut products. Peak concentrations in blood are attained in 30-60 minutes. The  $t_{1/2}$  is short, and metabolic degradation and excretion essentially are complete within 4 hours. Dimercaprol and its chelates are excreted in both urine and bile.

**Toxicity.** The administration of dimercaprol produces a number of side effects, which occur in ~50% of subjects receiving 5 mg/kg intramuscularly. One of the most consistent responses to dimercaprol is a rise in systolic and diastolic arterial pressures, accompanied by tachycardia. The rise in pressure may be as great as 50 mm Hg in response to the second of two doses (5 mg/kg) given 2 hours apart. The pressure rises immediately but returns to normal within 2 hours.

Dimercaprol also can cause anxiety and unrest, nausea and vomiting, headache, a burning sensation in the mouth and throat, a feeling of constriction or pain in the throat and chest, conjunctivitis, blepharospasm, lacrimation, rhinorrhea, salivation, tingling of the hands, a burning sensation in the penis, sweating, abdominal pain, and the occasional appearance of painful sterile abscesses at the injection site. The dimercaprol–metal complex breaks down easily in an acidic medium; production of an alkaline urine protects the kidney during therapy. Children react similarly to adults, although ~30% also may experience a fever that disappears on drug withdrawal. Dimercaprol is contraindicated in patients with hepatic insufficiency, except when this condition is a result of arsenic poisoning.

## Succimer

Succimer (2,3-dimercaptosuccinic acid [DMSA], *CHEMET*) is an orally effective chelator that is chemically similar to dimercaprol but contains two carboxylic acids that modify the spectrum of absorption, distribution, and chelation of the drug. It has an improved toxicity profile over dimercaprol.

***Absorption, Distribution, and Excretion.*** After its absorption in humans, succimer is biotransformed to a mixed disulfide with cysteine (Aposhian and Aposhian, 2006). Succimer lowers blood lead levels and attenuates lead toxicity. The succimer–lead chelate is eliminated in both urine and bile. The fraction eliminated in bile can undergo enterohepatic circulation.

*Succimer has several desirable features over other chelators.* It is orally bioavailable, and because of its hydrophilic nature, it does not mobilize metals to the brain or enter cells. It also does not significantly chelate essential metals such as zinc, copper, or iron. As a result of these properties, succimer exhibits a much better toxicity profile relative to other chelators. Animal studies suggest that succimer also is effective as a chelator of arsenic, cadmium, mercury, and other toxic metals (Andersen and Aaseth, 2002; Kalia and Flora, 2005).

***Toxicity.*** Succimer is much less toxic than dimercaprol. Transient elevations in hepatic transaminases have been observed with succimer treatment. The most commonly reported adverse effects are nausea, vomiting, diarrhea, and loss of appetite. In a few patients, rashes necessitate discontinuation of therapy.

Succimer has been approved in the U.S. for treatment of children with blood lead levels  $>45$   $\mu\text{g/dL}$ . Because of its oral availability, improved toxicity profile, and selective chelation of heavy metals, succimer also is used off label for the treatment of adults with lead poisoning and for the treatment of arsenic and mercury intoxication, although no large clinical trials have been undertaken for these indications.

## **Sodium 2,3-Dimercaptopropane Sulfonate (DMPS)**

DMPS is another dimercapto compound used for the chelation of heavy metals. DMPS is not approved by the FDA but is approved for use in Germany. DMPS is available from compounding pharmacies and is used by some doctors in the U.S.

***Chemistry and Mode of Action.*** DMPS is a clinically effective chelator of lead, arsenic, and especially mercury. It is orally available and is rapidly excreted, primarily through the kidneys. It is negatively charged and exhibits distribution properties similar to those of succimer. DMPS is less toxic than dimercaprol but mobilizes zinc and copper and thus is more toxic than

succimer. In a small clinical trial, DMPS exhibited some clinical benefit for the treatment of chronic arsenic poisoning. Similar benefits were not observed with either dimercaprol or succimer, suggesting that DMPS might be effective for treatment of chronic heavy metal poisonings (Kalia and Flora, 2005). However, more thorough clinical studies are needed.

## **Penicillamine; Trientine**

Penicillamine was first isolated in 1953 from the urine of patients with liver disease who were receiving penicillin. Discovery of its chelating properties led to its use in patients with Wilson's disease (excess body burden of copper due to diminished excretion) and heavy-metal intoxications. Penicillamine is more toxic and is less potent and selective for chelation of heavy metals relative to other available chelation drugs. It is therefore not a first-line treatment for acute intoxication with lead, mercury, or arsenic. However, because it is inexpensive and orally bioavailable, it often is given at fairly low doses following treatment with  $\text{CaNa}_2\text{EDTA}$  and/or dimercaprol to ensure that the concentration of metal in the blood stays low following the patient's release from the hospital.

Penicillamine is an effective chelator of copper, mercury, zinc, and lead and promotes the excretion of these metals in the urine.

### ***Absorption, Distribution, Biotransformation, and Excretion.***

Penicillamine (CUPRIMINE, DEPEN) is available for oral administration. For chelation therapy, the usual adult dose is 1-1.5 g/day in four divided doses. The drug should be given on an empty stomach to avoid interference by metals in food. In addition to its use as a chelating agent for the treatment of copper, mercury, and lead poisoning, penicillamine is used in Wilson's disease (hepatolenticular degeneration owing to an excess of copper), cystinuria, and rheumatoid arthritis (rarely). For the treatment of Wilson's disease, 1-2 g/day usually is administered in four doses. The urinary excretion of copper should be monitored to determine whether the dosage of penicillamine is adequate.

Penicillamine is well absorbed (40-70%) from the GI tract. Food, antacids, and iron reduce its absorption. Peak concentrations in blood are obtained between 1 and 3 hours after administration. Penicillamine is relatively stable *in vivo* compared to its unmethylated parent compound cysteine. Hepatic biotransformation primarily is responsible for degradation

of penicillamine, and very little drug is excreted unchanged. Metabolites are found in both urine and feces. *N*-Acetylpenicillamine is more effective than penicillamine in protecting against the toxic effects of mercury, presumably because it is more resistant to metabolism.

**Toxicity.** With long-term use, penicillamine induces several cutaneous lesions, including urticaria, macular or papular reactions, pemphigoid lesions, lupus erythematosus, dermatomyositis, adverse effects on collagen, and other less serious reactions, such as dryness and scaling. Cross-reactivity with penicillin may be responsible for some episodes of urticarial or maculopapular reactions with generalized edema, pruritus, and fever that occur in as many as one-third of patients taking penicillamine. The hematological system also may be affected severely; reactions include leukopenia, aplastic anemia, and agranulocytosis. These may occur at any time during therapy and may be fatal, so patients should be monitored carefully.

Renal toxicity induced by penicillamine usually is manifested as reversible proteinuria and hematuria, but it may progress to nephrotic syndrome with membranous glomerulopathy. More rarely, fatalities have been reported from Goodpasture's syndrome. Toxicity to the pulmonary system is uncommon, but severe dyspnea has been reported from penicillamine-induced bronchoalveolitis. Myasthenia gravis also has been induced by long-term therapy with penicillamine. Penicillamine is a teratogen in laboratory animals, but for pregnant women with Wilson's disease, the benefits appear to outweigh the risks. Less serious side effects include nausea, vomiting, diarrhea, dyspepsia, anorexia, and a transient loss of taste for sweet and salt, which is relieved by supplementation of the diet with copper. Contraindications to penicillamine therapy include pregnancy, renal insufficiency, or a previous history of penicillamine-induced agranulocytosis or aplastic anemia.

**Trientine.** Penicillamine is the drug of choice for treatment of Wilson's disease. However, the drug produces undesirable effects, as discussed in "Toxicity," and some patients become intolerant. For these individuals, trientine (triethylenetetramine dihydrochloride, SYPRINE) is an acceptable alternative. Trientine is an effective cupriuretic agent in patients with Wilson's disease, although it may be less potent than penicillamine. The drug is effective orally. Maximal daily doses of 2 g for adults or 1.5 g for children

are taken in two to four divided portions on an empty stomach. Trientine may cause iron deficiency; this can be overcome with short courses of iron therapy, but iron and trientine should not be ingested within 2 hours of each other.

## **Deferoxamine; Deferasirox**

Deferoxamine is isolated as the iron chelate from *Streptomyces pilosus* and is treated chemically to obtain the metal-free ligand. Deferoxamine has the desirable properties of a remarkably high affinity for ferric iron ( $K_a = 1031$ ) coupled with a very low affinity for calcium ( $K_a = 102$ ). *In vitro*, it removes iron from hemosiderin and ferritin and, to a lesser extent, from transferrin. Iron in hemoglobin or cytochromes is not removed by deferoxamine.

**Absorption, Distribution, and Excretion.** Deferoxamine (deferoxamine mesylate, *DEFERAL*) is poorly absorbed after oral administration, and parenteral administration is required. For severe iron toxicity (serum iron levels  $>500 \mu\text{g/dL}$ ), the intravenous route is preferred. The drug is administered at 10-15 mg/kg/hour by constant infusion. Faster rates of infusion (45 mg/kg/hour) have been used in a few cases; rapid boluses usually are associated with hypotension. Deferoxamine may be given intramuscularly in moderately toxic cases (serum iron 350-500  $\mu\text{g/dL}$ ) at a dose of 50 mg/kg with a maximum dose of 1 g. Hypotension also can occur with the intramuscular route.

For chronic iron intoxication (e.g., thalassemia), an intramuscular dose of 0.5-1.0 g/day is recommended, although continuous subcutaneous administration (1-2 g/day) is almost as effective as intravenous administration. During blood transfusion, patients with thalassemia should be given 2 g deferoxamine (per unit of blood) by slow intravenous infusion (rate not to exceed 15 mg/kg/hour) by a separate line. Deferoxamine is not recommended in primary hemochromatosis; phlebotomy is the treatment of choice. Deferoxamine also has been used for the chelation of aluminum in dialysis patients.

Deferoxamine is metabolized by plasma enzymes, but the pathways have not yet been defined. The drug is excreted readily in the urine.

**Toxicity.** Deferoxamine causes a number of allergic reactions, including pruritus, wheals, rash, and anaphylaxis. Other adverse effects include

dysuria, abdominal discomfort, diarrhea, fever, leg cramps, and tachycardia. Occasional cases of cataract formation have been reported. Deferoxamine may cause neurotoxicity during long-term, high-dose therapy for transfusion-dependent thalassemia major; both visual and auditory changes have been described. A “pulmonary syndrome” has been associated with high-dose (10-25 mg/kg/hr) deferoxamine therapy; tachypnea, hypoxemia, fever, and eosinophilia are prominent symptoms. Contraindications to the use of deferoxamine include renal insufficiency and anuria; during pregnancy, the drug should be used only if clearly indicated.

**Deferasirox.** Deferasirox (EXJADE) is an orally administered chelator of iron. It is FDA-approved for treatment of chronic iron overload in patients receiving therapeutic blood transfusions.

## *Appendix I*

# Principles of Prescription Order Writing and Patient Compliance

**Iain L. O. Buxton**

From the wrong drug prescribed to the wrong dosage or administration schedule advised, dispensed, or administered, the impact of medication misadventures is a costly problem. Errors of these sorts occur because human beings are involved, and such errors can be prevented only by systems that make it difficult to do the wrong thing. This appendix provides a primer on the proper approach to the medication prescription and order process and a resource for practitioners in effectively providing pharmaceutical care for their patients.

## THE MECHANICS OF PRESCRIPTION ORDER WRITING

### History

Early medicines were made up of multiple ingredients requiring complex preparation, and Latin was adopted as the standard language of the prescription to ensure understanding between physician and pharmacist and consistency in pharmaceutical composition. Latin no longer is the international language of medicine, but a number of commonly used abbreviations derive from old Latin usage. The symbol “Rx” is said to be an abbreviation for the Latin word *recipere*, meaning “take” or “take thus,” as a direction to a pharmacist, preceding the physician’s “recipe” for preparing a medication. The abbreviation “Sig” for the Latin *Signatura*, is used on the prescription to mark the directions for administration of the medication.

### Current Practice

The prescription consists of the *superscription*, the *inscription*, the *subscription*, the *signa*, and the *name and signature of the prescriber*, all contained on a single form ([Figure AI-1](#)).

The *superscription* includes the date the prescription order is written; the name, address, weight, and age of the patient; and the Rx (*Take*). The body of the prescription, or *inscription*, contains the name and amount or strength of the drug to be dispensed, or the name and strength of each ingredient to be compounded. The *subscription* is the instruction to the pharmacist, usually consisting of a short sentence such as: “make a solution,” “mix and place into 30 capsules,” or “dispense 30 tablets.” The *signa* or “*Sig*” is the instruction for the patient as to how to take the prescription, interpreted and transposed onto the prescription label by the pharmacist. In the U.S., prescriptions should always be written in English. Many physicians continue to use Latin abbreviations; for example, “1 cap tid pc,” will be interpreted by the pharmacist as “take one capsule three times daily after meals.” However, the use of Latin abbreviations for these directions only mystifies the prescription and is discouraged. This can be a hindrance to proper patient-physician communication and is an otherwise unnecessary source of potential dispensing errors. Because the pharmacist always writes the label in English (or, as appropriate, in the language of the patient), the use of such abbreviations or symbols is unnecessary. Many serious dispensing errors can be traced to the use of abbreviations (Cohen, 2007).

The instruction “take as directed” is not satisfactory and should be avoided by the physician. Such directions assume an understanding on the part of the patient that may not be realized and inappropriately exclude the pharmacist from the pharmaceutical care process. Such directions are inadequate for the pharmacist, who must determine the intent of the physician before dispensing the medication, and who shares the responsibility for the patient’s safe and proper use of the medication. The best directions to the patient will include a reminder of the intended purpose of the medication by including such phrases as “for relief of pain” or “to relieve itching.” The correct route of administration is reinforced by the choice of the first word of the directions. For an oral dosage form, the directions should begin with “take” or “give” for externally applied products, the word “apply” for suppositories, “insert” and for eye, ear, or nose drops, “place” is preferable to “instill.”

Superscription	Date: <u>April 10, 2010</u>	Aptus Medical Arts W.E. Hansen 123 Homestead Pl. Suite 2 Searchlight, NV 89046	
	Name: <u>Harry Hypertensive</u> (M/F)	Age: <u>59</u>	
	Address: <u>999 Gold Mine Rd</u>	Wt: <u>93.6</u> kg	
Inscription	<b>R<sub>x</sub></b> <u>Losartan 50 milligram Tabs, Dispense #30</u>		
	<b>Sig:</b> <u>Take one by mouth daily in the morning for blood pressure control</u>		
Subscription	Refill <u>6 (six)</u> times	Signature <u>WE Hansen, MD</u>	
	Generic Substitution <u>OK</u>	DEA #: _____	

**Figure AI-1. The prescription.** The prescription must be carefully prepared to identify the patient and the medication to be dispensed, as well as the manner in which the drug is to be administered. Accuracy and legibility are essential. Use of abbreviations, particularly Latin, is discouraged, because it leads to dispensing errors. Inclusion of the therapeutic purpose in the subscription (e.g., “*for control of blood pressure*”) can prevent errors in dispensing. For example, the use of losartan for the treatment of hypertension may require 100 mg/day (1.4 mg/kg/day), whereas treatment of congestive heart failure with this angiotensin II receptor antagonist generally should not exceed 50 mg/day. Including the therapeutic purpose of the prescription also can assist patients in organizing and understanding their medications. In addition, including the patient’s weight on the prescription can be useful in avoiding dosing errors, particularly when drugs are administered to children.

## Prescriptive Authority

In many states in the U.S., healthcare practitioners other than M.D. and D.O. physicians can write prescriptions. Licensed physician’s assistants (P.A.), nurse practitioners, pharmacists, and clinical psychologists can prescribe medications under various circumstances.

## Avoiding Confusion

Doses always should be listed by metric weight of the active ingredient; doses for liquid medications should include the volume. Older systems of measure such as minims for volume (15 minims = 1 mL) and grains for weight (1 grain = 60 mg) are obscure and should not be used. Writing “ $\mu\text{g}$ ” for micrograms can very easily be misinterpreted as “mg” (milligrams). Even the abbreviation “mcg” for micrograms can be misinterpreted (Koczmar et al., 2005). Writing out the word *micrograms* or *milligrams* is preferable. When specifying the dose to be dispensed, a zero should be used before a decimal (0.# milligrams, rather than.# milligrams) but not after (use # milligrams rather than #.0 milligrams). The metric system should be used in place of common household measurements such as “dropperful” and “teaspoon” in the directions for the patient except when the dropper is provided with the prescription, as in the case of pediatric antibiotic suspensions. Both the doctor and the pharmacist should be sure that the patient understands the measurement prescribed. For medical purposes, a “teaspoon” or “teaspoonful” dose is considered to be equivalent to 5 mL and a “tablespoon” equivalent to 15 mL, but the actual volumes held by ordinary household teaspoons and tablespoons are far too variable to be used reliably for measurement of medications. Prescribing oral medications in “drops” likewise can cause problems when accuracy of dose is important, unless the patient understands that only the calibrated dropper (for drops or teaspoon measures) provided by the manufacturer or pharmacist should be used to dispense the medication. Thus, one possible dosage for a pediatric iron product would be more accurately written “15 milligrams (0.6 mL) three times daily” instead of “one dropperful three times daily,” because a true dropperful could result in iron overdose.

Abbreviations lead to dispensing errors (Teichman and Caffee, 2002). A prescription intending every-otherday dosing (qod) may be miswritten as “od” by the physician for “other-day dosing” the pharmacist may interpret “od” as the abbreviation of the Latin for “right eye.” Once-daily dosing at bedtime (qhs) may be misinterpreted as “qhr” for “every hour.” The use of a slash mark (/) to separate names and doses can result in the incorrect drug or dose being dispensed; the slash mark may be interpreted as a letter or number. When medications are measured in units, or international units, the abbreviation “U” or “I” must NOT be used, as it leads to errors such as

misinterpretation of “U” as 0 or 4, or “IU” as 10 or 14. The word “unit” should be written as such. Drug products available in the U.S. that are dosed in units (e.g., corticotropin) or international unit measures are “harmonized” by those responsible for drug standardization to avoid errors in dosing (see “Drug Standards and Classification”). Examples of confusion in the interpretation of a physician order abound (Kohn, 2001) and are considered further in “Errors in Drug Orders.” *To avoid errors, practitioners in the U.S. must write out the Rx fully in English, and pharmacists must clarify their concerns with prescribers, not patients.*

## **Proper Patient Information**

The patient’s name and address are needed on the prescription order to ensure that the correct medication goes to the proper patient and also for identification and recordkeeping purposes. For medications whose dosage involves a calculation, a patient’s pertinent factors, such as weight, age, or body surface area, also should be listed on the prescription. Prescribers should view this effort as one that serves their goal of protecting their patient from errors rather than a burden (*safety first*).

Prescribers often commit errors in dosage calculations (Lesar et al., 1997) that can be prevented (Kuperman et al., 2001; Conroy et al., 2007). When prescribing a drug whose dosage involves a calculation based on body weight or surface area, both the calculated dose and the dosage formula used, such as “240 mg every 8 hours (40 mg/kg/day),” should be included to allow another healthcare professional to double-check the prescribed dosage. Pharmacists always should recalculate dosage equations when filling such prescriptions. Medication orders in hospitals and some clinic settings, such as those for antibiotics or anti-seizure medications that are sometimes difficult to adequately dose (e.g., phenytoin), can specify the patient diagnosis and desired drug and request dosing by the clinical pharmacist.

## **Proper Use of Prescription Pad**

All prescriptions should be written in ink; this practice is compulsory for schedule II prescriptions under the U.S. Controlled Substances Act (CSA) of 1970, because erasures on a prescription easily can lead to dispensing errors or diversion of controlled substances.

Prescription pad blanks normally are imprinted with a heading that gives the name of the physician and the address and phone number of the practice site ([Figure AI-1](#)). When using institutional blanks that do not bear the physician's information, the physician always should print his or her name and phone number on the face of the prescription to clearly identify the prescriber and facilitate communication with other healthcare professionals if questions arise. U.S. law requires that prescriptions for controlled substances include the name, address, and Drug Enforcement Administration (DEA) registration number of the physician.

The date of the prescription is an important part of the patient's medical record, and it can assist the pharmacist in recognizing potential problems. For example, when an opioid is prescribed for pain due to an injury, and the prescription is presented to a pharmacist 2 weeks after issuance, the drug may no longer be indicated. Compliance behavior also can be estimated using the dates when a prescription is filled and refilled. The CSA requires that all orders for controlled substances ([Table AI-1](#)) be dated as of, and signed on, the day issued and prohibits filling or refilling orders for substances in schedules III and IV >6 months after their date of issuance. When writing the original prescription, the physician should designate the number of refills allowed. For maintenance medications without abuse potential, it is reasonable to write for a 1-month supply and to mark the prescription form for refills to be dispensed over a period sufficient to supply the patient until the next scheduled visit to the physician.

### **Table AI—1 Controlled Substance Schedules**

**Schedule I** (examples: heroin, methylene dioxymethamphetamine, lysergic acid diethylamide, mescaline, and all salts and isomers thereof):

1. High potential for abuse.
2. No accepted medical use in the U.S. or lacks accepted safety for use in treatment in the U.S. May be used for research purposes by properly registered individuals.

**Schedule II** (examples: morphine, oxycodone, fentanyl, meperidine, dextroamphetamine, cocaine, amobarbital):

1. High potential for abuse.
2. Has a currently accepted medical use in the U.S.

3. Abuse of substance may lead to severe psychological or physical dependence.

**Schedule III** (examples: anabolic steroids, nalorphine, ketamine, certain schedule II substances in suppositories, mixtures, or limited amounts per dosage unit):

1. Abuse potential less than substances in schedule I or schedule II.
2. Has a currently accepted medical use in the U.S.
3. Abuse of substance may lead to moderate to low physical dependence or high psychological dependence.

**Schedule IV** (examples: alprazolam, phenobarbital, meprobamate, modafinil):

1. Abuse potential less than substances in schedule III.
2. Has a currently accepted medical use in the U.S.
3. Abuse of substance may lead to limited physical or psychological dependence relative to substances in schedule III.

**Schedule V** (examples: buprenorphine, products containing a low dose of an opioid plus a non-narcotic ingredient such as cough syrup with codeine<sup>a</sup> and guaifenesin, anti-diarrheal tablets with diphenoxylate and atropine):

1. Low potential for abuse relative to schedule IV.
2. Has a currently accepted medical use in the U.S.
3. Some schedule V products may be sold in limited amounts without a prescription at the discretion of the pharmacist; however, if a physician wishes a patient to receive one of these products, it is preferable to provide a prescription.

---

<sup>a</sup>Although codeine is a schedule II drug, its dosage in cough syrups is regarded as sufficiently low to permit their classification as schedule V substances.

A statement such as “refill prn” (refill as needed) is not appropriate, as it could allow the patient to misuse the medicine or neglect medical appointments. If no refills are desired, “zero” (not “0”) should be written in the refill space to prevent alteration of the prescriber’s intent. Refills for controlled substances are discussed later, in “Refills” under “Controlled Substances.”

Concern about the rising cost of healthcare has favored the dispensing of so-called “generic” drugs. A drug is called by its generic name (in the U.S., this is the U.S. Adopted Name or USAN) or the manufacturer’s proprietary name, called the trademark, trade name, or brand name. In most states in the U.S., pharmacists have the authority to dispense generic drugs rather than brand-name medications. The physician can request that the pharmacist not substitute a generic for a branded medication by indicating this on the prescription (“do not substitute”), although this generally is unnecessary because the U.S. Food and Drug Administration (FDA) requires that generic medications meet the same bioequivalence standards as their brand-name counterparts. In some jurisdictions, prescriptions may not be filled with a generic substitution unless specifically permitted on the prescription. Occasions when substituting generic medications is discouraged are limited to products with specialized release systems and narrow therapeutic indices, or when substantial patient confusion and potential noncompliance may be associated with substitution.

## **Choice and Amount of Drug Product Dispensed**

Inappropriate choice of drugs by physicians is a problem in prescribing. As learned recently with the cyclooxygenase-2 (COX-2) inhibitors, a drug’s therapeutic promise or popularity is not proof of its overall clinical superiority or safety (Topol, 2004). Physicians must rely on unbiased sources when seeking drug information that will influence their prescribing habits; use of the original medical literature will ensure instruction of the prescriber’s best judgment.

The amount of a drug to be dispensed should be clearly stated and should be only that needed by the patient. Excessive amounts should never be dispensed, because this not only is expensive for the patient but may lead to accumulation of medicines, which can lead to harm to the patient or members of the patient’s family if used inappropriately. It is far better to have several refills of a prescription than to have more than necessary prescribed at one time.

## **The Prescription as a Commodity**

Prescribers must be aware that patients may visit their doctor to “get” a prescription. Indeed, in an era when the time spent between physician and

patient is ever shorter due to limits and pressures of physician reimbursements, patients often feel that a trip to the doctor that does not result in a new prescription somehow is a failed visit or a lost opportunity. Similarly, physicians may feel that they have fulfilled their role if the patient leaves with a prescription. Physicians must educate their patients about the importance of viewing medicines as to be used only when really needed and that remaining on a particular medicine when their condition is stable may be preferable to seeking the newest medications available.

## **Prescription Drug Advertising**

The Federal Food, Drug, and Cosmetic Act as amended (Food and Drug Administration Modernization Act of 1997) permits the use of print and television advertising of prescription drugs. The law requires that all drug advertisements contain (among other things) summary information relating to side effects, contraindications, and effectiveness. The current advertising regulations specify that this information disclosure needs to include all the risk information in a product's approved labeling or must direct consumers to healthcare professionals to obtain this information. Typically, print advertisements will include a reprinting of the risk-related sections of the product's approved labeling (package insert), while television advertising will not. In addition, advertisements cannot be false or misleading or omit material facts. They also must present a fair balance between effectiveness and risk information.

The benefits of these types of direct-to-consumer (DTC) advertising, including Internet advertising, are controversial (Findlay, 2001). Dramatizations employed by television commercials may be a disservice to the physician's ability to educate and care for the patient if such advertisements only create brand loyalty. Alternatively, patients who learn about drugs on television may interact more effectively with their healthcare providers by asking questions about the medicines they take. Prescription drug advertising has alerted consumers to the existence of new drugs and the conditions they treat, but it has also increased consumer demand for drugs. This demand has increased the number of prescriptions being dispensed (raising sales revenues) and has contributed to the higher pharmaceutical costs borne by health insurers, government, and consumers. In the face of a growing demand for particular brand-name drugs driven by advertising,

physicians and pharmacists must be able to counsel patients effectively and provide them with evidence-based drug information (Khanfar et al., 2007).

## **ERRORS IN DRUG ORDERS**

The Institute of Medicine (IOM) estimates that the annual number of medical errors in the U.S. that results in death is between 44,000 and 98,000 (Kohn et al., 2000). Although there is some controversy about these estimates (Sox and Woloshin, 2000), it is clear that the large number of medical errors includes medication errors resulting in adverse events, including death (Mangino, 2004; Tzimenatos and Bond, 2009). Databases of anonymously reported errors are maintained jointly by the Institute for Safe Medication Practices (ISMP), the U.S. Pharmacopeia Medication Errors Reporting Program (USP MERP), and the FDA's MedWatch program. Adverse drug events occur in ~3% of hospitalizations, and this number is larger for special populations such as those in pediatric and neonatal intensive care units (Chedoe et al., 2007).

