cDNA libraries may be screened either by **hybridization** to the cloned inserts or by detection of RNA or protein expression products encoded by the cDNA inserts. Hybridization screening is similar in principle for both genomic and cDNA libraries and uses synthetic oligonucleotide probes or gene probes derived from existing clones. The probes are labeled with radioactivity or a fluorescent tag and then annealed to the total nucleic acids contained within a population of bacterial colonies or viral plaques. Colonies or plaques that contain nucleic acids complementary to the probe can then be detected and purified. Protein expression libraries can be screened based on affinity to antibodies, proteins, nucleic acids, or small-molecule ligands. In addition, functional properties can be screened for, such as catalysis or induction of transcription of a reporter gene.

Useful information regarding tissue-specific patterns of gene expression can be ascertained through screening cDNA libraries. By definition, a cDNA population is derived from the fraction of genes expressed in a given tissue through sampling the mRNA pool. These expressed sequences can be sampled and characterized in brute force fashion by high-throughput random sequencing of cDNA clones isolated from a library. It is not necessary to determine the full-length cDNA sequence in order to derive useful information from this approach. The partial sequences obtained are entered into an Expressed Sequence Tag (EST) database where the frequency of each partial sequence (known as a "tag") can be scored (1). In this manner, it is possible to determine the expression level of individual genes for any tissue. Furthermore, investigators that identify a gene product of interest in the EST database are already one step ahead on their sequencing efforts, because much of the open reading frame may already be in the public database. Finally, it is possible to request many EST clones from the I.M.A.G.E. Consortium (Integrated Molecular Analysis of Genomes and their Expression; `http://www-bio.llnl.gov/bbrp/image/image.html`), providing an easy source of genetic material for subcloning projects.

The concept of ESTs as quantitative indicators of gene expression levels has been further refined through a new method termed Serial Analysis of Gene Expression (SAGE) (2). SAGE provides a means of tagging every mRNA in the cell with a small, intrinsic nine-nucleotide sequence that is essentially unique to each transcript. In addition, SAGE provides a means to eliminate artifacts arising through processing and polymerase chain reaction (PCR) amplification of the original cDNA, thereby rendering the method highly quantitative. Finally, SAGE enables high throughput sequencing of the nine-nucleotide tags on a scale sufficient to quantify several hundred thousand cDNA species for a given tissue (3). Although the sequence information obtained from a single SAGE tag is minimal, it is usually sufficient to identify the transcript via hybridization or database searching methods. SAGE is being conducted on a large scale through the Cancer Genome Anatomy Project (CGAP; (site currently unavailable)), with the goal of rendering in detail the molecular differences between various normal tissues and tumors, in order to understand better the molecular basis of cancer. Ultimately the CGAP database, among others, will provide the capability of performing "virtual" **Northern blots**, in which any sequence segment can be screened through WWW-based databases to ascertain all known sequence, genetic, and biological information associated with mRNAs containing the sequence segment.

Tissue- or cell-specific gene expression can also be studied through specialized cDNA libraries derived from the subset of genes that are differentially expressed between two preparations of mRNA (4). For example, a cell culture line can be treated with a hormone, such as dexamethasone, and RNA can be prepared from samples of the cell culture before and after treatment. cDNAs prepared from the pretreatment population can then be used to remove selectively any complementary mRNAs from the post treatment preparation through a process known as subtractive hybridization. The majority of the mRNA species remaining in the post treatment pool should be those transcripts that were synthesized as a direct result of hormone treatment. These specific mRNAs can then be converted into cDNA and cloned into a suitable library vector, to constitute a differential cDNA library. Screening or sequence tagging a subtractive library greatly increases the efficiency of characterizing tissue-specific or stimulus-specific differences in gene expression.

Cell Adhesion Molecules

Cell adhesion molecules play central roles in embryonic development, tissue organization, and overall maintenance of the structure and form of multicellular organisms (1, 2) They provide the physical links between cells and other cells, and between cells and the extracellular matrix. Adhesion molecules are also involved in dynamic cell interactions, such as during tissue morphogenesis, cell migration, immunological and inflaemmatory responses, and possibly memory formation (1, 3-7). Adhesive proteins are also intimately involved in intracellular signaling processes that regulate cell growth, differentiation, gene regulation, and prograemmed cell death (8-13).

Cell adhesion molecules mediate adhesive interactions by forming specific protein-protein interactions or between proteins and complex carbohydrates. In addition, cell adhesion molecules frequently link directly to multimolecular protein complexes on the cytoplasmic face of the plasma membrane, which, in turn, mediate interactions with the cytoskeleton and signal transduction pathways (3, 9-13). Consequently, these cell adhesion and signaling complexes not only link cells with other cells and the extracellular matrix but also help to integrate extracellular physical information with the major signal transduction pathways within cells (see Integrins). For example, they appear to transduce information from inputs as diverse as transient contacts with other cells, binding of different connective tissue molecules, and tension or torsion at the cell surface. Each of these inputs connects to intracellular signaling pathways, such as phosphorylation cascades (9-12).

1. Types of Adhesion

The physical linkages involved in cell adhesion are provided by adhesion molecules that function as parts of general adhesion systems or in specialized adhesive structures. For example, epithelial cells can adhere to other cells along broad expanses of plasma membrane using general-purpose adhesive molecules such as cadherins (14-16). They can also adhere to each other by specialized adhesive structures, such as adherens junctions, desmosomes, and tight junctions (1). Each type of specialized junctional complex requires specific adhesion molecule components, which can include specialized cadherins and other proteins. Fibroblasts can also form complexes with other cells, but they most characteristically adhere to extracellular matrix. Cell-to-matrix adhesions can be broad and flat, as when epithelial cells adhere via integrins to basement membranes, or they can involve specialized structures that include hemidesmosomes or the focal contacts of fibroblastic and endothelial cells. The protein complexes involved in cell-to-matrix adhesion contain different complements of adhesive, cytoskeletal, and signal transduction molecules than those involved in cell-to-cell adhesion (1, 13, 15). This entry will first provide a general overview of specific types of cell adhesion proteins, then briefly discuss how they are integrated into cytoskeletal and signaling networks.

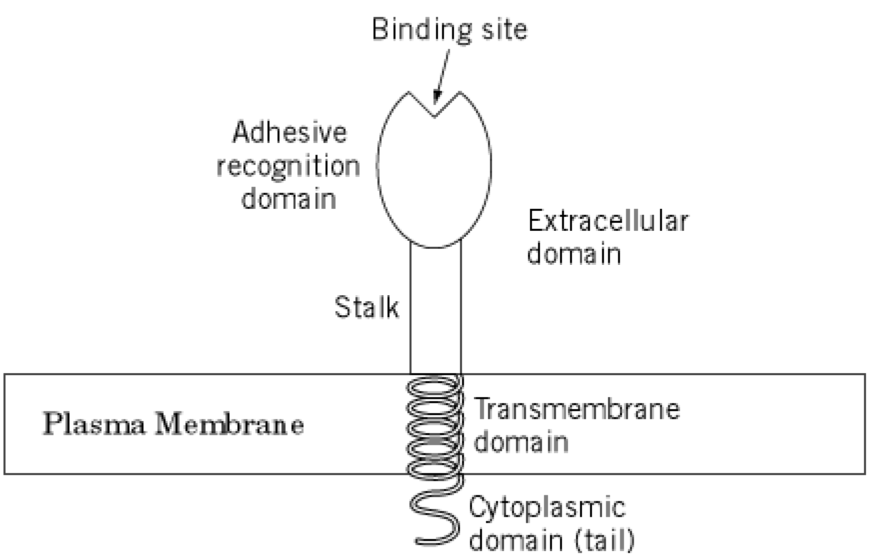
2. General Features of Cell Adhesion Proteins

Cell adhesiveness is generally based on the specific binding of a protein to another molecule at the cell surface. When adhesion results from binding of an adhesion molecule to the same type of protein on a neighboring cell, the interaction is termed '*homophilic*.' The cadherin family is a major mediator of such homophilic interactions (14-16) (see Cadherins). Cadherins form complexes in which both intercellular and lateral binding interactions cooperate to create tightly packed adhesion complexes that mediate adhesion with high avidity.

In many systems, however, adhesiveness involves binding of a receptor to a specific ligand. In cell-to-cell adhesion, the target protein of an adhesion receptor can be a "counter-receptor" or a complex carbohydrate on a protein anchor in the plasma membrane. In cell-to-matrix interactions, a plasma membrane adhesion protein such as an integrin can bind to an extracellular matrix protein that is itself considered to be an adhesive protein. For example, the protein bound could be a fibronectin or a laminin, which are complex, multifunctional proteins involved in both cell adhesion and anchorage to structural components of the extracellular matrix (2, 15, 17).

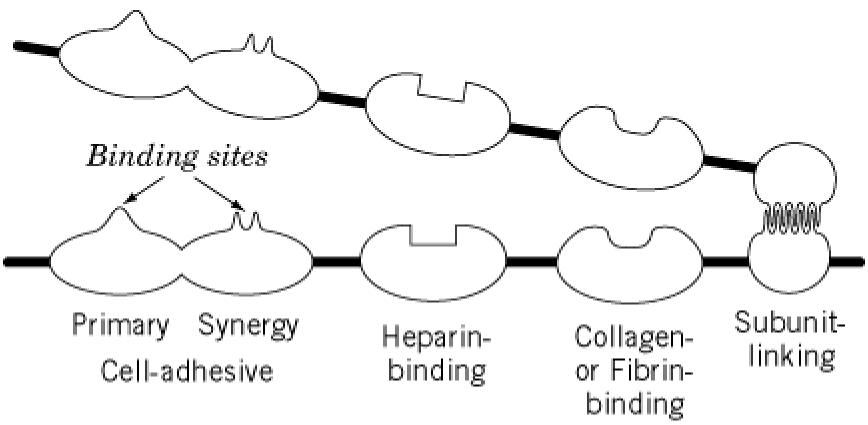
Consequently, there are two broad classes of adhesion molecules or receptors (Fig. 1). One class is bound to the plasma membrane, often as a transmembrane protein (Fig. 1). This type of molecule is generally a receptor, a homophilic adhesion molecule, or a counterreceptor. It often consists of an extracellular domain containing one or more cell-interaction domains or sites, as well as a stalk region, a hydrophobic transmembrane domain, and (usually) a cytoplasmic domain or tail. This type of molecule is often also involved in transmembrane transmission of signals.

Figure 1. Schematic diagram of a generalized transmembrane adhesion molecule consisting of an extracellular domain, transmembrane segment, and cytoplasmic domain. See text for discussion.



The second broad class of adhesion molecules consists of proteins that are often classified as cell surface or extracellular matrix proteins (see Extracellular Matrix), but that contain domains or sites involved in cellular adhesion (Fig. 2). Molecules in this class include fibronectins, laminins, vitronectin, tenascins, thrombospondins, and the collagens. All contain one or more cell-binding domains, which consist of a primary recognition motif consisting of a short peptide sequence (eg, Arg—Gly—Asp), and sometimes a synergy site that provides a substantial increase in receptor-binding specificity and affinity. As discussed below, many of these proteins also contain a variety of other functional domains.

Figure 2. Schematic suemmary of common features of extracellular matrix adhesion molecules. Linear arrays of structural and functional domains provide a series of specific binding sites. See text for further discussion.



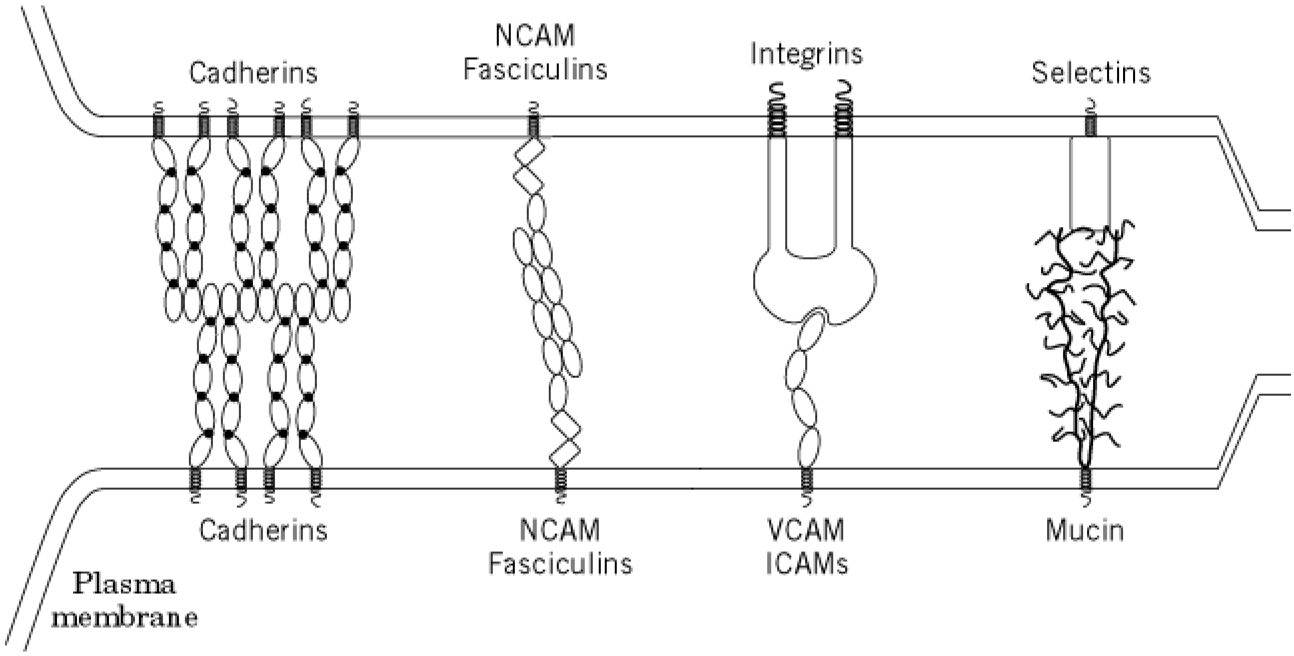
In general, adhesion molecules frequently have the following properties (1-3, 6, 14-16, 18-25):

- Composed of multiple repeats of protein motifs, such as the immunoglobulin (Ig) motif, the epidermal growth factor (EGF) repeat, or the fibronectin motif.
- Specialized functional domains, including a domain for formation of dimers or higher polymers.
- Moderate affinity, for example, with dissociation constants (K_d) in the range of 10^{-6}–$10^{-7}M$ for fibronectin, and even as weak as $10^{-4}M$ for leukocyte adhesion molecules that mediate rolling adhesion. In contrast, many well-known protein—protein interactions have affinities with $K_d = 10^{-9}$–10^{-11} M.
- High avidity after clustering. Adhesion molecules often form functional clusters or aggregates in the plane of the plasma membrane, which causes them to develop strong total avidity due to the cooperation of the otherwise weak binding of individual molecules.
- Regulation by activation, such as the "inside-out" signaling that increases the affinity of integrins in platelet activation and leukocyte adhesion, or regulation by phosphorylation of the cadherin system.

3. Specific Cell Adhesion Molecules

The broad class of adhesion molecules embedded in the plasma membrane contains several large groups of proteins that share common structural motifs, especially the Ig motif (Fig. 3). Cadherins represent a large superfamily of proteins involved in homophilic cell-to-cell adhesive interactions (14-16) (see Cadherins). Cadherins bind to cadherins of the same type on other cells via cell interaction sites that can include the recognition sequence His—Ala—Val. Besides the "classic" cadherins, such as E-cadherin and N-cadherin, there are a number of other types of cadherins, as the highly specialized cadherins termed *desmocollins* and *desmogleins* found exclusively on desmosomes, which link cells together at these particularly strong attachment sites connected to intermediate filaments such as keratins or vimentin. Cadherins are quite sensitive to depletion of calcium in the surrounding medium, accounting for the ability of calcium chelators such as EDTA to dissociate tissues into component cells. Although desmosomal cadherins are present in epithelia of all ages, cadherins appear to be of particular importance during embryonic development, when they mediate cell—cell adhesion and help define tissues by their propensity to bind primarily to cadherins of the same type, rather than to other cadherins on unrelated cell types (14-16). These specific adhesive interactions result in cell sorting to form tissue regions of closely related cells.

Figure 3. Examples of cell adhesion protein complexes linking plasma membranes of one cell (top) with another (botton are listed. Adhesion molecules comprising repeating immunoglobulin motifs include cadherins, NCAM, fasciculins, VC the plasma membrane. Cadherins appear to exist as dimers that form lateral and intercellular connections. Selectins bind carbohydrates in certain mucins. CD2, CD48, and CD58 contain only two Ig repeats. Myelin protein zero (P_0) forms hon spaced plasma membranes.



Integrins are major cell-surface receptors for a host of extracellular matrix proteins, as well as “counterreceptors” on other cells (8) (see Integrins). There are more than 20 types of integrin subunits. Genetic absence of most integrin subunits leads to disease or death, often in the embryo or near the time of birth. Integrins are heterodimers of one a and one b subunit, each of which provides adhesive specificity. They have a highly distinctive appearance, with a bulbous head domain contributed by each subunit, a binding site that also appears to involve part of each subunit, and two spindly legs (Fig. 3). The legs penetrate through the plasma membrane and usually terminate in rather short cytoplasmic domains. Although short, these cytoplasmic tails can mediate a remarkable range of signaling events (see text below). Integrin functions are also often inhibited by depletion of divalent cations.

Although cell adhesion molecules (CAMs) and counterreceptors are structurally related by their use of the Ig motif, and they often even share the -CAM designation, they can differ functionally (Fig. 3). Molecules such as NCAM are homophilic adhesive molecules that bind to the same type of molecule on adhering cell surfaces (22). In contrast, counterreceptors such as the ICAMs and VCAM have specialized peptide recognition sites that are bound specifically by integrins such as LFA-1 (CD11a/CD18 or a_1b_2) or VLA-4 (a_4b_1). The functions and sites of expression of these molecules differ widely. For example, molecules such as NCAM are implicated along with cadherins in embryonic developmental events, such as axonal bundling and guidance, whereas the ICAM counterreceptors are present as targets for binding by cells in the blood circulation. Levels of counterreceptors on the cell surface can often also be regulated rapidly in response to cytokines.

A new family of transmembrane proteins termed *ADAMs*, which are membrane proteins with a disintegrin and a metalloproteinase domain (26), contain a proteinase-like domain, as well as an integrin recognition site in the disintegrin domain. A member of this family is present on sperm and may play a role in adhesive interactions, but the functions of other members of this rapidly growing family remain to be characterized. Syndecans are cell-surface heparan sulfate proteoglycans, with a protein core that crosses the plasma membrane and terminates in a cytoplasmic tail. Syndecans appear to function as "coreceptors," mediating signaling in association with a primary adhesion molecule (27, 28). For example, syndecans bind to fibronectin at the same time that cell surface integrins bind to a cell-binding domain of fibronectin, and these binding partners cooperate during formation of the specialized adhesion sites known as focal contacts. Syndecans have several other signaling functions as well, and they can to interact with both cytoskeletal proteins and protein kinase C (27, 28).

4. Extracellular Adhesion Molecules

The second major class of adhesive molecules exists extracellularly, and its members are generally targets for cell-surface adhesion receptors such as the integrins. A gallery of such molecules is presented in Figure 4, showing functional binding sites for recognition by cell-surface receptors and domains for binding to a variety of ligands. Many contain one or more heparin-binding domains, which are used to bind to heparan sulfate proteoglycans in the extracellular matrix or in cell-surface syndecan molecules. Many also contain other types of binding domains for extracellular molecules, such as for collagen/gelatin, fibrin, entactin (nidogen), and fibulin (Figs. 2 and 4). Many of these molecules are both large and multimeric, with a specific domain for covalent cross-linking to other subunits. Finally, most of these proteins are either alternatively spliced or encoded by a set of closely related genes, thereby generating a number of isoforms. A number of reviews provide details about these complex proteins (see Extracellular Matrix and Refs. 2, 18-22).

Figure 4. Composite of six examples of cell adhesion molecules of the extracellular matrix: (**a**) Fibronectin, (**b**) Laminir Vitronectin, (**d**) Thrombospondin, (**e**) Tenascin, (**f**) Nidogen (entactin). These molecules vary widely in size and shape, a organized into functional binding domains. Specific molecular or cell-binding sites are labeled.

5. Peptide Adhesive Recognition Sites

A striking characteristic of a number of cell adhesion molecules is their frequent use of short peptide recognition sites (Refs. 18, 23-25, 29-31 and references cited therein). Short peptides with these sequences can at least partially mimic the binding function of intact molecules to adhesion receptors. Examples include Arg–Gly–Asp (RGD) and Leu–Asp–Val (LDV), which can bind directly to certain integrin receptors. Nevertheless, binding can be 25- to 200-fold more active in larger peptides or proteins, such as in association with a "synergy" site that functions synergistically with the primary adhesive peptide site (30). Some peptide recognition sites appear to be "cryptic" in the intact molecule, and may be active only in small fragments of the protein, such as after proteolysis. Table 1 lists the putative peptide recognition sequences in cell adhesion molecules. It is important to stress that a number of adhesion molecules also function by adhering to other proteins over much broader intermolecular contact areas, via multiple molecular contacts and with no simple peptide motif, in analogy to classic high affinity noncovalent protein–protein interactions (19). It is nevertheless striking that so many cell adhesion molecules use simple, specific, peptide adhesive-recognition motifs.