By examining aspects of prescription writing that can cause errors and by modifying prescribing habits accordingly, the physician can increase the probability that the patient will receive the correct prescription. By being alert to common problems that can occur with medication orders and communicating with the patient's physician, pharmacists and other healthcare professionals can assist in reducing medication errors (Murray et al., 2009). Good practice in the preparation of medication orders in both the institutional and outpatient settings can be summarized as follows:

- Write all orders clearly using metric measurements of weight and volume.
- Include patient age and weight on the prescription, when appropriate, so dosage can be checked.
- Use Arabic (decimal) numerals rather than Roman numerals (e.g., does “IL-II” mean “IL-11” or “IL-2”?); in some instances, it is preferable for numerals to be spelled out.
- Use leading zeros (0.125 milligrams, not .125 milligrams); never use trailing zeros (5 milligrams, not 5.0 milligrams).
- Avoid abbreviating drug names; abbreviations may lead to misinterpretation.

- Avoid abbreviating directions for drug administration; write out directions clearly in English.
- Be aware of possibilities for confusion in drug names. Some drug names sound alike when spoken and may look alike when spelled out. The U.S. Pharmacopeial Convention Medication Errors Reporting Program maintains a current list of drug names that can be confused ([www.usp.org](http://www.usp.org)). The list of alliterative drug names currently contains >750 pairs of potentially confusing names that could lead to harmful prescribing or dispensing errors. Alliterative drug names can be particularly problematic when giving verbal orders to pharmacists or other healthcare providers.
- Provide the patient's diagnosis on the prescription order. This is the single most important measure to prevent dispensing errors based on sound-alike or look-alike drug names. For instance, an order for administration of magnesium sulfate must not be abbreviated "MS," as this may result in administration of morphine sulfate. Including the therapeutic purpose and/or the patient's diagnosis can prevent this error.
- Write clearly. Poor handwriting is a well-known and preventable cause of dispensing errors. Both physician and pharmacist share in the responsibility for preventing adverse drug events by writing prescriptions clearly (*When in doubt, write it out!*) and questioning intent whenever an order is ambiguous (*When in doubt, check it out!*).
- Think.

## **CONTROLLED SUBSTANCES**

In the U.S., the DEA within the Department of Justice is responsible for the enforcement of the Federal Controlled Substances Act (CSA). The DEA regulates each step of the handling of controlled substances from manufacture to dispensing (21 U.S.C. § 811). The law provides a system that is intended to prevent diversion of controlled substances from legitimate uses. Substances that come under the jurisdiction of the CSA are divided into five schedules ([Table AI-1](#)), but practitioners should note that individual states may have additional schedules. Physicians must be authorized to prescribe controlled substances by the jurisdiction in which they are licensed, and they must be registered with the DEA or exempted from registration as defined under the CSA. The number on the certificate of registration must be indicated on all prescription orders for controlled substances. Criminal

prosecution and penalties for misuse generally depend on the schedule of a substance as well as the amount of drug in question.

State agencies may impose additional regulations, such as requiring that prescriptions for controlled substances be printed on triplicate or state-issued prescription pads or restricting the use of a particular class of drugs for specific indications. Some U.S. states, such as California, have placed marijuana, classified by the FDA as a schedule I substance, in a special category by decriminalizing its possession and sale for medical use. Under California's medical marijuana laws, patients and caregivers are exempt from prosecution by the state of California, notwithstanding contrary federal law. This legal difference of opinion between state and federal regulation is the source of considerable controversy. Generally, the most stringent law takes precedence, whether it is federal, state, or local.

## **Prescription Orders for Controlled Substances**

To be valid, a prescription for a controlled substance must be issued for a *legitimate medical purpose* by an *individual practitioner* acting in the *usual course of his or her professional practice*. An order that does not meet these criteria, such as a prescription issued as a means to obtain controlled substances for the doctor's office use or to maintain addicted individuals, is not considered a legitimate prescription within the meaning of the law, and thus does not protect either the physician who issued it or the pharmacist who dispensed it. Most states prohibit physicians from prescribing controlled substances for themselves; it is prudent to comply with this guideline even if it is not mandated by law.

## **Execution of the Order**

Prescriptions for controlled substances should be dated and signed on the day of their issuance and must bear the full name and address of the patient and the printed name, address, and DEA number of the practitioner and should be signed the way one would sign a legal document. Preprinted orders are not allowed in most states, and pre-signed blanks are prohibited by Federal law. When oral orders are not permitted (schedule II), the prescription must be written with ink or typewritten. The order may be prepared by a member of the physician's staff, but the prescriber is responsible for the signature and any errors that the order may contain.

## Oral Orders

Prescriptions for schedule III, IV, and V medications may be telephoned to a pharmacy by a physician or by trusted staff in the same manner as a prescription for a noncontrolled substance, although it is in the physician's best interest to keep his or her DEA number as private as reasonably possible (see "Preventing Diversion"). Schedule II prescriptions may be telephoned to a pharmacy only in *emergency* situations. To be an emergency:

- Immediate administration is necessary
- No appropriate alternative treatment is available
- It is not reasonably possible for the physician to provide a written prescription prior to the dispensing.

For an emergency prescription, the quantity must be limited to the amount adequate to treat the patient during the emergency period, and the physician must have a written prescription delivered to the pharmacy for that emergency within 72 hours. If mailed, the prescription must be postmarked within 72 hours. The pharmacist must notify the DEA if this prescription is not received.

## Refills

No prescription order for a schedule II drug may be refilled under any circumstance. For schedule III and IV drugs, refills may be issued either orally or in writing, not to exceed five refills or 6 months after the issue date, whichever comes first. Beyond this time, a new prescription must be ordered. For schedule V drugs, there are no restrictions on the number of refills allowed, but if no refills are noted at the time of issuance, a new prescription must be made for additional drug to be dispensed.

## Preventing Diversion

Prescription blanks often are stolen and used to sustain abuse of controlled substances and to divert legitimate drug products to the illicit market. To prevent this type of diversion, prescription pads should be protected in the same manner as one would protect a personal checkbook. A prescription blank should never be pre-signed for a staff member to fill in at a later time. Also, a minimum number of pads should be stocked, and they should be kept

in a locked, secure location except when in use. If a pad or prescription is missing, it should be reported immediately to local authorities and pharmacies; some areas have systems in place to allow the rapid dissemination of such information. Ideally, the physician's full DEA number should not be pre-printed on the prescription pad, because most prescriptions will not be for controlled substances and will not require the registration number, and anyone in possession of a valid DEA number may find it easier to commit prescription fraud. Some physicians may intentionally omit part or all of their DEA number on a prescription and instead write "pharmacist call to verify" or "call for registration number." This practice works only when the pharmacist may independently verify the authenticity of the prescription, and patients must be advised to fill the prescription during the prescriber's office hours. Pharmacists can ascertain the likely authenticity of a physician's DEA number using an algorithm.

Another method employed by the drug seeker is to alter the face of a valid prescription to increase the number of units or refills. By spelling out the number of units and refills authorized instead of giving numerals, the prescriber essentially removes this option for diversion. Controlled substances should not be prescribed excessively or for prolonged periods, as the continuance of a patient's addiction is not a legitimate medical purpose.

## **DRUG STANDARDS AND CLASSIFICATION**

The U.S. Pharmacopeial Convention, Inc. is a nongovernmental organization that promotes the public health and benefits practitioners and patients by disseminating authoritative standards and information on medicines and other healthcare technologies. This organization is home to the U.S. Pharmacopeia (USP), which, together with the FDA, the pharmaceutical industry, and health professions, establishes authoritative drug standards. These standards are enforceable by the FDA and the governments of other countries and are recognized worldwide. Drug monographs are published in the USP/National Formulary (USP-NF), the official drug standards compendia that organize drugs into categories based on pharmacological actions and therapeutic uses. The USP also provides chemical reference standards to carry out the tests specified in the USP-NF. For example, a drug to be manufactured and labeled in units must comply with the USP standard for units of that compound. Such

standards are essential for agents possessing biological activity, such as insulin.

The USP also is home to the *USP Dictionary of U.S. Adopted Names (USAN) and International Drug Names*. This compendium is recognized throughout the healthcare industry as the authoritative dictionary of drugs. Entries include one or more of the following: U.S. Adopted Names, official drug names for the *National Formulary* (NF), previously used official names, International Nonproprietary Names, British Approved Names, Japanese Accepted Names, trade names, and other synonyms. In addition to names, the records in this file contain other substance information such as Chemical Abstract Service (CAS), registry number (RN), molecular formula, molecular weight, pharmacological and/or therapeutic category, drug sponsor, reference information, and structure diagram, if available. The USP maintains an electronic web site that can be accessed for useful drug naming, classification, and standards information ([www.usp.org](http://www.usp.org)).

In the U.S., drug products also are coded under the National Drug Code (NDC). The NDC originally was established as an essential part of out-of-hospital drug reimbursement under Medicare. In the U.S., the NDC serves as a universal product identifier for drugs used in humans. The current edition of the National Drug Code Directory is limited to prescription drugs and a few selected over-the-counter products. Each drug product listed under the Federal Food, Drug, and Cosmetic Act is assigned a unique 10-digit, 3-segment number. This number, known as the NDC number, identifies the labeler/vendor, product, and package size. The labeler/vendor code is assigned by the FDA. The second segment, the product code, identifies a specific strength, dosage form, and formulation for a particular drug company. The third segment, the package code, identifies package sizes. Both the product and package codes are assigned by the manufacturer.

In addition to classification of drugs by therapeutic category, drugs also are grouped by control schedule. Drug schedules in the U.S. are listed in [Table AI-1](#) from schedule I to schedule V and are discussed above under “Controlled Substances.”

The FDA also categorizes drugs that may be used in pregnant women. These categories are similar to those used in other countries and provide guidance based on available science. The risk from a drug may be throughout

pregnancy or limited to a particular period of fetal development. The categories range from A to X, in increasing order of concern, as noted here:

**Pregnancy Category A:** Adequate and well-controlled studies have failed to demonstrate a risk to the fetus in the first trimester of pregnancy (and there is no evidence of risk in later trimesters). Because of the obvious nature of the risk associated with the use of medications during gestation, the FDA requires a body of high-quality data on a drug before it can be considered for Pregnancy Category A.

**Pregnancy Category B:** Animal reproduction studies have failed to demonstrate a risk to the fetus, and there are no adequate and well-controlled studies in pregnant women, OR animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester.

**Pregnancy Category C:** Animal reproduction studies have shown an adverse effect on the fetus, and there are no adequate and well-controlled studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks.

**Pregnancy Category D:** There is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience or studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks.

**Pregnancy Category X:** Studies in animals or humans have demonstrated fetal abnormalities, and/or there is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience, and the risks involved in use of the drug in pregnant women clearly outweigh potential benefits.

Physicians should realize that the pregnancy categories by themselves provide little guidance for the physician treating pregnant women. For example, angiotensin-converting enzyme (ACE) inhibitors such as captopril cause developmental toxicity (Category X) only after the first trimester. Physicians' primary responsibility remains treating the pregnant patient.

However, the risks of withholding treatment to the mother because of possible risks to the fetus have to be considered as well.

Drugs also are grouped by their potential for misuse under British and U.N. legal classifications as class A, B, or C. The classes are linked to maximum legal penalties in a descending order of severity, from A to C.

## COMPLIANCE

Compliance may be defined as the extent to which the patient follows a regimen prescribed by a healthcare professional. The assumption that the doctor tells the patient what to do and then the patient meticulously follows orders is unrealistic. The patient is the final and most important determinant of how successful a therapeutic regimen will be and should be engaged as an active participant who has a vested interest in its success. Whatever term is used—*compliance*, *adherence*, *therapeutic alliance*, or *concordance*—physicians must promote a collaborative interaction between doctor and patient in which each brings an expertise that helps to determine the course of therapy. The doctor is the medical expert; the patient is the expert on himself and his beliefs, values, habits, and lifestyle. The patient's quality-of-life beliefs may differ from the clinician's therapeutic goals, and the patient will have the last word every time when there is an unresolved conflict.

Even the most carefully prepared prescription for the ideal therapy will be useless if the patient's level of compliance is not adequate. Noncompliance may be manifest in drug therapy as intentional or accidental errors in dosage or schedule, overuse, underuse, early termination of therapy, or not having a prescription filled (Hagstrom et al., 2004); therapeutic failures can result (Hobbs, 2004). Noncompliance always should be considered in evaluating potential causes of inconsistent or nonexistent response to therapy. The reported incidence of patient noncompliance varies widely but usually is in the range of 30-60% (Zyczynski and Coyne, 2000); the rate for long-term regimens is ~50% but can be impacted by pharmaceutical care management (Klein et al., 2009).

Hundreds of variables that may influence compliance behavior in a specific patient or condition have been identified. A few of the most frequently cited are discussed here, along with some suggestions for improving compliance, although none provides 100% compliance ([Table AI-2](#)).

---

### **Table AI–2 Suggestions for Improving Patient Compliance**

- Provide respectful communication; ask how patient takes medicine.
- Develop satisfactory, collaborative relationship between physician and patient; encourage pharmacist involvement.
- Provide and encourage use of medication counseling.
- Give precise, clear instructions, with most important information given first.
- Support oral instructions with easy-to-read written information.
- Simplify whenever possible.
- Use mechanical compliance aids as needed (sectioned pill boxes or trays, compliance packaging, color-coding).
- Use optimal dosage form and schedule for each individual patient.
- Assess patient’s literacy, language, and comprehension, and modify educational counseling as needed. Be culturally aware and sensitive. To improve compliance, don’t rely on patient’s own knowledge of disease alone.
- Find solutions when physical or sensory disabilities are present (use nonsafety caps on bottles, use large type on labels and written material, place tape marks on syringes).
- Enlist support and assistance from family or caregivers.
- Use behavioral techniques such as goal setting, self-monitoring, cognitive restructuring, skills training, contracts, and positive reinforcement.

## **The Patient-Provider Relationship**

Patient satisfaction with the physician has a significant impact on compliance behavior and is one of few factors that the physician can directly influence. Patients are more likely to follow instructions and recommendations when their expectations for the patient–provider relationship and for their treatment are met. These expectations include not only clinical but also interpersonal competence, so cultivating good interpersonal and communication skills is essential. Cultural sensitivity is of growing importance, as healthcare providers see more patients from countries and cultures different from their own.

When deciding on a course of therapy, it can be useful to discuss a patient's habits and daily routine as well as the therapeutic options with the patient. This information may suggest cues for remembrance, such as storing a once-daily medicine atop the books on the bedside table for a patient who reads nightly, or in the cabinet with the coffee cups if it is to be taken in the morning (noting that the humid environment of a bathroom can be the worst place to store a medication in terms of its physical and chemical preservation). The information also can help tailor the regimen to the patient's lifestyle. A lack of information about a patient's lifestyle can lead to situations such as prescribing a medication to be taken with meals three times daily for a patient who only eats twice a day or a medication to be taken each morning for a patient who works a night shift and sleeps during the day. Rarely is there only one treatment option for a given problem, and it may be better to prescribe an adequate regimen that the patient will follow instead of an ideal regimen that the patient will not. Involving patients in the control of any appropriate aspects of their therapy may improve compliance, not only by aiding memory and making the dosage form or schedule more agreeable or convenient, but also by giving patients a feeling of empowerment and emphasizing their responsibility for the treatment outcome.

It is not unreasonable for the physician to ask the patient whether he or she intends to adhere to the prescribed therapy and to negotiate to get a commitment to do so. Attempts should be made to resolve collaboratively any conflicts that may hinder compliance.

## **Patients and Their Beliefs**

Behavioral models suggest that patients are more likely to be compliant when they *perceive* that they are susceptible to the disease, that the disease may have serious negative impact, that the therapy will be effective, and that the benefits outweigh the costs, and when they believe in their own efficacy to execute the therapy. From the standpoint of compliance, the *actual* severity of and susceptibility to an illness is not necessarily an issue; rather, the patient's perception of severity affects compliance (Dijkstra et al., 2008).

Patients' beliefs can lead them to deliberately alter their therapy, whether for convenience, for personal experiments, because of a desire to remove themselves from the sick role, as a means to exercise a feeling of control over their situation, or for other reasons. This reinforces the need for

excellent communication and a good patient–provider relationship to facilitate the provision of additional or corrective education when the beliefs would suggest poor compliance as an outcome.

It is difficult to predict whether a particular patient will be compliant, because there is no consistent relationship with isolated demographic variables such as age, sex, education level, intelligence, personality traits, and income. Certain of these variables have been implicated in specific situations, but they cannot be applied to the population as a whole. Social isolation generally has been found to be associated with poor compliance, although family members or other people close to the patient can undermine compliance as easily as they can support it. As noted above, the actual severity of the patient’s disease is not predictive of compliance behavior, but characteristics of the disease can make adherence less likely, as with certain neurodegenerative or psychiatric illnesses.

Pharmacists have a legal and professional responsibility to offer medication counseling in many situations—even though practice environments are not always conducive to its provision—and can educate and support patients by discussing prescribed medications and their use. Because they often see the patient more frequently than does the physician, pharmacists who take the time to inquire about a patient’s therapy can help identify compliance and other problems, educate the patient, and notify the physician as appropriate. Indeed, data from the Asheville Project indicate that a pharmacist-based medication management program provides significant advantages with respect to compliance, health outcomes, and cost (Bunting et al., 2008).

Elderly patients often face a number of barriers to compliance related to their age. Such barriers include increased forgetfulness and confusion; altered drug disposition and higher sensitivity to some drug effects; decreased social and financial support; decreased dexterity, mobility, or sensory abilities; and the use of a greater number of concurrent medicines (both prescription and over-the-counter) whose attendant toxicities and interactions may cause decreased mental alertness or intolerable side effects. There are drugs known to be inappropriate to prescribe to elderly patients (Curtis et al., 2004; Fick et al., 2003) and some that may adversely affect compliance. Despite these obstacles, evidence does not show that elderly patients in general are significantly less compliant than any other age group.

Still, as the U.S. population ages, elderly patients will consume a disproportionate fraction of medicines and healthcare resources, so there is great opportunity and motivation to improve their drug-taking habits. Physicians must be careful in choosing medications for the elderly (O'Mahony and Gallagher, 2008; Lopez and Goldoftas, 2009). Pharmacists must pay particular attention to thorough and compassionate counseling for elderly patients and should assist patients in finding practical solutions when problems, such as polypharmacy, are noted.

## **The Therapy**

Increased complexity and duration of therapy are perhaps the best-documented barriers to compliance. The patient for whom multiple drugs are prescribed for a given disease or who has multiple illnesses that require drug therapy will be at higher risk for noncompliance, as will the patient whose disease is chronic. The frequency of dosing of individual medications also can affect compliance behavior. Simplification, whenever possible and appropriate, is desirable.

The effects of the medication can make adherence less likely, as in the case of patients whose medicines cause confusion or other altered mental states. Unpleasant side effects from the medicine may influence compliance in some patients but are not necessarily predictive, especially if patient beliefs or other positive factors tend to reinforce adherence to the regimen. A side effect that is intolerable to one patient may be of minor concern to another. The cost of medicine can be a heavy burden for patients with limited economic resources, and healthcare providers should be sensitive to this fact (Restrepo et al., 2008). Mobile devices (e.g., iPhone) running drug formulary/therapeutic software now can provide the costs of medications, as can physicians who are familiar with the patient's insurance plan. Mobile phone systems that provide reminders and collect patient response information are being introduced and may become more popular as patients become increasingly tech savvy.

## **ELECTRONIC PRESCRIBING**

The era of e-prescribing has begun. Its implementation is still expensive, but the subsequent benefits to patients and savings in personnel costs, along with its integration with electronic medical records, drug inventory control, and

billing, point to the wide use of e-prescribing in the future. Computerized prescription ordering eliminates some of the subjective features of prescribing. Thus, if the proper information is entered correctly in the electronic system, medication errors due to illegible handwriting, incorrect dose, incorrect medication for medical condition, and drug interactions can be reduced, because each prescription can be linked to high-quality drug databases that check that the information on the prescription is appropriate for the patient (e.g., age, weight, gender, condition, lab values, disease being treated, concurrent medications) and that known warnings and potential problems are brought to the attention of the physician, pharmacist, and patient. Such systems must not be used as a substitute for personal attention to the individual patient by healthcare workers but, rather, as an adjunct measure that ensures safe, high-quality, efficient care.

## *Appendix II*

# **Design and Optimization of Dosage Regimens: Pharmacokinetic Data**

**Kenneth E. Thummel, Danny D. Shen Nina Isoherranen**

This appendix provides a summary of basic pharmacokinetic information pertaining to drugs that are in common clinical use and are delivered to the systemic circulation by parenteral or non-parenteral administration. Because of space limitations, this list cannot be exhaustive. Drugs designed exclusively for topical administration and not to be significantly absorbed into the bloodstream (e.g., ophthalmic and some dermal applications; [Chapters 64](#) and [65](#)) are not included. A few other selection criteria have influenced the makeup of the list, but, in general, the authors have tried to include one or more representative drugs in each of the therapeutic areas in this text, based on distinct mechanism(s) of action. In some instances, drugs may be excluded because pharmacokinetics are not relevant to their therapeutic management. An obvious case is when drug efficacy is not apparently correlated with drug concentration in a reversible fashion (e.g., some cytotoxic anticancer drugs). Also, for a number of therapeutic antibodies, the antibody is administered at a fixed dose at prolonged intervals that allows for its near complete clearance (e.g., infliximab).

Often, the issue comes down to deciding which of the many drugs within a class should be selected. This is particularly problematic when the choices are largely therapeutic equivalents. Two criteria that have proven useful are prevalence of use and uniqueness of mechanism of action. For the present edition, we have consulted the “2008 Top 200 Branded Drugs by Total Prescriptions” and “2008 Top 200 Generic Drugs by Total Prescriptions” published in the respective May 22 and 26, 2009, issues of *Drug Topics* (<http://drugtopics.modernmedicine.com>) for usage data. Drugs that fall into the top 200 list are selected. As mentioned above, a less used drug may be included if it has a different mechanism of action than the frequently used drugs, some additional actions that offer a unique therapeutic advantage, or a more acceptable side-effects profile.

Pharmacokinetic data for many older drugs not included in this appendix can be found in earlier editions of this book.

A major objective of this appendix is to present pharmacokinetic data in a format that informs the clinician of the essential characteristics of drug disposition that form the basis of drug-dosage regimen design. [Table AII-1](#) contains quantitative information about the absorption, distribution, and elimination of drugs; the effects of disease states on these processes; and the correlation of efficacy and toxicity with drug concentrations in blood/plasma. The general principles that underlie the design of appropriate maintenance dose and dosing interval (and, where appropriate, the loading dose) for the average patient are described in [Chapter 2](#). Their application using the data in [Table AII-1](#) for individualization of dosage regimens is presented here.

To use the data that are presented, one must understand clearance concepts and their application to drug-dosage regimens. One also must know average values of clearance as well as some measures of the extent and kinetics of drug absorption and distribution. The text below defines the eight basic parameters that are listed in the tabular material for each drug and key factors that influence these values in both normal subjects and patients with renal or liver disease. It obviously would be more straightforward if there were a consensus on a standard value for a given pharmacokinetic parameter; instead, literature estimates usually vary over a wide range, and a consensus set of pharmacokinetic values has been reached for only a limited number of drugs.

In [Table AII-1](#), a single set of values for each parameter and its variability in a relevant population has been selected from the literature, based on the scientific judgment of the authors. Most data are in the form of a study population mean value  $\pm 1$  standard deviation (mean  $\pm$  SD). However, some data are presented as mean and range of values (in parentheses) observed for the study population (i.e., the lowest and highest value reported). There are times when data are reported as a geometric mean with a 95% confidence interval. If sufficient data were available, we presented a range of mean values obtained from different studies of similar design in parentheses, sometimes below the primary study data. Occasionally, only a single mean value for the study population was available in the literature and is reported as such. Finally, some drugs can be administered intravenously in an unmodified form and orally as a prodrug. When relevant information about

both the prodrug and the active molecule are needed, we have included both, using an abbreviation to indicate the species that was measured, followed by another abbreviation in parentheses to indicate the species that was dosed [e.g.,  $G(V)$  indicates a parameter for ganciclovir after administration of the prodrug, valganciclovir].

A number of recently approved drugs are actually the active metabolite or stereoisomer of a previously marketed drug. For example, desloratadine is the *O*-desmethyl metabolite of loratadine, and esomperazole is the active *S*-enantiomer of omeprazole. Unless the parent drug and the active metabolite offer distinct therapeutic advantages, only the more established or more commonly used drug is listed, and relevant information on its alternate active form is presented in the same table. This approach has permitted us to include more drugs in the Appendix, hopefully without undue confusion. The only exception is with prednisone and prednisolone, which undergo interconversion in the body.

Unless otherwise indicated in footnotes, data reported in the table are those determined in healthy adults. The direction of change for these values in particular disease states is noted below the average value. One or more references are provided for each of the established drugs, typically an original journal publication, a review on its clinical pharmacokinetics, or web-based drug database; the latter two secondary sources provide a broader range of papers for the interested reader. In some instances, we have relied on unpublished data provided by the drug sponsor in its New Drug Application (NDA) files or package labeling submitted to the U.S. Food and Drug Administration (FDA).

## TABULATED PARAMETERS

## PHARMACOKINETIC

Each of the eight parameters presented in [Table AII-1](#) has been discussed in detail in [Chapter 2](#). The following discussion focuses on the format in which the values are presented as well as on factors (physiological or pathological) that influence the parameters.

***Bioavailability.*** The extent of *oral bioavailability* is expressed as a percentage of the administered dose. This value represents the percentage of the administered dose that is available to the systemic circulation—the

fraction of the oral dose that reaches the arterial blood in an active or prodrug form, expressed as a percentage (0-100). *Fractional availability* ( $F$ ), which appears elsewhere in this appendix, denotes the same parameter; this value varies from 0-1. Measures of both the *extent* and *rate* (see  $T_{\max}$ ) of availability are presented in the table. The extent of availability is needed for the design of an oral dosage regimen to achieve a specific target blood concentration. Values for multiple routes of administration are provided, when appropriate and available. In most cases, the tabulated value represents an absolute oral bioavailability that has been determined from a comparison of area under the plasma drug concentration–time curve (AUC) between the oral dose and an intravenous reference dose. For those drugs where intravenous administration is not feasible, an approximate estimate of oral bioavailability based on secondary information (e.g., urinary excretion of unchanged drug, especially when the nonrenal route of elimination is minimal) is presented, or the column is left blank (denoted by a long dash [—]). A dash also will appear when a drug is given by parenteral administration only.

A low bioavailability may result from a poorly formulated dosage form that fails to disintegrate or dissolve in the gastrointestinal fluid, degradative loss of drug in the gastrointestinal fluid, poor mucosal permeability, first-pass metabolism during transit through the intestinal epithelium, active efflux transport of drug back into the lumen, or first-pass hepatic metabolism or biliary excretion (see [Chapter 2](#)). In the case of drugs with extensive first-pass metabolism, hepatic disease may increase oral availability because hepatic metabolic capacity decreases and/or because vascular shunts develop around the liver.

***Urinary Excretion of Unchanged Drug.*** The second parameter in [Table AII-1](#) is the amount of drug eventually excreted unchanged in the urine, expressed as a percentage of the administered dose. Values represent the percentage expected in a healthy young adult (creatinine clearance  $\geq 100$  mL/min). When possible, the value listed is that determined after bolus intravenous administration of the drug, for which bioavailability is 100%. If the drug is given orally, this parameter may be underestimated due to incomplete absorption of the dose; such approximated values are indicated with a footnote. The parameter obtained after intravenous dosing is of greater

utility because it reflects the relative contribution of renal clearance to total body clearance irrespective of bioavailability.

Renal disease is the primary factor that causes changes in this parameter. This is especially true when alternate pathways of elimination are available; thus, as renal function decreases, a greater fraction of the dose is available for elimination by other routes. Because renal function generally decreases as a function of age, the percentage of drug excreted unchanged also decreases with age when alternate pathways of elimination are available. In addition, for a number of weakly acidic and basic drugs with  $pK_a$  values within the normal range for urine pH, changes in urine pH will affect their rate or extent of urinary excretion (see [Chapter 2](#)).

***Binding to Plasma Proteins.*** The tabulated value is the percentage of drug in the plasma that is bound to plasma proteins at concentrations of the drug that are achieved clinically. In almost all cases, the values are from measurements performed *in vitro* (rather than from *ex vivo* measurements of binding to proteins in plasma obtained from patients to whom the drug had been administered). When a single mean value is presented, it signifies that there is no apparent change in percent bound over the range of plasma drug concentrations resulting from the usual clinical doses. In cases in which saturation of binding to plasma proteins is approached within the therapeutic range of plasma drug concentrations, a range of bound percentages is provided for concentrations at the lower and upper limits of the range. For some drugs, there is disagreement in the literature about the extent of plasma-protein binding; in those cases, the range of reported values is given.

Plasma-protein binding is affected primarily by disease states, notably hepatic disease, renal failure, and inflammatory diseases, that alter the concentration of albumin,  $\alpha_1$ -acid glycoprotein, or other proteins in plasma that bind drugs. Uremia also changes the binding affinity of albumin for some drugs. Disease-induced changes in plasma-protein binding can dramatically affect the volume of distribution, clearance, and elimination  $t_{1/2}$  of a drug. In regard to clinical relevance, it is important to assess the change in unbound drug concentration or AUC, particularly when only unbound drug can cross biological barriers and gain access to the site of action.

***Plasma Clearance.*** Systemic clearance of total drug from plasma or blood (see Equations 2–5 and 2–6) is given in [Table AII–1](#). Clearance varies as a

function of body size and, therefore, most frequently is presented in the table in units of mL/min/kg of body weight. Normalization to measures of body size other than weight may at times be more appropriate, such as normalization to body surface area in infants to better reflect the growth and development of the liver and kidneys. However, weight is easy to obtain, and its use often offsets any small loss in accuracy of clearance estimate, especially in adults. Exceptions to this rule are the anticancer drugs, for which dosage normalization to body surface area is conventionally used. When unit conversion was necessary, we used individual or mean body weight or body surface area (when appropriate) from the cited study, or if this was not available, we assumed a body mass of 70 kg or a body surface area of 1.73 m<sup>2</sup> for healthy adults.

In some cases, separate values for renal and nonrenal clearance are also provided. For some drugs, particularly those that are excreted predominantly unchanged in the urine, equations are given that relate total or renal clearance to creatinine clearance (also expressed as mL/min/kg). For drugs that exhibit saturation kinetics,  $K_m$  and  $V_{max}$  are given and represent, respectively, the plasma concentration at which half of the maximal rate of elimination is reached (in units of mass/volume) and the maximal rate of elimination (in units of mass/time/kg of body weight).  $K_m$  must be in the same units as the concentration of drug in plasma ( $C_p$ ).

Intrinsic clearance from blood is the maximal possible clearance by the organ responsible for elimination when blood flow (delivery) of drug is not limiting. When expressed in terms of unbound drug, intrinsic clearance reflects clearance from intracellular water. Intrinsic clearance is tabulated for a few drugs. It also is mathematically related to the biochemical intrinsic clearance [ $V_{max}/(K_m + C)$ ] determined *in vitro*. In almost all cases, clearances based on plasma concentration data are presented in [Table AII-1](#), because drug analysis most often is performed on plasma samples. The few exceptions where clearance from blood is presented are indicated by footnote. Clearance estimates based on blood concentration may be useful when a drug concentrates in the blood cells.

To be accurate, clearances must be determined after intravenous drug administration. When only non-parenteral data are available, the ratio of  $CL/F$  is given; values offset by the fractional availability ( $F$ ) are indicated in

a footnote. When a drug, or its active isomer for racemic compounds, is a substrate for a cytochrome P450 (CYP) or drug transporter, this information is provided in a footnote. This information is important for understanding pharmacokinetic variability due to genetic polymorphisms and for predicting metabolically based drug-drug interactions.

**Volume of Distribution.** The total body volume of distribution at steady state ( $V_{ss}$ ) is given in [Table AII-1](#) and is expressed in units of L/kg or in units of L/m<sup>2</sup> for some anticancer drugs. Again, when unit conversion was necessary, we used individual or mean body weights or body surface area (when appropriate) from the cited study, or if such data were not available, we assumed a body mass of 70 kg or a body surface area of 1.73 m<sup>2</sup> for healthy adults.

When estimates of  $V_{ss}$  were not available, values for  $V_{area}$  were provided;  $V_{area}$  represents the volume at equilibrated distribution during the terminal elimination phase (see Equation 2-12). Unlike  $V_{ss}$ ,  $V_{area}$  varies when drug elimination changes, even though there is no change in the distribution space. Because we may wish to know whether a particular disease state influences either the clearance or the tissue distribution of the drug, it is preferable to define volume in terms of  $V_{ss}$ , a parameter that is less likely to depend on changes in the rate of elimination. Occasionally, the condition under which the distribution volume was obtained was not specified in the primary reference; this is denoted by the absence of a subscript.

As with clearance,  $V_{ss}$  usually is defined in the table in terms of concentration in plasma rather than blood. Further, if data were not obtained after intravenous administration of the drug, a footnote will make clear that the apparent volume estimate,  $V_{ss}/F$ , is offset by the fractional availability.

**Half-Life.** Half-life ( $t_{1/2}$ ) is the time required for the plasma concentration to decline by one-half when elimination is first order. It also governs the rate of approach to steady state and the degree of drug accumulation during multiple dosing or continuous infusion. For example, at a fixed dosing interval, the patient will be at 50% of steady state after one  $t_{1/2}$ , 75% of steady state after two half-lives, 93.75% of steady state after four half-lives, etc. Determination of  $t_{1/2}$  is straightforward when drug elimination follows a monoexponential pattern (i.e., one-compartment model). However, for a

number of drugs, plasma concentration follows a multiexponential pattern of decline over time. The mean value listed in [Table AII-1](#) corresponds to an effective rate of elimination that covers the clearance of a major fraction of the absorbed dose from the body. In many cases, this  $t_{1/2}$  refers to the rate of elimination in the terminal exponential phase. For a number of drugs, however, the  $t_{1/2}$  of an earlier phase is presented, even though a prolonged  $t_{1/2}$  may be observed at very low plasma concentrations when extremely sensitive analytical techniques are used. If the latter component accounts for  $\leq 10\%$  of the AUC, predictions of drug accumulation in plasma during continuous or repetitive dosing will be in error by no more than 10% if this longer  $t_{1/2}$  is ignored. The clinician should know the  $t_{1/2}$  that will best predict drug accumulation in the patient, which will be the appropriate  $t_{1/2}$  to use for estimating the rate constant in Equations 1-19 through 1-21 (see [Chapter 1](#)) to predict time to steady state. It is this  $t_{1/2}$  of accumulation during multiple dosing that is given in [Table AII-1](#).

Half-life usually is independent of body size because it is a function of the ratio of two parameters, clearance and volume of distribution, each of which is proportional to body size. It also should be noted that the  $t_{1/2}$  is preferably obtained from intravenous studies, if feasible, because the  $t_{1/2}$  of decline in plasma drug concentration after oral dosing can be influenced by prolonged absorption, such as when slow release formulations are given. If the  $t_{1/2}$  is derived from an oral dose, this will be indicated in a footnote of [Table AII-1](#).

***Time to Peak Concentration.*** Because clearance concepts are used most often in the design of multiple dosage regimens, the extent rather than the rate of availability is more critical to estimate the average steady-state concentration of drug in the body. In some circumstances, the degree of fluctuation in plasma drug concentration (i.e., peak and trough concentrations), which govern drug efficacy and side effects, can be greatly influenced by modulation of drug absorption rate through the use of sustained-or extended-release formulations. Controlled-release formulations often permit a reduction in dosing frequency from three or four times daily to once or twice daily. There also are drugs that are given on an acute basis (e.g., for the relief of breakthrough pain or to induce sleep), for which the rate of drug absorption is a critical determinant of onset of effect. Thus,

information about the expected average time to achieve maximal plasma or blood concentration and the degree of interindividual variability in that parameter have been included in [Table AII-1](#).

The time required to achieve a maximal concentration ( $T_{\max}$ ) depends on the rate of drug absorption into blood from the site of administration and the rate of elimination. From mass balance principles,  $T_{\max}$  occurs when the rate of absorption equals the rate of elimination from the reference compartment. Prior to this time, absorption rate exceeds elimination rate, and the plasma concentration of drug increases. After the peak is reached, elimination rate exceeds the absorption rate and, at some point, defines the terminal elimination phase of the concentration-time profile.

The rate of drug absorption following oral administration will depend on the formulation and physicochemical properties of the drug, its permeability across the mucosal barrier, and the intestinal villous blood flow. For an oral dose, some absorption may occur very rapidly within the buccal cavity, esophagus, and stomach, or absorption may be delayed until the drug reaches the small intestine or until the local pH in the intestine permits drug release from the dosage formulation. In the most extreme case, the rate of absorption can be sufficiently controlled by the drug formulation to permit sustained or extended delivery as the dosage form traverses the entire length of the gastrointestinal tract. In some instances, the terminal elimination of drug from the body following a peak concentration reflects the slower rate of absorption and not elimination.

When more than one type of drug formulation is available commercially, we have provided absorption information for both the immediate- and sustained-release formulations. Not surprisingly, the presence of food in the gastrointestinal tract can alter both the rate and extent of drug availability. We have indicated with footnotes when the consumption of food near the time of drug ingestion may have a significant effect on the drug bioavailability.

**Peak Concentration.** There is no general agreement about the best way to describe the relationship between the concentration of drug in plasma and its effect. Many different kinds of data are present in the literature, and use of a single-effect parameter or effective concentration is difficult. This is particularly true for antimicrobial agents because the effective concentration depends on the identity of the microorganism causing the infection. It also is important to recognize that concentration-effect relationships are most easily

obtained at steady state or during the terminal log-linear phase of the concentration-time curve, when the drug concentration(s) at the site(s) of action are expected to parallel those in plasma. Thus, when attempting to correlate a blood or plasma level to effect, the temporal aspect of distribution of drug to its site of action must be taken into account.

Despite these limitations, it is possible to define the minimum effective or toxic concentrations for some of the drugs currently in clinical use. However, in reviewing the list of drugs approved within the past 5 years, it is rare to find a declaration of an *effective concentration range*, even in the manufacturer's package labeling. Thus, it is necessary to infer therapeutic concentrations from concentrations observed following *effective dosage* regimens. For a given dosage regimen, a time-averaged steady-state blood or plasma concentration (i.e.,  $C_{ss}^-$  as estimated by dividing the mean AUC by the duration of the dosing interval) and the associated interindividual variability might be one appropriate parameter to report; however, such data often are not available. Also,  $C_{ss}^-$  does not take into account the onset and offset of effect during fluctuation of plasma drug concentration over a dosing interval. In some instances, drug efficacy may be more closely linked with peak concentration than with the average or trough concentration, and differences in peak concentration for special populations (e.g., elderly) sometimes are associated with increased incidence of drug toxicity.

For practical reasons, the most commonly reported parameter,  $C_{max}$  (peak concentration), rather than effective or toxic concentrations, is presented in [Table AII-1](#). This provides a more consistent body of information about drug exposure from which one can infer, if appropriate, efficacious or toxic blood levels. Although the value reported is the highest that would be encountered in a given dose interval,  $C_{max}$  can be related to the trough concentration ( $C_{min}$ ) through appropriate mathematical predictions (see Equation 1-21). Because peak levels will vary with dose, we have attempted to present concentrations observed with a customary dose regimen that is recognized to be effective in the majority of patients. When a higher or lower dose rate is used, the expected peak level can be adjusted by assuming dose proportionality, unless nonlinear kinetics are indicated. In some instances, only limited data pertaining to multiple dosing are available, so single-dose peak concentrations are presented. When specific information is available about an effective therapeutic range of concentrations or about concentrations

at which toxicity occurs, it has been incorporated in a footnote. For individual drugs, the reader also is referred to the index to locate pages where more detailed information is provided.

It is important to recognize that significant differences in  $C_{\max}$  will occur when comparing similar daily-dose regimens for an immediate-release and sustained-release product. Indeed, the sustained-release product sometimes is administered to reduce peak-trough fluctuations during the dosing interval and to minimize swings between potentially toxic or ineffective drug concentrations. Again, we report  $C_{\max}$  for both immediate- and extended-release formulations, when available. In addition to parent drug concentrations, we have included information on any active metabolite that circulates at a concentration that may contribute to the overall pharmacological effect, particularly those active metabolites that accumulate with multiple dosing. Likewise, for chiral drugs whose stereoisomers differ in their pharmacological activity and clearance characteristics, we present information on the levels of the individual enantiomers or the active enantiomer that contributes most to the drug's efficacy.

## **ALTERATIONS OF PARAMETERS IN THE INDIVIDUAL PATIENT**

Dose adjustments for an individual patient should be made according to the manufacturer's recommendation in the package labeling when available. This information generally is available when disease, age, or race has a significant impact on drug disposition, particularly for drugs that have been introduced within the past 10 years. In some cases, a significant difference in drug disposition from the "average" adult can be expected but may not require dose adjustment because of a sufficiently broad therapeutic index. In other cases, dose adjustment may be necessary, but no specific information is available. Under these circumstances, an estimate of the appropriate dosing regimen can be obtained based on pharmacokinetic principles described in [Chapter 1](#).

Unless otherwise specified, the values in [Table AII-1](#) represent mean values for populations of normal adults; it may be necessary to modify them for calculation of dosage regimens for individual patients. The fraction available ( $F$ ) and clearance ( $CL$ ) also must be estimated to compute a

maintenance dose necessary to achieve a desired average steady-state concentration. To calculate the loading dose, knowledge of the volume of distribution is needed. The estimated  $t_{1/2}$  is used in deciding a dosing interval that provides an acceptable peak-trough fluctuation; note that this may be the apparent  $t_{1/2}$  following dosing of a slowly absorbed formulation. The values reported in the table and the adjustments apply only to adults; exceptions are footnoted. Although the values at times may be applied to children who weigh more than ~30 kg (after proper adjustment for size; see “Clearance” and “Volume of Distribution” later), it is best to consult pediatrics textbooks or other sources for definitive advice.

For each drug, changes in the parameters caused by certain disease states are noted within the eight segments of the table. In all cases, the qualitative direction of changes is noted, such as “ $\searrow$  LD,” which indicates a significant decrease in the parameter in a patient with chronic liver disease. The relevant literature and the package label should be consulted for more definitive, quantitative information for dosage adjustment recommendations.

***Plasma-Protein Binding.*** Most acidic drugs that are extensively bound to plasma proteins are bound to albumin. Basic lipophilic drugs, such as propranolol, often bind to other plasma proteins (e.g.,  $\alpha_1$ -acid glycoprotein and lipoproteins). The degree of drug binding to proteins will differ in pathophysiological states that cause changes in plasma-protein concentrations. Significant pharmacokinetic effects from a change in plasma-protein binding will be denoted under clearance or volume of distribution.

Although pharmacokinetic parameters based on total drug or metabolite concentrations often are reported, it is important to recognize that in many cases it is the concentration of *unbound drug* that drives access to the site of action and the degree of pharmacological effect. Remarkable changes in the total plasma concentration may accompany disease-induced alteration in protein binding; however, the clinical outcome is not always affected because an increase in free fraction also will increase the apparent clearance of an orally administered drug and of a low-extraction drug dosed intravenously. Under such a scenario, the mean unbound plasma concentration at steady state will not change with reduced or elevated plasma-protein binding, despite a significant change in mean total drug concentration. If so, no adjustment of daily maintenance dose is needed.

**Clearance.** For drugs that are partly or predominantly eliminated by renal excretion, plasma clearance changes in accordance with the renal function of an individual patient. This necessitates dosage adjustment that is dependent on the fraction of normal renal function remaining and the fraction of drug normally excreted unchanged in the urine. The latter quantity appears in the table; the former can be estimated as the ratio of the patient's creatinine clearance ( $CL_{cr}$ ) to a normal value (100 mL/min/70 kg body weight). If urinary creatinine clearance has not been measured, it may be estimated from the concentration of creatinine in serum ( $C_{cr}$ ). In men:

$$CL_{cr} \text{ (mL/min)} = \frac{[140 - \text{age (yr)}] \cdot [\text{weight (kg)}]}{72 \cdot [C_{cr} \text{ (mg/dL)}]}$$

(Equation A-1)

For women, the estimate of  $CL_{cr}$  by the above equation should be multiplied by 0.85 to reflect their smaller muscle mass. The fraction of normal renal function ( $rfx_{pt}$ ) is estimated from the following:

$$rfx_{pt} = \frac{CL_{cr,pt}}{100 \text{ mL/min}} \quad \text{(Equation A-2)}$$

A more accurate measure of  $rfx_{pt}$  seldom is necessary because, given the considerable degree of interindividual variation in nonrenal clearance, the adjustment of clearance is an approximation. The following equation for adjustment of clearance uses the quantities discussed:

$$rf_{pt} = 1 - [fe_{nl} \cdot (1 - rfx_{pt})] \quad \text{(Equation A-3)}$$

where  $fe_{nl}$  is the fraction of systemic drug excreted unchanged in normal individuals (see [Table AII-1](#)). The renal factor ( $rf_{pt}$ ) is the value that, when multiplied by normal total clearance ( $CL_{nl}$ ) from the table, gives the total clearance of the drug adjusted for the impairment in renal function.

**Example.** The clearance of vancomycin in a patient with reduced renal function (creatinine clearance = 25 mL/min/70 kg) may be estimated as follows:

$$\begin{aligned}
 rf_{x_{pt}} &= \frac{25 \text{ mL/min}}{100 \text{ mL/min}} = 0.25 \\
 fe_{nl} &= 0.79 \text{ (see listing for vancomycin)} \\
 rf_{pt} &= 1 - [0.79 \cdot (1 - 0.25)] = 0.41 \\
 CL_{pt} &= (1.3 \text{ mL/min/kg}) \cdot 0.41 \\
 &= 0.53 \text{ mL/min/kg}
 \end{aligned}$$

Importantly, such a clearance adjustment should be regarded only as an initial step in optimizing the dosage regimen; depending on the patient's response to the drug, further individualization may be necessary.

Conventionally, clearance is adjusted for the size of the patient to reflect a difference in the mass of the eliminating organ. For orally administered drugs, the applicability of such an adjustment may be limited by the available dosage strengths of commercial formulations. In some cases, scored tablets can be split, or commercial tablet splitters are used to increase the range of available dosage strengths. However, this practice should be followed only with the recommendation of the drug manufacturer because splitting a tablet sometimes can compromise the bioavailability of a product.

With the exception of certain oncolytic agents, the data presented in the table are normalized to weight. Thus, interindividual variability in the weight-normalized clearance reflects a variation in the intrinsic metabolic or transport clearance and not the size of the organ. Further, these differences can be attributed to variable expression/function of metabolic enzymes or transporters. However, it is important to recognize that liver mass and total enzyme/transporter content may not increase or decrease in proportion to weight in obese or malnourished individuals. Alternative approaches such as normalization by body surface area or other measures of body mass may be more appropriate. For example, many of the drugs used to treat cancer are dosed according to body surface area (see [Chapter 51](#)). In the tabulation, if the literature reported dose per body surface area, we presented the data in the same unit. If the cited clearance data were not normalized, but the preponderance of the literature utilized body surface area, we followed the practice of using values of body surface area from the literature source or a standard of 1.73 m<sup>2</sup> for a healthy adult.

**Volume of Distribution.** Volume of distribution should be adjusted for the modifying factors indicated in [Table AII-1](#) as well as for body size. Again,

the data in the table most often are normalized to weight. Unlike clearance, volume of distribution in an individual most often is proportional to weight itself. Whether this applies to a specific drug depends on the actual sites of distribution of drug; no absolute rule applies.

Whether or not to adjust volume of distribution for changes in binding to plasma proteins cannot be decided in general; the decision depends critically on whether or not the factors that alter binding to plasma proteins also alter binding to tissue proteins. Qualitative changes in volume of distribution, when they occur, are indicated in the table.

**Half-Life.** Half-life may be estimated from the adjusted values of clearance ( $CL_{pt}$ ) and volume of distribution ( $V_{pt}$ ) for the patient:

$$t_{1/2} = \frac{0.693 \cdot V_{pt}}{CL_{pt}} \quad (\text{Equation A-4})$$

Because  $t_{1/2}$  has been the parameter most often measured and reported in the literature, qualitative changes for this parameter almost always are given in the table.

## INDIVIDUALIZATION OF DOSAGE

By using the parameters for the individual patient, calculated as described in the previous section, initial dosing regimens may be chosen. The maintenance dosage rate may be calculated with Equation 1–18, using the estimated values for  $CL$  and  $F$  for the individual patient. As described earlier, the target concentration may have to be adjusted for changes in plasma-protein binding in the patient, as described in “Plasma-Protein Binding.” The loading dose may be calculated using Equation 1–22 and estimates for  $V_{ss}$  and  $F$ . A particular dosing interval may be chosen; the maximal and minimal steady-state concentrations can be calculated by using Equations 1–20 and 1–19 or 1–21, and these calculated concentrations can be compared with the known efficacious and toxic concentrations for the drug. As with the target concentration, these values may need to be adjusted for changes in the extent of plasma-protein binding. Use of Equations 1–19 and 1–20 also requires estimates of values for  $F$ ,  $V_{ss}$ , and  $K$  ( $K = 0.693/t_{1/2}$ ) for the individual patient.

Note that these adjustments of pharmacokinetic parameters for an individual patient are suggested for the rational choice of initial dosing regimen. As indicated in [Chapter 1](#), steady-state measurement of drug concentrations in the patient then can be used as a guide to further adjust the dosage regimen. However, optimization of a dosage regimen for an individual patient ultimately will depend on the clinical response produced by the drug.

**Table AII-1 Pharmacokinetic Data**

BIOAVAILABILITY (ORAL) (%)	URINARY EXCRETION (%)	BOUND IN PLASMA (%)	CLEARANCE (mL/min/kg)	VOL. DIST. (L/kg)	HALF-LIFE (hours)	PEAK TIME (hours)	PEAK CONCENTRATION
<b>Acetaminophen<sup>a</sup></b>							
88 ± 15 ↔ Child	3 ± 1 ↔ Neo, Child	<20	5.0 ± 1.4 <sup>b</sup> ↓ Hep <sup>c</sup>  ↔ Aged, Child ↑ Obes, HTh, Preg	0.95 ± 0.12 <sup>b</sup> ↔ Aged, Hep <sup>c</sup> , LTh, HTh, Child	2.0 ± 0.4 ↔ RD, Obes, Child ↑ Neo, Hep <sup>c</sup> ↑ HTh, Preg	0.33–1.4 <sup>d</sup>	20 µg/mL <sup>e</sup>
<sup>a</sup> Values reported are for doses <2 g; drug exhibits concentration-dependent kinetics above this dose. <sup>b</sup> Assuming a 70-kg body weight; reported range, 65–72 kg. <sup>c</sup> Acetaminophen-induced hepatic damage or AVH. <sup>d</sup> Absorption rate, but not extent, depends on gastric emptying; hence, it is slowed after food as well as in some disease states and co-treatment with drugs that cause				gastroparesis. <sup>e</sup> Mean concentration following a 20-mg/kg oral dose. Hepatic toxicity associated with levels >300 µg/mL at 4 hours after an overdose.

### Ambisentan\*

>5	—	99	— ++ RD	—	9 <sup>†</sup>	2-3 <sup>†</sup>	1200 ng/mL <sup>‡</sup>
----	---	----	------------	---	----------------	------------------	-------------------------

\*Ambisentan appears to be cleared primarily by the liver; however, the relative contribution from acetylation (p-aminosalicylic acid) versus biliary excretion is unclear. It is expected into the extracellular space of endothelial cells (endothelial lipoprotein) possibly by P-glycoprotein. There also is evidence to suggest that it undergoes active hepatic uptake by organic anion-transporting polypeptide (OATP) transporters. The absolute bioavailability is unknown. No IV dose data available.  $CL_T$  = 0.27 mL/min/kg, following an oral dose in patients with pulmonary arterial hypertension (PAH).

<sup>†</sup>Effective  $t_{1/2}$  for accumulation of drug with multiple dosing in patients with PAH. A longer terminal  $t_{1/2}$  = 13 hours also reported. <sup>‡</sup>Following a 10-mg oral dose, given once a day to steady state in patients with PAH.

### Amphotericin B\*

<5	2-5	>90	0.46 ± 0.20 <sup>†</sup> ++ RD, Prem	0.76 ± 0.52 <sup>†</sup>	18 ± 7 <sup>†</sup>	—	1.2 ± 0.33 μg/mL <sup>‡</sup>
----	-----	-----	---	--------------------------	---------------------	---	-------------------------------

<sup>†</sup>Data for amphotericin B shown. <sup>‡</sup>Data for eight children (ages 6 months to 14 years) yielded a linear regression with  $CL_T$  decreasing with age:  $CL_T = -0.046 \times \text{age (years)} + 0.96$ . Newborns show highly variable  $CL_T$  values. <sup>†</sup>Volume of central compartment,  $V_c$ , increases with dose from 3.4 L/kg for a 0.25-mg/kg dose to 6.9 L/kg for a 1.5-mg/kg dose. Also variable is fractional unexcreted fraction (unexcreted and excreted). Amphotericin distribution and  $CL_T$  properties of these products are different from the acetylated form; they have a terminal  $t_{1/2}$  of 173 ± 70 and 110-135 hours, respectively, however, an effective steady-state concentration can be achieved within 4 days. <sup>‡</sup>For multiple dosing. In single-dose studies, a prolonged dose-dependent  $t_{1/2}$  is seen. <sup>†</sup>Following a 0.5-mg/kg IV dose of amphotericin B given to a 1-hour infusion, once daily for 7 days. Whole blood concentrations (free and protein-bound) of 1.7 ± 0.8 μg/mL and 3.1 ± 0.5 μg/mL, were reported following a 5-mg/kg/day IV dose (given over 60 to 120-minute infusions of amoxicil and amoxicillin, respectively).

-----	----	-----------------------------	---	---	--	------------------	-------------------------------

\*A metabolite, carbamazepine-10,11-epoxide, is equimolar in several studies. Its formation is catalyzed primarily by CYP3A and secondarily by CYP2C8. \*Data from oral, multiple-dose regimen. Values are CL<sub>T</sub> and V<sub>dss</sub>/f. \*Data from multiple-dose regimen. Carbamazepine induces its own metabolism: for a single dose, CL<sub>T</sub> = 0.36 ± 0.07 ml/min/kg and t<sub>1/2</sub> = 39 ± 3 hours. CL<sub>T</sub> also increases with dose. \*Mean (range) steady-state concentration following a daily 16.4-mg/kg oral dose (immediate release) given to adult patients with epilepsy. Therapeutic range for control of psychomotor seizures is 4-10 µg/ml.