Table 1. Adhesive Recognition Sequences

Protein and Peptide Name	Recognition Sequence
Fibronectin	
Cell-binding determinant	G*RGD*S
Synergy site	PHS*R*N
Potential synergistic sites	RNS, SDV
CS1 site of IIICS domain	DELPQLPHPNLHGPEI*LDV*PS
CS5 site of IIICS domain	*REDV*
FN-C/H-I	YEKPGSPPREVVPRPRPGV
FN-C/H-II	KNNQKSEPLIGRKKT
FN-C/H-III	YRYRYTPKEKTGPMKE
FN-C/H-IV	SPPRRARVT
FN-C/H-V	WQPPRARI
Type III5 site	KLDAPT
E1	TD*IDAP*S
Laminin a_1 chain	
PA22.2 (IKVAV)	SRARKNAAS*IKVAV*SADR
RGD site	RGDN
GD-1	KATPMLKMRTSFHGCIK
GD-2	KEGYKVRLDLNITLEFRTTSK
GD-3	KNLEISRSTFDLLRNSYGVRK
GD-4	DGKWHTVKTEYIKRKAF

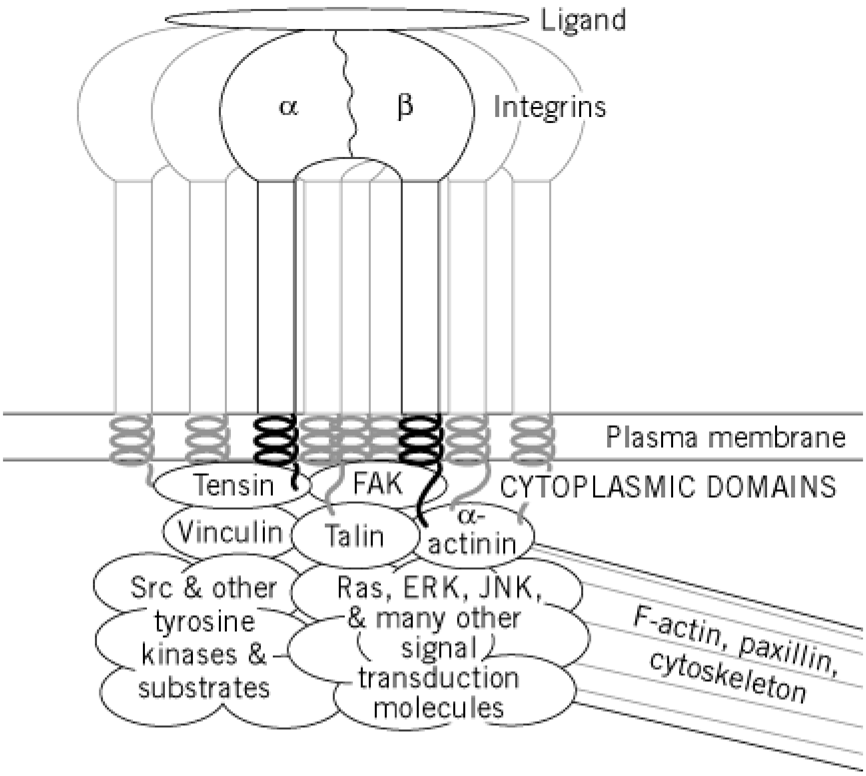
ICAM-2	GKSFTIECRVPTVEP
NCAM	KYSFNYDGSE
VCAM-1	
Domain 1 C-D loop	Q*IDS*P (cyclic peptide with terminal Cs)
(binding motifs)	IDSP, GNEH, KLEK
N-Cadherin	LRA*HAV*DVNG
Myelin protein 0 (P_0)	YSDNGTF
Ninjurin	PPRWGLRNRPIN
Leishmania pg63	¼*SRYD*¼
Streptavidin	*GRYDS*[a]

[a] See Refs. 14, 16, and 22 for additional information.

Two key sites of membrane adhesion molecules that allow them to function as signal transduction receptors are their ligand-binding domains and their cytoplasmic domains. The ligand-binding domains are of obvious importance in binding to extracellular molecules, but their roles are more intriguing in at least some cases. There appear to be separable functions for ligand occupancy, specifically, for filling the binding site with a ligand or an antibody, as opposed to receptor clustering (which can be induced by a multivalent ligand, such as fibrils of fibronectin or collagen). These two inputs can cooperate in promoting accumulation of specific cytoskeletal proteins, such as a-actinin and actin, which are thought to be crucial for forming strong adhesions (32). Even though they lack intrinsic enzymatic activities, integrins appear to be able to function as signaling receptors and as regulators of actin cytoskeletal organization by recruiting other molecules to their cytoplasmic domains. Integrins can reportedly bind directly to certain cytoplasmic proteins directly, such as to talin, a-actinin, and focal adhesion kinase, perhaps regulated by ligand occupancy on the outside of the cell. Integrin clustering appears to play a central role in forming large intracytoplasmic complexes of over 30 molecules that can serve as signaling centers, such as for MAP kinase activation (Fig. 5; Refs. 9-13, 32).

Figure 5. Integrin adhesion and signaling complex formed after cell adhesion molecule interactions. Binding of a ligand and aggregation of adhesion receptors in the plane of the plasma membrane results in the formation of multimolecular complexes that can contain over 30 cytoskeletal and signal transduction molecules, which link to the actin-containing cytoskeleton and mediate intracellular signaling.



6. Major Functions of Cell Adhesion Molecules Beyond Adhesiveness

Cell adhesion molecules and receptors can be intuitively understood as mechanisms for attaching cells to other cells, for permitting cell adherence to extracellular matrix molecules, and for mediating traction during cell migration. It has become clear, however, that they also play critical roles in cellular signaling. In fact, their signaling functions may be of equal biological importance. A current view is that “adhesion” proteins are actually “cell-interaction” proteins that have multiple functions involving the bidirectional transfer of information at the cell surface. In fact, some of these proteins, such as thrombospondin and tenascin, can have antiadhesive activities in certain situations and can modulate a host of cellular functions. Even classic “adhesive” proteins, such as fibronectin, can have a bewildering range of activities, mediated by integrin binding, that range from activating or modulating nearly every known maemmalian signal transduction pathway. These pathways include tyrosine phosphorylation by tyrosine kinases, mitogen-activated protein kinases (MAP kinases), Ca^{2+} and H^{+} fluxes, inositol phosphate pathways, and protein kinase C, which prevent apoptosis and activate specific gene transcription (9-12).

This same theme of complex formation, binding of cytoskeletal proteins such as actin, and accumulation of signaling molecules also appears to occur for cell-to-cell adhesion molecules (14-16, 22). Cadherin cytoplasmic domains interact with catenins, which then link to the actin cytoskeleton. In addition, however, the binding of b-catenin to cadherins can titrate its cytoplasmic levels; b-catenin molecules that are not bound by cadherins can enter the nucleus and regulate gene expression (3). A variety of other signaling pathways exist in cell-cell and cell-matrix adhesion systems. Although much more remains to be learned about precise pathways and overall integration of the many cytoplasmic effects of cell adhesion molecules, it is clear that adhesion molecules are crucial components of the basic regulatory mechanisms of cells and provide dynamic links to the external environment.

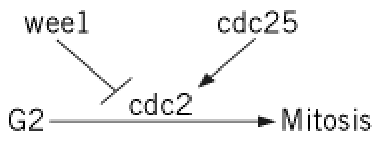
Cell Cycle

A dramatic change in how we understand the progression of the eukaryotic cell cycle, from phenomenological to biochemical, occurred in the late 1980s. The cell cycle consists of four main phases: G1, S, G2, and M. DNA replication occurs in S phase, and the chromosomes are segregated to daughter cells during mitosis (M phase). The so-called gap phases (G1 and G2) are defined simply as the periods separating DNA replication and mitosis. The length of the cell cycle ranges from just a few minutes in certain early embryos (which don't need to increase their mass between divisions), to 1.5 h in budding yeast, to approximately one day in typical mammalian tissue culture cells. In mammalian cells, the durations of S phase (~7 h) and mitosis (~1 h) are relatively inflexible, whereas the lengths of the gap phases can vary greatly. The length of G1 is particularly variable and is sensitive to the levels of nutrients and growth factors. In general, once a cell progresses past the “Restriction Point” in G1, it becomes committed to complete the cell cycle. A convergence of research in yeast, marine invertebrates, and frogs led to a phenomenal growth in our mechanistic understanding of how all eukaryotic cells regulate these events and the transitions between them. The basic machinery controlling the cell cycle consists of a subfamily of protein kinases, termed cyclin-dependent kinases (Cdk's). These enzymes are in turn regulated by a number of mechanisms, including transcription, inhibitory and activating **phosphorylations**, binding to inhibitory proteins, and **ubiquitin**-mediated protein degradation. Checkpoints that prevent the execution of one cellular event before a prior step has been completed further modulate cell cycle progression.

1. Historical Threads: Yeast Genetics, MPF, and Cyclins

Genetic studies of the cell cycle in the yeasts *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe* illuminated important principles underlying the logic of cell cycle control and identified many of its key players. Screens were performed for conditional temperature-sensitive mutations, causing cells to arrest quickly with uniform morphologies, indicative of defects in executing individual cell cycle steps. Analysis of a large collection of such *cdc* (cell division cycle) mutants from *S. cerevisiae* placed them into series of dependent and independent pathways (1). For example, inactivation of *CDC28* causes cells to arrest at “START” (equivalent to the restriction point of mammalian cells) and blocks pathways leading to formation of the bud, DNA replication, and duplication of the spindle pole body. Inactivation of genes acting after *CDC28* can block one of these pathways, while the other two continue. A similar screen in the distantly related yeast *Schizosaccharomyces pombe* successfully identified the most proximal regulators of the G2 to mitosis transition (Fig. 1) (2). *cdc*2^+ was found to be the key regulator of entry into mitosis and to encode a protein kinase. Inactivation of *cdc*2^+ causes cells to arrest in G2, whereas its premature activation leads to early entry into mitosis. Genetic analysis indicated that the *cdc*25$^+$ gene product functioned in a pathway leading to activation of Cdc2 and that the product of *wee*1$^+$ functioned in a pathway leading to inhibition of Cdc2. Sequence analysis of these genes indicated that both *cdc*2$^+$ and *wee*1$^+$ encoded protein kinases, but initially shed little light on the function of Cdc25 (see text below).

Figure 1. Regulation of the G2-to-mitosis transition in *Schizosaccharomyces pombe*. *cdc*2$^+$ is required for this transition. In the absence of its activity, cells arrest in G2. *cdc*25$^+$ is a positive regulator of *cdc*2$^+$, and its inactivation also gives a G2 arrest. In contrast, wee1$^+$ negatively regulates *cdc*2$^+$, and its inactivation leads to premature activation of Cdc2 and entry of cells into mitosis at an unusually small size (a "wee" phenotype).



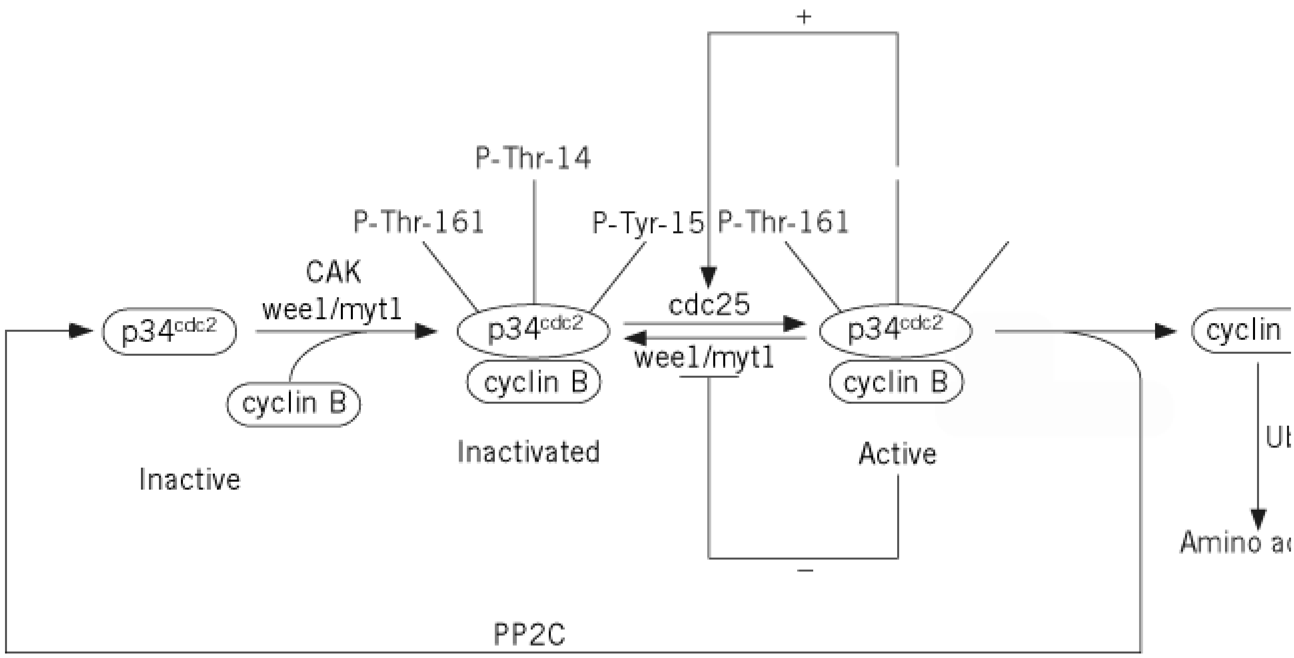
Two other lines of research provide essential historical threads leading to our current understanding of the cell cycle. The first involves maturation promoting factor (MPF), which was originally defined as a developmental factor found in the cytoplasm of metaphase-arrested frog eggs that could induce oocytes to proceed through meiosis and to "mature" into eggs following its injection into their cytoplasm (3). Subsequent research found that MPF activity is present in all eukaryotic cells during M phases (meiosis or mitosis). Thus, MPF is a universal regulator of entry into mitosis. The second thread concerns the cyclins. The first cyclins were found during studies of translational control before and after fertilization of sea urchin eggs conducted as part of the Physiology course at the Marine Biological Laboratory in Woods Hole (4). These proteins were synthesized continuously, and they accumulated until their abrupt degradation during mitosis. This pattern of accumulation hinted that cyclins might play an important role during the cell cycle. Later work showed that the injection of cyclin messenger RNA led to the maturation of frog oocytes, suggesting that cyclins, like MPF, functioned as positive regulators of the G2-to-mitosis transition (5).

Work on cyclins, MPF, and the yeast *cdc* genes came to an explosive convergence in the late 1980s with the purification of MPF and the identification of its subunits as homologs of *cdc*2$^+$ and cyclin (6-9). Thus, this key regulator of entry into mitosis was a protein kinase (Cdc2) whose activity was controlled at least in part via the cyclic accumulation and degradation of a regulatory subunit (cyclin). The activity of Cdc2 is typically assayed by its ability to **phosphorylate** a convenient substrate, histone H1. Cdc2 is a workhorse master regulator. Rather than sitting at the apex of a large regulatory pathway, Cdc2 generally phosphorylates the downstream-most targets of mitotic regulation. For example, its direct phosphorylation of nuclear lamins causes the disassembly of the lamin-containing filaments of the nuclear lamina (10, 11).

2. Regulation of Cdc2 Activity: Phosphorylation and Cyclin Degradation

In addition to cyclin binding, enzymes such as Cdc2 are regulated by multiple phosphorylations (12, 13) (see Fig. 2). Cdc2 is negatively regulated via phosphorylation of Thr14 and Tyr15. (The amino acid positions in this section refer to the phosphorylation sites in human Cdc2.) These sites are phosphorylated by Wee1 (the negative regulator of Cdc2 identified genetically in *Schizosaccharomyces pombe* (see Fig. 1)) and by Wee1-like protein kinases (Mik1 in *Schizosaccharomyces pombe* and the membrane-bound Myt1 protein in vertebrates). Dephosphorylation of these inhibitory sites is carried out by Cdc25 proteins, genetically identified activators of Cdc2 that share distant similarity to protein **tyrosine phosphatases**. Finally, activating phosphorylation of Cdc2 occurs on Thr161 within the so-called T-loop and is carried out by the Cdk-activating kinase (CAK). Dephosphorylation of Thr161 has not been as well studied. It occurs following cyclin degradation, possibly by a phosphatase termed KAP. Two feedback loops operate as cells enter mitosis and lead to the inhibition of Wee1-like enzymes and the stimulation of Cdc25, thus ensuring the abrupt and irreversible transition from G2 to mitosis. The roles of cyclin binding and activating phosphorylation have been studied using X-ray crystallography of Cdk2 (14-16), a close relative of Cdc2. Monomeric Cdk2 is inactive for two major reasons. First, residues that interact with the phosphates of ATP are out of position, resulting in the misalignment of the g-phosphate of ATP for phosphoryl transfer. Second, the T-loop is positioned so that it would physically prevent protein substrates from gaining access to the site of catalysis. Binding to cyclin relieves this steric block and moves residues that interact with ATP into their proper positions. The cyclin A-Cdk2 complex is about 1% active. Full activation requires activating phosphorylation (on Thr160 in Cdk2), which alters the positions of some T-loop residues and creates an acidic patch for the binding of optimal substrates containing a key basic residue.

Figure 2. Activation of Cdc2. Monomeric Cdc2 is unphosphorylated and inactive. Binding to cyclin induces its phosphorylation on inhibitory sites (Thr14 and Tyr15) by Wee1-like protein kinases and its phosphorylation on an activa site (Thr161) by CAK. The transition into mitosis is accompanied by two feedback loops involving stimulation of Cdc25 (the phosphatase acting on Thr14 and Tyr15) and inhibition of Wee1-like enzymes, resulting in the abrupt and irreversib activation of Cdc2 and entry into mitosis. The degradation of cyclin by the ubiquitin system toward the end of mitosis le to the inactivation of Cdc2 and its dephosphorylation, probably by a phosphatase called KAP.



One of the irreversible ratchet steps in the cell cycle is the degradation of cyclins by the ubiquitin system (17). Ubiquitin is a 76-residue protein whose covalent attachment to proteins can target them for **proteolysis** by the proteasome, a huge multiproteinase unwinding and degrading machine. Ubiquitin is activated by its ATP-dependent covalent attachment to an enzyme called E1. E1 then transfers ubiquitin to one of many E2 enzymes. The E2s can ubiquitinate substrates, often with the help of an E3. The E3s may be the most diverse and interesting components of this system. Some E3s receive the covalently bound ubiquitin; others serve as matchmakers that bring together a substrate and the appropriate E2. For the mitotic cyclins, the E3 was first termed the cyclosome, though it is now generally termed the *anaphase promoting complex* (APC), an 8- to 12-subunit complex. The APC is the regulated component of the ubiquitin system for the degradation of the mitotic cyclins and serves as the target for checkpoint signals (see below) that can block cyclin degradation. The ubiquitin-dependent degradation of cyclins that act earlier in the cell cycle generally does not require the APC and has been best studied in *S. cerevisiae*.

3. Relatives: Cdks and Cyclins

Both Cdc2 and the mitotic cyclins are members of large families of related proteins, many of which function in cell cycle regulation. The Cdc2 relatives are termed Cdks (for cyclin-dependent kinases) and the cyclin relatives are designated by letter. The different cyclins accumulate at various times during the cell cycle and pair with a limited subset of the Cdks to execute their respective functions. The major cyclin–Cdk complexes and their functions are shown in Table 1. Complexes of D-type cyclins with Cdk4 and Cdk6 function in progression through G1 and are the first kinases to phosphorylate the cell-cycle inhibitor retinoblastoma protein (Rb). The cyclin E–Cdk2 complex stimulates the initiation of DNA synthesis, and the cyclin A–Cdk2 complex is generally thought to promote passage through S phase. Cyclin B partners with Cdc2 to promote the G2-to-mitosis transition. All of these complexes are regulated by phosphorylations on sites equivalent to those used in Cdc2. In addition to these enzymes, a large number of cyclin–Cdk complexes function in processes other than cell cycle regulation, including transcription and neuronal differentiation. In general, the regulatory subunits of these Cdks are stable proteins and are classified as cyclins only on the basis of sequence similarity.

Table 1. Functions of Cyclin–Cdk Complexes Involved in Cell Cycle Control

Catalytic Subunit	Major Cyclin Partner	Function
Cdc2	Cyclin B	G2 to M
Cdk2	Cyclin A	S
Cdk2	Cyclin E	G1 to S
Cdk4	Cyclin D	G1
Cdk6	Cyclin D	G1

4. Cdk Inhibitors

In addition to cyclin binding and phosphorylation, Cdks are also regulated by the binding of inhibitory proteins (18). These can be divided into two classes: the CIP/KIP family (consisting of $p21^{CIP1}$, $p27^{KIP1}$, and $p27^{KIP2}$) and the INK4 family (consisting of $p15^{INK4b}$, $p16^{INK4a}$, $p18^{INK4c}$, and $p19^{INK4d}$). The CIP/KIP proteins bind preferentially to the cyclin–Cdk complex and cause its inactivation. These proteins bind to numerous Cdks, but show a preference for Cdk2. In contrast, the INK4 proteins bind preferentially to monomeric Cdks (inhibiting the binding of cyclin) and are specific for Cdk4 and Cdk6. Cdk inhibitors play very important roles both in cell cycle progression (particularly in responses to growth factors) and during development. One of the best-studied roles for a Cdk inhibitor involves the regulation of the initiation of DNA synthesis in *S. cerevisiae* by Sic1p. Entry into S phase in *S. cerevisiae* requires the activity of complexes containing an S-phase cyclin (Clb5p or Clb6p) and the budding yeast Cdk, Cdc28p. These complexes are inhibited by Sic1p. Degradation of Sic1p by the ubiquitin system is triggered following the phosphorylation of Sic1p by Cdc28p bound to G1 cyclins, thereby freeing the Clb5p and Clb6p complexes to initiation DNA replication (19).

5. Checkpoints

Among the key mechanisms for ensuring the orderly progression of cell cycle events are checkpoints, which monitor the completion of certain events and prevent the execution of subsequent events if the monitored event has not been completed (20, 21). For example, checkpoints can block entry into mitosis if the DNA is damaged or has not been fully replicated, or they can block exit from mitosis if the spindle has not been properly assembled. In *S. cerevisiae* a checkpoint even monitors whether a bud has formed. One of the defining features of a checkpoint sensor is that it is not part of the machinery being sensed and that it is dispensable, though only for the short term. The checkpoint that provides the paradigm for all others involves the sensing of **DNA damage** and unreplicated DNA by Rad9p in *S. cerevisiae*. A number of yeast *cdc* mutants cause G2 arrests that are dependent on this checkpoint. For example, inactivation of *CDC9*, which encodes DNA Ligase, leads to G2 arrest if *RAD9* is functional. In contrast, inactivation of *CDC9* in a *rad9* mutant does not lead to an immediate arrest. Instead, cells progress into mitosis and continue through a couple of cell cycles, until they arrest as microcolonies. The G2-arrested *RAD9* cells remain viable while they attempt to repair their DNA, whereas the *rad9* cells rapidly lose viability as they proceed through the checkpoint. Unperturbed wild-type cells grow normally in the absence of this checkpoint. The importance of checkpoints to a proper cell cycle and to human health is underscored by the p53 protein. p53 is the most frequently mutated protein in human cancers and functions as part of a checkpoint responding to DNA damage by transcriptionally inducing the p21 Cdk inhibitor (22), thereby blocking cell cycle progression. The absence of this checkpoint leads to genomic instability (the accumulation of further mutations, loss of chromosomes, etc.) and a greatly increased risk of tumor formation.

Cell Death

It is not initially obvious why cell death should be considered important. The death of single-celled organisms, such as **amoeba** or **bacteria**, has no apparent advantage for the individual cell. However, in multicellular organisms damage to an individual cell can have repercussions for the whole animal. It therefore makes biological sense to dispose of this cell and replace it with a healthy one. Cells become damaged in a variety of different ways, but for long-lived, multicellular animals, the greatest risk is from a damaged cell that has acquired an **oncogenic** mutation leading to unrestricted clonal growth. To minimize this risk, several pathways have evolved that limit the expansion of somatic cells, one of which is cell death.

Tissue size is restricted by several different methods, not all of which actually require the physical loss of the cell. The problem facing multicellular organisms is how to maintain the capacity to divide and replace damaged cells while minimizing the risk of mutation leading to enhanced growth potential. One way around this problem is to make tissues post-replicative, as occurs in the central nervous system (CNS). All the neurons within the CNS are produced during embryogenesis and are then maintained throughout the life span of the organism. For some tissues, however, such an approach is not practical due to persistent physical damage to the cells, such as occurs in the epithelial lining of the gut or skin. Here, cells are continuously produced by a select number of proliferating stem cells. The daughter cells they produce move upward, away from the basement membrane, terminally differentiate, and are eventually shed. Because these cells are continuously replaced, any damaged cell should be automatically eliminated. Tissue size is also restricted by the need for vascularization. If there is no blood supply, only a small proportion of cells can be maintained by the diffusion of solutes, which is one of the reasons why many solid tumors have central necrotic zones.

For tissues that require a significant number of cells in cycle, the risk of mutation is minimized by both senescence and cell death. Senescence is a pathway that is invoked once cells have undergone a specific number of doublings, causing them to arrest permanently. Cells in this senescent state are unable to reenter the cell cycle (1). Thus, a cell that does acquire a mutation allowing constant proliferation is limited in its capacity to divide, restricting clonal outgrowth [see Senescence]. Finally, cells can be triggered to die when no longer required, or when damaged. This "programmed cell death" is essential for the maintenance of tissue homeostasis and is invoked in disparate situations including DNA damage, absence of survival signals, and oncogene activation (2, 3) [see Programmed Cell Death and Apoptosis]. Thus, multicellular organisms are protected against somatic mutation by a number of independent mechanisms that act in concert to limit the potential for neoplastic transformation.

1. The Meaning of Cell Death

The concept that cell death is fundamentally important for restricting cell population expansion took some time to be accepted for several reasons. Dead cells are not obvious in healthy tissues, whereas they are abundant in areas of damaged tissue, such as ischemic heart tissue resulting from myocardial infarction, allowing dead cells to be fundamentally associated with disease. Only during embryogenesis are dying cells seen in abundance, but these were generally regarded as cells deleted as a result of overproduction during development. In addition, death is seen as a bad outcome in human terms, a misconception that has allowed human anthropomorphic confusions to outweigh scientific evidence. More recently, however, several of these objections have been overruled, allowing cell death to become an accepted, essential daily process.

Early investigators of both invertebrate and vertebrate development observed that developmental cell deaths occurred in response to several biological cues and could be suppressed by inhibitors of both protein and RNA synthesis (4, 5), suggesting a requirement for macromolecular synthesis (6, 7). Moreover, they made the important connection that these cell deaths were an essential part of the developmental program of the organism concerned; hence the term "programmed cell death" (PCD) (8). It is now possible in less complex invertebrate models, such as the nematode *Caenorhabditis elegans*, to map both the fate of all individual cells within the developing organism and the genes that dictate these fates (9) [see Programmed Cell Death].

For vertebrates, the importance of cell death was not appreciated until the detailed characterization of the form of cell death termed apoptosis (10). The programmed cell deaths observed during development are identical to apoptotic cells in mammalian tissues, suggesting that a regulated form of cell death has been conserved throughout evolution (11, 12). From these early observations, our understanding of apoptosis/PCD has grown to include a complex pathway that is both morphologically and biochemically distinct from classical necrosis or accidental cell death. Necrosis is a passive event, in which cells that become irreversibly damaged, and therefore useless, die (13, 14). This form of cell death, which requires no input from the dying cell, occurs in cells subject to physical disruption or severe toxic stress. Conversely, apoptosis/PCD describes a pathway of events in which the cell is actively involved. Due to the active nature of apoptosis, which is triggered by many physiological and toxic stimuli, this form of cell death is sometimes referred to as "cell suicide." Overall, the importance of "active" cell death is underlined by the fact that death is the default state for all cells. Hence, all cells are programmed to die, unless signaled to survive (15).

The importance of cell death in the regulation of tissue homeostasis is paramount. The number of proliferating cells determines the cell population number, as does the number of differentiating cells and the number of dying cells. Research over the last 20 years has graphically shown how cells that have mutations which disrupt their capacity to undergo apoptosis in response to physiological stimuli are involved in the etiology of several diseases, including Alzheimer's, AIDS, and cancer (16).

Aside from the three pathways of death described above, the "death" of a cell does not always result in the loss of viability or cellular function. Within a cell population, few cells are actually proliferating, many are in a resting state outside of the cell cycle, known as **GM_0** phase. Certain cells can reenter the cell cycle given the appropriate stimuli, but cells that enter a permanent G_0 state do not respond to these proliferation signals. Cells in the latter state are termed senescent and can complete all normal functions except division (1) [see Senescence]. Cells that escape the confines of senescence are able to proliferate continuously and, more important, the mutations that lead to the evasion of senescence are common and perhaps mandatory in tumor cells (17).

Thus, the description “cell death” encapsulates several diverse processes. This can involve the physical loss of the cells through apoptosis/PCD or, in some circumstances, necrosis. Alternatively, cell death can refer to a genetic death, where cells no longer retain the ability to replicate, but continue to survive. Which method of cell death is induced depends on several factors, including the cell's internal environment, its external environment, and its developmental history. It is not yet clear whether the genes that regulate apoptosis/PCD and senescence overlap. For example, genes such as p53 and **retinoblastoma** appear to be required for the regulation of apoptosis and senescence, but it is not clear whether these genes perform similar or different roles in each pathway. Indeed, cells that have evaded the first signal to senesce enter *crisis*, which is defined as the point at which the culture exhibits both apoptosis and proliferation. This suggests that there must be some overlap in the control of different types of cell death, and this may enable one type of cell death to be employed when another either is not suitable or is not able to be induced.

Cell Fusion, Cell Hybrids

Fusions of both the external and intracellular membranes of cells are important for differentiation and development. Moreover, enveloped **viruses** infect cells via fusion of their envelopes with cell or endosome membranes.

Cell fusion is the process of fusion of the membranes of two or more cells and results in the formation of cells with multiple **nuclei**. It occurs at various stages of the natural development of organisms, such as in the first step of fertilization of an **oocyte** with sperm and in myotube formation by fusion of myoblasts during differentiation of skeletal muscles. Artificial cell fusion can be induced by the addition of a high concentration of Sendai virus, an enveloped virus of the paramyxovirus group, as was demonstrated in 1957–63 (1-3). This finding coincided with cell biology's beginning focus on the culture of **somatic cells** of birds and mammals. In 1961, Barski et al. (4) reported the appearance of hybrid cells after a few months of mixed culture of two different mouse cancer cell lines. These hybrid cells had a single nucleus containing chromosomes from both parent cell lines, and their appearance was considered to be due to the spontaneous fusion of cells of the two cell lines.

Sendai virus proved to be an important development in this field because it has some useful characteristics for the fusion of somatic cells:

1. Its targets are sialoglycoproteins and sialolipids, which are present in the cell membranes of almost all mammalian and fowl cells. Consequently, it can induce the fusion of a wide range of cells (3).
2. Its cell fusion activity is not affected by procedures that inactivate the viral genome, such as exposure to ultraviolet (UV) light. Thus, fused cells could be prepared under conditions inhibiting virus growth, using a UV-inactivated virus.
3. There is no species specificity in its fusion of cells, so interspecific heterokaryons can be induced easily (5, 6), unlike in the case of fertilization.
4. The frequency of virus-induced hybrid formation is at least 1000 times greater than that of spontaneous hybridization.

Littlefield reported in 1964 (7) further progress in methods for the selection of hybrid cell clones, by fusing two different mutants defective in the **salvage pathway** for nucleotide biosynthesis and culturing them in a medium containing **aminopterin**, which inhibits *de novo* nucleotide synthesis. One of the mutant cell lines that were fused lacked **thymidine kinase**, the other **hypoxanthine-**

guanine phosphoribosyl transferase. The only cells that could grow from the mixed culture were fused cells that had acquired mutual complementation of the two mutant defects. Based on these new techniques, the field of *somatic cell genetics* was established in the 1960s.

That the chemical fusogen **polyethylene glycol** is effective for the fusion of protoplasts of **plant** cells was first reported in 1974 (8). With this fusogen, hybrid plants, such as the "pomato," can be prepared in cultures of somatic hybrid cells. Moreover, *electroporation* (see Transfection) was found to be useful as a physical method for cell fusion in the 1980s (10, 11). Cell fusion by these two methods does not require viral receptors, so they have made possible the fusion of cells from all kinds of organisms.

In the early stage of somatic cell genetics in the 1960s and 70s, many reports provided important information on some basic phenomena in cell biology, permitting a focus on molecular biology in the next stage of the 1980s and 90s. The main findings were as follows:

1. Immediately after multinucleated cell formation by artificial cell fusion, some nuclear proteins derived from the parents are rapidly transferred and mixed between the various nuclei. This tends to induce synchronization of the stage of DNA replication of the nuclei after the fusion of randomly growing cells. The degree of this synchronization is greatest in cells with only two nuclei and decreases sharply with an increasing number of nuclei in polykaryocytes (12, 13). This may be why almost all randomly isolated hybrid cells have in their nucleus one set of chromosomes derived from each parent. As a special case, the fusion of cells in **mitosis** with cells in interphase causes the rapid dissolution of the nuclear membrane of the interphase cells, followed by the condensation of its chromosomes, a process named *chromosomal pulverization* (14) or *premature chromosome condensation* (15). Reactivation of dormant nuclei from chick erythrocytes was demonstrated upon their fusion with cultured mammalian cells (16, 17). In the case of cell neoplastic transformation by tumor viruses, induction of Simian Virus 40 (SV40) production was observed after the fusion of SV40-transformed nonproducer hamster cells with monkey cells, which are a permissive host for SV40 (18). Later, a similar observation was reported on the fusion of Rous sarcoma virus (RSV)-transformed rat cells with chicken cells (a permissive host of RSV) (19). In the case of cell differentiation, the distinction between luxury and household functions of cells was observed by the formation of hybrids of cells with different phenotypes (20). The findings were important for choosing the correct combination of cells for hybridization of differentiated cells. In 1974, Köhler and Milstein (21) reported that monoclonal antibodies could be prepared from hybrid cells (hybridomas) of B cells and **myelomas** (tumor cells obtained from B cells). This method of preparing monoclonal antibodies is now a major technique in molecular, cell, and developmental biology, and in medicine.
2. Weiss and Green (22) observed that the chromosomal balance is unstable in interspecific man/mouse hybrids and human chromosomes disappear randomly during serial passage in culture. Based on this finding, mapping of the human chromosomes became possible (23) and was followed by the technique of direct in situ hybridization of the chromosomes with complementary DNA.
3. In 1972, Bootsma and colleagues (24) demonstrated that genetic complementation groups in a hereditary disease, *xeroderma pigmentosum*, could be classified by the cell fusion technique. This was the first successful genetic analysis of a human hereditary disease.

1. Mechanism of Cell Fusion

Artificial cell fusion using the various fusogens mentioned above has been established as a routine laboratory method. These fusogens, viral, chemical, and physical, have different modes of action on cell membranes, but induce similar changes in the cell membrane for fusion of the lipid bilayers. In general, **glycoproteins** are distributed on cell surfaces, with their **hydrophobic** domains embedded in the lipid bilayer of the cell membrane, their hydrophilic domains exposed to the outside, while their intracytoplasmic domains are associated with the cytoskeletal system. Water molecules are also associated with the outside of cell membranes. These structures on the exteriors of cells inhibit the close contact of lipid bilayers of neighboring cell membranes, which is essential for cell fusion. Close contact of membranes requires on the cell membrane surface the transient appearance of areas from which glycoproteins are excluded. All the fusogens can induce such areas.

Sendai virus has two glycoproteins: HN with **receptor** binding and destroying activities, and F with fusogenic activity that is essential for fusion. The first step in cell fusion is the attachment of the virus to cell surfaces and agglutination of the cells, which is produced by HN activity. The second step is insertion of the fusogenic domain of F into the lipid bilayer. This domain is located at the N-terminus of F and consists of 15 relatively hydrophobic residues (25); it has the unique characteristic of trapping cholesterol molecules in its tertiary structure at 37°C (26). The amino acid sequence of this domain is well conserved in paramyxoviruses.

Simultaneous removal of cholesterol molecules from multiple sites in the cell membrane by the attachment of several hundred virus particles perturbs the cell membrane and causes breakdown of the normal barrier to ions. At this stage, calcium ions from the medium promptly penetrate the cell and induce changes in cell structures, such as separating the connection between the cytoplasmic domains of membrane proteins and the cytoskeletal system (see Calcium Signaling). Macromolecules can also **diffuse** through the cell membrane, and membrane fluidity increases, so that membrane proteins can move more freely in the lipid bilayer. This results in clustering of intramembrane domains of the proteins (demonstrable as cold-induced clustering) and the appearance of areas with no membrane proteins. The appearance of these areas is followed by close attachment of the lipid bilayers of neighboring cells, due to strong hydrophobic interactions, and cell fusion (27).

Polyethylene glycol is reported to induce clustering of membrane proteins similar to that induced by Sendai virus (28). Electroporation by electric pulses causes pores to be formed in cell membranes that may allow Ca^{2+} ions into the cytoplasm, as is also caused by Sendai virus. Thus, the fundamental mechanisms of these three fusogens appear to be similar.

It is known that calcium ions (29) and an energy (ATP) supply (2) are required for cell fusion. In the absence of either one, cells rapidly degenerate and fusion is greatly decreased. Evidence suggests that calcium ions associate directly with phospholipid molecules to normalize the perturbed membrane structure and promote a connection between the two lipid bilayers, in addition to acting in the cytoplasm as mentioned above. Why does cell fusion require an energy supply? In simple terms, cell fusion would be expected to produce a favorable decrease in **free energy**, by changing from a number of small vesicles to one large one, in which case an energy supply would not be necessary. Energy may be required for the removal of excess calcium ions introduced into the cytoplasm during cell fusion, but not for the membrane fusion itself. On culture of fused cells, the calcium ions are rapidly sequestered in **organelles** of the cells, and their level in the cytoplasm returns to normal. If the supply of energy is delayed, the cells degenerate.

2. Supplement

1. In the case of Sendai virus, cell-to-cell fusion is also possible as a result of viral envelope fusion itself, if one virus envelope fuses with the membranes of two different cells. But envelope fusion is slower than that induced by a high concentration of the virus and is observed to occur after completion of cell-to-cell fusion. Finally, as a result of viral envelope fusion, many viral glycoproteins are integrated into the fused cell surfaces, which are excluded from the cell surface by internalization by coated vesicles in culture (30) (see Clathrin).

Polykaryocytes (syncytia) are often observed in pathological tissues infected by an enveloped virus, such as paramyxoviruses, retroviruses and the Herpes virus. This polykaryocyte formation may occur by cell fusion via viral envelope fusion. Newly synthesized viral glycoproteins are distributed massively on the surfaces of infected cells, which consequently are quite similar to the viral envelope, and they may fuse with neighboring noninfected cells, as in viral envelope fusion.

2. Enveloped viruses cause infection by fusion of their envelopes either (a) with cell membranes at neutral pH or (b) with endosome membranes at acidic pH after their internalization from the cell surface. Infections by paramyxoviruses, retroviruses, and the Herpes virus are of the first type and induce syncytia formation *in vivo* and *in vitro*. Influenza virus is of the second type and does not induce syncytia *in vivo*, but the viral envelope can fuse with cell membranes under acidic conditions *in vitro*. This is because the influenza fusogenic glycoprotein (HA, or hemagglutinin) is not functional at neutral pH, but becomes functional under acidic conditions by a conformational change, forming trimers (31).

The fusogenic glycoproteins of various enveloped viruses differ, but all of them contain a hydrophobic domain that can interact with the lipid bilayer of cellular membranes. In some cases, the glycoproteins of the viruses are known to be synthesized in an inactive form in which their hydrophobic domain is hidden and then activated by **proteolytic** cleavage exposing this domain. This was first demonstrated by Homma (32) with the Sendai virus. In this virus, the F glycoprotein is synthesized as an inactive form F_0 and is then cleaved to F_1 and F_2, with the fusogenic domain being exposed at the N-terminus of F_1. The glycoprotein (gp160) of human immunodeficiency virus (HIV) a retrovirus, is cleaved to gp120 and gp41, and the fusogenic domain is exposed at the N-terminus of gp41 (33). The HA glycoprotein of influenza virus is also activated by the cleavage of inactive HA_0 to HA_1 and HA_2, with the hydrophobic domain being exposed at the N-terminus of HA_2 (34) and becoming functional by trimer formation under acidic conditions.

3. Application of Fusogenic Reactions to Cell Engineering

Various biotechniques for the reconstitution of cells or introduction of macromolecules into cells have been developed using the unique characteristics of the interactions of fusogens with cell membranes. Introduction of macromolecules such as DNA, RNA, and proteins from the medium into the cytoplasm has become possible by perturbation of the cell membrane. Electroporation is usually used for that purpose (35), but treatment of the cells with Sendai virus can also be used (36).

Another technique for the introduction of macromolecules is based on the mechanism of infection of Sendai virus with cell membranes. In 1979, Uchida et al. (37) reported on the reassembly of viral envelopes as artificial **vesicles**, with HN and F glycoproteins embedded in their surface and any macromolecules present trapped inside. These pseudovirus particles containing the macromolecules instead of viral nucleocapsids will introduce those macromolecules into a cell that they “infect.” This technique is especially useful *in vivo*. Subsequently, modifications have been made to simplify the preparation procedure, using spontaneous fusion of the UV-inactivated virus with simple, artificial liposomes containing the desired macromolecules. Using such a preparation, the human hepatitis B virus genome has been introduced into rat liver cells *in vivo* to induce hepatitis (38). This technique is useful for drug delivery *in vivo* and gene therapy (39).

Reconstruction of cells was first reported by Veomett et al. in 1974 (40). On incubation with cytochalasin, cells could be separated into *nucleoplasts* (enclosed by cell membranes but lacking cytoplasm) and *cytoplasts* (without a nucleus). Viable cells could be reconstituted by the fusion of nucleoplasts with cytoplasts. Heterologous combinations could also be constituted. This technique has been expanded to the preparation of cloned animals. Introduction of nuclei from somatic cells at the early stages after cleavage of fertilized eggs into enucleated eggs, by Sendai virus-mediated fusion, is reported to result in a high frequency of development of animals (41).