— <sup>§</sup>	5.3 ± 2.1	—	18 ± 7 <sup>†</sup>	—	-2	2.1 ± 1.0	S: 165 ± 77 ng/ml <sup>‡</sup> S-CR: 81 ± 29 ng/ml <sup>‡</sup>
----------------	-----------	---	---------------------	---	----	-----------	---

\*Data from healthy adult subjects. Combined with levodopa for treatment of Parkinson's disease. \*Absolute bioavailability is unknown, but it is presumably low based on a high ratio for CL<sub>T</sub>. Bioavailability of levodopa (as D-CR) is 55% of standard (levo) (S). \*CL<sub>T</sub> reported for 2 tablets of levodopa (25/100). \*Following a single oral dose of 2 tablets levodopa 25/100 or 1 tablet levodopa (x 50/200).

### Clopidogrel<sup>o</sup>

— <sup>a</sup>	—	Clo: 98	—	—	Clo: 4-6 AM: 0.5 <sup>b</sup>	Clo: 0.5-1 AM: 1.0 <sup>b</sup>	Clo <sup>b</sup> EM: 3.8 ± 2.5 ng/mL PM: 6.8 ± 3.6 ng/mL PM: 18 ± 14 ng/mL AM <sup>b</sup> EM: 39 ± 15 ng/mL PM: 20 ± 11 ng/mL PM: 23 ± 6 ng/mL
----------------	---	---------	---	---	----------------------------------	------------------------------------	--

<sup>a</sup>Clopidogrel (Clo) is a prodrug that is converted to a more suitable active metabolite (AM) via two sequential cytochrome P450-dependent reactions. The majority of the dose gets converted rapidly to an inactive hydrolytic product by esterase. Although multiple P450 isoforms contribute to the formation of AM, blood levels of AM have been associated with the CYP2C19 genotype and phenotypic status, with poor metabolizers (PM) exhibiting lower levels, on average, than extensive metabolizers (EM). Formation of AM accounts for <10% of the administered dose and may be dose dependent due to saturable metabolism. The absolute bioavailability of Clo is unknown. There is one report of food greatly enhancing the systemic exposure of Clo following oral administration. The reported value was representative of high levels of metabolites formed during first pass and not the terminal  $t_{1/2}$ , which should be formation limited. Following a single 300-mg loading dose of Clo

**Escitalopram, Citalopram<sup>1</sup>**

— Rac: 80 ± 13	Esc: 8 Rac: 10.5 ± 1.4	Esc: 50 Rac: 80	Esc: 8.8 ± 3.2 <sup>a</sup> Rac: 4.3 ± 1.2 <sup>b</sup> ↓ Aped, LD <sup>c</sup>	Esc: 15.4 ± 2.4 <sup>d</sup> Rac: 12.3 ± 2.3	Esc: 22 ± 6 <sup>e</sup> Rac: 33 ± 6 <sup>f</sup> ↑ Aped, LD <sup>g</sup> , RD <sup>h</sup>	— Rac/Exc: 4-5 <sup>i</sup>	Exc: 21 ± 4 ng/mL <sup>j</sup> Rac: 50 ± 9 ng/mL <sup>k</sup>
-------------------	---------------------------	--------------------	---	---	---	--------------------------------	--

<sup>a</sup>Escitalopram is the active S-enantiomer of racemic citalopram. Pharmacokinetic data after dosing of escitalopram (E) and citalopram racemate (Rac) are reported. No significant gender differences. Citalopram is metabolized by CYP2C19 (polymorphic) and CYP3A4 to desmethylcitalopram. <sup>b</sup>Data from CYP2C19 extensive metabolizers. CYP2C19 poor metabolizers exhibit a lower (~44%) CL<sub>R</sub> and longer  $t_{1/2}$  than extensive metabolizers. <sup>c</sup>CL<sub>R</sub> and V<sub>d</sub>/V<sub>T</sub> for E are reported. <sup>d</sup>Alcoholic, oral, or biliary excretion. <sup>e</sup>Moderate renal impairment. <sup>f</sup>Following a single 40-mg (Rac) or 20-mg (E) oral dose.

**Esomeprazole\***

Es: 89 (81-98) <sup>†</sup>	Es/Rac: <1	Es/Rac: 95-97	Es: 4.1 (3.3-5.0) <sup>†*</sup>	Es: 0.25 (0.23-0.27)	Es: 0.9 (0.7-1.0) <sup>†</sup> Rac: 0.7 ± 0.5	Es: 1.5 (1.3-1.7) <sup>†</sup> Rac, EM: -1 <sup>†</sup>	Es: 4.5 (3.8-5.7) μM <sup>†</sup> Rac, EM: 0.68 ± 0.47 μM <sup>†</sup> Rac, PM: -3-4 <sup>†</sup> Rac, PM: 3.5 ± 1.4 μM <sup>†</sup>
Rac: 53 ± 29 <sup>†</sup>			Rac: 7.5 ± 2.7 (LD) <sup>†</sup>	Rac: 0.34 ± 0.09	↑ LD <sup>†</sup>		

\*Esomeprazole is the *S*-enantiomer of omeprazole. Both esomeprazole (Es) and racemic omeprazole (Rac) are available. Data for both formulations are reported. †Bioavailability determined after multiple dosing. ‡Lower Es value (64% (54-75%)) reported for single dose. †The metabolic CL of the Es is slower than that of the R-enantiomer. Both Es and Rac are metabolized by CYP2C19 (polymorphic) and CYP3A4. CL of Es and Rac is decreased and  $t_{1/2}$  increased in CYP2C19 poor metabolizers. †Following a single 40-mg IV dose, CL of Es decreases and  $t_{1/2}$  of Es increases with multiple dosing. †Reduced CL and increased  $t_{1/2}$  in patients with severe (Child-Pugh class C) hepatic impairment. †Following a 40-mg oral dose

of Es given once daily for 1 day to healthy subjects of unspecified CYP2C19 phenotype. †Following a 20-mg oral dose of Es given twice daily for 4 days to healthy subjects phenotyped as CYP2C19 extensive metabolizers (EM) and poor metabolizers (PM).

### Gentamicin

IM: ~100	>90	<10	CL = 0.82CL <sub>cr</sub> + 0.11 ↓ Obes	0.31 ± 0.19 ↔ RD, Aged, CF, Child ↓ Obes ↑ Neo	2-3 <sup>†</sup>	IV: 1 <sup>†</sup> IM: 0.3-0.75 <sup>†</sup>	IV: 4.9 ± 0.5 µg/mL <sup>†</sup> IM: 5.0 ± 0.4 µg/mL <sup>†</sup>
----------	-----	-----	--	--	------------------	---	--

<sup>†</sup>Gentamicin has a very long terminal t<sub>1/2</sub> of 33 ± 25 hours (slow release from tissues), which accounts for urinary excretion for up to 3 weeks after a dose. <sup>†</sup>Following a single 100-mg IV infusion (1 hour) or IM injection given to healthy adults.

References: Maitre GR, et al. Pharmacokinetics of gentamicin in the elderly and patients with renal insufficiency. *Ann Allergy*. 1987; 59:25-30. Rejzovsky C, et al. Comparative pharmacokinetics of streptomycin and gentamicin. *Clin Pharmacol Ther*. 1973; 14:396-403.

### Glipizide<sup>†</sup>

>100	<0.5	>99.5	0.62 ± 0.26 ↑ RD <sup>†</sup>	0.18 ↑ RD <sup>†</sup>	3.4 ± 2.0 ↔ RD <sup>†</sup>	2-3 <sup>†</sup>	159 ± 98 ng/mL <sup>†</sup>
------	------	-------	----------------------------------	---------------------------	--------------------------------	------------------	-----------------------------

<sup>†</sup>Data from healthy study subjects. No significant gender differences. Glipizide is metabolized by CYP2C9 to an active (approximately one-third potency) metabolite. MI: <sup>†</sup>CL/F, V<sub>d</sub>/F increased and t<sub>1/2</sub> unchanged, moderate to severe renal impairment, presumably mediated through an increase in plasma free fraction. MG AUC also increased. <sup>†</sup>Following a single 5-mg oral dose.

References: Balkin M, et al. Determination of the absolute bioavailability of glipizide (H00400), a new sulphonylurea. *Br J Clin Pharmacol Ther Toxicol*. 1992; 30:401-402. *PD054*. 2000, pp. 1346-1349. Brownstein B, et al. Pharmacokinetics and safety of glipizide in clinically effective doses to diabetic patients with renal impairment. *Diabetologia*. 1996; 39:1617-1624.

### Glipizide

95	<5	98.4	0.52 ± 0.19 <sup>a</sup> ** RD, Aged	0.17 ± 0.02 <sup>a</sup> ** Aged	3.4 ± 0.7 ** RD, Aged	2.1 ± 0.9 <sup>b</sup>	465 ± 139 ng/mL <sup>c</sup>
----	----	------	---	-------------------------------------	--------------------------	------------------------	------------------------------

<sup>a</sup>CL<sub>T</sub> and <sup>b</sup>V<sub>d</sub> (l) reported. <sup>c</sup>Following a single 5-mg oral dose immediate-release tablets given to healthy young adults. An extended-release formulation exhibits a delayed T<sub>max</sub> of 6-12 hours.

References: Kohliyaqi KA, et al. Glipizide pharmacokinetics in young and elderly volunteers. *Clin Pharmacol*. 1988; 7:224-228.

### Glyburide

G: 90-100 <sup>a</sup> M: 64-90 <sup>a</sup>	Negligible <sup>b</sup>	99.8 ↓ Aged	1.3 ± 0.5 ↓ LD	0.20 ± 0.11	4 ± 1 <sup>b</sup> ↑ LD, NIDDM	G: -1.5 <sup>b</sup> M: 2.4 <sup>b</sup>	G: 106 ng/mL <sup>c</sup> M: 104 ng/mL <sup>c</sup>
---	-------------------------	----------------	-------------------	-------------	-----------------------------------	---	--

<sup>a</sup>Data for (G) oral extended-release tablet (G) and the (M) oral tablet. <sup>b</sup>V<sub>d</sub> (l) reported. <sup>c</sup>T<sub>max</sub> for M formulation is 6-10 hours, reflecting absorption rate limitation. A long terminal t<sub>1/2</sub> (13 hours), reflecting redistribution from tissues, has been reported. Following a 3-mg oral (GLYNASE) tablet taken with breakfast or a 5-mg oral (MICRONASE) tablet given to healthy adult subjects.

References: Imeson A, et al. Slow elimination of glyburide in NIDDM subjects. *Diabetes Care*. 1994; 17:142-145. <https://doi.org/10.2337/diacare.17.1.142> [PubMed]. Accessed July 10, 2010.

### Haloperidol<sup>b</sup>

60 ± 18	↓	92 ± 2 ↑ LD ** Aged, Child ↓ Aged	11.8 ± 2.9 <sup>b</sup> ↓ Child, Sink	18 ± 7	18 ± 5 <sup>b</sup> ↓ Child	IM: 0.6 ± 0.1 <sup>b</sup> PO: 1.7 ± 3.2 <sup>b</sup>	IM: 22 ± 18 ng/mL <sup>c</sup> PO: 9.2 ± 4.4 ng/mL <sup>c</sup>
---------	---	---	--	--------	--------------------------------	--	--

<sup>a</sup>Undergoes reversible metabolism to a less active reduced haloperidol. <sup>b</sup>Reported net CL of parent drug, reduced haloperidol CL = 10 ± 5 mL · min<sup>-1</sup> · kg<sup>-1</sup> and t<sub>1/2</sub> = 62 ± 11 hours. Slow conversion from reduced haloperidol to parent compound probably responsible for prolonged

terminal t<sub>1/2</sub> (70 hours) for haloperidol observed with 7-day sampling. Following a single 20-mg oral or 10-mg IM dose. Effective concentration (in 4-20 ng/mL).  
References: Poonam J, et al. Pharmacokinetics of haloperidol. *Clin Pharmacol Ther*. 1989; 45:396-403.

### Heparin

—	Negligible	Extensive	110.65 ± 0.088(D) ± 0.1 <sup>a</sup> ↓ Fem	0.058 ± 0.11 <sup>b</sup>	(26 ± 0.32(D) ± 3) 12 min <sup>b</sup> ↓ Sink	3 <sup>b</sup>	70 ± 39 ng/mL <sup>c</sup>
---	------------	-----------	--	---------------------------	---	----------------	----------------------------

<sup>a</sup>Dose (D) is in IU/kg. CL and CL<sub>T</sub> are dose dependent, perhaps due to saturable metabolism with end-product inhibition. <sup>b</sup>V<sub>d</sub> reported. <sup>c</sup>Mean of above critical length molecules following a single 5000 IU dose (intravenously) given by SC injection.

References: Boodhoo AW, et al. **Laprasole\***

→ <sup>a</sup> ↑ Food	<3	04-09	1.2 <sup>b</sup>	0.6 <sup>b</sup>	5.3 ± 2.3	4.4 ± 2.4 <sup>b</sup>	0.8 ± 3.7 µg/mL <sup>c</sup>
--------------------------	----	-------	------------------	------------------	-----------	------------------------	------------------------------

Currently formulated in combination with simvastatin (4.5/14.5). Elsewhere tablets for CYP3A-dependent metabolism of laprasole, exhibiting its bioavailability, increasing plasma concentration (C<sub>0</sub> to 100-fold) and extending its t<sub>1/2</sub>. Pharmacokinetic data from male and female patients with HIV are reported. \*Absolute bioavailability is not known; its relative bioavailability increases with a high-fat meal. \*CL/F and V<sub>d</sub>/F reported, calculated from steady-state AUC data. Following a 400/140-mg laprasole/simvastatin oral dose given twice daily in combination with simvastatin and simvastatin to steady state.

**Loratadine**

L: → <sup>a</sup>	L: Negligible	L: 97	L: 142 ± 57 <sup>b</sup> → RD ↓ LD	L: 120 ± 80 <sup>b</sup> → RD	L: 8 ± 6 → RD ↑ LD	L (L): 2.0 ± 2.0 <sup>b</sup> DL (L): 2.6 ± 2.9 <sup>b</sup>	L (L): 3.4 ± 3.4 ng/mL <sup>c</sup> DL (L): 4.1 ± 2.6 ng/mL <sup>c</sup>
DL: → <sup>a</sup>	DL: →	DL: 82-87 <sup>b</sup>	DL: 14-18 <sup>b</sup> ↓ RD, LD	DL: 26 <sup>b</sup>	DL: 21-24	DL (DL): 3.2 ± 1.8 <sup>b</sup> HDL (DL): 4.8 ± 1.9 <sup>b</sup>	DL (DL): 4.0 ± 2.1 ng/mL <sup>c</sup> HDL (DL): 2.0 ± 0.6 ng/mL <sup>c</sup>

\*Loratadine (L) is converted to a major active metabolite, desloratadine (DL). Almost all patients achieve higher plasma concentrations of DL than of L. DL (0.166/0.0) is approved for routine clinical indications as L. DL is eliminated by metabolism. DL is eliminated by metabolism to an active metabolite, 3-hydroxydesloratadine (HDL), ~7-50% of patients are slow metabolizers of DL, frequency varies with ethnicity. \*Bioavailability of L and DL is not known; L is probably low due to extensive first-pass metabolism. \*Dose-protein binding of HDL is 95-99%. \*CL/F and V<sub>d</sub>/F reported. For DL, oral CL/F calculated from AUC data following a single 5- to 20-mg oral dose given to healthy adults. \*Mean for L and DL following a 10-mg oral L dose (CLAKITIN-D 24 HOURS) given once daily for 7 days to healthy adults. \*Mean for DL and HDL following a 5-mg oral DL dose (0.166/0.0) given once daily for 10 days to healthy adults.

**Lovastatin**

≤5	10	≥95	4.3-18.3 <sup>b</sup> ↓ RD	—	1-4	AI: 2.0 ± 0.9 <sup>b</sup> TI: 3.1 ± 2.9 <sup>b</sup>	AI: 41 ± 6 ng-Eq/mL <sup>c</sup> TI: 50 ± 8 ng-Eq/mL <sup>c</sup>
----	----	-----	-------------------------------	---	-----	--	--

<sup>a</sup>Lovastatin is an inactive lactone form is metabolized to the corresponding active β-hydroxy acid. Pharmacokinetic values are based on the sum of 3-hydroxy-3-methylglutaryl-Coenzyme A (HMG-CoA) reductase inhibition activity by the β-hydroxy acid and other less potent metabolites. <sup>b</sup>The lactone (in equilibrium with β-hydroxy acid metabolite) is metabolized by CYP3A. Following an 80-mg oral dose given once daily for 17 days. Peak levels represent total active inhibitors (AI) and total inhibitors (TI) of HMG-CoA reductase.

### Oxaliplatin

— <sup>†</sup>	—	90 <sup>†</sup>	49 (11-64) <sup>†</sup>	1.5 (1.1-2.1)	0.52 (0.27-0.40) <sup>†</sup>	—	OU: 0.33 (0.28-0.38) µg Pt/mL PtDC: 0.008 (0.004-0.014) µg Pt/mL <sup>‡</sup>
----------------	---	-----------------	-------------------------	---------------	-------------------------------	---	--

\*Oxaliplatin is an organoplatin complex. Pt is coordinated with diamine cyclohexane (DACH) and an oxalic ligand as a leaving group. Oxaliplatin (Ox) undergoes non-cytotoxic biotransformation to reactive derivatives, notably PtDACHCl<sub>2</sub> (PtDC). Antitumor activity and toxicity are thought to relate to the concentrations of oxaliplatin and PtDC in plasma ultrafiltrate (i.e., unbound concentration). \*Two IV administration only. ~54% of the platinum element is recovered in urine. \*Binding to plasma proteins is reversible. \*Cl<sub>R</sub> of total platinum is much lower, ~5-4 mL/min/kg. \*The elimination of platinum species in plasma follows

a triexponential pattern. The second  $t_{1/2}$  reflects the  $t_{1/2}$  of the free phase, which is the clinically relevant phase. The  $t_{1/2}$  for the slower two phases are 17 and 791 hours. \*Steady-state plasma ultrafiltrate concentrations of Ox and PtDC after an 85-mg/m<sup>2</sup> IV infusion over 2 hours during cycle 1 and 2.

**Oxcarbazepine<sup>a</sup>**

—	O: <1 HC: 27	— HC: 45	O: 67.4 <sup>b</sup> HC: ↓ RD/ Aged HC: ↑ Child <sup>b</sup>	—	O: -2 HC: 8-15 HC: ↑ RD, Aged	HC: 2-4 <sup>c</sup>	HC: 8.5 ± 2.0 µg/mL <sup>d</sup>
---	-----------------	-------------	--	---	-------------------------------------	----------------------	----------------------------------

<sup>a</sup>Data from healthy adult male subjects. No significant gender differences. Oxcarbazepine (O) undergoes extensive first-pass metabolism to an active metabolite, 10-hydroxycarbazepine (HC). Reduction by cytochrome enzymes is stereoselective (CYP 2C19/2C9/2C19/2C9). *E*-isomerism), but both show similar pharmacological activity. <sup>b</sup>CL<sub>T</sub> for O reported. HC<sup>c</sup> determined by pharmacokinetics. <sup>d</sup>ADC for HC increased, moderate to severe renal impairment. <sup>e</sup>ADC for HC decreased, children <6 years of age. Following a 800 mg oral oxcarbazepine dose given twice daily for 12 days.

<sup>a</sup>Review by: Banno D, et al. Clinical pharmacokinetics of antiepileptic drugs in pediatric patients. Part II. **Oxybutynin<sup>a</sup>**

1.6-10.9	<1	—	8.4 ± 7.7 <sup>b</sup>	1.3 ± 0.4 <sup>c</sup>	IV: 1.9 ± 0.33 <sup>b</sup>	IR: 5.0 ± 4.2 <sup>d</sup> XL: 5.2 ± 3.7 <sup>d</sup>	IR: 12.4 ± 4.1 ng/mL <sup>d</sup> XL: 4.2 ± 1.6 ng/mL <sup>d</sup>
----------	----	---	------------------------	------------------------	-----------------------------	--	---

<sup>a</sup>Data from healthy female subjects. No significant gender differences. Racemic muscarinic-anticholinergic activity readily partitioned with *R*-enantiomer; no stereoselectivity exhibited for anti-spasmodic activity. Oxybutynin undergoes extensive first-pass metabolism to *N*-desethyl oxybutynin (DEO), an active, anticholinergic metabolite. Metabolized primarily by intestinal and hepatic CYP3A. Racemic oxybutynin kinetic parameters reported. <sup>b</sup>Data reported for a 1 mg IV dose, assuming a 70 kg body weight. A larger volume (2.8 L/kg) and longer t<sub>1/2</sub> (3.3 hours) reported for a 5-mg IV dose. <sup>c</sup>Exhibits a longer apparent t<sub>1/2</sub> following oral dosing due to absorption rate-limited kinetics; immediate release (IR) t<sub>1/2</sub> = 9 ± 2 hours.

extended-release (XL) t<sub>1/2</sub> = 14 ± 3 hours. The apparent t<sub>1/2</sub> for DEO was 4.0 ± 1.4 hours and 6.7 ± 2.5 hours for the IR and XL formulations, respectively. Following a dose of 5 mg IR given three times daily or 15-mg XL given once daily for 4 days. Peak DEO levels of steady state were 45 and 23 ng/mL for IR and XL, respectively. <sup>d</sup>Review by: Gupta SK, et al. Pharmacokinetics of an oral once-a-day controlled-release oxybutynin formulation compared with immediate-release oxybutynin. *J Clin Pharmacol*. 1999; 39:289-296. PMID: 2000, p. 507.

**Oxycodone<sup>a</sup>**

CR: 60-87 <sup>b</sup> IR: 42 ± 7 <sup>b</sup>	— <sup>c</sup>	45	12.4 (9.2-15.4)	2.0 (1.1-2.9)	2.6 (2.1-3.1) <sup>b</sup>	CR: 3.2 ± 2.2 <sup>d</sup> IR: 1.6 ± 0.8 <sup>d</sup>	CR: 15.1 ± 4.7 ng/mL <sup>d</sup> IR: 15.5 ± 4.5 ng/mL <sup>d</sup>
---	----------------	----	-----------------	---------------	----------------------------	--	--

<sup>a</sup>Oxycodone is metabolized primarily by CYP3A4/5, with a minor contribution from CYP2D6. Oxycodone is an active metabolite produced by CYP2D6-mediated O-demethylation. The circulating concentrations of oxycodone are too low to contribute significantly to the opioid effects of oxycodone. Data from healthy male and female subjects reported. <sup>b</sup>Values reported for OXYCONTIN (oxycodone controlled-release (CR)) and immediate-release (IR) tablets. <sup>c</sup>Up to 10% excreted unchanged after an oral dose. <sup>d</sup>The apparent t<sub>1/2</sub> for the CR and IR formulations is ~5 hours; this most likely reflects absorption limited terminal elimination.

kinetics. Following 10 mg of oxycodone (CR) given twice daily to steady state or a 5-mg IR tablet given every 6 hours to steady state. <sup>b</sup>Review by: Benninger DP, et al. Differential effects of food on the bioavailability of controlled-release oxycodone tablets and immediate-release oxycodone tablets. *J Pharm Sci*. 1996; 85:407-410. PMID: 2004, pp. 2854-2855. **Paclitaxel<sup>a</sup>**

Low	5 ± 2	88-90 <sup>b</sup>	5.5 ± 3.5 ↔ Child	2.01 ± 1.2 ↔ Child	11 ± 1 <sup>c</sup>	—	0.85 ± 0.21 µM <sup>d</sup>
-----	-------	--------------------	----------------------	-----------------------	---------------------	---	-----------------------------

<sup>a</sup>Metabolized by CYP2C8 and CYP3A, and excreted by P-glycoprotein. <sup>b</sup>Binding of drug to dialysis filter membranes may lead to overestimation of protein binding fraction (88% suggested). <sup>c</sup>Average accumulation t<sub>1/2</sub> longer terminal t<sub>1/2</sub> up to 50 hours are reported. <sup>d</sup>Steady-state concentrations during a 120 mg/m<sup>2</sup> IV infusion given over 24 hours to adult cancer patients.

<sup>a</sup>Review by: Scousset DS, et al. Clinical pharmacokinetics of paclitaxel. *Clin Pharmacokinet*. 1994; 27:256-260.

**Paliperidone<sup>a</sup>**

28 (oral ER) <sup>b</sup>	59 (51-67) (oral ER)	74 ↓ LD	3.70 ± 1.04 <sup>b</sup> ↑ LD <sup>b</sup>	9.1 <sup>b</sup> (oral ER)	28.4 ± 5.1 <sup>b</sup> (oral ER) 28-49 days (IM PP)	22 (2.0-24) <sup>b</sup> (oral ER) 13 days (IM PP)	10.7 ± 3.3 ng/mL <sup>b</sup> (oral ER)
---------------------------	-------------------------	------------	---	----------------------------	---	---	--

<sup>a</sup>Paliperidone, otherwise known as the *R*-hydroxy active metabolite of risperidone, is marketed as an oral extended-release (ER) tablet (INVEGA) or in the form of its water-soluble paliperidone enantiomer as a once-monthly long-acting IM injection (INVEGA TRINVO). Paliperidone is equivalent in treatment have similar pharmacological profiles. The (+) and (-)-enantiomers of paliperidone interconvert, reaching an AUC (+) to (-) ratio of ~1.6 in steady state. <sup>b</sup>High-fat high-calorie meal increased C<sub>max</sub> and AUC by 60% and 54%, respectively. <sup>c</sup>No data on the absolute bioavailability of IM paliperidone paliperidone (IM PP). The initiation regimen for INVEGA TRINVO (24 mg/150 mg in the deltoid muscle on day 1) and 8) produces paliperidone concentrations matching the range observed with 6- to 12 mg oral ER paliperidone. <sup>d</sup>In a study done during once-daily doses of 7 mg, assuming an average body weight of 75 kg.

V<sub>d</sub> is estimated from CL<sub>T</sub> and t<sub>1/2</sub>. <sup>b</sup>Patients with moderate hepatic impairment showed a modest increase in clearance and plasma free fraction with no significant change in unbound AUC. <sup>c</sup>The apparent long terminal t<sub>1/2</sub> of paliperidone following IM depot injection reflects the slow dissolution of paliperidone paliperidone and release of active paliperidone. <sup>d</sup>Review by: Boone S, et al. Single- and multiple-dose pharmacokinetics and dose proportionality of the psychotropic agent paliperidone extended-release. *J Clin Pharmacol*. 2009; 49:1318-1330. Drug@FDA. Invega label approved on 4/27/07. Invega TRINVO label approved on 7/31/09. Available at: [http://www.accessdata.fda.gov/drugsatfda/drugsatfda/Approved/January\\_1\\_2010](http://www.accessdata.fda.gov/drugsatfda/drugsatfda/Approved/January_1_2010).

**Pantoprazole<sup>a</sup>**

77 (67-89)	— <sup>b</sup>	98	2.8 ± 0.9 ↑ LD ↔ RD	0.17 ± 0.04	1.1 ± 0.4 ↑ LD ↔ Aged	2.6 ± 0.9	2.5 ± 0.7 µg/mL <sup>c</sup>
------------	----------------	----	---------------------------	-------------	-----------------------------	-----------	------------------------------

<sup>a</sup>Pantoprazole is cleared primarily by CYP2C19 (polysomylidyl-dependent metabolism). Two metabolites (PM) exhibit profound differences in CL (lower) and t<sub>1/2</sub> (higher), compared to extensive metabolites (EM). Pantoprazole is available as a racemic mixture of (+) and (-) isomers. In CYP2C19 EM, no significant differences in the pharmacokinetics of (+) and (-) pantoprazole were observed, whereas in CYP2C19 PM, the CL of (-) pantoprazole was significantly greater than that of (+) pantoprazole. <sup>b</sup>No unchanged drug recovered in urine. <sup>c</sup>Following a single 40-mg oral dose.

<sup>a</sup>Review by: Drug@FDA. Product label approved on 11/12/09. Available at: <http://www.accessdata.fda.gov/drugsatfda/drugsatfda/index.cfm>. Accessed on December 26, 2009. Hober R, et al. **Prednisolone**

82 ± 13	26 ± 9 <sup>a</sup>	90-95 (<200 ng/mL) <sup>b</sup> -70 (>1 µg/mL) ↓ Alb, NS, Aged, HTB, LD, ↔ Hep	1.0 ± 0.10 <sup>c</sup> ↔ Hep, CUSH, Sink, CR1, NS <sup>d</sup> HTB <sup>e</sup> ↓ Aged, LD <sup>f</sup>	0.42 ± 0.11 <sup>g</sup>	2.2 ± 0.5 <sup>h</sup> ↔ Hep, CUSH, Sink, RD, CR1, NS <sup>d</sup> Aged, Obese <sup>g</sup> ↓ HTB <sup>e</sup> ↑ Aged <sup>f</sup>	1.5 ± 0.5 <sup>i</sup>	488 ± 150 ng/mL <sup>j</sup>
---------	---------------------	---	---	--------------------------	--	------------------------	------------------------------

\*Prednisolone and prednisone are interconvertible; an additional 1 × 2% is exerted as prednisone. \*Extent of binding to plasma proteins is dependent on concentration over range encountered. \*Total CL increases as protein binding is saturated. CL of unbound drug increases slightly but significantly with increasing dose. \*Changes are for unbound drug. \*Increases with dose due to saturable protein binding. \*Following a 30-mg oral dose given twice daily for 1 day to healthy adult male subjects. The ratio of prednisolone/prednisone is

dose dependent and can vary from 1-20 over a prednisolone concentration range of 50-800 ng/mL.

**Progabalin\***

200 <sup>†</sup>	90-99	0	0.96-1.2 <sup>†</sup> ↓ RD <sup>†</sup>	0.5	5-6.5	P <sup>†</sup>	8.5 µg/mL <sup>†</sup>
------------------	-------	---	--	-----	-------	----------------	------------------------

\*Progabalin undergoes minimal metabolism; an N-methylated metabolite has been identified in urine and accounts for 0.9% of oral dose. >90% of dose is excreted in urine as unchanged drug. Progabalin pharmacokinetics is dose independent and predictable from single to multiple dosing. Bioavailability does not vary with dose up to 600 mg. T<sub>max</sub> is delayed from 1 hour to 1 hour and C<sub>max</sub> decreased by 25-30% when progabalin is given with food. No change in AUC or extent of absorption is noted. Mean renal clearance in healthy young subjects ranges from 87 to 81 mL/min and assuming 70 kg body weight. Progabalin clearance is proportional to CL<sub>CR</sub> hence, dosage can be adjusted in accordance to CL<sub>CR</sub> in renal dysfunction. Plasma

progabalin decreased by ~50% after 4 hours of hemodialysis. Steady-state concentration in healthy subjects receiving 300 mg progabalin every 8 hours.

**Propofol\***

PO: 27.9 ± 19.8 <sup>†</sup>	0.64 ± 0.49	93	15.7 ± 5.7	13.4 ± 3.6 <sup>†</sup>	12.2 ± 2.2	PO: 2.8 ± 1.4 <sup>†</sup>	PO: 21.8 ± 14.0 ng/mL <sup>†</sup>
Rectal: 21.7-23.4 <sup>†</sup>						Rectal: 8.2 ± 3.4	Rectal: 11.3 ± 8.5 ng/mL

\*Propofol undergoes ring hydroxylation mediated by CYP2D6, N-demethylation by CYP2B6, and S-oxidation to a sulfide. Propofol is well absorbed following oral administration (80%) but is subject to first-pass metabolism, which explains its low systemic availability. Oral bioavailability at 75-mg dose as compared to IV bolus. Bioavailability of oral (rectal) propofol is 27-33% at 75-mg dose compared to an IM dose. Steady-state volume. Data for a 50 mg oral dose of propofol in solution. Following a 50 mg dose of propofol rectal suppository.

				++ Aged, RD, Obes, Fam, Preg			

\*Racemic mixture. For S-(+)-enantiomer (100-fold more active) compared to R-(-)-enantiomer. CL is 19% lower and V<sub>d</sub> is 15% lower because of a higher degree of protein binding (11% lower free fraction) hence, there is no difference in V<sub>d</sub>. Active metabolite, 4-hydroxypropoprol (HP). Drug is bound primarily to α<sub>1</sub>-acid glycoprotein, which is elevated in a number of inflammatory conditions. Based on blood measurements. Blood-to-plasma concentration ratio = 0.89 ± 0.03. CYP2D6 catalyzes the formation of HP. CYP2A2 is responsible for most of the N-desisopropyl metabolite. UGT catalyzes the major conjugation pathway of elimination. Following a single 40-mg oral dose given to healthy adults. Plasma

accumulation factor was 3.6-fold after 40 mg was given four times daily at steady state. A concentration of 20 ng/mL gave a 50% decrease in exercise-induced cardiovascular. Any significant effects manifest at 15-30 ng/mL. A concentration up to 1000 ng/mL may be required for control of ventricular arrhythmias.

**Rabeprazole\***

32 <sup>†</sup>	0 <sup>†</sup>	95-98	4.2 ± 1.2 <sup>†</sup>	0.37 <sup>†</sup>	1.0 ± 0.6 <sup>†</sup>	3.8-4.6	EM: 437 ± 241 ng/mL <sup>†</sup> PM: 600 ± 319 ng/mL <sup>†</sup>
-----------------	----------------	-------	------------------------	-------------------	------------------------	---------	--

\*Rabeprazole is primarily converted to rabeprazole disulfide; some of it is oxidized to dimethylrabeprazole and rabeprazole sulfone by CYP2C19 and CYP3A4, respectively. CYP2C19 genetic polymorphism has a modest effect on rabeprazole clearance. Rabeprazole possesses an asymmetric sulfur center; the enantiomers exhibit R/R<sub>1</sub>/A/P<sub>1</sub> with equal potency *in vivo*. ~90% of radiolabeled oral dose is recovered *in vitro*, indicating near-complete gastrointestinal absorption. Incomplete systemic availability is due to instability and first-pass metabolism of rabeprazole. Based on data from a 20-mg IV dose of rabeprazole in subjects with various CYP2C19 genotype or phenotype, most likely reflecting characteristics of extensive metabolizers (EM). Elimination t<sub>1/2</sub> up to 3-3 hours has been observed in poor metabolizers (PM) of CYP2C19 following oral rabeprazole. <sup>†</sup>At steady state during a 20-mg once-a-day regimen for duodenal ulcer.

<sup>†</sup>Data from pharmacopausal women. Undergoes extensive first-pass metabolism (UGT 1A1/2 and CYP2C19 recycling). ~100% absorption from the gastrointestinal tract; not significantly affected by food. CL<sub>R</sub> and V<sub>D</sub> reported for an oral dose. <sup>†</sup>Following a single 1-mg/kg oral dose.

References: Hachover-Golubker D. Pharmacokinetics of rabeprazole and its clinical application. *Eur J Obstet Gynecol Reprod Biol*. 1999; 83:25-29. PDR94, 2000, p. 3363.

**Raltegravir\***

≥31.8 ± 9.4 <sup>†</sup>	8.8 ± 4.7	83	16.1 (11.4, 22.6) <sup>†</sup> ↔ RD ↓ Hemodialysis ↔ LD (modest)	0.092 ± 0.21 <sup>†</sup> β: 12.5 ± 4.6 <sup>†</sup>	1.0 <sup>†</sup>	4.5 (2.0, 10.2) μM <sup>†</sup>
--------------------------	-----------	----	---	---	------------------	---------------------------------

\*Raltegravir undergoes 0% glucuronidation mediated largely by UGT1A1 and to a lesser extent by UGT1A3 and UGT1A9. Raltegravir AUC is only modestly elevated in individuals with UGT1A1/\*2/\*2 genotype compared to /\*/\* genotype. The absolute oral bioavailability of raltegravir has not been determined. This maximum extent of oral absorption is based upon recovery of radioactivity in urine following oral administration of [<sup>14</sup>C]-labeled raltegravir in healthy human subjects. Geometric mean (95% confidence interval) of pharmacokinetic parameters following a single 400-mg oral dose: Apparent oral clearance (CL<sub>R</sub>) is listed. Plasma concentration-time course of raltegravir exhibits multiphasic washout kinetics. Initial oral and terminal (β)<sub>1/2</sub> are reported because the early phase accounts for a large portion of the AUC from time 0 to ∞. Median for T<sub>1/2</sub> and geometric mean (95% confidence interval)

for C<sub>min</sub> following a 400-mg twice-daily monotherapy regimen for 10 days in treatment-naïve patients with HIV-1 infection.

\*Ramelteon undergoes primary oxidative metabolism followed by glucuronidation as secondary metabolites. CYP1A2 is the major enzyme involved in oxidative metabolism. CYP3A4 and CYP2C9 also are involved as minor enzymes. Remarkable elevation in C<sub>min</sub> and AUC were observed with the concurrent administration of the strong CYP1A2 inhibitor fluvoxamine. The M-II metabolite contributes to the hypnotic effects of ramelteon. M-II has 1/10th to 1/100th the affinity of ramelteon as an agonist for the melatonin receptors (MT<sub>1</sub> and MT<sub>2</sub>); however, it circulates at 20- to 100-fold higher concentrations relative to ramelteon. Their systemic availability of ramelteon is due to extensive first-pass metabolism. C<sub>min</sub> and AUC are elevated by a high-fat meal. T<sub>1/2</sub> is slightly delayed. Inter-subject variability is notably large.

<sup>†</sup>Four- and 10-fold elevation in AUC in mild and moderate hepatic impairment. <sup>†</sup>P = parent drug; M = M-II metabolite. C<sub>min</sub> following a single 10-mg oral dose of ramelteon in young adult subjects. There is no measurable accumulation of parent drug of active metabolite because of their short elimination t<sub>1/2</sub>.

Hydrolyzed to its active metabolite, ramiprilat (RT). Pharmacokinetic data for ramipril (R) and RT following oral and IV administration are presented. <sup>†</sup>Based on plasma AUC of R and RT after IV and oral R administration. <sup>†</sup>Following an oral dose of R. <sup>†</sup>CL<sub>R</sub> of R calculated from reported AUC data. <sup>†</sup>No data available; mean renal CL of RT is ~1.1 mL/min/kg. V<sub>D</sub> for the elimination phase reported. A longer terminal t<sub>1/2</sub> of ~120 hours most likely corresponds to the release of drug from ACE; contributes to the duration of effect, but does not contribute to systemic drug accumulation. <sup>†</sup>Following a single 10-mg oral dose.

**Risperidone<sup>a</sup>**

PK: 66 ± 28 <sup>b</sup> (M: 103 ± 31)	3 ± 2 <sup>c</sup>	80 <sup>d</sup>	3.4 ± 1.4 <sup>e</sup> ↓ RD, Aged <sup>f</sup>	1.1 ± 0.2	3.2 ± 0.8 <sup>g</sup> ↑ RD, Aged <sup>h</sup>	R: - <sup>i</sup>	R: 10 ng/mL <sup>j</sup> TA: 45 ng/mL <sup>j</sup>
---	--------------------	-----------------	---	-----------	---	-------------------	---

<sup>a</sup>The active metabolite, 9-hydroxyrisperidone, is the predominant circulating species in extensive metabolizers and is equivalent to parent drug. 9-Hydroxyrisperidone has a  $t_{1/2}$  of 20 ± 3 hours. In extensive metabolizers, 35 ± 7% of an IV dose is excreted in this metabolite; its elimination is primarily renal and therefore correlates with renal function. <sup>b</sup>Formation of 9-hydroxyrisperidone is catalyzed by CYP2D6. Parameters reported for extensive metabolizers. In poor metabolizers,  $R'$  is higher, ~20% of an IV dose is excreted unchanged, 10% of the 9-hydroxy metabolite; CL is slightly <1 mL/min/kg, and  $t_{1/2}$  is similar to that of the active metabolite, ~30 hours. <sup>c</sup>75% for 9-hydroxyrisperidone. <sup>d</sup>Changes in elderly subjects due to

decreased renal function affecting the elimination of the active metabolite. <sup>e</sup>Mean steady-state  $C_{10}$  for risperidone (R) and total active (TA) drug, risperidone + 9-OH risperidone, following a 3-mg oral-dose given twice daily to patients with chronic schizophrenia. No difference in total active drug levels between CYP2D6 extensive and poor metabolizers. <sup>f</sup>Review: Cohen JL. Risperidone. *Pharmacotherapy*. 1994; 14:255-265. Heykants J, et al. ------------------	---	-----------------	--------------------------	-----------------------	--------------------------	--	---

<sup>o</sup>Data from male and female renal transplant patients. All subjects were on a stable cyclosporine regimen. Sildenafil is metabolized primarily by CYP3A and is a substrate for P-glycoprotein. Several sildenafil metabolites are pharmacologically active. <sup>o</sup>Cyclosporine co-administration increases sildenafil bioavailability. <sup>o</sup>F increased by high fat meal. <sup>o</sup>Concentration to blood cells/blood-plasma concentration ratio = 38 ± 13. <sup>o</sup>Blood  $CL_{CR}$ ,  $f_e$ , and  $t_{1/2}$  reported for oral dose. <sup>o</sup>Following a single 15-mg oral dose (SD) in healthy subjects and 4- to 5.5-mg<sup>o</sup> oral dose (with cyclosporine) given twice daily to study case (MD) to renal transplant patients.

### Spironolactone<sup>o</sup>

— <sup>a</sup>	<1 <sup>b</sup>	>90 <sup>b</sup>	93 <sup>b</sup>	10 <sup>b</sup>	S: 1.3 ± 0.3 <sup>c</sup> C: 11.2 ± 2.3 <sup>c</sup> TS: 2.8 ± 0.4 <sup>d</sup> HTS: 10.1 ± 2.3 <sup>e</sup> † LD <sup>b</sup>	S: 1.0 <sup>f</sup> C: 2.9 ± 0.6 <sup>f</sup> TS: 1.8 ± 0.5 <sup>f</sup> HTS: 3.1 ± 0.6 <sup>f</sup>	S: 185 ± 51 ng/mL <sup>g</sup> C: 231 ± 49 ng/mL <sup>g</sup> TS: 571 ± 74 ng/mL <sup>g</sup> HTS: 202 ± 54 ng/mL <sup>g</sup>
----------------	-----------------	------------------	-----------------	-----------------	--	---	---

<sup>a</sup>Spironolactone (S) is extensively metabolized; it has three known active metabolites: canrenone (C), 7α-thioesterlyspironolactone (TS), and 6β-hydroxy-7α-thioesterlyspironolactone (HTS). <sup>b</sup>Absolute bioavailability is not known; old values reported in the literature were based on nonspecific assays for C, likely to exhibit first-pass metabolism. AUC of parent drug and metabolites increased when S taken with food. <sup>c</sup>Measured after an oral dose. <sup>d</sup>Binding of S and its active metabolites. <sup>e</sup>CL<sub>R</sub> and V<sub>z</sub> (P<sub>z</sub>) calculated from reported AUC and C<sub>z</sub> data. <sup>f</sup>Following a single 200 mg oral dose of S, C accumulates 2.5-fold with multiple S dosing. <sup>g</sup>A<sub>z</sub> of parent drug and metabolites increased in patients with cirrhosis.

Search label approved on 2/20/07. Available at: <http://www.accessdata.fda.gov/drugsatfda/drugs/infodatabases.cfm>. Accessed on December 30, 2009. Hook BE, et al. A population pharmacokinetic meta-analysis of sunitinib malate (SU12662) and its primary metabolite (SU12662) in healthy volunteers and oncology patients. *Clin Cancer Res*. 2009; 15:2197–2206.

### Tacrolimus

25 ± 10 <sup>b,c</sup> ↔ RD ↓ Food	<1 <sup>b</sup>	75–99 <sup>b</sup>	0.90 ± 0.29 <sup>b</sup> ↔ RD, LD	0.91 ± 0.29 <sup>d</sup> ↔ RD ↑ LD	12 ± 5 <sup>e</sup> ↔ RD	1.4 ± 0.5 <sup>f</sup>	31.2 ± 10.1 ng/mL <sup>g</sup>
--	-----------------	--------------------	--------------------------------------	--	-----------------------------	------------------------	--------------------------------

<sup>a</sup>Drug disposition parameters calculated from blood concentrations. Data from liver transplant patients reported. Metabolized by CYP3A; also a substrate for P-glycoprotein. <sup>b</sup>A similar bioavailability (F = 21 ± 19%) reported for kidney transplant patients. <sup>c</sup>F = 16 ± 7% for normal subjects. Low oral bioavailability likely due to incomplete intestinal availability. <sup>d</sup>Difference values for plasma protein binding reported. Concentrations in blood cells, blood-to-plasma concentration ratio = 35 (12–67). <sup>e</sup>Slightly higher V<sub>z</sub> and CL<sub>R</sub> reported for kidney transplant patients. Because of the very high and variable blood-to-plasma concentration ratio,

markedly different V<sub>z</sub> values are reported for parameters based on plasma concentrations. <sup>f</sup>Following a single 7 mg oral dose given to healthy adults. <sup>g</sup>Consensus report C<sub>z</sub> at steady state at 5–20 mg/d.

<sup>h</sup>References: Belzicky L, et al. Dose linearity after oral administration of tacrolimus 1-mg capsules at doses of 1, 2, and 10 mg. *Clin Ther*. 1999; 27:2058–2064. Jusko WJ, et al. Pharmacokinetics of tacrolimus in liver transplant patients. *Clin Pharmacol Ther*. 1995; 57:261–270. <sup>i</sup>PM24, 2000, pp. 1099–1099.

### Tadalafil<sup>o</sup>

—	—	94	0.59 <sup>b</sup> ↓ RD	0.89 <sup>b</sup>	17.5	2 <sup>c</sup>	378 ng/mL <sup>d</sup>
---	---	----	---------------------------	-------------------	------	----------------	------------------------

<sup>a</sup>Eliminated primarily by CYP3A4-dependent metabolism. <sup>b</sup>CL<sub>R</sub> and t<sub>1/2</sub> reported. <sup>c</sup>AUC increased in patients with mild or moderate (2–6-fold) and severe (4–6-fold) renal insufficiency. <sup>d</sup>Following a single 20 mg oral dose.

<sup>e</sup>References: Curran M, et al. Tadalafil. *Drugs*. 2004; 64:2205–2212. Discussion 2213–2214. Product labeling: Cialis® (tadalafil tablets). Bausch, WA, Lilly Inc., 2004.

### Tamoxifen\*

—	<1	>95	1.4 <sup>3</sup>	50-60 <sup>2</sup>	4-11 days <sup>2</sup>	5 (3-7)	720 (67-183) ng/mL
---	----	-----	------------------	--------------------	------------------------	---------	--------------------

\*Has active metabolites; 4-hydroxytamoxifen and 4-hydroxy-N-desmethyltamoxifen are active metabolites that exhibit affinity for the estrogen receptor that is greater than that of parent (non-tamoxifen). The  $t_{1/2}$  of all metabolites are rate limited by tamoxifen elimination.  $^{14}C$  and  $V_{dss}$  reported. The major pathway of elimination, N-demethylation, is catalyzed by CYP3A.  $t_{1/2}$  consistent with accumulation and approach to steady state. Significantly

### Tamulosin\*

100 ↓ Food	12.7 ± 3.0	99 ± 1 ↑ RD	0.62 ± 0.31 ↑ RD, Aged	0.20 ± 0.06	6.8 ± 3.5 <sup>2</sup> ↑ RD, Aged	5.3 ± 0.7 <sup>2</sup> ↑ Food	16 ± 5 ng/mL <sup>2</sup> ↑ Food
---------------	------------	----------------	---------------------------	-------------	--------------------------------------	----------------------------------	-------------------------------------

\*Data from healthy male subjects. Metabolized primarily by CYP3A and CYP2D6.  $^{14}C$  reduced, moderate renal impairment. Unbound AUC relatively unchanged. Apparent  $t_{1/2}$  after oral dose in patients is ~14-15 hours, reflecting controlled release from modified-release granules. <sup>3</sup>Following a single 0.4-mg modified-release oral dose in healthy subjects.

The ketolides: A critical review. *Drugs*. 2002; 62:1771-1804.

### Tenofovir†

—	4.6 <sup>2</sup>	—	3.8 ± 0.6 <sup>2</sup>	3.3 ± 0.5 <sup>4</sup>	12.8 ± 1.1	—	595 ± 102 ng/mL <sup>2</sup>
---	------------------	---	------------------------	------------------------	------------	---	------------------------------

\*Tenofovir, a water-soluble ester analog of zidovudine or zalcitabine, is available for IV use. Following IV administration, tenofovir is converted to tenofovir, blood AUC of tenofovir is 3-fold higher than that of tenofovir at the recommended dose of 25 mg for the treatment of advanced renal cell carcinoma. Both tenofovir and tenofovir (after  $\alpha$ -D-glucosidase activity and undergo oxidative metabolism mediated by CYP3A. <sup>3</sup>Recovery of tenofovir after a single IV dose of [<sup>14</sup>C]tenofovir. <sup>4</sup>Both tenofovir and zidovudine partition extensively into blood cells, a major fraction of tenofovir and zidovudine in plasma is bound to plasma proteins. <sup>5</sup>Based on CL of 85.1 ± 2.8 L/hr and  $V_d$  of 232 ± 30 l at a dose of 25 mg, assuming an average body weight of 70 kg. All pharmacokinetic parameters are based on whole blood concentration. <sup>6</sup>Following the first dose of a 25-mg/week regimen.

References: Atkins MB, et al. Randomized phase II study of multiple dose levels of CCI-779, a novel mammalian target of rapamycin kinase inhibitor, in patients with advanced refractory renal cell carcinoma. *J Clin Oncol*. 2004; 22:300-310. Drugs@FDA. Tenofovir label approved on 5/30/07. Available at: [http://www.accessdata.fda.gov/drugsatfda\\_docs/nda/nda021468s010.pdf](http://www.accessdata.fda.gov/drugsatfda_docs/nda/nda021468s010.pdf). Accessed on December 31, 2010.

### Tenoxicam\*

25 <sup>2</sup> ↑ Food	82 ± 13	<1	2.6 ± 0.9 <sup>2</sup> ↓ RD	0.6 ± 0.1 <sup>2</sup>	8.1 ± 1.8 <sup>2,3</sup> ↑ RD	2.3 <sup>2</sup>	326 ng/mL <sup>2</sup>
---------------------------	---------	----	--------------------------------	------------------------	----------------------------------	------------------	------------------------

\*Tenoxicam is formulated in an enter coating, vanillin (inactive dispersant), for oral administration. Bioavailability under fasted state reported. Increased to 75% with high fat meal. <sup>2</sup>Data reported for steady-state 5-mg/kg IV dose given once a day for 2 weeks to HIV-1 infected male and female adults. Slightly higher CL with single IV dose. <sup>3</sup>Longer apparent plasma  $t_{1/2}$  (17 hours) reported for steady-state oral dosing; this may reflect a longer duration of blood sampling; also, phenylglyoxal "active" metabolite exhibits a longer intracellular  $t_{1/2}$  (60 hours). <sup>4</sup>Following a 300-mg oral dose given once a day with a meal to steady state.

**Tolterodine<sup>o</sup>**

EM: 26 ± 18 PM: 91 ± 40 EM: ↑ Food	EM: Negligible PM: <2.5	T: 96.3 S-IM: 64	EM: 9.6 ± 2.8 PM: 2.0 ± 0.3 ↓ LD <sup>o</sup>	EM: 1.7 ± 0.4 PM: 1.5 ± 0.4	EM: 2.3 ± 0.3 PM: 9.2 ± 1.2 ↑ LD	EM: 1.2 ± 0.3 <sup>o</sup> PM: 1.9 ± 1.0 <sup>o</sup>	EM: 5.2 ± 5.7 ng/mL <sup>o</sup> PM: 35 ± 35 ng/mL <sup>o</sup>
--	----------------------------	---------------------	---	--------------------------------	--	--	--

<sup>o</sup>Data from healthy adult male subjects. No significant gender differences. Tolterodine (T) is metabolized primarily by CYP2D6 to an active (100% parent) metabolite, 5-hydroxymethyl tolterodine (5-HM), in extensive metabolizers (EM);  $t_{1/2}$  5-HM = 2.9 ± 0.1 hour. Also metabolized by CYP3A to an N-alkyl product, particularly in poor metabolizers (PM); <sup>o</sup>CL/F reduced and AUC 5-HM<sub>0-24h}</sub> increased. Hepatic cirrhosis. <sup>o</sup>Following a 4-mg oral dose given twice daily for 8 days, C<sub>max</sub> of 5-HM was 5 ± 3 ng/mL for EM.

### Vardenafil<sup>o</sup>

15 (8-25)	2-6	93-95 (parent and M1)	56	3.0 <sup>b</sup>	4-5 (parent and M1)	0.7 (0.25-3) <sup>c</sup>	19.3 ± 1.7 ng/mL <sup>d</sup>
-----------	-----	-----------------------	----	------------------	---------------------	---------------------------	-------------------------------

<sup>a</sup>Vardenafil is primarily metabolized by CYP3A4 with minor involvement of CYP2C8. The major oxidative metabolite (M1), a product of N-demethylation at the piperazine ring, is a low power PDE5 inhibitor and circulates at a level 28% that of the parent drug. It contributes only 7% of the in vivo activity of vardenafil. <sup>b</sup>CL<sub>r</sub> of 28 L, assuming 70 kg bodyweight. <sup>c</sup>Following a single 20-mg dose. There is no change in pharmacokinetics between single and multiple dosing.

Reference: Drugoff FDA. Levitra label approved on 30/000. Available at: <http://www.accessdata.fda.gov/drugsatfda/drugsatfda/index.cfm>. Accessed on December 31, 2009. Gupta M, et al. The clinical pharmacokinetics of phosphodiesterase-5 inhibitors for erectile dysfunction. *J Clin Pharmacol*. 2005; 45:987-1003.

### Varenicline<sup>o</sup>

2879 <sup>a</sup>	86.2 ± 6.2	≤20	2.27 ± 0.34 <sup>b</sup>	6.2 <sup>c</sup>	31.5 ± 7.7 <sup>d</sup>	2.0 (1.0-4.0) <sup>e</sup>	10.2 ± 1.0 ng/mL <sup>f</sup>
-------------------	------------	-----	--------------------------	------------------	-------------------------	----------------------------	-------------------------------

<sup>a</sup>Varenicline is eliminated mostly by renal excretion with minimal metabolism. Organic cation transporter 2 (OCT2) is involved in renal tubular secretion, as evidenced by inhibition of varenicline renal clearance by cimetidine, a known OCT2 inhibitor. 78% ± 5.5% of radioactivity is excreted in urine after an oral dose of [<sup>14</sup>C]-varenicline. Minimal first pass metabolism is expected. <sup>b</sup>CL<sub>r</sub> and <sup>c</sup>V<sub>d</sub> estimated from steady-state AUC and t<sub>1/2</sub> during 1-mg twice-daily dosing of varenicline in healthy adult smokers and assuming an average body weight of 70 kg. <sup>d</sup>After the first dose of a multiple-dosing regimen. An accumulation factor of 2.85 ± 0.11 was reported.