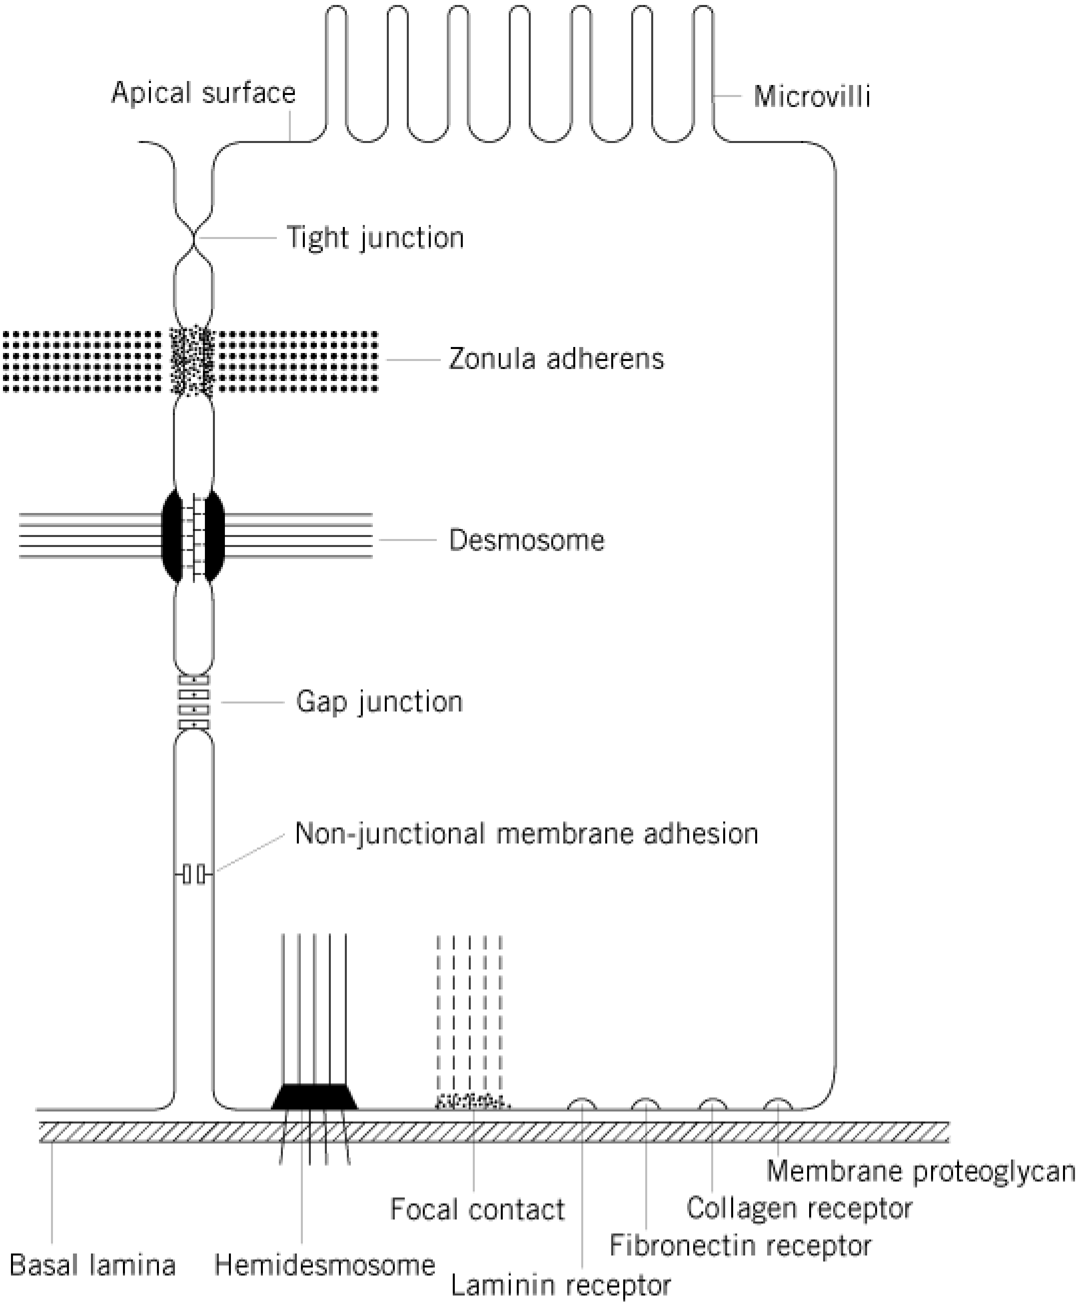
Cell Junctions

A cell junction is a cell surface structure observed by electron microscopy that mediates cellular interactions. Cell junctions are of two types, those that mediate cell–cell interactions and those that mediate cell–substratum interactions. In the former category, the cells of vertebrates possess four principal types, all of which are represented at the lateral surfaces of simple epithelial cells, such as those that line the intestine and kidney tubules (Fig. 1). The four principal types of cell–cell junction are (i) the tight junction or zonula occludens (pl. zonulae occludentes); (ii) the intermediate junction or zonula adherens (pl. zonulae adherentes); (iii) the **desmosome** or macula adherens (pl. maculae adherentes); (iv) the gap junction or nexus. The principal type of cell–substratum junction is the hemidesmosome, which is present in contact with the basement membrane in the basal cells of stratified epithelia, such as epidermis, in some simple epithelial cells, especially amnion, and mammary epithelium. Cells that are well spread in culture exhibit a second type of cell–substratum junction, the focal adhesion or focal contact (Fig. 1). This is a region where the lower cell surface is most closely apposed to the culture substratum (separation 10 to 15 nm). It is not clear whether the focal contact has a strict equivalent *in vivo*, but its study has made an extensive and important contribution to the understanding of cell adhesion. The basic structures of the principal types of cell junctions were elucidated by electron microscopy in the 1960s (1-3). Since then, a substantial amount of detailed knowledge of the molecular composition of each junctional type has been revealed.

Figure 1. Generalized simple epithelial cell showing cell junctions and other adhesion mechanisms. The lateral surface mediates cell–cell interactions via adhesive junctions, the zonula adherens (intermediate junction) and the desmosome, and communicating gap junctions that allow small molecules to be exchanged between the cytoplasm of adjacent cells. The tight junction, or zonula occludens, restricts and regulates paracellular permeability. The basal surface mediates adhesion to the basement membrane. Hemidesmosomes are present in some simple epithelia but are most numerous in epidermis. Integrin and non-integrin receptors for several matrix components are present here. When cells are cultured, many of these become localized in focal contacts, small areas where adhesion to the substratum is strongest. (From *Journal of Cell Science*, with permission of the Company of Biologists.)



The intermediate junction, the desmosome, the hemidesmosome, and the focal contact are primarily adhesive junctions that bind cells to each other or to their substratum. Each represents a cell-surface site at which cell adhesion molecules (see Cell Surface Adhesion Receptors) are concentrated. In desmosomes and intermediate junctions, the adhesion molecules are specific types of cadherins (4, 5); in hemidesmosomes and focal contacts, they are integrins (6). These junctions also represent cell-surface attachment points for elements of the cytoskeleton. In desmosomes and hemidesmosomes, the associated cytoskeletal elements are intermediate filaments, also known as tonofilaments. These are important in providing structural continuity throughout a tissue. This continuity is disrupted in certain **autoimmune** and genetic diseases of desmosomes (eg, pemphigus) (7), hemidesmosomes (eg, bullous pemphigoid, junctional epidermolysis bullosa) (8), or intermediate filaments (eg, epidermolysis bullosa simplex) (9). Such diseases result in structural disruption of the epidermis and/or mucosal tissues, with effects ranging from mild to lethal. In intermediate junctions and focal contacts, the cytoskeletal elements are actin filaments, also known as microfilaments. The actin filaments associated with focal contacts are organized into large bundles, called stress fibers, of several micrometers in length. During animal development, morphogenetic events such as gastrulation and neural tube rolling involve gross changes in cell shape that appear to be caused by contraction of submembranous microfilament rings associated with zonula adherens-type junctions (10, 11). More limited contractile activity of such rings may be involved in regulation of the permeability of tight junctions, with which zonulae adherentes are frequently closely associated in the simple epithelial junctional complex, a region where junctions are concentrated at the extreme apicolateral interface between the cells.

Transduction of signals across the plasma membrane is a vital function in the regulation of normal cell behavior in both developing and adult organisms. Many adhesion receptors have now been shown to transduce signals, either from inside the cell to outside regulating the function of the receptors themselves, or from outside to inside regulating signalling pathways and gene expression in response to adhesive stimuli. Such signal transduction is an additional important function of adhesive junctions (12).

The principal function of the tight junctions is to occlude the paracellular channels of epithelia, thereby restricting intercellular leakage of molecules between the distinct biological compartments separated by the epithelium (13). Tight junctions are also important in forming tight seals between some endothelial cells, such as those of the blood–brain barrier. Their sealing properties arise because they are zonular in nature, encircling the entire apicolateral margins of simple epithelial cells, and because there is direct contact between the plasma membranes of adjacent cells. Tight junctions are also important in maintaining the composition of the different membrane domains of epithelial cells, because they prevent diffusion of molecules within the outer leaflet of the plasma membrane, thereby restricting them to either the apical or the basolateral domain (14). This property is sometimes referred to as the “fence” function of tight junctions, and their occluding properties are described as a “gate” function.

Gap junctions, so-called because they exhibit a regular plasma membrane separation of 2 nm, are punctate membrane sites that provide hydrophilic channels for direct cell-to-cell communication (15). They permit diffusion of molecules of less that 1000 daltons between cells. These ubiquitous junctions are important in both excitable and nonexcitable tissues. In the former they facilitate direct transmission of electrical impulses, while in the latter they mediate a phenomenon called metabolic cooperation, and they may also transmit signaling molecules such as **calcium** and **inositol phosphates** between cells. Their function is essential in embryonic development (16) and in the normal functioning of adult tissues—for example, in coordination of the contraction of cardiac muscle and smooth muscle in the uterus during parturition (17, 18).

Gap junctions appear to be widespread in the animal kingdom, being present even in primitive organisms such as *Hydra*. Intermediate junctions have also been clearly demonstrated in invertebrates (eg, in *Drosophila*). The occurrence of desmosomes and tight junctions in invertebrates is much less clear. Desmosome-like structures are clearly present in insects—for example, between the apposed epithelia of the upper and lower surface of the wing blade in *Drosophila*. However, these desmosome-like structures appear to be associated with microtubules rather than intermediate filaments, and their adhesion may be mediated by integrins rather than cadherins. Tight junctions are absent from insects, which instead possess septate junctions, structures that have a ladder-like ultrastructural appearance between adjacent plasma membranes and which, like tight junctions, appear to restrict paracellular permeability (19).

Cell Line

When a primary cell culture (see Tissue Culture) is subcultured, it becomes a cell line. This implies that multiple lineages of cells, not necessarily distinct from each other, coexist in the culture (1). Serial subculture, while maintaining these parallel lineages, will tend to show convergence towards whatever common **phenotype** is best adapted to the culture conditions being employed, as the cell type with the greatest proliferative ability will predominate. The cell line may be finite and die out after a fixed number of population doublings, or become a continuous cell line (see Immortalization) (Fig. 1). Cell lines, particularly continuous cell lines, can become a valuable resource, particularly if preserved in liquid nitrogen after appropriate characterization and validation. Many continuous cell lines are currently available, with wide-ranging properties, including drug resistance markers, inducibility for specific enzymes, estrogen sensitivity, cornification, blood vessel formation, hemoglobin synthesis, myogenesis, and transfection susceptibility (Table 1). Finite cell lines with distinct phenotypic properties are also becoming available through the development of serum-free selective media (2-4). (see Serum Dependence) and can be derived in the laboratory or purchased from commercial suppliers.

Figure 1. Effect of continued culture passage on cumulative cell number, assuming that no cells are discarded. The curve shows the initial decline due to selection, then exponential growth during the replicative phase, and then growth arrest and eventual deterioration following senescence, in a finite cell line, or continued proliferation, often at an enhanced rate, following transformation. Reproduced from Freshney's *Culture of Animal Cells, A Multi-Media Guide*, 1999, Wiley-Liss, N.Y.

1. Origin of Cell Lines

Regenerating tissues *in vivo* are made up of a small, self-repopulating, stem cell pool, an expandable pool of proliferating **progenitor cells**, and a nonproliferating differentiated cell pool. On demand, cells leave the stem cell pool and enter the progenitor compartment, where expansion is regulated to meet the current demand in the differentiated cell compartment. When cells enter the differentiated cell compartment, this may be an irreversible process, as seen with erythrocytes, keratinocytes, and neurons; or it may be reversible, as seen with hepatocytes, endothelial cells, and fibrocytes. Cell lines can be derived from any tissue with a proliferating compartment, or from cells that can re-enter a proliferating compartment. It is possible that cell lines will contain stem cells, but, except for hemopoietic cells (see Hematopoiesis), markers are unavailable to determine this. As many cell lines express lineage markers and can, under appropriate conditions, differentiate, it seems most likely that they are derived from the progenitor cells of the tissue.

As cell lines are derived from random outgrowth or from disaggregated cells, multiple lineages of cells will be present. The purity of the culture will be determined by how well these lineages are matched, that is, derived from cells with the same phenotypic fate, or are derived from cells with dissimilar fates. In practice, the selective pressure exerted by the medium will tend to limit the cell population to cells of like phenotype with similar survival capacity, and cells that proliferate less rapidly will gradually be overgrown. It is possible that cells within one phenotypic group have different proliferative capacities but interactions between them produces a uniform proliferative rate in the entire population.

2. Finite Cell Lines

When a cell line is generated at the first subculture of a primary culture, its lifespan is determined, initially, by the environmental conditions. If the conditions are inadequate, the cell line will die out within one or two subcultures, but if the medium, substrate, and other conditions are satisfactory, then the cell line may progress through several serial subcultures. The ultimate limit to the number of subcultures will be determined by the potential regenerative life-span of the cells (see Senescence; Immortalization). Most cell lines from normal tissues will undergo a fixed number of population doublings (Fig. 1), given by the product of the number of passages and the estimated number of doublings per passage (5). These are known as finite cell lines. Normal human skin fibroblasts will usually achieve around 50–60 population doublings and then enter senescence. Senescent cells no longer proliferate, may be partially differentiated, and can remain viable for several months. Cultures of finite cell lines must, therefore, be stored frozen at an early passage level, thawed when required, and used between predetermined passage levels, usually between 10 and 30, to ensure an adequate and consistent supply.

3. Continuous Cell Lines

Some cell lines, such as those derived from mice or from tumors of many species, are not limited by a finite lifespan. They progress either by smooth transition to an immortal cell line (see Immortalization) or undergo neoplastic transformation at some stage and, instead of dying out after a set number of population doublings, continue to proliferate unchecked. Some cultures show evidence of selection and go through a period called *crisis*, when most cells in the population die out by senescence, but a transformed subpopulation survives, usually with an enhanced growth rate, increased cloning efficiency, loss of contact inhibition, acquisition of anchorage-independent growth, ability to grow to a higher saturation density, and increased tumorigenicity in animals (see: Neoplastic Transformation).

There are a large number of continuous cell lines in existence, many of which are banked in repositories such as the American Type Culture Collection (ATCC) or the European Collection of Animal Cell Cultures (ECACC). They form a valuable resource of vigorously growing cultures, capable of unlimited expansion, but are subject to several caveats.

1. Their origin must be validated before use. Acquisition from a reputable cell bank, or the originator, will usually guarantee this, but there are many instances of continuous cell lines being cross-contaminated by other, more vigorously growing cell lines such as HeLa Cells (6-8). The identity of a cell line needs to be confirmed prior to extensive use. This is done most effectively by performing a DNA fingerprinting, but it is also possible by immunotyping, **isoenzyme** analysis, or chromosome analysis.

2. The cells must be shown to be free from infection. Continuous cell lines form an ideal substrate for mycoplasma, which can grow undetected in the culture (9). Again, most reputable cell banks will be able to demonstrate that cell lines being distributed are mycoplasma-free, but stocks still need regular checks every 1 or 2 months to ensure that they remain uninfected.

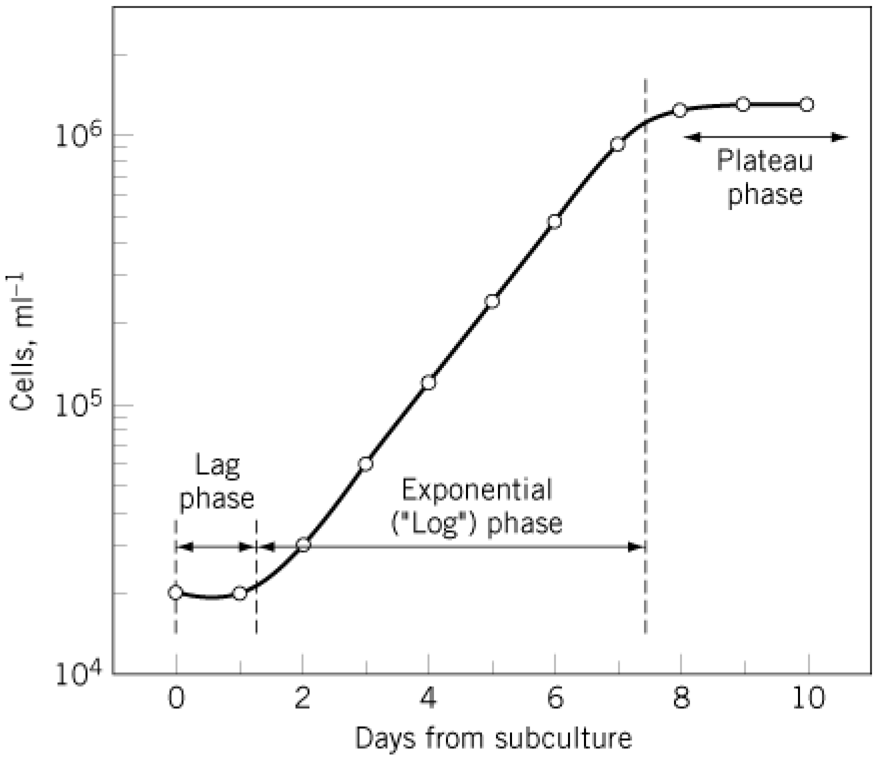
3. Continuous cell lines are genetically unstable. They are usually aneuploid (the chromosomal complement differs in number, and by chromosomal rearrangements, from the donor) and heteroploid (contain subpopulations with differing chromosomal constitutions). This is reflected in their phenotypic diversity, including variations in morphology, enzyme activity, antigenic expression, and growth characteristics. It is normal practice to clone such populations, select a clone with the required properties, and cryopreserve sufficient ampoules (12–100) for future use. Cultures are generally maintained for a limited period, usually about 3 months, and then replaced from frozen stock.

4. Subculture

Subculture, or passage, is the transfer of a culture from one vessel to another, usually using **trypsin** to dislodge the cells from the substrate and dissociate them from each other. If the cell line is proliferating, then subculture will also imply diluting the cell concentration achieved at the end of the culture period, to a new seeding concentration to initiate a new culture. Growth from seeding until the next subculture is known as a growth cycle, which is repeated each time the culture is passaged. A series of growth cycles constitute serial propagation, and this should not normally proceed beyond about 3 months without replacing stock from the freezer (see above).

Each growth cycle is composed of a lag phase (Fig. 2), where the cells are recovering from trypsinization, synthesizing new extracellular matrix, adhering to the substrate, spreading, repolymerizing the actin microfilament cytoskeleton, and responding to signaling from extracellular matrix adhesions and cytoskeletal rearrangements, which leads to expression of cyclins and, eventually, reentry to the cell cycle. When the cells start to divide, they enter the exponential or "log" phase of the growth cycle and will continue exponential growth until all the available growth surface is occupied or the medium is exhausted. If the medium is limiting, it is customary to replace it half way through the exponential phase of growth. When all the available growth surface is occupied, the culture is said to be *confluent* and will require to be subcultured again. If the culture is allowed to progress beyond confluence, growth will slow down, as a result of density limitation of growth (see Contact Inhibition), and the culture enters the plateau phase of the growth cycle. If the cells are normal and respond to normal growth control signals, there will be little evidence of cell proliferation or cell loss in plateau, specifically, minimal turnover. If, however, the cells are transformed, they will continue to proliferate for several cell generations after reaching confluence and reach a higher saturation density at plateau, due to deficiencies in contact inhibition of cell motility and density limitation of cell proliferation (10, 11). Even in plateau, there will be continued cell proliferation, although at a lower level than in exponential growth, balanced by increased cell loss from apoptosis, resulting in a greater turnover than occurs in normal cells in plateau.

Figure 2. Phases in the growth cycle of cultured cells following subculture. Modified from Freshney's *Culture of Animal Cells, A Multi-Media Guide*, 1999, Wiley-Liss, N.Y.



The numerical parameters that can be derived from the growth curve are the duration of the lag period, the doubling time in mid–log phase, and the saturation density in plateau. The last will depend on the feeding regimen and, if cell kinetics are being determined, should be measured under nonlimiting medium conditions. Where these parameters are consistent, they can be used to calculate the split ratio, the degree of dilution required to reinitiate a new growth cycle with a short lag period and to achieve the appropriate density for subculture at a convenient time in the future, usually around one week. The split ratio should be a power of 2 when handling finite cell lines. This allows an approximate calculation of the number of generations that have elapsed since the last subculture; for instance, a split ratio of 8 would imply that the cells had undergone 3 population doublings in each growth cycle. Split ratios are less useful with continuous cell lines. They are not needed to determine the stage in the life cycle of the cell line, as it is immortal, and the population doubling time is so much shorter that split ratios of the order of 1–100 are required to produce a week-long growth cycle. At this level of dilution, it is more advisable to determine the cell concentration at each subculture and to dilute to give the seeding concentration that will allow growth to the next subculture in a suitable interval, say, one week.

5. Selective Culture

Alterations in the choice of medium and/or substrate will determine which cells survive in primary and early passage cultures. Most selective media are serum-free (see Serum Dependence), and recipes are available for the culture of many different cell types, including fibroblasts, epithelial cells (epidermal, mammary), glial cells, melanocytes, endothelial cells, and smooth muscle Table 2. Selection of a purified cell culture, with defined characteristics, by cloning, use of a selective medium, or physical separation, allows the resultant culture to be called a *cell strain*.

6. Characterization

Cell morphology and growth characteristics are simple criteria for characterization. Spindle-shaped cells are usually considered to be fibroblast-like, without necessarily implying that they are known to be of the fibrocyte lineage. Similarly, cells that grow in patches of polygonal, or pavement-like, cells with distinct boundaries between the cells are said to be epithelial-like, although numerous other cell types can assume a similar morphology. Characterization of a cell strain employs such criteria as (*1*) identification of the type of intermediate filament protein (eg, cytokeratin subtype in different epithelial cells, desmin in muscle cells, glial fibrillary acidic protein in astrocytes, and neurofilament protein in neurons and some neurendocrine cells) (12); (*2*) expression of cell-surface antigens, such as epithelial membrane antigen (13); (*3*) enzymes, such as tyrosine aminotransferase and its inducibility by glucocorticoids in hepatocytes (14); (*4*) marker chromosomes (15); (*5*) **isoenzymes** (16); and (*6*) the **DNA fingerprint** (17, 18). The same criteria may be used to characterize a cell line, but would give only an average for the population in a cell strain.