Reference: Drugoff FDA. Chantix label approved on 7/1/07. Available at: <http://www.accessdata.fda.gov/drugsatfda/drugsatfda/index.cfm>. Accessed on December 31, 2009. Foye WD, et al. ↔ RD			↔ RD, Child	↔ RD, Aged, Obes	↔ RD, Child		

<sup>a</sup>Basic mixture; (S)-verapamil is more active. Bioavailability of (S)-verapamil is 2.8-fold greater than that for (R)-verapamil because of a lower CL<sub>r</sub> (10 × 2 versus 18 × 3 mL/min/kg). Relative concentration of the enantiomers changes as a function of route of administration. <sup>b</sup>Active metabolite, norverapamil, is a vasodilator but has no direct effect on heart rate or P-R interval. At steady state (oral dosing), AUC is equivalent to that of parent drug (t<sub>1/2</sub> = 9 × 5 hours). <sup>c</sup>Multiple dosing causes a greater than 2-fold decrease in CL<sub>r</sub> and prolongation of t<sub>1/2</sub> in some studies, but no change of t<sub>1/2</sub> in others. <sup>d</sup>Verapamil is a substrate for CYP3A4, CYP2C8, and other CYPs. <sup>e</sup>Mean data following a 120-mg oral conventional tablet (CR) given twice daily or range of data following a 240-mg oral extended-release (XR) dose given once

daily, both for 7-10 days to healthy adults. <sup>f</sup>EC<sub>50</sub> for prolongation of P-R interval after an oral dose of verapamil is 120 ± 20 ng/mL; the value for IV administration is 40 ± 25 ng/mL. After oral administration, maximum concentrations >100 ng/mL cause >25% reduction in heart rate in Atr Fib, >10% prolongation of P-R interval, and >50% increase in duration of exercise in normal persons. A level of 120 ± 40 ng/mL (after IV administration) was found to attenuate treatment refractory ventricular tachycardia.

<sup>a</sup>Two lipid-filled gelatin capsules. <sup>b</sup>Elimination kinetics of vinorelbine follow a three-compartment model with extensive tissue distribution. Values for the terminal elimination phase are reported. <sup>c</sup>Following a single 100 mg/m<sup>2</sup> oral dose (gel capsules). <sup>d</sup>Following a single 30-mg IV infusion over 15 minutes.

**References:** Longue D, et al. Clinical pharmacokinetics of vinorelbine. *Clin Pharmacokinet*. 1996; 37:144-192.

**Vincristine**

96 <sup>a</sup> ↓ Food	<2	58	3.8 <sup>b</sup> ↓ LD <sup>a</sup>	1.0 <sup>c</sup>	6.7 <sup>c</sup>	PO: 1.1 <sup>d</sup> ↑ Food	PO: 2356 ng/mL <sup>e</sup> ↓ Food IV: 3621 ng/mL <sup>e</sup>
---------------------------	----	----	---------------------------------------	------------------	------------------	--------------------------------	--

<sup>a</sup>Metabolic study to an inactive N-oxide by CYP3C9 (major), CYP3A4, and CYP2C9. <sup>b</sup>Elimination is dose and time dependent. Pharmacokinetic parameters determined in steady state are reported. Mean CI was reduced (64%), V<sub>d</sub> reduced (32%), and t<sub>1/2</sub> increased (16%) with 12 days of twice-daily 3-mg IV administration. Also, CI decreased 41% when dose was increased from 300-500 mg twice daily. <sup>c</sup>CI reduced in patients with mild to moderate hepatic insufficiency. <sup>d</sup>Following a 3-mg/kg oral dose given twice daily for 12 days. <sup>e</sup>Following a 3-mg/kg IV infusion over 1-hour given twice daily for 12 days.

    for ophthalmic use, [1781t](#)  
    pharmacokinetics of, [1816t](#)

volume distribution, [1816t](#)  
Azlocillin, [1484](#)  
Azoles  
arrhythmias caused by, [832](#)  
for cutaneous fungal infection, [1818](#)  
indications for, [1816t](#)  
and statins, interactions, [896](#)  
AZOPT (brinzolamide), [680](#)

## **B**

Babesiosis, [1423](#)  
Bacillus Calmette-Guérin (BCG), [1022](#)  
Bacitracin, [1543](#)–1544  
prophylaxis, for superficial infections, [1817](#)  
Baclofen, pharmacokinetics of, [1816t](#)  
Bacteria, susceptibility testing in, [1369](#)–1370  
Bacterial endocarditis, gentamicin for, [1515](#)–1516  
Bacterial infections, of skin, [1817](#)  
Bacterial vaginosis, [1842t](#)  
BACTRIM (trimethoprim-sulfamethoxazole), [1817](#)  
BACTROBAN (mupirocin), [1817](#)  
Balantidiasis, [1423](#)  
Baldness  
female pattern, [1829](#)–1830  
male pattern, [1829](#)–1830  
Barbiturates  
absorption, fate, and excretion of, [473](#)  
abuse and addiction to, [472](#)  
addiction, [657](#)  
as anesthetics, [539](#)–540  
cardiovascular system and, [472](#)  
central nervous system and, [469](#)–472  
chemistry of, [469](#)  
as dose-dependent toxicity, [75](#)  
for epilepsy, [593](#)–594

gastrointestinal tract and, [472](#)–473  
liver and, [472](#)–473  
peripheral nervous structures and, [472](#)  
pharmacological properties of, [469](#)–473  
poisoning, [474](#)  
respiration and, [472](#)  
sleep and, [472](#)  
therapeutic uses of, [473](#)–474  
tolerance to, [472](#)

Bare lymphocyte syndrome, [104t](#)

Baroreceptors, intrarenal, and renin release, [722](#), [723f](#), [724](#)

Bartter's syndrome, [947](#)–948

Bartter syndrome, [972](#)

Basal cell carcinoma (BCC)  
5-fluorouracil for, [1821](#)  
imiquimod for, [1823](#)

Base(s), organic, secretion in proximal tubule, [676f](#)

Basophils, increased proliferation of, histamine and, [915](#)

BAY [58](#)–2667, [808](#)

Bayh-Dole Act, [12](#)

BBB. *See* Blood-brain barrier (BBB) B cell targeting, [1019](#)

BCG. *See* Bacillus Calmette-Guérin (BCG)

BCR-ABL kinase, inhibitors, [1732](#)–1734. *See also* Dasatinib; Imatinib mesylate; Nilotinib  
resistance, mechanisms of, [1732](#)–1733, [1733f](#)  
BCRP *See* Breast cancer resistance protein (BCRP)

Bed bugs, [1818](#)

Behavior, dopamine and, [356](#)–357

Behçet's disease  
azathioprine for, [1821](#)  
cyclophosphamide for, [1821](#)  
dapsons for, [1823](#)  
tacrolimus for, [1822](#)  
thalidomide for, [1824](#)

Belladonna alkaloids, [226](#). *See also* Atropine; Scopolamine

Bemotrizinol, [1827](#)

BENADRYL (diphenhydramine), [1816](#)

BENADRYL (diphenhydramine hydrochloride), [921t](#)

Benazepril

as anti-hypertensive agent, [774t](#), [784](#)–785

clinical pharmacology of, [733](#)

structure of, [732f](#)

Bendroflumethiazide

pharmacology of, [688t](#)

structure, [688t](#)

BENICAR (olmesartan medoxomil), [745](#)

Benign prostatic hyperplasia (BPH), alpha-adrenergic receptor antagonists  
for, [308](#)

BENOQUIN (monobenzene), [1830](#)

BENSAL HP (antifungal combination), [1817](#)

BENZAACLIN (antibiotic-benzoyl peroxide combination), [1817](#)

Benzathine penicillin, for syphilis, [1842t](#)

Benzbromarone, [999](#)–1000

Benzimidazoles

absorption, fate, and excretion of, [1450](#)–1451

anthelmintic action of, [1450](#)

in children, [1453](#)

history of, [1449](#)–1450

precautions and contraindications with, [1452](#)–1453

in pregnancy, [1452](#)–1453

toxicity and side effects of, [1452](#)–1453

Benznidazole, [1431](#)–1432

Benzocaine, [138t](#)

for pruritus, [1828t](#)

Benzodiazepine-receptor agonists, novel, [467](#)–469

Benzodiazepines absorption, fate, and excretion of, [463](#)–465

addiction to, [656](#)–657

adverse psychological effects, [465](#)

as anesthetic adjunct, [552](#)–553

antidote for, [86t](#)

as antiepileptics, [598](#)–599  
central nervous system and, [460](#)  
chemistry of, [458](#), [459t](#)  
for nausea and vomiting, [1345](#)–1346  
pharmacological properties of, [458](#)–465  
for pruritus, [1828t](#)  
sleep and, [460](#)–461  
therapeutic uses of, [465](#)–467, [466t](#)  
tolerance to, [460](#)

Benzoic acid, [1589](#)

Benzothiadiazides, [686](#)

Benzothiadiazines (thiazide diuretics), as anti-hypertensive agents, [775](#)–777

Benzothiazepines, [102t](#)

Benzothiazipines, [761](#)

Benzoyl peroxide, for acne, [1817](#)  
interactions with tretinoin, [1810](#)

Benzphetamine, structure of, [279t](#)

Benztropine, as antidote, [86t](#)

Benztropine mesylate, for parkinsonism, [234](#)

Benzyl alcohol, for lice, [1819](#)

Bepotastine, for ophthalmic use, [1789](#)

BEPREVE (bepotastine), [1789](#)

Bepidil, antiarrhythmic use of, [830](#)

Berberine, [1339](#)

Besifloxacin, for ophthalmic use, [1781t](#)

BESIVANCE (besifloxacin), [1781t](#)

Beta adrenergic agonists, [289](#)–294  
hypoglycemia and, [1248t](#)  
long-acting  $\beta_2$ , [293](#)–294  
for prevention of preterm labor, [1848](#)  
for respiratory disease, [1035](#)–1040  
selective  $\beta_2$ , [290](#)–291  
for prevention of preterm labor, [1848](#)  
short acting  $\beta_2$ , [291](#)–293

Beta adrenergic antagonist antidote, [86t](#)

Beta adrenergic receptor(s), and renin release, [722](#), [723f](#), [724](#)

Beta adrenergic receptor agonists

- cardioprotective effects of, [767](#)
- mechanism of action of, [767](#)

Beta adrenergic receptor agonists, therapeutic uses of, for heart failure, [804](#)–  
805

Beta adrenergic receptor antagonists, [310](#)–316

- adverse effects and side effects of, [779](#), [831](#)
- adverse effects of, [316](#)–317
- as antianginal agents, [752](#), [768](#)
- antiarrhythmic use of, [824t](#), [828](#), [831](#)–832
- as anti-hypertensive agents, [774t](#)
- arrhythmias caused by, [821t](#)
- for cardiovascular diseases, [317](#)–319
- cardiovascular system and, [313](#)–314, [316](#)
- central nervous system and, [317](#)
- chemistry and structures of, [310](#)
- contraindications to, [833t](#)
- drug interactions with, [317](#)
- effects on renin-angiotensin system, [746t](#)
- electrophysiological actions of, [829t](#)
- for glaucoma, [319](#), [1787](#)
- for heart failure, [317](#)–318
- hemodynamic effects of, with long-term administration, [774t](#)
- history of, [310](#)
- for hypertension, [314](#)–315
- hypoglycemia and, [1248t](#)
- mechanism of action of, in heart failure, [800](#)–801
- metabolic effects of, [315](#)
- in myocardial infarction, [317](#)
- nonselective, [320](#), [326](#), [1787](#)
- overdosage, [317](#)
- pharmacological properties of, [312](#)–316
- precautions with, [779](#)

pulmonary system and, [315](#), [316](#)–317  
selection of, [319](#)–320  
selective, [1787](#)  
therapeutic uses of, [317](#)–320, [767](#)–768  
  for heart failure, [800](#)–801

Beta blockers, polymorphisms and response to, [159t](#), [160t](#)

BETADINE (povidone iodine), [1790](#)

Betamethasone, relative potencies and equivalent doses of, [1216t](#)

Betamethasone dipropionate  
  cream, [1225t](#)  
  lotion, [1225t](#)  
  ointment, [1225t](#)

Betamethasone valerate  
  cream, [1225t](#)  
  lotion, [1225t](#)  
  ointment, [1225t](#)

BETAPACE (sotalol), [845](#)

BETATREX (betamethasone valerate ointment), [1225t](#)

Betaxolol, [312f](#)  
  absorption, fate, and excretion of, [328](#)

as anti-hypertensive agent, [774t](#)  
for ophthalmic use, [1787](#)  
therapeutic uses of, [328](#)

#### Bethanechol

actions of, [222](#)  
cholinergic receptors and, [206t](#)  
gastrointestinal tract and, [224](#)  
pharmacological properties of, [223t](#)  
structure of, [222f](#)  
therapeutic use of, [224](#)  
urinary tract and, [224](#)

#### Betrixaban, [866](#)

Bevacizumab, [1738](#), [1739](#), [1745](#), [1746t](#)  
clinical pharmacology, [1739](#)  
dosage and administration of, [1747t](#)  
for retinal neovascularization and macular degeneration, [1794](#)  
toxicity of, [1739](#)–1740, [1747t](#)

Bexarotene, [1809](#), [1810t](#), [1811t](#) [1811](#)–1812  
adverse effects and side effects of, [1812](#)  
for cutaneous T-cell lymphoma, [1811](#), [1812](#)  
drug interactions with, [1812](#)  
formulation, [1810t](#)  
irritancy, [1810t](#)  
mechanism of action of, [1812](#)  
pregnancy category, [1810t](#)  
receptor specificity, [1810t](#), [1811t](#)  
structure of, [1810t](#), [1811t](#)  
systemic

    pharmacokinetics of, [1811t](#)  
    standard dosing range, [1811t](#)

BEXXAR (iodine-131 tositumomab), [1749](#)

#### Bezafibrate

adverse effects of, [902](#)–903  
chemistry of, [901](#)  
and lipoproteins, [902](#)

- mechanism of action of, [902](#)
- structure of, [901f](#)
- BG9179, therapeutic uses of, [793](#)
- Bicalutamide, [1205](#), [1765](#)–1766
  - pharmacokinetics of, [1817t](#)
  - structure of, [1761f](#)
- BICNU (carmustine), [1821](#)
- BIDIL (hydralazine), [795](#)
- Biguanides, [91](#)–92
- Bile acid binding resins, [1266](#)
- Bile acids, [1346](#)–1347
- Bile acid sequestrant agents, [1336](#)–1337
- Bile-acid sequestrants, [898](#)–899
  - adverse effects of, [899](#)
  - chemistry of, [898](#)–899
  - drug interactions with, [899](#)
  - and lipoprotein levels, [899](#)
  - mechanism of action of, [899](#)
  - structures of, [898f](#)
  - therapeutic uses of, [899](#)
- Bile acid synthesis, [127](#)
- Bile salt export pump (BSEP), [93](#), [107](#)
- Bile salt malabsorption, primary, [102t](#)
- Bile salts, ABC transporters and, [105t](#)
- Biliary excretion, [26](#)
- Biliary tract
  - muscarinic antagonists and, [229](#)
  - opioids and, [498](#)
- Bilirubin monoglucoronide, [105t](#)
- Bimatoprost, [952](#)
  - for glaucoma, [1787](#)
- nor-Binaltorphimine, actions and selectivities of, [485t](#)
- Bioavailability
  - absorption vs., [19](#)
  - of common drugs, [1809t](#)–1890t

- definition of, [19](#)
- disposition and, [28](#)
- extent of, [33](#)–[34](#)
- factors influencing, [20](#)
- first-pass effect and, [19](#)–[20](#)
- hepatic disease and, [1802](#)
- in parenteral administration, [20](#)
- as pharmacodynamic parameter, [1802](#)
- rate of, [33](#)–[34](#)

Biocompatible polymers, [23](#)

Bioequivalence, [23](#)

Biological agents

- classes, [1824](#)
- in dermatology, [1824](#)–[1827](#), [1825t](#)
- for inflammatory bowel disease, [1359](#)–[1360](#)
- for psoriasis, [1824](#)
  - mechanism of action of, [1826f](#)

Biological induction therapy, [1006](#)–[1007](#)

Biological License Application (BLA), [79](#)

Biological response modifier(s), in cancer treatment, [1745](#)–[1750](#)

Biological response modifiers

- for inflammatory bowel disease, [1352t](#)
- for neoplastic disease, [1668t](#)–[1670t](#)

Biological toxins, [575](#)

Biotransformation, in liver, [27](#)

Biperiden, [234](#)

Bipolar (manic-depressive) disorder

- lithium for, [447](#)
- prophylactic treatment of, [448](#)

Birth defects, oral anticoagulant-induced, [864](#)

Bishydroxycoumarin, [860](#)

Bismuth compounds, [1337](#)

Bisotrizole, [1827](#)

Bisoprolol, [312f](#), [327](#)–[328](#)

- as anti-hypertensive agent, [774t](#)

Bisphosphonates, [1294](#)–1296  
absorption of, [1296](#)  
adverse effects of, [1296](#)  
excretion of, [1296](#)  
for osteoporosis, [1299](#)

Bitolterol, [292f](#), [293](#)

Bivalirudin, [859](#)–860  
therapeutic uses of, in myocardial ischemia, [771](#)

BLA. *See* Biological License Application (BLA)

“Black box,” [9](#)

Bladder, urinary

ABC transporters in, [106t](#)  
acetylcholine and, [221](#)–222  
atony, anticholinesterase agents for, [250](#)  
in autonomic nervous system, [179t](#)  
bethanechol and, [224](#)  
choline esters and, [223t](#)  
muscarinic antagonists and, [231](#)  
opioids and, [497](#)

Bladder cancer, drugs for, [1668t](#)–1670t

BLENOXANE (bleomycin), [1823](#)

Bleomycin(s), [1668t](#)–1670t  
for cancer, [1716](#)–1718  
intralesional  
adverse effects and side effects of, [1823](#)  
for squamous cell carcinoma, [1823](#)  
for warts, [1823](#)  
mechanism of action of, [1820t](#)  
systemic, for Kaposi sarcoma, [1823](#)

Blepharitis  
fungal, [1784t](#)  
yeast, [1784t](#)

Blepharoconjunctivitis, bacterial, treatment of, [1781t](#)

Blinking, [1773](#)

Blistering diseases, autoimmune, [1816](#)

mycophenolate mofetil for, [1823](#)

Blood-cerebrospinal fluid barrier, intrathecal injection and, [22](#)

Blood-brain barrier (BBB), [365](#)–366

- ABC transporters and, [104](#)
- distribution of drugs and, [25](#)
- intrathecal injection and, [22](#)
- transporters and, [91](#)–93, [116](#)
- vectorial transport in, [96f](#)

Blood-cerebrospinal fluid barrier

- intrathecal injection and, [22](#)
- transporters and, [116](#)

Blood circulation, muscarinic antagonists and, [228](#)

Blood dyscrasias, androgens for, [1204](#)

Blood pressure

- angiotensin II and, [727f](#), [730](#)
- epinephrine and, [282](#)–283
- kinins and, [931](#)
- normal, in adults, [773t](#)
- pharmacological lowering of, effects on RAS, [746t](#), [747](#)
- regulation, role of kidneys and fluids and electrolytes, [698f](#)

Blood vessels

- alpha adrenergic receptors in, [203t](#)
- in autonomic nervous system, [178t](#)

BMS-354825 (dasatinib), [1732](#)

Body temperature

- ethanol and, [637](#)
- muscarinic antagonists and, [229](#)–230
- opioids and, [498](#)

Bolus injection, [22](#)

Bone

- disorders of, [1286](#)–1290
- distribution in, [24](#)–25
- eicosanoids and, [951](#)
- infections of, quinolones for, [1473](#)
- mass, [1285](#)

- parathyroid hormone and, [1279](#)
- physiology, [1285](#)–1286
- remodeling, [1285](#)–1286
- skeletal organization and, [1285](#)

Bone marrow, alkylating agents and, [1681](#)

Bone mineral, mobilization of, vitamin D and, [1283](#)

Bone mineral density (BMD)

- bone physiology and, [1285](#)
- postmenopausal, estrogens and, [1838](#)

Bortezomib, [1742](#)–1743

- absorption, [1743](#)
- chemistry, [1742](#)
- elimination, [1743](#)
- mechanism of action of, [1743](#)
- pharmacokinetics of, [1743](#)
- structure of, [1743](#)
- therapeutic uses of, [1743](#)
- toxicity of, [1743](#)

Bosentan, [110](#)

Botulinum toxin

- adverse effects and side effects of, [1792](#)
- cholinergic receptors and, [206t](#)

Bowel irrigation, [84](#)–85

Bowen's disease

- 5-fluorouracil for, [1821](#)
- imiquimod for, [1823](#)

Bowman's membrane, [1774](#)–1775

Bradycardia

- atropine for, [233](#)
- differential diagnosis of, in toxicity, [83t](#)

Bradykinin, [911](#), [926](#)–932, [927f](#)

- antagonists, [932](#)
- degradation, [930f](#)
- [des-Arg<sup>9</sup>]-, structure of, [928t](#)
- history of, [926](#)

- and inflammation, [931](#), [960](#)
- pain and, [930](#)–931
- as pruritogen, [1815](#)
- structure of, [928t](#)
- therapeutic uses of, potential, [926](#)

Bradykinin receptor(s), [926](#), [929](#)–930

Brain

- cellular organization of, [364](#)
- drug action in, transporters and, [115](#)–116
- microanatomy of, [364](#)–366

Brain natriuretic peptide (BNP), [695](#)–696

Brainstem, [364](#)

- alpha adrenergic receptors in, [203t](#)
- beta adrenergic receptors in, [204t](#)

Brain tumor, drugs for, [1668t](#)–1670t

Bran, constipation and, [1331](#)

Brater's algorithm, for diuretic therapy, [699](#), [700f](#)

Breast, progestins and, [1182](#)

Breast cancer

- drugs for, [1668t](#)–1670t
- ER+, anti-estrogen therapy for, [1756](#)–1760, [1757t](#)
- HER2/neu-overexpressing, [1737](#)
- metastatic, [1755](#)–1756
- risk, oral contraceptives and, [1834](#)
- tamoxifen for, [1179](#)
- treatment
  - androgens in, [1756](#)
  - estrogens in, [1756](#)

Breast cancer resistance protein(BCRP), [107](#), [116](#)

Breast milk, drugs in, [1847](#)

Bremazocine, actions and selectivities, [485t](#)

BRETHINE (terbutaline), [1848](#)

Bretylium

- adrenergic receptors and, [206t](#)
- antiarrhythmic use of, [837](#)

contraindications to, [833t](#)  
BRETLYLOL (bretylum tosylate), [837](#)  
BREVIBLOC (esmolol), [840](#)  
BREVICON (ethinyl estradiol/norethindrone), [1835t](#)  
BRILINTA (ticagrelor), [871](#)–872  
Brimonidine, [297](#)  
    for ophthalmic use, [1787](#)  
Brinzolamide, [680](#)  
    for ophthalmic use, [1787](#)  
Broad Institute Software, [153t](#)  
Bromfenac, for ophthalmic use, [1789](#)  
Bromocriptine, [1114](#)  
    as antidote, [86t](#)  
    dosage of, [614t](#)  
    hypoglycemia and, [1248t](#)  
    therapeutic use of, for parkinsonism, [614t](#)  
BROMPHEN (brompheniramine maleate), [921t](#)  
Brompheniramine maleate, [921t](#)  
Bronchial muscle, eicosanoids and, [950](#)  
Bronchodilators, [1035](#)  
    arrhythmias caused by, [832](#)  
    novel classes of, [1046](#)  
Bronchomotor tone, acetylcholine and, [221](#)  
Bronchospasm  
    angina pectoris with, recommended treatment for, [769t](#)  
    histamine and, [917](#)–918  
Brotizolam, structure of, [459t](#)  
BRUFEN (ibuprofen), [988](#)

Castor oil, [1334](#)

Castration  
medical, [1763](#)

surgical, [1763](#)

CATAFLAM (diclofenac), [987](#)

Cataracts, [1777](#)

    corticosteroid therapy-related, [1227](#)

    steroid-related, [1792](#)

Catecholaminergic polymorphic ventricular tachycardia (CPVT), [818](#)

Catecholamines

    angiotensin II and, [729](#)

    in central nervous system, [382](#)–384

    dopamine and, [355](#)

    endogenous, [282](#)–289

    monoamine oxidase and, [200](#)

    refractoriness to, [209](#)–210

    release, [199](#)

        angiotensin II and, [729](#)

    storagae, [196](#)–199

    synthesis, [194](#)–196

    termination of actions of, [200](#)–201

Catechol-*O*-methyltransferase (COMT), [138](#)

    catecholamine termination and, [200](#)

Catechol-*O*-methyltransferase (COMT) inhibitors, for parkinsonism, [617](#)–618

Cathartics, [85](#), [1328](#)–1336

Causative polymorphism, [153](#)

Caveolac, [17](#)

Caveolin, [17](#)

CCR5. *See* Chemokine receptor 5 (CCR5)

CECLOR (cefaclor), [1494t](#), [1496t](#)

Cefaclor

    antibacterial spectrum of, [1496t](#)

    chemistry of, [1494t](#)

    dosage and dosage forms of, [1494t](#)

Cefadroxil

    chemistry of, [1494t](#)

    dosage and dosage forms of, [1494t](#)

## Cefamandole

chemistry of, [1494t](#)

dosage and dosage forms of, [1494t](#)

## Cefazolin

antibacterial spectrum of, [1496t](#)

chemistry of, [1494t](#)

dosage and dosage forms of, [1494t](#)

pharmacokinetics of, [1820t](#)

Cefdinir, pharmacokinetics of, [1821t](#)

## Cefepime

chemistry of, [1494t](#)

dosage and dosage forms of, [1494t](#)

pharmacokinetics of, [1821t](#)

Cefixime, for gonococcal urethritis, [1842t](#)

CEFIZOX (cefizoxime), [1494t](#)

CEFOBID (cefoperazone), [1494t](#)

## Cefonicid

chemistry of, [1494t](#)

dosage and dosage forms of, [1494t](#)

## Cefoperazone

chemistry of, [1494t](#)

dosage and dosage forms of, [1494t](#)

## Ceforanide

chemistry of, [1494t](#)

dosage and dosage forms of, [1494t](#)

CEFOTAN (cefotetan), [1494t](#), [1496t](#)

Cefotaxime, antibacterial spectrum of, [1496t](#)

## Cefotetan

antibacterial spectrum of, [1496t](#)

chemistry of, [1494t](#)

dosage and dosage forms of, [1494t](#)

for pelvic inflammatory disease, [1842t](#)

## Cefoxitin

antibacterial spectrum of, [1496t](#)

chemistry of, [1494t](#)

dosage and dosage forms of, [1494t](#)  
for pelvic inflammatory disease, [1842t](#)