7. Cell Banks

Most of the cell lines in common use are lodged in cell banks containing records of their identifying characteristics. Cell lines or strains that have been characterized and shown to be free of mycoplasma can be submitted to a cell bank for safe-keeping, with or without authority to distribute to other users. Cell lines may be obtained from cell banks for a set charge (Table 3) (19).

Cell Lineage

The daunting complexity of vertebrate organisms has led investigators to adopt a reductionist approach to their investigation. This approach is based on the assumption that an otherwise impossibly complicated system can be effectively understood through an analysis of its constituent cells and molecules. A reductionist concept of development envisions the process as the assembly of elementary units in many combinations and permutations, unfolding over time in stages that escalate progressively in their complexity. The transition from one stage to the next is influenced by the conditions that prevailed during the earlier period. Developmental biology thus seeks to infer the mechanisms of morphogenesis and histogenesis from the properties, activities, and responses of the precursors that give rise to the various lineages of the cells of the body.

That the concept of lineage should be an important one in developmental biology is something of a paradox. In a simplistic sense, it seems odd that lineage can be a meaningful issue, when all of the cells of an animal descend from a single precursor, the fertilized zygote. Distinct lineages, however, arise very early in embryogenesis. Formation of a body plan in lower vertebrates, including amphibia, is a process that begins in the oocyte, continues after fertilization and cleavage, and is finally completed at gastrulation (1, 2). Polarity in the oocyte causes cytoplasmic constituents to be distributed asymmetrically in the egg and newly formed blastula (3-6). This asymmetric distribution establishes different lineages in blastomeres, which do not each inherit identical cytoplasmic determinants from their predecessors. The resulting differential inheritance creates cellular differences between the blastomere-derived lineages and allows cells to interact with one another (7, 8). Regional inequalities and cellular interactions may then be expressed as functional differences between cells in different locations. These processes form an ordered cascade that leads to the establishment of a pattern of small groups of like cells that follow a developmental agenda common to themselves, but different from those followed by other small groups of cells located elsewhere in the embryo (4). Functional differences between cells located in particular sites in the developing embryo are necessary for the differential cellular behaviors that underlie morphogenetic movements, like gastrulation and neurulation (9-11). It is also these different cellular loci, and the progeny to which they give rise, that provide developmental meaning to the concept of lineage.

In mammals, the establishment of lineages is delayed relative to that in amphibian embryos. Early cleavage cells of mammalian embryos appear to be identical to one another and totipotent (12). Each of the blastomeres of a two-cell embryo is capable of generating a complete adult, and will do so if the embryo is split (13, 14). Destruction of a single blastomere, moreover, may not prevent the normal development of a mature animal. **Chimeric** animals can also be constructed by combining morulae (15). It is thus unlikely that localized determinants play a role in mammalian development prior to or during the eight-cell stage. The pattern of cell diversification must be generated at subsequent stages, through the interactions of cells with one another and with their microenvironment.

1. Lineage as a Pedigree

Lineage, understood as a set of cells for which the ancestry can be traced back to a single progenitor, can possibly be delineated in simple transparent embryos, such as that of Caenorhabditis *elegans* by direct observation (16, 17). Cells can be recognized and followed from egg to adult in a living embryo as they divide, migrate, differentiate, and/or die. Keeping track of the cells is facilitated by the fact that nematode development is virtually invariant. Because the process is so constant, it is possible to predict the fates of descendant cells from their positions on the lineage tree. It is, of course, not possible to use similar direct observation by itself to determine the pedigrees of the cells of an adult mammal. Not only are the numbers of cells in a mammalian embryo too large to permit the progeny of unmarked individual cells to be followed, the details of cell lineage in mammals may also show random variations, even between genetically identical individuals. Lineage can possibly be followed in mammals by marking individual precursor cells in one or another location, for example, with a replication-deficient retrovirus that carries the gene encoding *Escherichia coli* **beta-galactosidase** (18-20). The activity of the bacterial enzyme or the protein can then be detected histochemically or immunocytochemically, respectively, thereby permitting all of the cells of the clone that ultimately develops from the single virus-infected progenitor to be identified. This type of analysis has been especially powerful in studies of the development of the central nervous system (CNS).

Studies of *C. elegans* have been particularly important in establishing that the terminally differentiated cells of an adult animal do not necessarily constitute the lineal descendants of a single founder cell (16, 17, 21). Different phenotypic classes of cells (with the exception of intestinal and germ cells) in *C. elegans* thus arise from several founder cells, which themselves are found on different arms of the lineage tree. The descendants of a single primitive embryonic precursor, therefore, may become cells of the hypodermis, musculature, and nervous system of the mature animal (21). Lineage in the straightforward pedigree sense thus does not predict the commitment of multipotent precursor cells to a specific phenotype. That choice, the moment when a cell's fate has become determined, may be made long before the terminally differentiated phenotype becomes evident in the appearance of the cell, and may be shared by cells originating from more than a single progenitor (22). Determination in this sense implies that a cell has undergone a lasting and autoperpetuating change that will forevermore distinguish that cell and its progeny from other kinds of cell and will commit the determined cell and its descendants to a common specialized developmental program. Cells may become determined either before, or when, they overtly differentiate (display their ultimate phenotype in a detectable manner); moreover, all of the cells that are determined to follow a shared developmental program do not necessarily arise from a common precursor, and multipotent precursor cells may divide asymmetrically so that not all of their progeny are identically determined. The observation that cells of a particular terminally differentiated phenotype may not share an origin from a single "founder" has led the concept of lineage to acquire a meaning distinct from its linkage to cellular pedigrees.

2. Lineage and Determination

Cells of embryos that share a determined fate, as well as those that descend from a common founder, are often referred to as members of a common lineage. For example, the multipotent stem cells that are found in the neuroepithelium of the neural tube are self-sustaining, but they also give rise to progeny determined to be neurons or glia; following determination, the cells are said to be developing in neuronal or glial lineages (23). Lineage is used to denote their common determined phenotype, not their origin from a common precursor. The neuroepithelial stem cells proliferate in response to the actions of defined mitogens, including epidermal growth factor (EGF) and fibroblast growth factor (FGF), and differentiate as neurons or glia under the influence of a variety of microenvironmental factors. Factors that have been found under at least some circumstances (*in vitro* or *in vivo*) to promote the restriction of subsets of central nervous system stem cells to the glia lineage include sonic hedgehog (Shh) (24), ciliary neurotrophic factor (CNTF) (25), leukemia inhibitory factor (LIF) (25), and bone morphogenetic protein 4 (BMP4) (26).

The generation of the phenotypic diversity of cells in various brain regions occurs in stages, progressing from pluripotentiality to lineage restriction (a phenomenon that prevents cells from giving rise to certain types of progeny), to the determination of specific phenotypes, and finally to the manifestation of the features of the terminally differentiated cells (27). Because of their responsiveness to their microenvironment, transplanted stem cells can integrate into a variety of brain regions, and thus potentially may provide a tool for treating the diseased or injured brain (23). The progenitor cells of the vertebrate brain, however, are themselves heterogeneous and thus members of different lineages (27). These differences help to explain how and when neuroepithelial cells begin to respond to the molecular signals provided by their microenvironment. Environmental factors, be they mitogens, trophic growth factors, or morphogens, can only affect cells that have prepared themselves to be affected. To respond to an extracellular factor, the responding cell must have previously acquired the relevant receptors. Most of the stem cells of the vertebrate nervous system express the intermediate filament protein, nestin (23, 25). Lineages of progenitors, however, can be defined by the expression in common of molecular properties that distinguish the cells of the lineage from other progenitors in the neuroepithelium; such lineage-defining molecular traits include expression of the ***achaete/scute*** family of basic helix–loop–helix (bHLH) transcription factors, **EGF receptors**, ventricular zone gene 1 (*vzg-1*), and the embryonic neural cell adhesion molecule (E-NCAM) (27). Progenitors in different locations may respond differently to the gliogenesis-promoting factors noted above.

3. Lineages in the Development of the Neural Crest

A source of precursor cells in developing vertebrates that has been extremely valuable for studies of the role(s) of cell lineage in development has been the neural crest (28, 29). This is a transitory structure that appears during embryogenesis and disappears as its component cells disperse, migrating through the embryo to give rise to a wide variety of terminally differentiated cell types (30, 31). The lineages of cells as diverse as melanocytes, fibroblasts, endocrine cells, smooth and skeletal muscle, cartilage, bone, meningeal cells, Schwann cells, satellite cells, enteric glia, autonomic, enteric, and sensory neurons can all be traced back to the neural crest. A great deal of investigation has been devoted to understanding when crest-derived cells become determined, and what factors cause them to become so. Considerable evidence indicates that at least some of the cells of the premigratory crest are pluripotent. Clones of these cells give rise in culture to several different classes of terminally differentiated cells (32-35). Lineage studies that have marked (by microinjection) individual cells of the premigratory crest (36, 37), as well as early-migrating crest-derived cells (38), have shown that progeny of the marked precursors reach different destinations and thus give rise to a variety of cell types. Furthermore, cultures of stem cells can be prepared from the neural crest (39, 40), just as they can from the neuroepithelium of the neural tube (23, 25).

Although it is clear that the neural crest contains multipotent cells, the population of cells in the premigratory crest is actually heterogeneous. Some of the cells, even in the premigratory crest itself, are already determined (41). Cells determined to develop in the melanocytic lineage, for example, migrate selectively along the dorsolateral pathway (42). Among the uncommitted cells, there appears to be a progressive loss of developmental potential that occurs as a function of age (28, 29, 43). Whether the loss of developmental potential is simply determined by the age of the cells, or by the signals the cells receive as a result of their position in the embryo, has yet to be determined.

Some of the crest-derived cells that arrive in the organs that lie at the ends of their migratory pathways are still multipotential when the crest-derived cells arrive. The bowel has been carefully investigated in this regard and is a good model to illustrate the role of lineages in neural crest development (44). Two techniques have been employed to investigate the developmental potential of the crest-derived cells that colonize the gut. One, back-transplantation, consists of placing a segment of avian gut that has received a complement of émigrés from the neural crest in a migration pathway of a younger host embryo (45, 46). When this is done, crest-derived cells leave the grafts and remigrate in their new hosts. Where they go depends on where the grafts are placed. If the grafts are situated so as to replace the host's crest in locations that normally provide crest-derived émigrés for the bowel, the donor cells migrate to the host's gut and participate in forming the enteric nervous system (ENS). On the other hand, if the grafts are placed anywhere else in the embryo, the enteric crest-derived cells of the donor fail to migrate to the host's bowel. Instead, they migrate to peripheral nerves, sensory, and sympathetic ganglia. Donor cells that arrive in sympathetic ganglia become catecholaminergic sympathetic neurons, even though catecholaminergic neurons are not found in the enteric ganglia of the avian gut. Donor cells that find themselves in peripheral nerves develop as Schwann cells, even though the ENS contains glia rather than Schwann cells. Enteric crest-derived cells thus learn nothing from their previous journey to the bowel and evidently remember nothing of it. Crest-derived cells from the donor gut, however, never give rise to muscle, melanocytes, or connective tissue, indicating that they have lost at least some of developmental potential of their ancestors; nevertheless, they remain pluripotent to the extent that they are able to give rise to cell types that they would not have done had they been left *in situ*.

Clonal analysis of crest-derived cells isolated from the embryonic avian (47) or fetal mammalian bowel (48, 49) has also suggested that the population of crest-derived émigrés that colonizes the gut is a heterogeneous mixture of multipotent and determined cells. One or more terminally differentiated types of cells may be found in clones arising from individual precursors. None of the clones developing *in vitro* from enteric crest-derived cells contain melanocytes, endocrine cells, or skeletal muscle, although some contain smooth muscle. The heterogeneity of the crest-derived cell population that colonizes the bowel is reflected in the birthdays of the different types of enteric neuron (50). Some of these cells, containing acetylcholine or serotonin, are born very early in embryonic life, beginning in the mouse at E8.5, an age that precedes the arrival in the bowel of even the most precocious of enteric neurons. The crest-derived population that arrives in the gut, therefore, must contain a mixture of already-determined postmitotic neurons, as well as the undetermined pluripotent precursors that were revealed by the experiments involving back-transplantation and clonal analysis described above. On the other hand, other types of enteric neuron, such as those that contain calcitonin gene-related peptide (CGRP), do not even begin to leave the mitotic cycle until after the last serotonergic neurons have been born. The fact that the timing of the birthdays of enteric neurons is a function of their phenotypic class was among the earliest observations to suggest that multiple lineages of crest-derived precursors participate in the formation of the ENS. It is at least plausible that neurons in the same lineage might be born at similar times.

Confirmation of the idea that the ENS is formed by multiple lineages of crest-derived precursors came from a study that combined an *in vitro* investigation of enteric neuronal development with an analysis of the effects of the targeted deletion of the mash-1 transcription factor (51). It had previously been known that cells in the developing mammalian (but not avian) bowel are transiently catecholaminergic (TC) (52-55), and that these cells are derivatives of the neural crest (56-58). The TC cells were found not to be neurons, because they proliferate (56, 57, 59), although it was postulated that the TC cells might be neural precursors. That hypothesis was confirmed, and the disappearance of TC cells was found to occur not because they die, but because they lose their catecholaminergic properties as they acquire the characteristics of their terminally differentiated phenotype (56).

When it was discovered that TC cells express the same cell-surface differentiation antigens as precursors in the sympathoadrenal lineage, it was proposed that enteric and sympathetic neurons arise from a common lineage of crest-derived progenitors (60, 61). This idea was furthered by the demonstration that *mash-1* is expressed during the development of both sympathetic and enteric neurons (62, 63). On the other hand, knockout of *mash-1* is accompanied by the loss of almost the entire sympathetic nervous system (the superior cervical ganglion is spared), while the development of the ENS (except for that of the esophagus, which is lost) is merely delayed (63, 64).

The shared features expressed by sympathoadrenal and ENS precursors made it possible to test the hypothesis that sympathetic and enteric neurons are derivatives of a common precursor lineage. **Complement**-mediated lysis of all of the cells isolated from the bowel that express **antigens** common to the sympathoadrenal lineage reduces the numbers of enteric neurons developing *in vitro*, but it does not prevent their formation (51). No serotonergic neurons develop *in vitro* following lysis of TC cells, although neurons expressing CGRP appear normally. The cells in the developing bowel that express *mash-1* were found to be TC cells, and the knockout of *mash-1* in mice was demonstrated to result in the complete loss of early-developing serotonergic neurons, while late-born CGRP-containing cells appear on schedule. The apparent delay in timing of the formation of the ENS in *mash-1* knockout mice is thus due to the selective loss of the early-developing lineage of enteric neurons. These observations established for the first time that the ENS is, in fact, derived from at least two lineages of crest-derived precursors. One of these, which may be common to the precursors of sympathoadrenal cells, obligatorily expresses *mash-1*, gives rise to neurons that are born early, and is the origin of all of the serotonergic neurons of the bowel. The other lineage is never catecholaminergic, does not express *mash-1*, gives rise to neurons that are born late, and is the origin of peptidergic enteric neurons, including those that contain CGRP.

Since the discovery of the role of *mash-1* in the development of one lineage of enteric neurons, additional lineages or sublineages of enteric neuronal precursor have been discovered. All of the crest-derived cells that colonize the bowel appear to express $p75^{NTR}$, the common neurotrophin receptor (44, 56, 65). The cells (from the vagal and sacral regions of the neural crest) evidently also express Ret (66, 67), which must be stimulated by its functional ligand, glial cell line-derived neurotrophic factor (GDNF) (68-70). Actually, in order to stimulate Ret, GDNF has to form a complex with an a-component, GFRa-1 (71-73). If Ret (74, 75), GDNF (69, 76), or GFRa-1 (77) are knocked out, there are no neurons or glia in the entire bowel below the esophagus and in the immediately adjacent region of the stomach. GDNF is a mitogen for early crest-derived enteric neuronal precursors and later supports their development as neurons (78-80). Because the defect in the *mash-1* knockout mice is much more limited than that seen after the elimination of Ret or the components of its ligand complex, it follows that the *mash-1*-dependent lineage is a subset of a larger lineage of GDNF-dependent precursors.

More limited sublineages have been identified by the dependence of subsets of enteric neurons on other growth factor/receptor complexes, such as a still-to-be identified neuropoietic cytokine that activates the alpha component of the receptor for CNTF (65). Other factors, such as NT-3/TrkC (81) and **laminin**-1 (82, 83), have been identified that promote the development of enteric neurons, but these factors do not define particular lineages. Endothelin-3 (ET-3) and its preferred receptor, endothelin B (ET_B), also appear to be necessary for a subset of enteric neurons (84, 85). This factor/receptor complex, however, does not appear to define a particular lineage of enteric neurons. When either ET-3 (84) or ET_B (85) is knocked out in mice, the terminal colon becomes aganglionic, just as it does in humans with Hirschsprung's disease, some of whom also display ET-3 (86) or ET_B (87) mutations. The lesion that results from deletion of ET-3 or ET_B thus is geographically restricted, but within the affected zone all lineages of crest-derived enteric neurons are affected. ET-3 has been found to inhibit enteric neuronal development, and it has been postulated to act by preventing the premature differentiation of enteric neurons before their crest-derived have completed their colonization of the gut (78, 88).

4. Summary

The concept of lineage is used in two ways in describing development. In the pedigree sense, lineage is used to refer to the descendants of a common progenitor. Sharing a lineage defined as a pedigree, however, does not necessarily mean that the descendants of the common progenitor share the same developmental program or fate. Lineage as a pedigree is thus independent of the determination of its members. In a second developmental sense, the term *lineage* is used to refer to cells that do follow a common developmental program, regardless of whether these cells trace their ancestry back to a single shared precursor. Usually they do not. Identity of determination thus is now the common denominator that defines lineage.

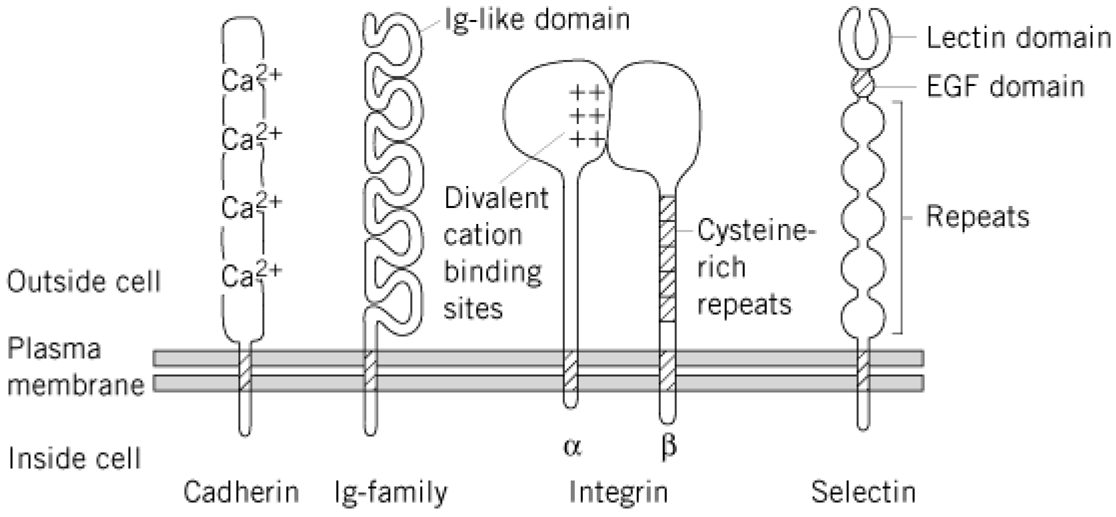
Cell Surface Adhesion Receptors

Cell surface adhesion receptors are molecules that mediate cell adhesion by binding to other molecules on the surface of an adjacent cell or to a component of the extracellular matrix. Many adhesion receptors have been described. Most of them belong to one of a small number of families of related molecules in which individual members share the same basic molecular structure. The principal families are the cadherins, the immunoglobulin (Ig) superfamily, the integrins, and the selectins (Fig. 1) as follows.

Figure 1. Diagram showing the generalized molecular structures of the four principal families of cell-surface adhesion receptors. (From Ref. 7, with permission of BMJ Publishing Group.)



1. Cadherins

In most tissues, a major contribution to intercellular adhesion is made by calcium-dependent cell adhesion molecules knows as cadherins (1). In general, these are simple transmembrane glycoproteins. The extracellular domain has an adhesion site toward the *N*-terminal region and several **calcium-binding** sites. Adhesive binding is mainly homophilic: a cadherin molecule on one cells binds to another cadherin molecule of the same type on the next cell. Linkage of the cytoplasmic **domain** to the cytoskeleton through proteins known as catenins is necessary for cadherin function. The best characterized is epithelial cadherin, E-cadherin. This appears very early in development, when it is involved in compaction of the eight-cell embryo and cell polarization. In adult epithelia—for example, intestinal epithelium—it is present on the lateral cell surfaces but is concentrated in intercellular junctions, known as the zonulae adherentes (see Cell Junctions; Intermediate Junction), which ring the apicolateral margins of cells. These junctions are characterized by a cortical ring of cytoskeleton, the major component of which is actin. Cadherins are also present in the nervous system, where they play an essential role in neural development.

The adhesive glycoproteins of the other major intercellular junctions of epithelia, the **desmosomes** are also members of the cadherin family (2). Their extracellular domains are very like those of cadherin, but their cytoplasmic domains differ, being specialized for forming desmosomal plaques and, thereby, attachment to the keratin intermediate filament cytoskeleton, rather than to actin.

2. Immunoglobulin Superfamily

Another major group of cell-to-cell adhesion molecules are members of the Ig superfamily. Their extracellular portions are characterized by the presence of at least one, and usually multiple, immunoglobulin-like domains (3, 4). Included in this group are several nervous system cell adhesion molecules, such as the neural cell adhesion molecule (N-CAM), L-1, and TAG, which are involved in neuronal guidance and fasciculation. Several members of the immunoglobulin family are concerned with antigen recognition and adhesion in T cells. These include the following: the T-cell receptor (CD3) and its co-receptors CD4 and CD8, which together recognize the complexes of antigen peptide and major histocompatibility complexes on other cells; the major histocompatibility complex molecules themselves; and lymphocyte function related antigen 2 (LFA-2 or CD2), a receptor for another immunoglobulin-like molecule, LFA-3, expressed on other cells. Another group of immunoglobulin-like cell adhesion molecules includes the so-called intercellular adhesion molecules, ICAM-1, -2, and -3, which are more widely expressed, for example, on epithelial and endothelial cells, and V-CAM on endothelial cells. These are involved in the inflammatory response.

The immunoglobulin superfamily is large and diverse, probably because the basic structure of the immunoglobulin domain is versatile and readily adaptable to different binding functions (see Immunoglobulin Structure). Among these molecules, however, the T cell receptor and the immunoglobulins themselves have somatically-variable domains necessary for antigen recognition. Members of the superfamily are even present in insects, where they are involved in nerve connections; the association of immunoglobulin-like domains in cellular recognition preceded the immune system in evolution.

3. Integrins

Both cell-to-cell and cell-to-matrix receptors are contained within this large family of adhesion molecules. Integrins are heterodimers consisting of one a chain and one b chain, both of which are necessary for adhesive binding (5). Seventeen different a chains and eight different b chains are now known. Integrins may be classified into subfamilies according to which b subunit is involved in the complex. Thus b1 integrin may associate with one of nine different a subunits, to give a series of matrix receptors of differing specificity. The b2 integrins, on the other hand, are a family of cell-to-cell adhesion molecules of lymphoid cells with three alternative a subunits. The classification is made more complicated because some a subunits can associate with different b subunits (for example, a6b1 and a6b4).

Some integrins are apparently quite specific in their ligand-binding properties—for example, a5b1 for the Arg–Gly–Asp tripeptide sequence of fibronectin—whereas others are promiscuous—for example, avb3, once regarded as the vitronectin receptor, also binds fibronectin, fibrinogen, von Willebrand factor, thrombospondin, and ostepontin. An interesting example is a4b1, which binds both the IIICS domain of fibronectin and V-CAM on endothelial cells. To complicate matters further, individual cell types usually express multiple integrins. A good example to consider here is the blood platelets that express predominantly aIIbb3 (GPIIb/IIIa), which binds fibrinogen, fibronectin, von Willebrand factor, and vitronectin, but also lesser amounts of aVb3, a5b1, a2b1 (collagen), and a6b1 (laminin).

4. Selectins

Most cellular interactions seem to entail homophilic or heterophilic protein–protein interactions. However, the selectins constitute a family of cell adhesion proteins that bind to carbohydrate. Selectins have **lectin**-like carbohydrate-binding domains at their extracellular *N*-terminal extremities (6). One of these, L-selectin (L = leucocyte) is a “homing receptor,” mediating regionally specific adhesion of lymphocytes to endothelium in peripheral lymph nodes. This molecule is also involved in the adhesion of neutrophils to endothelium during the inflammatory response. Two other members of this family, E-selectin (E = endothelial) and P-selectin (P = platelet), also participate in the inflammatory response. E-selectin is unregulated on endothelial cells over a period of hours after stimulation by inflammatory mediators. P-selectin is contained within Wiebel–Palade bodies of endothelial cells and platelet a granules, from which it is rapidly mobilized on activation, mediating adhesion to neutrophils and monocytes.

CEN Sequences

Autonomously replicating sequences (ARS) are not stable *in vivo* during cell division and cannot be used readily as plasmid **vectors**. But, if certain DNA sequences that function as centromeres in yeast (CEN sequences) are grafted onto a **plasmid** already containing an ARS, the resulting vector plasmid is stabilized and segregates accurately during **mitosis** and **meiosis**. The CEN sequences are necessary for attaching chromosomes to the **mitotic spindle**, presumably through some specific connector proteins that join the microtubules to the centromere. In addition, CEN sequences can be used to construct linear chromosomes by preventing circularization by the addition of **telomeric** sequences that are normally at the end of chromosomes (1, 2).

Conserved features of *Saccharomyces cerevisiae* CEN SEQUENCES are confined to a region of about 120 bp. The highly conserved 8 bp at the left (PuTCACPuTG, where Pu = purine) constitute the left boundary of a functional CEN sequence. The right boundary lies within or just beyond the 25 bp at the right, with the consensus sequence TGT-T-TG–TTCCGAA—AAA, where - indicates no specific base. A mutant that lacks the left conserved element can still assemble into a centromere that is partially functional in mitosis and well functioning in meiosis. The sequences between the two conserved terminal DNA elements are not essential for centromere function. Their lengths can be increased by 50% or their sequence from 6 to 12% in GC content without measurable changes in mitotic or meiotic segregation of plasmids carrying such CEN mutations (3). The right boundary sequence appears to be a binding site for a protein, as evidenced by various inactive mutations, especially in the central CCG sequence, and by an exonuclease blocking assay (4). The left element, which carries the **palindromic** sequence CACPuTG, binds the **helix–loop–helix motif** protein CPF1 (5).

Centrifugation

Centrifugation is a technique often employed during isolation or analysis of various cells, **organelles**, and biopolymers, including proteins, **nucleic acids**, lipids, and carbohydrates dissolved or dispersed in biologically relevant solvents (ie, typically aqueous buffers). It is also applicable to synthetic macromolecules dispersed or dissolved in nonaqueous, organic solvents. In this technique, the sample (comprising a liquid phase and a solute) is placed in a suitable vessel, and the vessel is spun in a centrifugal rotor. The centrifugal force created by the spinning rotor causes the solute sample to sediment out of solution (typically, though not always, toward the base of the vessel) (Fig. 1). The centrifugal force applied to the sample is akin to gravitational force (acceleration) and is measured in gravities, as in $n \times G$ (the gravitational constant G equals 6.6720×10^{-11} N-m^2/Kg^2). The extent to which the sample sediments toward the base of the vessel is a function of a series of complex interacting factors related to the properties of the solute alone and of the system as a whole (solvent and solute) (Fig. 1, Tables 1 and 2).

Figure 1. A schematic diagram of a centrifugation experiment.

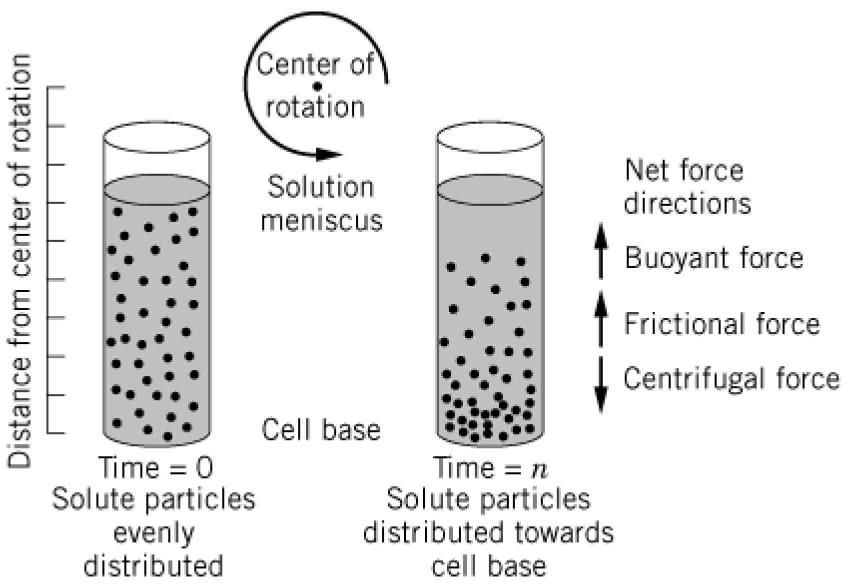

Table 1. The Forces Involved in Centrifugation

Proportionality Constant or Force Equation	Cause or Definition	Dimensions

Centrifugal force = w^2rm	Centrifugation of solute of mass, *m*	(g-cm) (radians/sec)
Buoyant force = $-w^2rm_s$	Solvent of mass m_s; displacement by sedimenting solute	(g-cm) (radians/sec)
Frictional force = $-fv$	Resistance to movement of solute particle at velocity *v* through solvent	$g\text{-}cm/sec^2$

Table 2. General Proportionality and Descriptive Constants for Centrifugation

Term	Definition	Dimensions
Angular velocity = w = (2r/60) × rpm	$2\pi\left(\frac{\text{radians}}{\text{revolution}}\right)\left(\frac{\text{revolutions}}{\text{min}}\right)\left(\frac{1\text{min}}{60\text{sec}}\right)$	radians/sec
Frictional coefficient = *f* = 6phr$_s$	Stokes' law frictional coefficient for a sphere of equivalent radius r_s in a solvent of viscosity h.	g/sec
Diffusion coefficient *D*	Defined by Fick's first law (see Refs. 1 and 2) for an ideal solution at infinite dilution as D = RT/N*f*, e.g., 1 Fick = 10^7 cm^2/sec	cm^2/sec
Sedimentation coefficient *s*	The velocity of sedimentation per unit of centrifugal force	sec
Solution density r	Mass per unit volume	g/cm^3
Solution viscosity h	The resistance to change within a fluid, a type of internal friction	poise or dyne-sec/cm^2
Solute partial specific volume *v*	The change in volume per unit mass	cm^3/g
Solute buoyant density	Effective density determined by isopycnic centrifugation in a specific gradient medium	g/cm^3
Avagadro's number *N*	6.022×10^{23}	$mole^{-1}$
Gas constant *R*	8.314×10^7	ergs/K-mole

The factors that define the entire sedimenting system include (1) the rate w at which the rotor spins; (2) the length of time for which the centrifugal force is applied; (3) the solvent density r; and (4) the system temperature *T*. The factors specific to the sedimented solute include (1) the radial distance *r* of the solute from the central axis of rotation; (2) the solute partial specific volume *v*; (3) the solute diffusion coefficient *D*; (4) the solute **frictional coefficient** *f*; and (5) the solute sedimentation coefficient *s*. During centrifugation (Fig. 1), the centrifugal force is opposed by buoyant density and frictional forces. Under these conditions it can be shown that the rate of sedimentation of the solute molecules of weight-average molecular weight M_w and moving as a radial boundary r_b is defined by

$$\text{Boundary velocity} = v = \frac{M_w(1-\bar{v}\rho)}{Nf}\omega^2 r_b. \tag{1}$$

Operationally, the technique can be divided into preparative and analytical modes, which differ principally in whether the actual recovery of the materials that have been centrifugally separated is desired or practical (Fig. 2).

Figure 2. Common preparative and analytical methods used in centrifugation.

Preparative Isolation and Recovery of Solute(s)	Solute Analytical Information
Common Methods	Common Methods
Selective pelleting	Sedimentation velocity
Density gradient separations	Sedimentation equilibrium
Rate zonal	
Flotation	
Isopynic	

1. Preparative Centrifugation and Ultracentrifugation

Preparative centrifugation (Fig. 2) is routinely employed in isolating, separating, and purifying a variety of biological and cellular/subcellular components. Some examples include chromatin, coated vesicles (see Clathrin), cytosolic proteins, DNA, **Golgi**, inclusion bodies, **lipoproteins**, **lysosomes**, **Microorganisms**, **Microsomes**, mitochondria, myelin, **nuclei**, **glycoproteins**, **RNA**, **Peroxisomes**, plasma membranes, **polysomes**, proteoglycans, ribosomes, synaptosomes, and **viruses**. Preparative centrifugation has two primary modes of separation. Solutes can be selectively pelleted from solution, as described here, or they can be subjected to separation along a solution density gradient (see Density Gradient Centrifugation).

1.1. Selective Pelleting or Differential Centrifugation

Clearing macromolecular components from solution is probably the most commonly employed preparative centrifugation technique. In this method the sample is subjected to centrifugation, usually, though not necessarily, at a constant rotor velocity. Over time, a pellet of sedimented material is deposited along the most radially distant wall of the tube containing the sample (Table 3). At a sufficiently high rotor speed (and therefore high centrifugal force), virtually all macromolecular solute components heavier than the solvent are pelleted out of solution over time. Because it is possible to select a variety of rotor velocities, sample tube dimensions, rotor types, centrifugation run times, etc., it is often possible to accomplish a significant level of purification by pelleting alone because the method of separation relies on the differential sedimentation rates of small and large solute components. For example, large components are typically removed by sedimentation at low speeds for short periods of time. If the supernatant from such a centrifugation is placed in a new container and centrifuged again at a higher rotor velocity for an appropriate period of time, it is possible to collect another distribution of particles from solution, this time of smaller dimensions than the first. Therefore repeating this process yields a series of pelleted samples with distributions of solute molecules, each of which have accumulated under conditions differing only in their centrifugal forces and thus have different sedimentation rates. Most samples of biological interest are complex mixtures of interacting solutes in solution at widely different concentrations. Because the size, shape, and concentration distributions of these components are routinely broad, together they exhibit very broad distributions of sedimentation rates. Thus the technique of solute pelleting, though widely applied, is only rarely sufficient to purify a single component completely. Typically it is used to selectively enrich, often to a high degree, a preparation of cellular or subcellular components in a single component. For small biological solutes, such as soluble cytosolic proteins prepared by a protein isolation procedure, pelleting is routinely employed along with differential precipitation (**salting out**) using ammonium sulfate (see Sulfate Salts) to yield highly enriched, sedimented precipitates of the desired protein components.

Table 3. Descriptive Constants for Preparative Centrifugation

Term	Definition
Clearing factor, k	time (hours) = $k/s, s$ = *svedbergs*; the value of k varies with each rotor type and compares the relative rotor efficiencies for pelleting
Clearing time, t	t = k/s (see clearing factor, above); the time required to pellet a particle to the base of the tube
Flotation Coefficient, f_s	For particles which float in a particular solution in a centrifugal field, it is similar to the sedimentation coefficient, units are in sec.
Relative centrifugal force or (RCF)	RCF = $1.12r\,(\text{rpm}/1000)^2$, where r is in mm; the ratio of the centrifugal force at a specific rotation rate in rpm for a particular rotor at a particular radius r from the center of rotation of that rotor to the gravitational force of the Earth at sea level.
Square-root speed reduction law	$[\text{Maximum allowed rotor speed} = \dfrac{\text{Desired speed}}{\sqrt{\dfrac{\text{Max allowed solution density}}{\text{actual solution density}}}}$ Used to calculate the permissible rotor speed in rpm when using nonprecipitating gradient materials at densities greater than the manufacturer permits in a rotor

Pelleting is also of great use when applied to harvesting viruses or cells from various growth media. When cells or viruses are used to produce various recombinant proteins of pharmaceutical interest, centrifugal harvesting is often employed to capture the biological component from the (usually large) fermentation broth. In these applications, a preparative centrifuge and rotor capable of accepting a continuous flow into and through the rotor are employed. The centrifugal force applied to the sample stream as it passes through the rotor is adjusted to permit selective pelleting of cells within the centrifuge rotor. The cell-depleted broth passes out of the rotor/centrifuge and into a receiver vessel, and, then the harvested cells are recovered from the centrifuge rotor.

Centromeres

The centromere (kentron = center; meros = part) is the region of the mitotic chromosome that participates in chromosomal movement. The mitotic spindle attaches to a specialized structure at the centromere known as the kinetochore. The motor responsible for the movement of the chromosomes toward the spindle poles during mitosis is also located at the centromere. Morphologically, centromeres are distinguished by their appearance at metaphase and anaphase as constrictions in the chromatin and by their heterochromatin staining pattern. A chromosome without a centromere is described as acentric. It does not segregate properly during cell division and is rapidly lost in successive cell cycles.

Centromeres occupy different positions in chromosomes, and they are useful markers. Chromosomes with a single centromere are called monocentric. Chromosomes with centromeres near one end are called acrocentric, those with the centromere visible at or near the middle are metacentric, and those with the centromere truly at the end are telocentric. The monocentric chromosomes found in most metazoan plants and animals almost always have centromeres embedded in segments of heterochromatin. Some organisms, such as plants in the genus *Luzula*, have holocentric chromosomes with diffuse centromeres. In these chromosomes the spindle attaches to the centromeric heterochromatin that is distributed along the entire length of the chromosome (1). Mammalian tissue culture cells occasionally develop chromosomes with multiple centromeres (2). A chromosome with two centromeres is called dicentric. Dicentric chromosomes are often the result of chromosome breakage followed by fusion. A dicentric chromosome normally breaks at anaphase, when the centromeres are pulled in opposite directions. The holocentric chromosomes found in certain plants have developed as yet unknown mechanisms to avoid this problem.

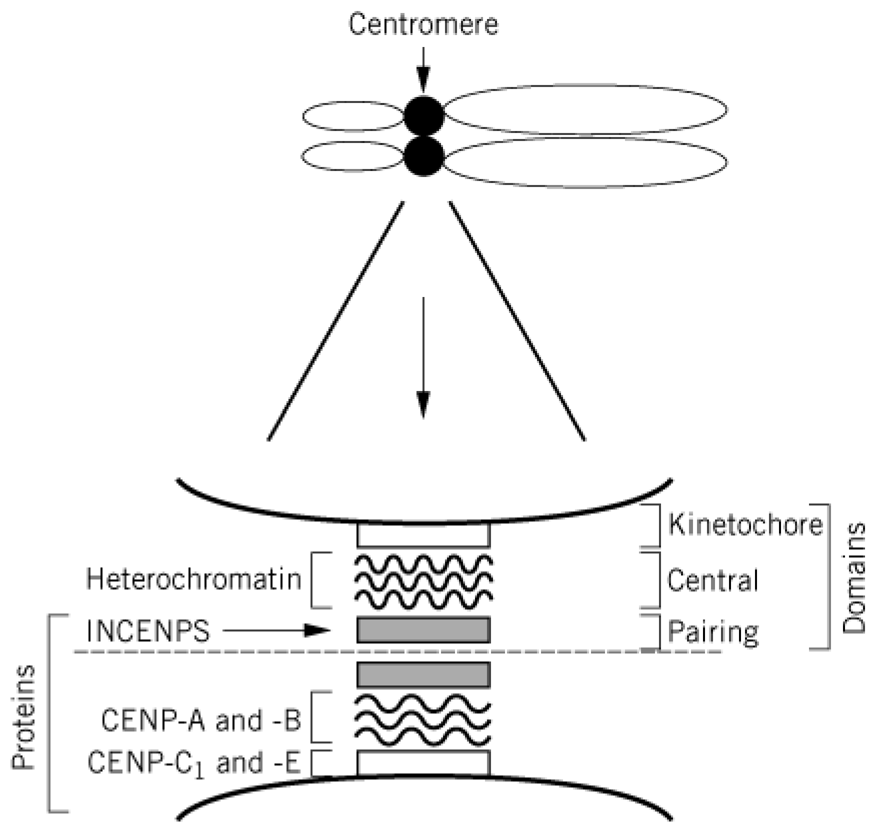
Centromeres represent highly specialized chromosomal organelles. The simplest types of centromeres are found in the yeast *Saccharomyces cerevisiae*. The presence of these centromeric sequences, together with the autonomously replicating sequences that serve to direct DNA replication within exogenous plasmid DNAs allow these small minichromosomes to be stably maintained through cell division. The centromeric sequence allows the minichromosomes to be segregated in mitosis and meiosis with accuracy. Maintenance of minichromosomes through cell division also provides a simple assay for the definition of functional centromeric sequences in yeast.

All of the yeast centromeres are functional as small segments of DNA about 1,000 base pairs (1 kbp) or less in length. Nucleosomes are assembled in specific positions on these DNA sequences, and they contain a specialized histone H3 molecule (Cse4p) (16). Within each segment of centromeric DNA are similar nucleotide sequences. In the middle of the centromeric DNA is a 220-bp segment that constitutes the centromeric core, that contains the minimal sequence necessary for centromeric function. Only a single spindle fiber attaches to a yeast centromere (4). If this attachment is to the core, then the nucleoprotein complex assembled on the core also functions as a kinetochore.

Mammalian centromeres are considerably more complex than those in *S. cerevisiae*. Early experiments on the centromere of the human Y-chromosome established that much more DNA is required for the chromosomal segregation function than in yeast. Over 300 kbp of DNA, including 200 kbp of a-satellite DNA, are required to generate a functional centromere, suggesting the epigenetic—i.e., meta-DNA—mechanisms establish centromere location in cells of metazoa (17), a notion supported by the appearance of neo-centromeres in mammalian cells over nonrepetitive DNA (18). For native centromeres, however, deletion of the a-satellite DNA makes the centromere inactive (5).

The centromere can be broken up into three distinct structures, the kinetochore and the central and pairing domains (Fig. 1). The protein constituents of the centromere have been identified primarily through the use of autoantibodies from patients with rheumatic disease. These include the inner centromeric proteins (INCENP) and the CENP A, B, and C proteins. Immunological staining reveals that the INCENPs are in the pairing domain. The central domain contains dense chromatin known as constitutive heterochromatin. The kinetochore is anchored to this heterochromatin (Fig. 1). The DNA within this heterochromatin is composed primarily of various families of repetitive DNA (satellite DNA).

Figure 1. An expanded view of the centromere of a mammalian chromosome. The centromere is a bipartite structure. The central axis between the pairing domains is indicated by the dashed line. The relative positions of heterochromatin, the INCENPS, and CENPS are indicated within the kinetochore and the central and pairing domains.