Cefpodoxime proxetil  
chemistry of, [1494t](#)  
dosage and dosage forms of, [1494t](#)

Ceftazidime  
antibacterial spectrum of, [1496t](#)  
chemistry of, [1494t](#)  
dosage and dosage forms of, [1494t](#)  
pharmacokinetics of, [1821t](#)

CEFTIN (cefuroxime axetil), [1494t](#), [1496t](#)

Ceftizoxime  
chemistry of, [1494t](#)  
dosage and dosage forms of, [1494t](#)

Ceftriaxone  
antibacterial spectrum of, [1496t](#)  
for chancroid, [1842t](#)  
chemistry of, [1494t](#)  
dosage and dosage forms of, [1494t](#)  
for gonococcal urethritis, [1842t](#)  
for pelvic inflammatory disease, [1842t](#)  
pharmacokinetics of, [1822t](#)

Cefuroxime  
antibacterial spectrum of, [1496t](#)  
chemistry of, [1494t](#)  
dosage and dosage forms of, [1494t](#)

Cefuroxime axetil  
chemistry of, [1494t](#)  
dosage and dosage forms of, [1494t](#)

CELEBREX (celecoxib), [964](#)–[965](#), [991](#)

Celecoxib, [964](#)–[965](#), [991](#)  
absorption, [991](#)  
adverse effects and side effects of, [991](#)  
arrhythmias caused by, [832](#)  
in cancer prevention, [972](#)–[973](#)

## I

Ibandronate, pharmacokinetics of, [1849t](#)

Ibopamine, for heart failure, [805](#)

IBUDONE, [988](#)

Ibuprofen, [987](#)

absorption, [988](#)

adverse effects and side effects of, [988](#)

compared to aspirin, [968t](#)

COX isoform selectivity, [962f](#)

distribution of, [988](#)

dosage and administration of, [968t](#)

elimination, [988](#)

metabolism of, [128t](#)

pharmacokinetics of, [968t](#), [988](#), [1850t](#)

pharmacology of, [962f](#)

plasma pharmacokinetics of, [962f](#)

structure of, [988f](#)  
therapeutic uses of, [968t](#), [988](#)

#### Ibutilide

antiarrhythmic use of, [835t](#), [841](#)  
arrhythmias caused by, [821t](#)  
contraindications to, [833t](#)  
dosage and administration of, [835t](#), [841](#)  
electrophysiological actions of, [829t](#)  
mechanism of action of, [830](#)  
pharmacokinetics of, [835t](#)  
structure of, [841](#)

Icatibant, [930](#), [932](#)

ICCS. *See* Interstitial cells of Cajal (ICCs)

#### Ichthyosis

keratolytics for, [1829](#)  
retinoids for, [1811](#)

Idiosyncratic reactions, [76–77](#)

Idoxifene, [1756](#)

Idoxuridine, [1596t](#), [1604–1605](#)

Idoxuridine ophthalmic solution, [1153t](#)

Idrabiotaparinus, [858](#)

Idraparinux, [858](#)

Idrarubicin, pharmacokinetics of, [1850t](#)

Ifosfamide, [1668t–1670t](#)

toxicity of, extramedullary, [1682t](#)

ILARIS (canakinumab), [961](#)

Ileus, paralytic, anticholinesterase agents for, [250](#)

Ileus, post-operative, [1335](#)

#### Iloperidone

dosage of, [425t](#)  
metabolism of, [433t](#)  
side effects of, [425t](#)

Iloprost, [952](#)

#### Imatinib mesylate

ABC transporters and, [106t](#)

chemistry, [1732](#)  
mechanism of action of, [1732](#)  
pharmacokinetics of, [1733](#)–1734, [1850t](#)  
resistance, mechanisms of, [1732](#)–1733, [1733f](#)  
structure of, [1732](#)  
therapeutic uses of, [1732](#), [1734](#)  
toxicity of, [1734](#)

Imatinib (STI-565), [1668t](#)–1670t

IMDUR (isosorbide-5-mononitrate), [754t](#)

Imidazoles, [1576](#), [1817](#)–1818  
for ophthalmic use, [1784t](#)  
for topical use, [1586](#)–1587

IMiDs. *See* Immunomodulatory analogs

Iminostilbenes, [594](#)–596

Imipenem, pharmacokinetics of, [1851t](#)

Imipramine  
adrenergic receptors and, [206t](#)  
disposition of, [409t](#)  
dose and dosage forms of, [400t](#)  
metabolism of, [128t](#)  
potencies  
at human transporters for monamine neurotransmitters, [406t](#)  
at neurotransmitter receptors, [410t](#)  
side effects of, [400t](#)

Imiquimod, [1596t](#), [1617](#)–1618  
adverse effects and side effects of, [1823](#)  
for cutaneous viral infections, [1818](#)  
in dermatology, [1823](#)  
for genital warts, [1823](#)  
mechanism of action of, [1820t](#)  
structure of, [1823](#)

Immune globulins, [1023](#)–1024

Immune response, [1005](#)–1006  
eicosanoids and, [948](#), [949](#)–950

Immunization, [1023](#)–1024

Immunoglobulin(s)  
in anaphylactic reactions, [76](#)  
in arthrus reactions, [76](#)  
in cytolytic reactions, [76](#)  
intravenous, in dermatology, [1827](#)

Immunomodulators, topical, for pruritus, [1828t](#)

Immunomodulatory agents, for ophthalmic use, [1790](#)

Immunomodulatory analogs. *See also* Lenalidomide; Thalidomide  
in cancer treatment, [1740](#)–1742

Immunomodulatory therapy, [1054](#)–1058

Immunostimulation, [1021](#)–1024

Immunosuppression, [1006](#)–1019  
biological, [1015](#)–1016  
tolerance and, [1019](#)–1021

Immunosuppressive agents  
in dermatology, [1820](#)–1822  
for inflammatory bowel disease, [1357](#)–1359  
mechanism of action of, [1820t](#)

Immunosuppressive agents, ABC transporters and, [105t](#)

IMPDH. *See* Inosine monophosphatase dehydrogenase (IMPDH)

Impentamine, [925](#)

Impetigo, [1817](#)

IMPLANON, [1834t](#), [1836](#)

Implanted cardiac defibrillator (ICD), [823](#), [824t](#)

Impotence, eicosanoids for, [952](#)

Impulsivity, 5-HT and, [343](#)

Inactivation, [78](#)

Inamrinone, for heart failure, [805](#)

IND. *See* Investigational New Drug (IND) application; Notice of Claimed  
Investigational Exemption for a New Drug (IND)

Indacaterol, [292f](#), [294](#)

Median lethal dose (LD<sub>50</sub>), [73](#), [74f](#)  
animal testing of, [78](#)

Mediator antagonists, [1052](#)–1054

Medical addict, [654](#)

Medical errors, [1883](#)

“Medical imperialism,” [13](#)

Medication errors, reduction of, [80](#)–81

Medication errors, “Swiss cheese” model of, [81t](#)

Medication seeking, [1882](#)–1883

Medroxyprogesterone, in cancer chemotherapy, [1756](#)

Medroxyprogesterone acetate (MPA), [1668t](#)–1670t, [1766](#)

Mefenamic acid, [989](#)  
adverse effects and side effects of, [989](#)  
compared to aspirin, [968t](#)  
dosage and administration of, [968t](#)  
pharmacokinetics of, [968t](#)  
therapeutic uses of, [968t](#)

Mefloquine, [1392t](#), [1408](#)–1409  
pharmacokinetics of, [1860t](#)

MEFOXIN (cefoxitin), [1494t](#), [1496t](#)

MEGACE (megestrol acetate), [1668t](#)–1670t, [1756](#)

Megestrol acetate, [1668t](#)–1670t, [1765](#)

in cancer chemotherapy, [1756](#)  
structure of, [1761f](#)

MEH. *See* Microsomal epoxide hydrolase (mEH)

Meibomian glands, [1773](#)

Meibomianitis, bacterial, treatment of, [1781t](#)

Meissner's plexus. *See* Submucosal plexus

Melanocytes, [1804](#)

$\alpha$ -Melanocyte-stimulating hormone ( $\alpha$ -MSH), [1106t](#)

$\beta$ -Melanocyte-stimulating hormone ( $\beta$ -MSH), [1106t](#)

Melanoma, PUVA and, [1814](#)

Melarsoprol, [1427](#)–1428

Meloxicam, [965](#)

- adverse effects and side effects of, [990](#)
- compared to aspirin, [970t](#)
- COX isoform selectivity, [962f](#)
- dosage and administration of, [970t](#)
- pharmacokinetics of, [970t](#)
- pharmacology of, [962f](#)
- plasma pharmacokinetics of, [962f](#)
- therapeutic uses of, [970t](#), [990](#)

Melperone, potencies at neurotransmitter receptors, [427t](#)

Melphalan, [1668t](#)–1670t

- toxicity of, extramedullary, [1682t](#)

Melphalan, SLC transporters and, [102t](#)

Memantine, pharmacokinetics of, [1860t](#)

Memory, dopamine and, [357](#)

Menaquinone, [872](#)

MENEST (esterified estrogens), [1839t](#)

Ménière's disease, H<sub>1</sub>-receptor antagonists for, [923](#)

Meningitis

- bacterial, chloramphenicol for, [1528](#)
- gentamicin for, [1515](#)
- pneumococcal, penicillin for, [1485](#)–1486

Meningococcal infections, penicillin for, [1486](#)

Menopausal hormone therapy, [1175](#)–1177

## Menopause

age at, [1838](#)

definition of, [1838](#)

hormone-replacement therapy for, [1838](#)–1840

signs and symptoms, [1838](#)

MENOSTAR (estradiol), [1839t](#)

Menstrual cycle, neuroendocrine control of, [1166](#)–1169

## Meperidine

absorption, fate, and excretion of, [506](#)

cardiovascular system and, [506](#)

central nervous system and, [503](#)–505

contraindications to, [506](#)

dosage of, [500t](#)

drug interactions with, [506](#)–507

effects on organ systems, [503](#)–505

metabolism of, [128t](#)

pharmacokinetics of, [1860t](#)

smooth muscle and, [506](#)

structure of, [504f](#)

therapeutic uses of, [507](#)

untoward effects of, [506](#)

Mephentermine, [295](#)

structure of, [279t](#)

Mephenytoin, polymorphisms and response to, [159t](#)

Mephenytoin hydroxylase, [157](#)

Mephobarbital, [470t](#)

polymorphisms and response to, [159t](#)

Mepivacaine, [573](#)

Meprobamate, [476](#)

metabolism of, [128t](#)

## Mequinol

for hyperpigmentation, [1830](#)

mechanism of action of, [1830](#)

Mercaptopurine, [1668t](#)–1670t, [1701](#)–1702

metabolism of, [128t](#), [139](#)

- pharmacokinetics of, [1861t](#)
- polymorphisms and, [158](#)
- polymorphisms and response to, [161t](#)
- therapeutic uses of, for inflammatory bowel disease, [1352t](#)

Mercury, [1864](#)–1867

Mercury antidote, [86t](#)

Mesalamine

- chemistry, [1354](#)–1355
- for inflammatory bowel disease, [1354](#)–1356
- mechanism of action, [1354](#)–1355
- pharmacological properties, [1354](#)–1355

Mesenteric ganglia, [173f](#)

Mesoridazine, potencies at neurotransmitter receptors, [427t](#)

Metabolic effects

- of beta-adrenergic receptor antagonists, [315](#)
- of epinephrine, [285](#)–286
- of estrogens, [1169](#)–1170
- of oral contraceptives, [1187](#)–1188
- progestins and, [1182](#)
- of thyroid hormones, [1141](#)

Metabolic rickets, [1289](#)

Metabolic syndrome, [877](#)–878, [891](#)

- clinical identification of, [891t](#)

Metabolism interaction, [77](#)

Metabolism of drugs, [27](#)

- absorption and, [18f](#)
- binding and, [18f](#)
- cytochrome P450 superfamily and, [127](#)–130
- distribution and, [18f](#)
- drug development and, [123](#)–124, [142](#)
- effectiveness and, [139](#)–142
- endoplasmic reticulum in, [126](#)–127, [126f](#)
- excretion and, [18f](#)
- flavin-containing monooxygenases in, [125](#), [125t](#), [130](#)
- hydrolysis reactions in, [128t](#)

hydrolytic enzymes and, [130](#)–131, [131f](#)  
induction of, [140](#)–142, [140t](#), [141f](#)  
intestine in, [126](#)  
major reactions in, [128t](#)  
metabolism interaction, [77](#)  
methylation in, [138](#)–139  
nasal mucosa in, [126](#)  
oxidative reactions in, [128t](#)  
phase I, [124](#)–125, [125t](#), [127](#)–130  
phase II, [125](#), [125t](#), [131](#)–139  
phases of, [124](#)–125  
“poor,” 157  
safety and, [139](#)–142  
sites of, [125](#)–127, [126f](#)  
“ultra-rapid,” 157  
xenobiotic exposure and, [123](#)–124

Metabolites, as drugs, [1802](#)

Metabolomics, [142](#)

*Metagonimus yokogawai*, [1449](#)

Metals. *See also* Heavy metals  
as environmental toxins, [1860](#)–1872  
treatment of exposure to, [1872](#)–1876

Metamizole, [138t](#)

Metaproterenol, [291](#)  
adrenergic receptors and, [206t](#)  
structure of, [279t](#)

Metaraminol, [295](#)

Met-enkephalin, actions and selectivities, [485t](#)

Metered-dose inhalers, [1035](#)

Metformin, [1258](#)–1260  
pharmacokinetics of, [1861t](#)  
polymorphisms and response to, [159t](#)  
SLC transporters and, [102t](#)  
transporters and, [91](#)–92

Methacholine

- acetylcholine vs., [222](#)
- cholinergic receptors and, [206t](#)
- pharmacological properties of, [223t](#)
- respiratory tract and, [224](#)
- structure of, [222f](#)
- therapeutic use of, [224](#)
- Methadone, [508](#)–509
  - actions and selectivities of, [485t](#)
  - arrhythmias caused by, [832](#)
  - dosage of, [500t](#)
  - pharmacokinetics of, [1861t](#)
  - structure of, [504f](#)
- Methamphetamine, [299](#)
  - structure of, [279t](#)
- Methanol, pharmacokinetics of, [631](#)–632
- Methanol antidote, [86t](#)
- Methazolamide, [678](#)
  - pharmacology of, [679t](#)
  - structure of, [679t](#)
- Methemoglobinemia antidote, [86t](#)
- Methemoglobinemia, dapsone and, [1824](#)
- Methenamine, [1474](#)
- METHERGINE (methylergonovine), [1850](#)
- Methicillin
  - chemistry of, [1479t](#)
  - properties of, [1479t](#)
- Methicillin-resistant *Staphylococcus aureus* (MRSA)
  - infection, antibiotics for, [1817](#)
  - nasal colonization, antibiotic for, [1817](#)
- Methohexital
  - formulations of, [538t](#)
  - pharmacological properties of, [538t](#)
  - structure of, [470t](#)
- Methotrexate, [994t](#), [1668t](#)–1670t
  - ABC transporters and, [105t](#), [106t](#)

- as abortifacient, [1837](#)
- adverse effects and side effects of, [1820](#)
- contraindications to, [1820](#)
- in dermatology, [1820](#)
- drug interactions with, [1820](#)
- hepatic fibrosis caused by, [1820](#)
- for inflammatory bowel disease, [1358](#)
- intraocular use, [1790](#)
- leucovorin rescue for, [1820](#)
- mechanism of action of, [1820](#), [1820t](#)
- pharmacokinetics of, [1862t](#)
- polymorphisms and action of, [162](#)–163
- polymorphisms and response to, [159t](#), [161t](#)
- for psoriasis, [1805](#), [1820](#)
- SLC transporters and, [102t](#)
- therapeutic uses of, for inflammatory bowel disease, [1352t](#)

Methotrexate antidote, [86t](#)

Methoxamine, structure of, [279t](#)

Methoxsalen, [1809](#), [1813](#)

- formulations, [1813](#)
- structure of, [1813](#)

Methoxyphenol. *See* Mequinol

Methscopolamine bromide, [234](#)

Methyclothiazide

- pharmacology of, [688t](#)
- structure of, [688t](#)

3-methyl, 4-hydroxy phenylglycol(MOPEG), [200](#)–201

Methylaminolevulinate, [1815](#)

Methylation, [128t](#), [138](#)–139

- DNA, [97](#)
- of mercaptopurine, [158](#)

Methylclothiazide, as anti-hypertensive agent, [774t](#)

Methyldopa, [297](#), [780](#)–781

- adrenergic receptors and, [206t](#)
- as anti-hypertensive agent, [774t](#)

arrhythmias caused by, [821t](#)  
for hypertension, in pregnancy, [1847](#)  
metabolism of, [128t](#)

$\alpha$ -Methyldopa. *See* Methyldopa

Methylene blue, as antidote, [86t](#)

Methylenetetrahydrofolate reductase(MTHFR), [162](#)

Methylergonovine, for postpartum hemorrhage, [1850](#)

Methylguanine-methyltransferase polymorphism, [161t](#)

4-Methylhistamine, [912](#), [912f](#), [916](#)

*N*-Methylhistamine, [913](#)

Methylhydrazine derivative, for neoplastic disease, [1668t](#)–1670t

Methylhydrazines, [1687](#)

*N*-Methylimidazole acetic acid, [913](#)

Methylmelamines, [1668t](#)–1670t

Methylparathion, [243](#)

Methylphenidate, [299](#)–300  
pharmacokinetics of, [1862t](#)

Methylprednisolone  
pharmacokinetics of, [1863t](#)  
relative potencies and equivalent doses of, [1216t](#)

Methylprednisolone sodium succinate, dosage and administration of, [1809](#)

Methyl salicylate, structure of, [977f](#)

Methyltransferases (MT), [125](#), [125t](#), [138](#)–139

Methylxanthines, [1040](#)–1044  
chemistry of, [1040](#)  
clinical use, [1043](#)  
mechanism of action, [1040](#)–1042  
metabolism of, [1042](#)  
nonbronchodilator effects, [1042](#)  
pharmacokinetics, [1042](#)  
preparations of, [1042](#)–1043  
routes of administration, [1042](#)–1043  
side effects, [1043](#)

Methysergide, [349](#), [351](#)

Metoclopramide

- adverse effects of, [1326](#)
- chemistry of, [1325](#)
- effects on bowel function, [1330t](#)
- mechanism of action of, [1325](#)
- pharmacokinetics of, [1325](#), [1863t](#)
- pharmacological effects of, [1325](#)
- therapeutic uses of, [1325](#)
  - as anti-nausea agent, in cancer chemotherapy, [1344t](#)

Metocurine, [264t](#)

- dosing of, [265t](#)

Metolazone, [776](#)–[777](#)

- as anti-hypertensive agent, [774t](#)
- pharmacology of, [688t](#)
- structure of, [688t](#)

“Me too” drugs, [13](#)–[14](#)

Metoprolol, [777](#)

- absorption, fate, and excretion of, [326](#)
- adrenergic receptors and, [207t](#)
- for angina, [767](#)
- antiarrhythmic use of, [831](#)
- as anti-hypertensive agent, [774t](#)
- cardioprotective effects of, [767](#)
- pharmacokinetics of, [1863t](#)
- structure of, [311f](#)
- therapeutic uses of, [326](#)–[327](#)
  - for myocardial ischemia, [767](#)

Metrifonate, [1458](#)

Metrizamide, [1153t](#)

METROCREAM (metronidazole), [1817](#)

METROGEL (metronidazole), [1817](#)

Metronidazole

- absorption, fate, and excretion of, [1429](#)
- antiparasitic and antimicrobial effects of, [1428](#)–[1429](#)
- for bacterial vaginosis, [1842t](#)
- bioequivalency with, [23](#)

- contraindications to, [1430](#)
- drug interactions with, [1430](#)
- mechanism of action of, [1429](#)
- pharmacokinetics of, [1864t](#)
- resistance to, [1429](#)
- therapeutic uses of, [1429](#)–1430
  - for inflammatory bowel disease, [1352t](#)
- topical, for acne, [1817](#)
- toxicity of, [1430](#)
  - for *trichomonas*, [1842t](#)

METVIXIA (methylaminolevulinate), [1815](#)

Metyrapone, [1235](#)–1236

Metyrosine, as anti-hypertensive agent, [783](#)

MEVACOR (lovastatin), [897](#)

Mevastatin, [893](#), [894](#)

- structure of, [893f](#)

Mexiletine

- antiarrhythmic use of, [828](#), [836t](#), [842](#)
- contraindications to, [833t](#)
- dosage of, [836t](#)
- electrophysiological actions of, [829t](#)
- pharmacokinetics of, [836t](#)
- structure of, [842](#)

MEXITIL (mexiletine), [842](#)

MEXORYL SX (ecamsule), [1827](#)

Mezlocillin, [1484](#)

- chemistry of, [1479t](#)
- properties of, [1479t](#)

Mianserin, potencies at human transporters for monamine neurotransmitters, [406t](#)

Mibefradil, and statins, interactions, [896](#)

Micafungin, [1584](#)

- pharmacokinetics of, [1864t](#)

MICARDIS (telmisartan), [738](#)

MICATIN (miconazole), [1818](#)

Michaelis constant, [95](#)  
Michaelis-Menten equation, [95](#)  
Miconazole, [1587](#)  
    for cutaneous fungal infection, [1818](#)  
    for vaginal candidiasis, [1842t](#)  
MICRONASE (glyburide), [1257t](#)  
MICRONOR (norethindrone), [1836t](#)  
Microsomal epoxide hydrolase (mEH), [130](#)  
Microsomal triglyceride transfer protein (MTP), [878](#), [882](#)  
*Microsporidia*, [1424](#)  
Microtubule-damaging agents, [1705](#)  
MIDAMOR (amiloride), [690](#)–692, [690t](#)  
Midazolam  
    administration of, [466t](#)  
    metabolism of, [128t](#)  
    pharmacokinetics of, [1864t](#)  
    polymorphisms and response to, [159t](#)  
    therapeutic uses of, [466t](#)  
Midbrain, [364](#)  
Midodrine, [295](#)  
MIFEPREX (mifepristone), [1837](#)  
Mifepristone, [1184](#)–1185  
    as abortifacient, [1837](#)  
    for postcoital contraception, [1837](#)  
    risks (black box warning), [1837](#)  
    in therapeutic abortion, [952](#)  
Migraine  
    angina pectoris with, recommended treatment for, [769t](#)  
    drug therapy for  
        ergot alkaloids, [347](#)  
        5-HT-receptor agonists, [344](#)–345  
    prophylaxis, [767](#)  
Milk of Magnesia, [1316t](#)  
Milnacipran, potencies at human transporters for monamine neurotransmitters, [406t](#)

Milrinone, [771](#)  
for heart failure, [805](#)

Miltefosine, [1430](#)–1431

Mineral(s)  
ethanol and, [638](#)  
homeostasis, [1275](#)–1277  
homeostasis disorders, [1286](#)–1290

Mineralocorticoid receptors, antagonists of  
pharmacology of, [693t](#)  
structures of, [693t](#)

Mineralocorticoids, regulation of gene expression by, [1218](#)

MINOCIN (minocycline), [1817](#)

Minocycline, [994t](#)  
for acne, [1817](#)  
adverse effects and side effects of, [1817](#)  
pharmacokinetics of, [1865t](#)

Minoxidil, [777](#)  
adverse effects and side effects of, [788](#)–781, [1829](#)  
for androgenetic alopecia, [1829](#)  
as anti-hypertensive agent, [774t](#), [788](#)–781  
hypertrichosis caused by, [781](#)  
pharmacology of, [788](#)  
precautions with, [788](#)–781  
site of action of, [788](#)  
structure of, [788](#), [1829](#)  
therapeutic uses of, [781](#)  
topical, [1829](#)

MIOCHOL-E (acetylcholine), [1788](#)

Miosis, [495](#), [1776](#)

Miotic agents, for glaucoma, [1788](#)

Miproxifene, [1756](#)

MIRCETTE (ethinyl estradiol/desogestrel), [1835t](#)

MIRENA, [1836](#)

Mirtazapine  
disposition of, [409t](#)

dose and dosage forms of, [403t](#)  
pharmacokinetics of, [1865t](#)  
potencies  
    at human transporters for monamine neurotransmitters, [406t](#)  
    at neurotransmitter receptors, [410t](#)  
side effects of, [403t](#)

#### Misoprostol

adverse effects of, [1315](#)  
for cervical ripening, [1849](#)–1850  
chemistry of, [1314](#)  
pharmacokinetics of, [1315](#)  
pharmacological properties of, [1314](#)  
for postpartum hemorrhage, [1851](#)  
for pregnancy termination, [1837](#)  
therapeutic uses of, [1315](#)  
    for gastric cytoprotection, [952](#)  
    in therapeutic abortion, [952](#)  
    for ulcers, [1319t](#)

Mistrust of science and industry, [11](#)

Misuse, poisoning and, [80](#)

Mitogen-activated protein kinase inhibitors, [1056](#)

Mitomycin, [1668t](#)–1670t

    for cancer, [1718](#)–1719

Mitotane, [1236](#), [1668t](#)–1670t

    for cancer, [1719](#)

Mitoxantrone, [1668t](#)–1670t, [1715](#)

    ABC transporters and, [106t](#)

    pharmacokinetics of, [1865t](#)

Mitral regurgitation, angina pectoris with, recommended treatment for, [769t](#)

Mitral stenosis, angina pectoris with, recommended treatment for, [769t](#)

#### Mivacurium

    characteristics of, [264t](#)

    dosing of, [265t](#)

Mizolastine, [922t](#)

MIZOLLEN (mizolastine), [922t](#)

MK249, [925](#)

MM. *See* Multiple myeloma (MM)

MOBIC (meloxicam), [990](#)

Modafinil, pharmacokinetics of, [1866t](#)

Moexipril, [733](#)–734  
as anti-hypertensive agent, [774t](#), [784](#)–785  
structure of, [732f](#)

Molindone hydrochloride  
dosage of, [424t](#)  
potencies at neurotransmitter receptors, [427t](#)  
side effects of, [424t](#)

Molluscum contagiosum, [1818](#)  
imiquimod for, [1823](#)

Mometasone furoate  
cream, [1225t](#)  
ointment, [1225t](#)

*Monascus purpureus*, [893](#)

Monitoring, therapeutic drug, [37](#)–38

Monoamine oxidase inhibitors (MAOIs), [404](#), [913](#)  
adrenergic receptors and, [207t](#)  
adverse effects of, [411](#)  
catecholamine transformation and, [200](#)  
drug interactions with, [412](#)  
manifestation of overdose symptoms, [75t](#)  
mechanism of action, [408](#)  
for Parkinson, [618](#)  
pharmacokinetics, [408](#)

Monoamine oxidase (MAO), [913](#)  
in catecholamine transformation, [200](#)

Monoamine oxidase (MAO) inhibitors, false-transmitter concept and, [282](#)

Monobenzene, [1830](#)

MONOCID (cefonicid), [1494t](#)

Monoclonal antibodies, [1016](#)–1018

Monoclonal antibody(ies) (MAb), [1745](#)–1750  
antitumor activity, mechanism of action of, [1731](#)

- chimeric, nomenclature for, [1745](#)
- cytotoxic conjugates, [1745](#), [1748](#)–1750
- dosing, [1747t](#)
- fully humanized, nomenclature for, [1745](#)
- for hematopoietic and solid tumors, [1746t](#)
- linked to toxin, [1745](#)
- radioimmunoconjugate, [1745](#), [1749](#)
- therapeutic, nomenclature for, [1745](#)
- toxicity of, [1747t](#)
- unarmed, [1745](#)–1748

Monocyte/macrophage colony-stimulating factor (CSF-1; M-CSF), [1070t](#)

MONODOX (doxycycline), [1817](#)

Monogenic trait, [152f](#)

MONOPRIL (fosinopril), [733](#), [797](#)

Montelukast, [942](#)

- pharmacokinetics of, [1866t](#)

Mood alteration, with opioids, [493](#)–494

MOPEG. *See* 3-methyl, 4-hydroxy phenylglycol (MOPEG)

8-MOP (methoxsalen), [1813](#)

Morphine

- absorption, distribution, fate, and excretion of, [501](#)
- actions and selectivities of, [485t](#)

- as anti-hypertensive agent, [774t](#), [784](#)
- cardiovascular pharmacology of, [762t](#)
- as dose-dependent toxicity, [75](#)
- pharmacokinetics of, [1868t](#)
- pharmacology of, [764](#)
- for prevention of preterm labor, [1848](#)
- structure of, [762t](#)

therapeutic uses of, [767](#)  
antiarrhythmic, [830](#)  
for hypertension, in pregnancy, [1847](#)

#### Nifurtimox

absorption, fate, and excretion of, [1432](#)  
antiprotozoal effects of, [1431](#)–1432  
therapeutic uses of, [1432](#)  
toxicity and side effects of, [1432](#)

NILANDRON (nilutamide), [1765](#)

Nilotinib, [1732](#)–1734

resistance, mechanisms of, [1733f](#)

Nilutamide, [1205](#), [1765](#), [1766](#)

structure of, [1761f](#)

Nimesulide, [965](#), [992](#)

Nimodipine, [761](#)

pharmacology of, [764](#)  
therapeutic uses of, [767](#)

Nisoldipine, [761](#)

as anti-hypertensive agent, [774t](#)

pharmacology of, [764](#)

Nitazoxanide, [1432](#)–1433

#### Nitrates

organic, [756](#)–760, [808](#)  
chemistry of, [753](#)  
dosage and administration of, [754t](#)  
effects on smooth muscle, [756](#)–757  
history of, [753](#)  
interaction with phosphodiesterase inhibitors, [758](#)–759  
mechanism of action of, [753](#)–754  
nomenclature for, [754t](#)  
pharmacological properties of, [753](#)–757  
and angina relief, [756](#)–757  
cardiovascular, [755](#)  
and coronary blood flow, [755](#)  
hemodynamic, [755](#)

- and myocardial oxygen requirement, [755](#)–756
- plasma concentrations of, [757](#)
- preparations, [757](#)
- structures, [754t](#)
- therapeutic uses of, [759](#)–761
  - for heart failure, [794](#)–795
  - for myocardial ischemia, [753](#)–761
  - for unstable angina, [760](#)
- tolerance, [757](#)–758, [795](#)
- toxicity of, [758](#)–759
- tolerance, [808](#)
- transdermal, for prevention of preterm labor, [1848](#)

Nitrazepam, [138t](#)

- structure of, [459t](#)

Nitroergic nerves, [172](#)

Nitric oxide (NO), [753](#), [926](#), [927f](#)

- in acetylcholine cardiac action, [221](#)
- in central nervous system, [390](#)
- diagnostic uses, [563](#)
- methods of administration, [564](#)
- modulation of vascular response with, [214](#)
- as neurotransmitter, [182](#)
- in peripheral autonomic system, [172](#)
- toxicity of, [563](#)–564

Nitric oxide (NO) donors, for prevention of preterm labor, [1848](#)

Nitric oxide synthase, [64](#)–65

Nitric oxide synthase inhibitors, [1055](#)–1056

Nitric oxide synthase (NOS), [753](#), [927f](#)

- isoforms, [753](#)

NITRO-BID (nitroglycerin), [754t](#)

NITRO-DUR (nitroglycerin), [754t](#)

Nitrofurantoin, [1474](#)–1475

- pharmacokinetics of, [1869t](#)

Nitrogen mustards, [1668t](#)–1670t, [1682](#)–1684

Nitroglycerin

absorption, fate, and excretion of, [757](#)  
adverse effects and side effects of, [755](#)  
cardiovascular effects, with long-term use, [752](#)  
chemistry of, [753](#)  
cutaneous administration, [760](#)  
dosage and administration of, [754t](#)  
history of, [753](#)  
intravenous, therapeutic uses of, for heart failure, [796](#)  
oral, [759](#)–760  
pharmacokinetics of, [1869t](#)  
preparations, [754t](#)  
for prevention of preterm labor, [1848](#)  
structure of, [754t](#)  
sublingual administration of, [759](#)  
therapeutic uses of  
    in myocardial infarction, [760](#)–761  
    for unstable angina, [760](#)  
    transmucosal or buccal administration, [760](#)  
NITROL (nitroglycerin), [754t](#)  
NITROPRESS (sodium nitroprusside), [795](#)–796  
Nitroprusside, [793](#)  
Nitrosoureas, [1668t](#)–1670t, [1686](#)  
NITROSTAT (nitroglycerin), [754t](#)  
Nitrous oxide  
    clinical uses of, [551](#)  
    pharmacokinetics of, [551](#)  
    side effects of, [551](#)–552  
        cardiovascular, [551](#)  
        gastrointestinal, [552](#)  
        hepatic, [552](#)  
        muscular, [552](#)  
        neurological, [551](#)–552  
        renal, [552](#)  
        respiratory, [551](#)  
Nitrovasodilators, [753](#)

as antianginal agents, [752](#)  
for congestive heart failure, [793](#)–795

Nizatidine  
pharmacokinetics of, [1816t](#)  
therapeutic uses of, for ulcers, [1319t](#)

NIZORAL (ketoconazole), [1841](#)

NMR. *See* Nuclear magnetic resonance(NMR) spectroscopy

NNMT. *See* Nicotinamide *N*-methyltransferase (NNMT)

NO. *See* Nitric oxide (NO)

Nobel, Alfred, [753](#)

Nocardiosis, sulfonamides for, [1467](#)

Nocturnal acid breakthrough, [1318](#)

Nodal depolarizations, premature, management of, [824t](#)

NOLAHIST (phenindamine tartrate), [921t](#)

Nolvadex Adjuvant Trial Organization(NATO), [1758](#)

Nomenclature, of genomic regions, [148f](#)

Nomifensine, potencies at human transporters for monoamine neurotransmitters, [406t](#)

Nonarteritic ischemic optic neuropathy (NAION), phosphodiesterase inhibitors and, [1792](#)

Noncoding single nucleotide polymorphisms, [148](#), [155](#)

Noncompetitive inhibition, [96](#)

Nondigestible alcohols, [1332](#)

Nondigestible sugars, [1332](#)

- and inflammation, [954](#)
- in inflammation, [960](#)
- and leukocytes, [954](#)
- mechanism of action of, [953](#)
- pharmacology of, [953](#)–955
- physiological and pathological functions of, [954](#)–955
- and platelets, [954](#)
- receptor antagonists, [955](#)
- renal effects of, [955](#)
- and reproduction/parturition, [954](#)
- and smooth muscle, [954](#)
- structure of, [952](#)

Platelet-derived growth factor (PDGF), [1738](#)

Platelet factor 4, [855](#)

Platelets, alpha adrenergic receptors in, [203t](#)

Platinum coordination complexes

- chemistry of, [1688](#)
- cytotoxic actions of, [1680](#)–1681
- mechanism of action of, [1688](#)
- for neoplastic disease, [1668t](#)–1670t
- pharmacological actions of, [1680](#)–1681
- resistance to, [1688](#)
- structure-activity relationships, [1678](#)–1680

PLC. *See* Phospholipase C (PLC)

PLENDIL (felodipine), [762t](#)

PML. *See* Progressive multifocal leukoencephalopathy (PML)

*Pneumocystis jiroveci*, [1469](#)–1470

Pneumonia, pneumococcal, penicillin D for, [1485](#)

PNMT. *See* Phenylethanolamine-Nmethyltransferase (PNMT)

Podophyllin/podofilox

- adverse effects and side effects of, [1830](#)
- for anogenital warts, [1830](#)
- for cutaneous viral infections, [1818](#)
- dosage and administration of, [1830](#)

mechanism of action of, [1830](#)

Podophyllum resin. *See* Podophyllin/podofilox

Poison, definition of, [73](#)

Poisoning

- absorption and, [75](#)
- anticholinesterase, [234](#)
- in children, [80](#)
- clinical toxicity pattern identification in, [82](#)
- decontamination of patient in, [82–85](#)
- differential diagnosis in, electrocardiographic, [83t](#)
- elimination and, [75](#)
- epidemiology of, [79–80](#)
- home prevention of, [81–82](#)
- with H<sub>1</sub> receptor antagonists, [923](#)
- intentional, [80](#)
- most-frequent substances in, [80t](#)
- mushroom, [225](#)
- prevention of, [80–82](#)
- resources, [85–86](#)
- scenarios for, [79t](#)
- stabilization of patient in, [82](#)
- treatment principles, [82–85](#)

Poison ivy, H<sub>1</sub> receptor antagonists for, [922](#)

Polyarteritis nodosa, cyclophosphamide for, [1821](#)

Polycystic ovary syndrome (PCOS)

- effects on ovulation and fertility, [1845](#)
- and hirsutism, [1840](#)
- insulin sensitizers for, [1845](#)
- and obesity, [1841](#)

Polycythemia vera, drugs for, [1668t–1670t](#)

Polyenes, for ophthalmic use, [1784t](#)

Polyethylene glycol electrolyte solution, [84–85](#), [1332–1333](#)

Polyhexamethylene biguanide, for ophthalmic use, [1784](#)

POLY-HISTINE-D (pyrilamine maleate), [921t](#)

Polymers, biocompatible, [23](#)

Polymorphism, [147](#), [147f](#), [148](#)  
causative, [153](#)  
cosmopolitan, [150](#)

Retinoic acid receptors (RARs), [1809](#)

isoforms, [1809](#)

Retinoic acid-responsive elements(RAREs), [1809](#)

Retinoid dermatitis, [1812](#)

Retinoid receptor(s), [1809](#)

## Retinoids

for acne, [1809](#)

adverse effects and side effects of, [1811](#)–1812

aromatic, [1809](#)

for cancer, [1722](#)–1723

contraindications to, [1811](#)

definition of, [1809](#)

dermatological uses of, [1809](#)

first-generation, [1809](#)

functions in body, [1809](#)

for photoaging, [1809](#)

for psoriasis, [1809](#)

second-generation, [1809](#)

systemic, [1811](#)–1812, [1811t](#)

and serum lipids, [1812](#)

teratogenicity of, [1812](#)

third-generation, [1809](#)

topical, [1810t](#)

Retinoid X receptor (RXR), [140t](#), [1809](#)

isoforms, [1809](#)

Retinoid X receptors, [1798](#)

Retinol, [1809](#)

isomers, [1795](#)

Retinoscopy, cycloplegic, autonomic agents for, [1785t](#)

Retrobulbar region, [1773](#)

RETROVIR (zidovudine), [1626t](#)

REVATIO (sildenafil), [758–759](#), [805](#), [1792](#)

“Reversible” carbamate inhibitors, [242](#)

REVLIMID (lenalidomide), [1742](#)

Rewarding properties, of opioids, [493–494](#)

Reye’s syndrome, [975–976](#)

Rhabdomyolysis, statins and, [896](#)

Rhabdomyosarcoma, drugs for, [1668t–1670t](#)

Rheologic modifiers, [771–772](#)

Rheumatic disorders, glucocorticoids for, [1232](#)

Rheumatic fever, penicillin for, [1487](#)

Rheumatoid arthritis, [960](#)

Rheumatoid arthritis (RA), biological agents for, [1825t](#)

RHEUMATREX (methotrexate), [1820](#)

Rhinorrhea, muscarinic antagonists and, [231](#)

Rh-null regulator, [103t](#)

Rho(D) immune globulin, [1024](#)

Ribavirin, [1596t](#), [1612–1614](#)  
    pharmacokinetics of, [1883t](#)

Riboflavin, [1086](#)

Rickets, [1289](#), [1293](#)

sotalol for, [845](#)

Ventricular depolarization, premature, management of, [824t](#)

Ventricular dysfunction, systolic, ventricular outflow resistance and stroke volume in, [796f](#)

Ventricular fibrillation, [823](#)

- drug-induced, [821t](#)
- ECG of, [825f](#)
- management, [823](#)
- management of, [824t](#)

Ventricular tachycardia, [830](#). *See also* Catecholaminergic polymorphic ventricular tachycardia (CPVT)

- drug-induced, [821t](#)
- management of, [824t](#)
- monomorphic, ECG of, [825f](#)

Verapamil, [761](#)

- ABC transporters and, [105t](#)
- absorption, fate, and excretion of, [765](#)
- adverse effects of, [766](#)
- antiarrhythmic use of, [824t](#), [830](#), [831](#), [836t](#)
- as anti-hypertensive agent, [774t](#)
- arrhythmias caused by, [821t](#)
- cardiovascular pharmacology of, [763t](#)
- contraindications to, [833t](#)
- dosage of, [836t](#)
- drug interactions with, [766](#), [839](#), [845](#)
- electrophysiological actions of, [829t](#)
- hemodynamic effects of, [765](#)
- pharmacokinetics of, [836t](#), [1898t](#)
- pharmacology of, [764](#), [765](#)
- structure of, [763t](#)
- therapeutic uses of, [767](#)
  - for angina, [766](#)

VERELAN (verapamil), [831](#)

Vernakalant

- antiarrhythmic use of, [845](#)

mechanism of action of, [845](#)  
pharmacokinetics of, [845](#)  
pharmacology of, [845](#)  
structure of, [845](#)

Verrucae, [1818](#)  
keratolytics for, [1829](#)

VERSED (midazolam), [466t](#)

VERSCLEAR LOTION (antifungal combination), [1817](#)

Vertigo, H<sub>1</sub> receptor antagonists for, [923](#)

Very-low-density lipoproteins (VLDL), [878](#), [882](#)  
characteristics of, [879t](#)  
gemfibrozil and, [902](#)  
metabolism, [881f](#)  
nicotinic acid and, [900](#)

Vesamicol, cholinergic receptors and, [206t](#)

Vesicle-associated membrane protein 2(VAMP2), [187](#)

Vesicular ACh transporter (VAChT), [187](#)

Vesnarinone, for heart failure, [805](#)

Viability, economic, in drug development, [6](#)

VIAGRA (sildenafil), [758–759](#), [1792](#)

VICOPROFEN, [988](#)

Vidarabine, [1596t](#)

VIDEX (didanosine), [1626t](#)

VIDEX EC (zidovudine), [1626t](#)

Vigabatrin, [103t](#), [603](#)  
retinal effects of, [1792](#)

VIGAMOX (moxifloxacin), [1781t](#)

Viloxazine, potencies at human transporters for monoamine neurotransmitters, [406t](#)

Vinblastine, [1668t–1670t](#), [1706](#)  
in dermatology, [1823](#)  
mechanism of action of, [1820t](#)

Vinca alkaloids, [1705–1707](#)  
therapeutic uses of, for neoplastic disease, [1668t–1670t](#)

Vincristine, [1668t–1670t](#), [1706–1707](#)

ABC transporters and, [105t](#)  
pharmacokinetics of, [1899t](#)  
and vasopressin secretion, [704](#)

Vinorelbine, [1707](#)  
pharmacokinetics of, [1899t](#)

VIOXX (rofecoxib), [992](#)

VIP. *See* Vasoactive intestinal polypeptide (VIP)

VIRA-A (vidarabine), [1596t](#)

VIRACEPT (nelfinavir), [1626t](#)

Viral infections, of skin, [1818](#)

VIRAMUNE (nevirapine), [1626t](#)

VIRAZOLE (ribavirin), [1596t](#)

Virilization, [1840](#)

VIROPTIC (trifluridine), [1596t](#), [1782](#)

Viruses, susceptibility testing in, [1370](#)–1371

Visceral afferent fibers, [171](#)–172

Visceral nervous system. *See*  
Autonomic nervous system (ANS)

VISCOAT (chondroitin sulfate), [1790](#)

Viscoelastic substances, in ocular surgery, [1790](#)

VISIONBLUE (trypan blue), [1788](#)

VISKEN (pindolol), [326](#)

VISTARIL (hydroxyzine pamoate), [921t](#)

VISTIDE (cidofovir), [1596t](#), [1818](#)

Visual cycle, [1796](#)–1797, [1797f](#)

Vitamin(s)  
dose-response curve for, [74f](#)  
ethanol and, [638](#)  
iodine-containing, [1153t](#)

Vitamin A, [1809](#)  
deficiency of, [1796](#)  
mechanism of action of, [1797](#)–1798

Vitamin analogs, in dermatology, [1812](#)–1813

Vitamin B<sub>12</sub>, [1086](#)–1096  
as ABC transporter, [97](#)

deficiency of, [1090](#)  
folic acid and, [1087](#)–1088  
metabolic functions of, [1089](#)  
therapeutic uses of, [1090](#)–1092

#### Vitamin D

absorption of, [1280](#)–1281  
adverse effects of, [1294](#)  
bone mineral mobilization and, [1283](#)  
calcium and, [1280](#)–1283  
chemistry and occurrence of, [1280](#)  
clinical uses of, [1291](#)–1292  
deficiency of, [1289](#)  
disorders, [1288](#)–1290  
excretion of, [1280](#)–1281  
history of, [1280](#)  
hydroxylation of, [1281](#)–1282  
metabolic activation of, [1281](#)  
for osteoporosis, [1300](#)  
physiological functions of, [1282](#)–1283  
requirements for, [1280](#)  
and statin-associated myalgias, [897](#)  
therapeutic indications for, [1293](#)–1294  
therapeutic uses of, [1291](#)–1294

Vitamin D receptor, [140](#)*t*

Vitamin D receptor polymorphism, [161](#)*t*

#### Vitamin K

absorption, [873](#)  
    inadequate, [874](#)  
as antidote, [86](#)*t*  
biliary obstruction/fistula and, [874](#)  
chemistry, [872](#)  
deficiency, symptoms, [873](#)  
excretion, [873](#)  
history, [872](#)  
human requirements for, [873](#)

inadequate intake of, [873](#)  
inadequate utilization of, [874](#)  
occurrence, [872](#)  
pharmacokinetics of, [873](#)  
pharmacological actions of, [872](#)–873  
physiological role of, [872](#)  
therapeutic uses of, [873](#)–874  
toxicity of, [873](#)

Vitamin K antagonist(s), [860](#)  
    clinical use and monitoring of, [865](#)  
    structures of, [860f](#)

Vitamin K cycle, [861f](#)

Vitamin K epoxide reductase, [861](#)

Vitamin K oxoreductase (VKORC1), [160t](#)

Vitiligo  
    photochemotherapy for, [1813](#)–1814, [1814t](#)  
    tacrolimus for, [1822](#)

VITRASERT (ganciclovir), [1596t](#)

VITRAVENE (formivirsen), [1596t](#)

Vitreous, [1774](#), [1776f](#), [1778](#)

VIVELLE-DOT (estradiol), [1839t](#)

VIVELLE (estradiol), [1839t](#)

VKORC1. *See* Vitamin K oxoreductase (VKORC1)

*VKORC1*, genotype/haplotype  
    effects on warfarin, [862](#)–863, [863t](#), [864](#)  
    frequencies in different populations, [863t](#)

VMA. *See* Vanillylmandelic acid (VMA)

Voltage-gated channels, [59](#)

VOLTAREN (diclofenac), [986](#)–987

VOLTAREN-XR (diclofenac), [986](#)–987

VOLTAROL (diclofenac), [987](#)

Volume of distribution, [30](#)–32  
    alteration for individual patients, [1807](#)  
    of common drugs, [1809t](#)–1890t  
    disposition and, [28](#)

as pharmacodynamic parameter, [1804](#)  
Voriconazole, [1580](#)–1581  
arrhythmias caused by, [832](#)  
pharmacokinetics of, [1899t](#)  
polymorphisms and response to, [159t](#)  
Vorinostat, [1723](#)–1724  
VPA-977, [717](#)  
vSGLT. *See* Sodium galactose transporter (vSGLT)  
VYTORIN (ezetimibe and simvastatin), [904](#)

## W

Warfarin, [857](#)  
clinical use and monitoring of, [865](#)  
decreased effect of, causes, [863](#)–864  
dosage, [862](#)  
dose requirements, genetic factors affecting, [862](#)–863, [863t](#)  
history of, [860](#)  
mechanism of action of, [861f](#)  
metabolism of, [128t](#)  
monitoring, [862](#)  
pharmacokinetics of, [1899t](#)  
polymorphisms and, [157](#)–158, [162f](#)  
polymorphisms and response to, [159t](#), [160t](#)  
and statins, interactions, [896](#)  
structure of, [860f](#)  
therapeutic uses of, [855](#)  
Warfarin-like anticoagulants, manifestation of overdose symptoms, [75t](#)  
Warts  
bleomycin for, [1823](#)  
genital, imiquimod for, [1823](#)  
imiquimod for, [1823](#)  
Water, gastrointestinal flux of, [1328](#)–1330  
Water homeostasis, [701](#)  
WBI. *See* Whole bowel irrigation (WBI)  
Wegener's granulomatosis, cyclophosphamide for, [1821](#)

Weight, diuretics and, [677f](#)  
Weight reduction, sympathomimetic amines for, [303](#)  
WELCHOL (colesevelam hydrochloride), [899](#)  
WELLFERON (interferon), [1596t](#)  
WESTCORT (hydrocortisone valerate), [1225t](#)  
WHI. *See* Women's Health Initiative  
WHITFIELD'S OINTMENT (antifungal combination), [1817](#)  
Whole bowel irrigation (WBI), [84](#)–85  
Wilms' tumor, drugs for, [1668t](#)–1670t  
Withdrawal syndrome, drug abuse/addiction and, [653](#)–654  
Wolff-Parkinson-White syndrome, management of, [824t](#)  
Wolff-Parkinson-White (WPW) syndrome, [822](#), [822f](#)  
    management of, [822f](#)  
Women's Health Initiative, [1838](#)  
World War II, [239](#)  
Writing prescriptions abbreviations in, [1880](#)–1881  
    authority for, [1880](#)  
    compliance and, [1881](#)–1882  
    confusion in, [1880](#)–1881  
    current practice, [1879](#)–1880  
    date in, [1881](#)–1882  
    drug product choice and amount in, [1882](#)  
    errors in, [1883](#)  
    history of, [1879](#)  
    mechanics of, [1879](#)–1883  
    patient information in, [1881](#)  
    refills in, [1881](#)–1882  
    signa in, [1879](#)  
    subscription in, [1879](#)  
*Wuchereria bancrofti*, [1446](#)

## X

XALATAN (latanoprost), [1787](#)  
XANAX (alprazolam), [466t](#)  
Xanthine oxidase, and vascular dysfunction, [807](#)–808

Xanthine oxidase inhibitor(s), [806](#)  
XARELTO (rivaroxaban), [866](#)  
Xenobiotic metabolizing enzymes, [125t](#)  
Xenobiotics  
    coping with exposure to, [123](#)–124  
    sources of, [123](#)  
Xenon  
    cardiovascular effects, [552](#)  
    effects on organ systems, [552](#)  
    neurological effects of, [552](#)  
    properties of, [552](#)  
    respiratory effects of, [552](#)  
Xerophthalmia, [1795](#)  
Xerosis, keratolytics for, [1829](#)  
Xerostomia, [224](#)  
XIBROM (bromfenac), [1789](#)  
XIGRIS (drotrecogin alfa), [860](#)  
X-linked creatine deficiency syndrome, [102t](#)  
X-linked sideroblastic anemia, [104t](#)  
X-ray crystallography, in drug development, [5](#)  
XYLOCAINE (lidocaine), [841](#)  
XYSAL (levocetirizine hydrochloride), [921t](#), [1816](#)

## Y

YASMIN (ethinyl estradiol/drosperinone), [1835t](#)  
YAZ (ethinyl estradiol/drosperinone), [1833](#)–1834, [1836t](#)  
Yeast, ocular infections, agents for, [1784t](#)  
YM [87](#), [716t](#)  
YM150, [866](#)  
YM-471, [716t](#)  
Yohimbe, adrenergic receptors and, [207t](#)  
Yohimbine, [306f](#), [309](#)  
Yttrium-90 ibritumomab tiuxetan, [1745](#), [1746t](#), [1749](#)  
    dosage and administration of, [1747t](#)  
    toxicity of, [1747t](#)

## Z

ZADITOR (ketotifen fumarate), [922](#)

Zafirlukast, [942](#)

Zalcitabine, [1626t](#), [1634](#)

    pharmacokinetics of, [1630t](#)

Zanamivir, [1596t](#), [1608](#)–1609

Zankiren, [745](#)

ZAROXOLYN (metolazone), [688t](#)

ZD 164384, [1759](#)

ZEMURON (rocuronium), [264t](#)

ZERIT (stavudine), [1626t](#)

ZESTRIL (lisinopril), [733](#), [797](#)

ZEVALIN (yttrium-90 ibritumomab tiuxetan), [1749](#)

ZEVALIN (yttrium-90-ibritumomab tiuxetan), [1745](#)

ZIAGEN (abacavir), [1626t](#)

Zidovudine, [1626t](#)

    absorption of, [1632](#)

    antiviral activity of, [1632](#)

    chemistry of, [1632](#)

    distribution of, [1632](#)

    drug interactions with, [1633](#)

    elimination of, [1632](#)

    mechanism of action of, [1632](#)

    pharmacokinetics of, [1630t](#), [1900t](#)

    precautions with, [1633](#)

    resistance to, [1632](#)

    therapeutic uses of, [1633](#)

    untoward effects, [1632](#)–1633

Zileuton, [942](#)

Zimelidine, potencies at human transporters for monamine neurotransmitters, [406t](#)

ZINACEF (cefuroxime), [1494t](#), [1496t](#)

Zinc, in ophthalmology, [1795t](#)

Zinc oxide, [1827](#)

## Ziprasidone

- arrhythmias caused by, [832](#)
- dosage of, [426t](#)
- metabolism of, [434t](#)
- pharmacokinetics of, [1900t](#)
- potencies at neurotransmitter receptors, [427t](#)
- side effects of, [426t](#)

ZIPSOR (diclofenac), [986](#), [987](#)

ZK 191703, [1756](#), [1759](#)

ZOCOR (simvastatin), [897](#)

ZOLADEX (goserelin), [1119t](#), [1764t](#), [1765](#), [1840](#)

ZOLICEF (cefazolin), [1496t](#)

Zollinger-Ellison syndrome, [1321](#)

Zolmitriptan, [345](#)–347

- arrhythmias caused by, [832](#)

Zolpidem, [467](#)–468

- pharmacokinetics of, [1900t](#)

ZONALON (diphenhydramine), [1816](#)

Zonisamide, [602](#)

- pharmacokinetics of, [1900t](#)

Zonule(s), [1774](#), [1776](#)–1777, [1776f](#)

Zopiclone, pharmacokinetics of, [1839t](#)

ZOSTRIX (capsaicin), [1830](#)

Zotepine, potencies at neurotransmitter receptors, [427t](#)

ZOVIRAX (acyclovir), [1596t](#), [1818](#)

ZYLOPRIM (allopurinol), [997](#)

ZYMAR (gatifloxacin), [1781t](#)

ZYRTEC (cetirizine), [921t](#), [1816](#)