The a-satellite family of DNA sequences (which comprises 5% of the human genome) is probably present at the centromeres of all human chromosomes. The basic repeat 171 bp long, occurs in large arrays up to 3×10^6 bp long. The a-satellite repeats assemble a specialized chromatin structure that provides many insights into the molecular nature of constitutive heterochromatin. It has been long that nucleosomes are positioned with respect to the nucleotide sequence found in a-satellite DNA so that histone-DNA contacts would begin and end at particular sites (6). An important point is that a single nucleosome is believed to exist on every 171 bp repeat. In modified form, this DNA sequence also provides the foundation for crystallization of the nucleosome more (7). Several interesting specialized chromosomal proteins also associate with a-satellite DNA. A 10-kDa protein, high mobility group protein (HMG-I/Y) binds to a-satellite DNA specifically *in vitro* (8). The HMG-I/Y protein binds selectively in the minor groove of the double helix, associating with runs of six or more AT base pairs. In addition HMG-I/Y also probably recognizes certain secondary structural features of the DNA molecule. CENP-B specifically recognizes a 17-bp DNA sequence (5′ CTTCGTTGGAA CGGGA 3′) in a subset of a-satellite DNA repeats. The DNA-binding domain of CENP-B is necessary and sufficient for localization to the centromere in vivo (9). CENP-B contains anionic regions rich in aspartic and glutamic acid residues, which are characteristic of many proteins that interact with chromatin. CENP-B is found throughout the centromeric heterochromatin beneath the kinetochore plates (see Kinetochore). Although the exact functions of CENP-B in heterochromatin are not known, it may play a role in the higher order folding of centromeric chromatin through self-assembly mechanisms. Although CENP-B is found at all mammalian centromeres examined, the CENP-B recognition element is not found in all a-satellite DNA (10). It is possible that CENP-B can also be targeted to centromeres through interactions with other protein components.

CENP-A is also specifically associated with centromeric DNA and is especially interestin because it shares homology with core histone H3. Recent sequence analysis has revealed that CENP-A is a very specialized H3 variant (11). Each core histone and CENP-A have two domains, and amino-terminal tail domain that lies on the outside of nucleosomal DNA and a carboxyl-terminal, histone-fold domain that is involved in protein—protein interactions and in wrapping the DNA. CENP-A has a highly divergent amino-terminal tail domain and a relatively conserved carboxy-terminal, histone-fold domain. The targeting of CENP-A to centromeric DNA is directed by the histone-fold domain, and it is very likely that a highly specialized, dedicated chromatin assembly mechanism exists to enable the selective heterodimerization of CENP-A with histone H4 over centromeric DNA (19). Although the exact mechanism by which this is achieved is still unknown. Characterization of a CENP-A homologue in yeast (CSE4, Ref. 3) establishes that this specialized histone is essential for normal chromosomal segregation during mitosis. Genetic evidence suggest that CSE4 heterodimerizes with histone H4 (19). This establishes that specialized nucleosomal structures are present at the centromere, in addition to the presence of positioned nucleosomes. Clearly, the centromere represents a highly differentiated chromosomal domain even at the most fundamental level of chromatin structure.

CENP-C is a large 107-kDa protein that is highly hydrophilic and basic (pI = 9.4) (13). CENP-C is concentrated in a narrow band immediately below the inner kinetochoric plate at the interface between the chromosome and the kinetochore (Fig. 1). CENP-C binds DNA directly and is required for normal kinetochoric assembly. CENP-C is found only at the active centromere of a stable dicentric chromosome, suggesting a direct role in centromeric function (14). Other components of the centromere include CENP-E, which resembles microtubule-binding motor proteins. CENP-E is a 312-kDa polypeptide chain with a tripartite structure consisting of globular domains at the N- and C-termini, separated by a 15,000-residue a-helical domain that is predicted to form coiled-coils. CENE-E colocalizes to the centromere and kinetochore during metaphase, but it is released from the centromere at the onset of anaphase, when it is degraded. CENE-E functions as a kinetochoric motor during the early part of mitosis (15) (See Kinetochore). The proper cohesion between centromeres on sister chromatids prior to the metaphase-anaphase transition in mitosis, and centromere nondisjunction on sister chromatids during meiosis I are essential for proper chromosome behavior. Both are effected by the preferential association of the cohesion complex (120) with centromeres (16, 21); in addition to the cohesins, in metazoa, noncohesion proteins as MEI-S322 also associate with the centromere and mediate kinetochore assembly as well as sister chromatid cohesion during meiosis (22).

The assembly of the centromere and the mechanisms of kinetochoric association with chromatin offer perhaps our best opportunity to understand the construction of a specialized chromosomal domain at the biochemical level.

Čerenkov Radiation

Čerenkov radiation, or the Čerenkov effect, is the visible bluish-white light surrounding a radioactive source observed in a pool of water. The phenomenon was first reported by the Russian physicist P. A. Čerenkov in 1934 (1), who was one of several scientists who observed the glow of light in close proximity to intense gamma-radiation sources. This effect is the reason why radiation sources are said to “glow in the dark.” Its importance for molecular biology is that it is routinely used to measure the amount of the isotope ^{32}P in a sample (see Radioactivity and Phosphorous Isotopes).

The Čerenkov effect can be explained by classic electromagnetic theory and principles of optic science. Analysis of Čerenkov radiation has shown fundamental relationships between the velocity of charged particles, light, the intensity of the light, and its wavelength spectrum (2). Only a small fraction (<0.1%) of the charged-particle radiation is emitted by the absorbing medium as coherent light. According to Jelley (3), who provided the first scientific explanation for the Čerenkov effect, the observed light results from charged particles traversing a transparent dielectric medium, one that does not conduct electricity. Charged particles are produced in the absorbing medium (water) when gamma radiation from the radioactive source interacts with the absorber. These charged particles produce local polarization along their path in the dielectric. Light in the visible spectrum is emitted when the polarized molecules in the medium return to their rest state soon after passage of the charged particle. If the velocity of the charged particles is less than that of light in the same medium, the light emitted from molecules in the dielectric is overridden and not observed. However, if the velocity of the charged particles is greater than that of light in the dielectric, a wavefront of light is produced from individual molecules in the dielectric, and the emission is reinforced by constructive interference. The Čerenkov effect is analogous to the bow wave from a ship that travels faster than the velocity of the surface waves, or to the shock wave trailing a supersonic aircraft passing though air. In other words, if the velocity v of a charged particle traversing a transparent dielectric material of refractive index n (= bc) exceeds the velocity of light (c/n) in the medium, or v > c/n and b > 1/n, then Čerenkov radiation is emitted at an angle x relative to the particle direction, where x = arccos (1/bc). The velocity c of light in a vacuum is 2.997×10^{10} cm/s, and b = v/c. The Čerenkov photons form a conical wavefront of half-angle (90° – x) behind the particle.

The polarization effect actually decreases the energy lost by a charged particle that traverses a condensed medium, whereas the production of Čerenkov radiation increases the loss of energy by the particle. The visible spectrum is produced at a frequency interval of about 3×10^{14} Hz. Applications of Čerenkov radiation theory have been developed for detecting single high energy charged particles, measuring the energy of charged particles, and determining angles of incidence.

The light pulses emitted by charged particles traveling in a transparent medium can be collected and counted by modern scintillation counters. The amount of light produced in water is small compared to that produced in the presence of a scintillator, but it can be detected from beta-emitting radionuclides if their energy is greater than the threshold energy of 265 keV. The average energy of phosphorous-32 beta particles is 695 keV, so the majority of emitted beta particles can be detected.

Chain-Termination (Dideoxy) DNA Sequencing

The relative length of a DNA chain is determined easily and accurately by gel electrophoresis, and the most common types of DNA sequencing use methods that map sequence information to DNA chain lengths. For chain-termination DNA sequencing, this is done by synthesizing the complement of the DNA using a **DNA polymerase** under conditions that terminate synthesis at sites where only one of the four bases occurs. Thus, all sequencing experiments are done in three steps. First, a single pure DNA segment is isolated for sequencing. Second, this DNA is used as a template for synthesis catalyzed by a **DNA polymerase** with mixtures of normal and chain-terminating nucleotides. Finally, the products of this synthesis are separated according to size by gel electrophoresis. Numerous variations on each of these steps are commonly used.

1. Isolation of Specific Segments of DNA

Most of the techniques of molecular biology rely on isolating specific segments of DNA, and sequencing is no exception. In fact, the first practical application of chain-termination sequencing relied on cloning specific DNA segments using vectors derived from **M13 bacteriophage**. These bacteriophages contain a single-stranded DNA **chromosome** that accommodates inserts of more than 5000 bases. Isolating the single-stranded DNA in pure form from these phages is simple and inexpensive, so these vectors are still commonly used. Similarly, virtually all plasmid vectors are commonly used for DNA sequencing, and essentially any clone of up to about 200 kb can be sequenced by cycle sequencing techniques, provided sufficient DNA can be purified. Another popular way of isolating DNA for sequencing is by using the polymerase chain reaction (**PCR**). With nested PCR primers, it is now relatively simple to amplify segments of **genomic** DNA for direct sequencing in a matter of hours.

2. Chain Termination Reactions

Chain termination reactions require the isolated template DNA, a suitable primer, 2′-deoxynucleoside triphosphates (dNTPs), 2′,3′-dideoxynucleoside triphosphate (ddNTP) chain terminators, and a DNA polymerase. The most critical component is the DNA polymerase. Many DNA polymerases have been used for sequencing, including those from eubacteria, such as the DNA polymerase I (**Klenow fragment**) of *Escherichia coli*, **reverse transcriptases** from retroviruses, such as avian myeloblastosis virus, polymerases from bacteriophage, such as **T7 phage** DNA polymerase, and polymerases from archaea, such as *Thermococcus litoralis*. Virtually all of these have been genetically or chemically modified to eliminate exonuclease activities or to improve reaction rates with the ddNTPs.

The most recent examples of polymerases specifically engineered for DNA sequencing are enzymes derived from *Thermus aquaticus*, Taq DNA polymerase. Two regions of this polymerase are modified to produce particularly effective polymerases for DNA sequencing. First, *Taq* DNA polymerase has 5′-3′ exonuclease activity, which degrades sequencing primers. The first 300 amino acid residues at the N-terminus of this enzyme are required for this exonuclease activity. Portions of this **domain** can be deleted, or the activity can be eliminated by point mutation. Secondly, normally *Taq* DNA polymerase is relatively inefficient at using ddNTPs. As discovered by Tabor and Richardson, this can be improved more than 10^4-fold by changing residue Phe667 to Tyr. This modification improves ddNTP usage, and it also greatly improves the quality of the sequence data obtained. Native *Taq* DNA polymerase produces sequencing bands that vary in intensity more than 15-fold, depending on the nearby sequence. In contrast, Tyr667 polymerase produces bands that vary in intensity by less than threefold. This makes interpretating the results of the electrophoretic separation much more accurate. A number of polymerases that have this modification are now commercially available, as is T7 DNA polymerase, which naturally has a tyrosine at the corresponding position.

3. Cycle Sequencing

Cycle sequencing is the process of using repeated cycles of thermal denaturation and polymerization to produce greater amounts of product in a DNA sequencing reaction. The amount of product DNA increases linearly with the number of cycles. (This distinguishes it from PCR, which uses two primers so that the amount of product increases exponentially with the number of cycles.) During each cycle, the thermostable DNA polymerase extends the annealed primer molecules, typically at 60° to 70°C. The mixture is heated above the melting temperature of DNA (95°C), dissociating the extended primer from the template. Then, the mixture is cooled, allowing another molecule of primer (which is present in excess) to anneal to the limited supply of template. Further cycles of extension and denaturation result in producing much more extended primer than the amount of template used. This improves the sensitivity of the sequencing experiment, and it also allows ready use of double-stranded templates for sequencing. Generally, cycle sequencing works much more reliably over a wider range of template concentrations than noncycled protocols. This accounts for its nearly universal application for large-scale DNA sequencing projects.

4. Methods for Labeling DNA Sequences

The products of the chain termination reactions must be labeled for all practical DNA sequencing methods. The original label was a-^{32}P dATP that was simply added to the chain-termination reaction. Newly synthesized DNA was labeled with radioactive phosphorous, and detected by simple autoradiography. More recently, the lower energy isotopes ^{33}P and ^{35}S (in the form of a-thio-dATP) have been used because they generate autoradiograms with higher resolution. These offer the advantage of using less total radioactivity than other methods. In addition, only specifically terminated, elongated DNA chains are labeled and therefore visualized by autoradiography, which eliminates the background bands and stops normally observed on DNA sequencing autoradiograms and results in extremely clean sequence data.

Automated, **fluorescent** DNA sequencing methods were introduced in 1987 and have become essential tools for large-scale sequencing efforts. The sequence products used by these automated systems are labeled by fluorescent primers (dye primers) or fluorescent dideoxynucleotides (dye terminators). These have been used in single-color detection instruments, and in four-color multiplex instruments in which the four bases are distinguished by color. Recent innovations include fluorescent dye-labeled DNA primers that exploit fluorescent **energy transfer** to optimize the absorption and emission properties of the label. These primers carry a fluorescein derivative at the 5′-end as a common donor and rhodamine derivatives attached to a modified thymidine within the primer sequence as acceptors. Adjustment of the donor–acceptor spacing by placing the modified thymidine in the primer sequence allows generating four primers. All have strong absorption at a common excitation wavelength (488 nm) and efficient fluorescent emission at 525, 555, 580, and 605 nm. These improve the sensitivity and accuracy of the automated sequencing system.

Fluorescent dye-labeled ddNTP terminators have also been used extensively for DNA sequencing, and those that use the energy-transfer principle are also commercially available. Like the radio-labeled terminators, they have the advantage of labeling only specifically terminated, elongated DNA chains, so that background bands are eliminated.

5. Electrophoresis and Automated Sequencing

The high-resolution separation of DNA fragments by size is essential for all sequencing methods. For radioactively labeled DNA sequencing experiments, this is done by using gels cast in glass plates that are 0.2 to 0.4 mm thick, 40 to 80 cm long, and wide enough to accommodate 32 to 96 samples. Typically, the gels are 4 to 8% polyacrylamide cross-linked with *N*,*N*′-methylene bisacrylamide (see Polyacrylamide) and contain tris borate buffer (0.089 M, pH 8.3) and 7 to 8 M urea. After electrophoresis for 2 to 18 hours, the gels must be removed from the glass plates for autoradiography and reading of the sequence of 200 to 400 nucleotides. Because these gels are cumbersome to make and use, considerable effort has been made to improve separation methods. The most commonly used methods involve a sensitive fluorescent detection instrument that continuously monitors the migration of fluorescent-labeled DNA past a fixed position on the gel. The results are collected and evaluated directly by computer, producing finished sequence information. This saves considerable labor in "reading" the sequence from the gels and improves the resolution sufficiently to read 500 or more bases routinely from a single sequence experiment. Noncross-linked "gels" have also been introduced that run in 50 to 100 micron diameter, 40 to 70 cm long capillaries with fluorescent detection. The efficient heat transfer of these electrophoresis media allow faster, high-resolution separations.

Chaotropes: Kosmotropes

Compounds that increase and decrease, respectively, the aqueous solubility of proteins are classified as chaotropes and kosmotropes (1). Therefore, the Hofmeister series of ions may be divided into these two categories. For the series of anions, solubilization in water is promoted in the order

$$SCN^- > CLO_4 > I^- > Br^- > Cl^- > F^- > HPO_4^{2-} > SO_4^{2-}$$

Those on the left-hand side of Cl^- generally increase the solubility; they are called *chaotropes*.

Those on the right-hand side of Cl^- act as salting-out agents; they are called *kosmotropes*. Chaotropes are **water**-structure breakers; kosmotropes, to the contrary, are water-structure makers. A similar division may be made about the Na^+ ion in the cationic Hofmeister series. In the salts, the predominant effect is that of anions. An important characteristic is that the effects are additive for all the species in the solution.

Organic molecules also affect water structure and can be classified as chaotropes and kosmotropes. Thus, urea, glycine, formamide, and acetamide are chaotropes. Organic kosmotropes are sucrose, polyols, the methylacetamines, methyl formamides, and methyl ureas. Except for sugar and the polyols, caution must be exercized in using organic kosmotropes, since their action may reverse itself at high concentration.

The mechanism of action of these molecules in stabilizing or destabilizing protein structure, and as a corollary in acting as **salting in** or **salting out** agents, is related to their effects on the orientation of water molecules through polar interactions with the water hydrogen bond donor and acceptor properties. By perturbing or strengthening the interactions between water molecules (maximization of hydrogen bond formation), these molecules exercise their chaotropic or kosmotropic actions. At interfaces, the water structure is already perturbed by the nonavailability at the surface of other water molecules for hydrogen bond formation. This is true for the water–air interface. Similar perturbations may occur at interfaces with proteins and other biological entities—hence, the effect on their properties. Control of reactions by the chaotropic/kosmotropic effect is very widespread in biological systems. Its principal diagnosis is that the compound which affects a particular process must be present at a high concentration (local concentration for cell compartments and organelles).

Chaperonin

The chaperonins are a family of **molecular chaperone** found in all types of cell whose function is to assist the correct folding of certain polypeptide chains that have been either newly synthesized or generated from native proteins by environmental stresses that cause partial unfolding.

1. Nomenclature

The term *chaperonin* was suggested by Sean Hemmingsen (1) to describe a family of highly sequence-related molecular chaperones found in chloroplasts, mitochondria, and **eubacteria** such as *Escherichia coli*. This term was proposed to simplify the existing complex nomenclature for different members of this family whose close relationship was only realized when cDNA for the chloroplast chaperonin was sequenced (1). The term was subsequently extended to distant homologues found in **archaebacteria** and the eukaryotic cytosol (2, 3). The two subfamilies of the chaperonin family are referred to as follows:

1. The GroE or group I subfamily, found in chloroplasts and other plastids, mitochondria, and all eubacteria
2. The TCP-1 or group II subfamily, found in archaebacteria and the eukaryotic cytosol

The GroE terminology reflects the fact that the eubacterial protein was first identified by genetic studies in four laboratories in 1972/73 as a bacterial protein required for the replication of **bacteriophage** such as lambda in *E. coli* (4). “Gro” refers to phage growth, and the suffix “E” refers to the observation that the phage growth defect is overcome when the phage carries a mutation in the head gene E. The TCP-1 terminology is derived from the identification of a protein called the *t*-complex polypeptide encoded by the mouse T locus (5). The mitochondrial members of the GroE subfamily are sometimes referred to as “hsp60” proteins, but this terminology should not be used to describe the chaperonins as a whole, since the eukaryotic TCP-1 members and the chloroplast GroE members are not **heat shock** proteins.

Table 1 presents a suggested nomenclature and useful abbreviations for members in both subfamilies, and lists other names that are used. Some authors confine the abbreviation “cpn60” to the GroE subfamily, but this restriction is inconsistent with the fact that the TCP-1 members share with the GroE members subunit molecular masses of approximately 60 kDa.

Table 1. Nomenclature of the Chaperonins

Preferred Name	Other Names	Useful Abbreviations
GroE subfamily		
Eubacterial chaperonin 60	GroEL (*E. coli*), 65-kDaantigen	Eu cpn60
Eubacterial chaperonin 10	GroES (*E. coli*), cochaperonin	Eu cpn10
Mitochondrial chaperonin 60	hsp60, mitonin, HuCha60	Mt cpn60
Mitochondrial chaperonin 10	hsp10, cochaperonin	Mt cpn10
Chloroplast chaperonin 60	Rubisco subunit binding protein	Ch cpn60
Chloroplast chaperonin 10	chaperonin 21, cochaperonin	Ch cpn10, Ch cpn21
TCP-1 subfamily		
Cytosolic chaperonin 60	*t*-Complex polypeptide 1, chaperonin-containing TCP-1, TCP-1 ring complex	Cyt cpn60, TCP-1, CCT, TRiC
Archaebacterial chaperonin 60	Thermophilic factor 55, thermosome	Ar cpn60, TF55

2. Function

The main function of the chaperonins is to assist the folding of certain newly synthesized polypeptide chains into their biologically active conformations (see Protein Folding In Vivo). They achieve this end, not by providing steric information required for each chain to fold correctly, but by sequestering each partially-folded chain in a protected compartment generated by the oligomeric structure of the chaperonin molecule. In this compartment, each chain can continue to fold to a point where aggregation with other partially folded chains is no longer a problem (6-9). This aggregation arises because some proteins fold via intermediate states that expose **hydrophobic** surfaces transiently and are thus subject to intermolecular interactions with similar states. This aggregation effect can sometimes be observed when chemically denatured proteins refold spontaneously in dilute solution *in vitro* (see Protein Folding In Vitro), but its magnitude is expected to be enhanced in the intact cell because of the phenomenon of macromolecular crowding, or excluded volume, thus increasing the effective concentrations of these states by two or three orders of magnitude (8, 9). It should be stressed that, although the chaperonins increase the yield of correctly folded proteins by minimizing aggregation, they do not increase the rate of folding above that achieved by the fastest folding fraction of spontaneously refolding chains that manage to avoid aggregation.

The best evidence for this view of chaperonin function comes from genetic and **pulse-chase** labeling studies with living cells. Several proteins imported into the mitochondria of yeast cells form aggregates when the function of the mitochondrial chaperonin is impaired by mutation (10), whereas about 30% of newly synthesized soluble cytoplasmic proteins in *E. coli* cells become either insoluble or inactive when cpn60 function is switched off by means of a temperature-sensitive mutation (11). *In vitro* studies of the ameliorating effect of added GroE proteins on the aggregation of various pure denatured proteins during their refolding after removal of denaturant are consistent with this antiaggregation role (12-14). *In vitro* studies also suggest that a side effect of this antiaggregation role is the partial unfolding of nonaggregated chains that have become kinetically trapped in misfolded conformations, thus allowing these chains another chance to fold correctly (15); it is not clear how important such an effect may be *in vivo*. In addition, the GroE chaperonins in eubacteria and mitochondria (16) and the TCP-1 chaperonins in the archaebacteria (17) are stress proteins that prevent and reverse the denaturation of some fully folded proteins by stresses such as high temperature.

It must be emphasized that the actual spectrum of proteins that use chaperonin function to fold correctly in intact cells is not known, but preliminary calculations and observations suggest that it is probably a minority in the case of both the GroE chaperonins (9, 18) and the TCP-1 chaperonins (7). Genetic evidence derived from the study of yeast mutants suggests that a major function of the eukaryotic TCP-1 is to assist the folding of tubulin and actin (19), consistent with the observation that newly synthesized chains of actin and tubulin can be isolated from pulse-labeled cells of **CHO** cells in the form of complexes with TCP-1 chaperonin oligomers (20). *In vitro* protein refolding experiments also suggest that the substrate specificities of the GroE chaperonins and the TCP-1 chaperonins are different (6).

3. Structure

The chaperonins occur as large oligomeric structures consisting of two stacked rings of subunits, each about 55–60 kDa in size, surrounding a central cavity or cage in which the protein substrate binds; each subunit catalyzes the slow hydrolysis of ATP to ADP. The GroE chaperonins have seven subunits per ring, whereas the TCP-1 chaperonins have eight or nine. The subunit sequence identity between members of the GroE subfamily is in the range 42–76%, whereas that between members of the TCP-1 subfamily is around 30–40%, but the identity between the subfamilies is much less (15–20%) and is confined to regions corresponding to the ATPase domain in GroE cpn60. The evolutionary implications of these similarities are under debate (7, 21).

A convenient abbreviation for the chaperonin(s) is cpn(s). Thus the subunits of the ring can be called *cpn60 subunits*, and the oligomer can be called *cpn60*. The GroE subfamily also contains another type of oligomeric ring made of seven smaller 10-kDa subunits, called *cpn10*, because there is a slight similarity between the cpn10 subunit sequence and part of the cpn60 subunit sequence (21). GroE cpn60 and cpn10 oligomers bind to each other in 1:1 and 1:2 ratios in the presence of either ATP or ADP, and these binary complexes play an essential role in the protein folding function of these molecules (8, 9). The chloroplast cpn10 oligomer is unusual in that each subunit consists of two copies of a cpn10 sequence fused head to tail and thus is often referred to as *cpn21* (22).

The TCP-1 oligomers found in the eukaryotic cytosol are much more variable than those found in either the archaebacteria or the GroE subfamily, since subunits of the latter consist of only one or two sequences, whereas the former have at least eight different, but related, subunit sequences in each ring (6, 7, 23). For this reason, the eukaryotic TCP-1 oligomers are also called *CCT complexes*, for chaperonin-containing TCP-1 complexes, or *TriC* for TCP-1 ring complexes (see Table 1). The TCP-1 chaperonins do not appear to contain cpn10-like members.

The best-studied chaperonins are the cpn60 and cpn10 oligomers from *E. coli*, termed GroEL and GroES, respectively. GroEL has been extensively studied by both negative stain and cryoelectron microscopy (24, 25) and by X-ray crystallography of a double mutant form (26). GroEL is a cylindrical structure containing a central cavity about 50 Å in diameter (Fig. 1a). Each subunit consists of (*1*) an apical domain to which the protein substrate and GroES bind; (*2*) an equatorial domain that protrudes into the central cavity, which contains the ATPase site and is responsible for most of the intersubunit interactions; and (*3*) an intermediate domain that contains potential hinge sites responsible for the considerable movements of the other two domains revealed by electron microscopy (24, 25). These conformational changes result from the binding of nucleotide and GroES to the GroEL (26) cylinder. The crystal structure of GroES shows a dome-shaped structure with a hydrophilic inner surface that fits over one end of the GroEL cylinder (24, 27, 28) (see also Fig. 1b,c), creating a large enclosed dome-shaped space about 65 × 80 Å in size, inside which the protein substrate continues to fold (29-32) (see also Fig. 1c,d).

Figure 1. Structure and function of the chaperonin system. (**a**,**b**) Space-filling representations showing a top and side view, respectively, of the crystal structure of a double mutant form of GroEL (26). Two adjacent subunits are colored with the apical domains in red and purple, the intermediate domains in orange and yellow, and the equatorial domains in blue and green, respectively. Free passage between the GroEL rings is obstructed by *N*- and *C*-terminal residues not resolved in the crystal structure. (**b**) side view of GroES (28) at the top; two adjacent domains and a single mobile loop that is structured in the GroES crystal due to crystal packing are colored. The loop regions normally protrude from the base of GroES downward toward the GroEL. (**c**) Asymmetrical GroEL/GroES complexes as revealed by cryoelectron microscopy (45). Note the upward and outward movement of the apical GroEL domains interacting with GroES. (**d**) Model of the GroEL/GroES reaction cycle in assisting protein folding (30); see text for details. The term *unfolded protein* refers to a partially folded intermediate that is represented by the light pink spheres; folded protein is represented by the dark pink sphere, while the hatched spheres represent a mixture of folded and partially- folded proteins expected in a population of GroEL molecules. At step 4, GroES may associate with either the protein-containing ring of GroEL or with the opposite empty ring; the latter possibility is not shown. No crystal structure for any TCP-1 chaperonin is yet available, but electron-microscopic studies suggest that the general architecture and overall domain structure of the TCP-1 cylinder resembles that of GroEL (33, 34). The archaebacterial chaperonin was originally termed thermophilic factor 55, because it is virtually the only protein made by thermophilic archaebacteria under heat-shock conditions (35), but it is now termed the *thermosome* (36). Thermosomes generally contain eight subunits per ring, but there are several reports that a significant subset of particles contain nine subunits per ring, while the chaperonins of some *Sulfolobus* species appear all to contain nine subunits per ring (37). The thermosomes of *Pyrodictium*, *Thermoplasma*, and *Sulfolobus* consist of two different but related subunits of almost identical molecular mass (33). Electron-microscopic image analysis suggests that the two types of subunit in the thermosome of *Thermoplasma acidophilum* alternate within each ring, generating a four-fold symmetry (38).

Averaged electron-microscopic images of the mammalian TCP-1 particle reveal a ringlike structure with eightfold quasi-rotational symmetry with a central channel (33). Primary structures of eight distinct types of related subunit have been determined by cloning and sequencing of mouse cDNA; these types share about 30% amino acid residue identity. A striking observation is that the sequence of each type is more highly conserved among different eukaryotic species than are the sequences between types in any one species; in mammals the sequence identity is over 96% for each type of subunit, and around 60% between yeast and mouse. These observations have prompted the conclusion that each type of subunit diverged early in evolution, has changed only slowly during the evolution of eukaryotes, and thus may have a specific function in binding subsets of sequences in substrate proteins and/or other molecular chaperones (6, 7). Consistent with this suggestion is the observation that the different types of subunit in each TCP-1 chaperonin ring deviate most from one another in the sequences of the apical domains, where the protein substrate binds.

4. Mechanism of Action

The molecular details of how the chaperonins function have, and continue to be, studied by means of *in vitro* protein refolding experiments using defined components, but such experiments suffer from the disadvantage that the conditions under which they are performed are different in important respects from those operating during protein folding in the intact cell (9, 18). Thus it is not surprising that this field is subject to intense debate between people supporting different views (39). Since the chaperonins evolved to fold proteins inside cells,and not inside test tubes, it is essential when evaluating the validity of these views to define those aspects of chaperonin action observed *in vitro* that are mechanistically essential to improve the yield of correctly folded protein, when extrapolated as far as possible to *in vivo* conditions. In our opinion, the model outlined in Figure 1d best meets this criterion for the GroE chaperonins (30, 40).

In this model, newly synthesized polypeptide chains are released from ribosomes in the form of partially folded intermediates that may contain bound molecular chaperones of the hsp70/DnaJ families (see Protein Folding In Vivo). The latter chaperones prevent aggregation and premature folding before each chain is complete. Such intermediates are commonly referred to as *unfolded proteins*, but in fact they often are molten globules. These partially folded, compact intermediates lose the hsp70/DnaJ chaperones by an uncharacterized mechanism that results in each intermediate molecule binding by hydrophobic interactions to the apical domains at one end of a GroEL cylinder; the other end of the cylinder is occupied by GroES as a result of ADP binding to the GroEL ring proximal to the GroES (see Fig. 1d, step 1). The binding of polypeptide and the hydrolysis of ATP by the ring not occupied by GroES causes the GroES and the ADP to dissociate (step 2). GroES and ATP then rebind with equal probability to either ring (not both rings), resulting in 50% of the bound polypeptide being encapsulated inside the cavity capped by GroES (step 4). This rebinding of GroES results in the displacement of the bound polypeptide into the cavity, where it can continue to fold; it is for this reason that this model has been dubbed the ”Anfinsen cage” model to stress the idea that the protein in the cavity folds in a similar, but not necessarily identical, manner to that by which it folds in a protein renaturation experiment of the type pioneered by Anfinsen (41, 42). Thus one essential difference between chaperonin-assisted protein folding *in vivo* and spontaneous protein refolding *in vitro* is that the former process segregates each chain into the protected compartment provided by the GroEL/GroES cylinder to avoid the problem of aggregation.

The time available for this protected folding is set by the time it takes each ring of GroEL to hydrolyze seven ATP molecules. This hydrolysis is positively cooperative in each ring, and two rounds take about 10 s at 37°C (steps 4 and 5). The GroES then dissociates, and the protein is free either to diffuse into the cytosol or to rebind to the apical domains of the same GroEL cylinder (step 6). Rebinding occurs only if sufficient hydrophobic residues are still exposed on the surface of the compact intermediate. The cycle of release into the cage then repeats until the protein is folded sufficiently to the point where aggregation with other partially folded proteins is no longer a problem for the cell. The number of reaction cycles will vary, depending on the rate at which a given protein can fold when released into the cavity. Even with a single type of protein substrate, the population of folding chains will not be in synchrony or occupy the same number of cycles, since some chains fold more rapidly than others of the same sequence (see Protein Folding In Vitro). Usually only a fraction of the polypeptide chains fold to completion in a single cycle of GroES binding and unbinding, depending on the intrinsic rate of folding of a particular polypeptide and its tendency to become trapped in misfolded states. Rebinding of these intermediates to the apical domains of GoEL results in partial unfolding in preparation for a subsequent folding trial (30). This unfolding function distinguishes the GroEL/ES machinery from a simple folding cage,which acts solely to prevent intermolecular aggregation.

Uncertainties about this model include the fate of the 50% of polypeptide bound to the GroEL ring not capped by GroES; such polypeptides would be prone to aggregation and degradation if released into the cytosol. Release of such polypeptides *in vitro* is reduced in the presence of high concentrations of synthetic polymers that mimic the macromolecular crowding, excluded volume effect present in the cytosol (40). However, some release of partially folded chains may be essential *in vivo* because of the danger that proteins that are unable to fold correctly as a result of mutation will clog up the GroEL apical domains; an escape route for such molecules may be provided by release from the ring not capped by GroES.

Another problem concerns the significance of GroEL molecules with GroES bound to each end of the cylinder that have been observed *in vitro* (43). The ratio of total GroES subunits to total GroEL subunits in extracts of *E. coli* cells is equimolar, consistent with such GroES/GroEL/GroES complexes occurring *in vivo*, where their formation may be favored by the effect of macromolecular crowding on protein association. Nevertheless, such complexes are not mechanistically essential, at least as deduced from *in vitro* refolding experiments, nor can they be permanent if the compact intermediates are to enter the GroEL cavities.

Another limitation imposed by this model is the size range that can be accommodated inside the cage, which is likely to have an upper limit around 60 kDa. Larger proteins than this, up to about 150 kDa, exist inside bacterial cells and even larger ones in the cytosol of eukaryotic cells. A GroES equivalent to cap the TCP-1 chaperonin oligomer has not been identified, so it is possible that the latter assists protein folding in a manner somewhat different from that for the GroE chaperonins. There is evidence that, unlike GroEL,the mammalian TCP-1 chaperonin binds to chains of actin being synthesized by extracts of reticulocytes before the chains have been released from the ribosomes (44).

There are four known intracellular compartments in which proteins fold that do not appear to contain any type of chaperonin: the endoplasmic reticulum lumen, the intermembrane **mitochondrial** space, the intrathylakoidal lumen, and the **periplasmic** space of **Gram-negative** bacteria. Additionally, the eukaryotic cytosol seems to lack a general chaperonin, since the TCP-1 chaperonin appears to be restricted to a small subset of protein substrates, including actin and tubulin. Thus it is certainly not the case that the folding of all proteins in all cells involves the chaperonins. Given that the intracellular environment strongly favors aggregation, it is likely that the chaperonin-independent proteins utilize the assistance of other types of molecular chaperone for their folding. This assistance may also apply to proteins larger than 60 kDa that cannot fit into the chaperonin cage. For these proteins, the cotranslational and sequential folding of protein **domains** may circumvent the requirement for a sequestered folding compartment.

It is also possible that some chaperonins have roles additional to those discussed above with respect to protein folding, since there are sporadic reports of chaperonin-like molecules occurring on the cell surface in both prokaryotic and eukaryotic cells and in the blood serum, as well as stimulating **cytokine** production by animal cell cultures. The bacterial chaperonins are also the major immunogens in all human bacterial infections, and their possible roles in protective immunity and autoimmune disease is an active area of research (45).

5. Note Added in Proof

The cage mechanism for chaperonin-assisted protein folding is strongly supported by recent structural and functional data. The crystal structure of the asymmetrical GroEL:GroES complex with bound ADP shows that the cage is sufficient to accept proteins up to at least 70 kDa and that the wall of the cage provides a hydrophilic environment permissive for folding (Z. Xu et al. *Nature* **388**, 741–750, 1997). Crystal structures of the archaean thermosome suggest that in this chaperonin the folding cage is closed by loop sequences that emanate from the apical domains of the chaperonin subunits, explaining the lack of a separate GroES-like factor (M. Klumpff et al. *Cell* **91**, 263–270, 1997; L. Ditzel et al. *Cell* **93**, 125–138, 1998). A single ring mitochondrial chaperonin is fully functional in protein folding in a GroES-dependent manner *in vivo* (K. L. Nielsen et al. *Mol. Cell* **2**, 93–99, 1998). The size range of GroEL substrate proteins and their kinetics of interaction *in vivo* are consistent with the cage mechanism (K. L. Ewalt et al. *Cell* **90**, 491–500, 1997). Oligomeric GroEL with an intact central cavity is essential for the maintenence of growth of *E. coli* (F. Weber et al. *Nature Struct. Biol.* **11**, 977–985, 1998).

Chemical Modification

Chemical modification is one of the most useful methods of identifying the functional groups of a protein. Chemical modification is also used for labeling proteins with reporter groups to monitor their conformations for **radiolabeling** and to increase their stability. If proteins are modified chemically under mild conditions, the modifications occur to the native conformation, and the modified proteins usually retain their native conformations. However, conformational changes in the modified proteins sometimes occur, and one must be careful about checking the conformation of the modified proteins, especially when they lose their functions. One must also be careful about the side reactions that often accompany otherwise specific chemical modifications.

It is possible to modify chemically the residues of aspartic acid, glutamic acid, histidine, lysine, arginine, methionine, tryptophan, tyrosine, and cysteine, and less easily serine, threonine, asparagine, and glutamine, but it is not possible to modify specifically glycine, alanine, valine, leucine, isoleucine, phenylalanine, and proline residues.

Residues that participate in the function are usually **accessible** to the **solvent** and consequently susceptible to reaction with a chemical reagent. The residues that show different reactivity in the presence and absence of a **ligand** are important for the function. A good method for discriminating the functional residues after modification involves analyzing the responsible residues within the proteins retained by an appropriate affinity column [see Affinity Chromatography]. Affinity labeling is a sophisticated way of modifying active site residues selectively. Modification with a **suicide substrate** is a very good method for modifying catalytic residues specifically.

The stability of a protein can be altered by chemical modification (see Protein Stability). Proteins are stabilized by introducing additional stabilizing forces such as **hydrophobic** forces, electrostatic interactions, and hydrogen bonds. Intra- or intermolecular **cross-links** are also effective for stabilizing proteins, as is attaching polymers to their surfaces.

Amino groups are reactive nucleophiles that can be modified by many chemical reactions, including acylation, amidination, and guanidination. Carboxyl groups can be modified after activation with **carbodiimides** or by esterification. Tyrosine residues are modified by nitration with tetranitromethane, **iodination**, or **acetylation** with acetylimidazole. The thiol group is the strongest nucleophile among all of the functional groups of amino acids, so there are many reagents that react specifically with it. Among these reactions are metal binding with *p*-mercurylbenzoate (PCMB); mixed-disulfide formation with disulfide reagents, such as 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB, or Ellman's reagent) or dithiodipyridine; alkylation with **iodoacetate**, methyl iodide, ethyleneimine or ***N*-ethylmaleimide**, cyanylation with 2-nitro-5-thiocyanobenzoic acid (NTCB), and oxidation with many oxidants. Reduction of the disulfide bonds of proteins and alkylation of the resulting thiol groups is an important step in protein chemistry. The imidazole group of histidine residues can be modified with diethylpyrocarbonate, or they can be photooxidized in the presence of photosensitizing dyes. The sulfur of methionine residues can be oxidized to the sulfoxide by air or by oxidants, or alkylated with agents like methyl iodide under acidic conditions. The latter reaction can be reversed by thiols, so an isotopic label can be introduced in 50% of the terminal methyl group of methionine residues using labeled methyl iodide. The guanido group of arginine residues forms heterocyclic condensation products with 1,2- and 1,3-dicarbonyl compounds, such as phenylglyoxal, 2,3-butanedione, and 1,2-cyclohexanedione. The indole ring of the tryptophan residue can be modified with various oxidants, such as *N*-bromosuccinimide, iodine, or ozone, or by electrophilic reagents, such as 2-hydroxy-5-nitrobenzylbromide or 2-nitrophenylsulfenylchloride.

Chemical Shift

A nuclear magnetic resonance (NMR) spectrum of the protons (hydrogen atoms), ^{13}C, or other nuclei of a molecule typically features groups of signals displayed over a range of frequencies. The frequencies can ultimately be related to the Larmor (resonance) frequencies of the nuclei under study. The frequencies of absorbed or emitted energy represented in, for example, the proton NMR spectrum are different for protons in structurally or chemically distinct environments. Chemical shift refers to the sensitivity of the Larmor frequency to the covalent structure of which the observed nucleus is part, sensitivity to the intra- and intermolecular interactions present, and sensitivity to other sample variables, such as temperature, concentration, and pressure. The chemical shift is an important aspect of the NMR experiment because it ultimately provides a unique "signature" for each spin of a molecule of interest.

Atomic nuclei such as ^1H, ^{13}C, and ^{15}N, which have the property referred to as spin, take up certain quantum-mechanically allowed orientations when they are in a magnetic field. In the magnetic field, these nuclei undergo a precessional motion around the direction of the magnetic field. The frequency of this motion (n) is characteristic of the type of nucleus and its local chemical environment and can be expressed as

$$\nu = \gamma B_o(1 - \sigma)/2\pi$$

where g is the gyromagnetic ratio of the nucleus, B_o is the magnitude of the laboratory magnetic field, and s is the chemical shielding parameter, or screening constant. (The precessional frequency is also dependent on possible scalar and dipolar coupling interactions between nuclei; in terms of energy these are smaller influences on the precessional frequency and are neglected for the present discussion [see scalar coupling].) Chemical and structural information is implicit in the value of the shielding parameter; it is the purpose of NMR experiments to measure nuclear precessional frequencies and thus define the values of s for nuclear spins of a sample. The shielding parameter is dimensionless and typically is in the range $1 - 1000 \times 10^{-6}$. Values for s are conveniently discussed in terms of parts per million (ppm).

The chemical shift, as represented by the shielding parameter (s), for a given spin in a molecule depends principally on the chemical bonds that hold the spin to the molecule. The carbon atom of a methyl group has a shielding parameter that is about 180 ppm different from the shielding parameter of the carbon atom of a carbonyl group, primarily because the local electronic structures about the two carbons are so different (see NMR (Nuclear Magnetic Resonance)). Because local electronic structures for a given chemical group tend to be similar from molecule to molecule, the shielding parameters for the molecules' nuclei tend to fall into narrow, identifiable bands. Thus constructing correlation tables that reliably indicate the approximate expected values of the shielding parameters of each nucleus in a molecule is possible. Organic chemistry textbooks generally contain such tables.

Shielding parameters also subtly reflect the entire electronic structure of a molecule and the electronic structures of solvent molecules or other solutes that are present in a sample. The tertiary structures of biopolymers result in characteristic effects on the shielding parameters of their component nuclei (1, 2).

When considered in detail, it becomes apparent that the value of the shielding parameter is dependent on the orientation of the molecule in a magnetic field. That is, s is anisotropic and must be represented by a tensor. In gases and most liquid samples, rotational and translational motions of the molecules are rapid, and molecules change their positions and orientations rapidly in the magnetic field. Consequently, in these samples the value of the shielding parameter detected experimentally is the average of all possible orientations of the molecule. If the motions of the molecules in a sample are restricted, as would be the case in solids or in liquid crystalline solutions that are partially ordered, a range of s values will be detected for a given nucleus.

By convention, NMR spectra are displayed so that shielding parameters (or their equivalents) increase from left to right along a chemical shift axis. That is, the NMR absorption or emission signals for nuclei with the largest shielding parameter appear to the right in the spectrum, whereas nuclei with smaller shielding parameters appear progressively to the left. Also, by convention the algebraic signs of the numbers along the shielding parameter axis are the negatives of the actual number. Finally, measuring absolute values of shielding parameters with confidence is impractical. The NMR signal from a convenient material is thus chosen as a standard or reference signal, and shielding parameters are measured relative to this signal. Therefore, a signal appearing in a proton NMR spectrum at the position labeled 7 ppm has a shielding parameter that is 7 ppm smaller than the shielding parameter that is characteristic of the reference signal, arbitrarily assigned 0 ppm.

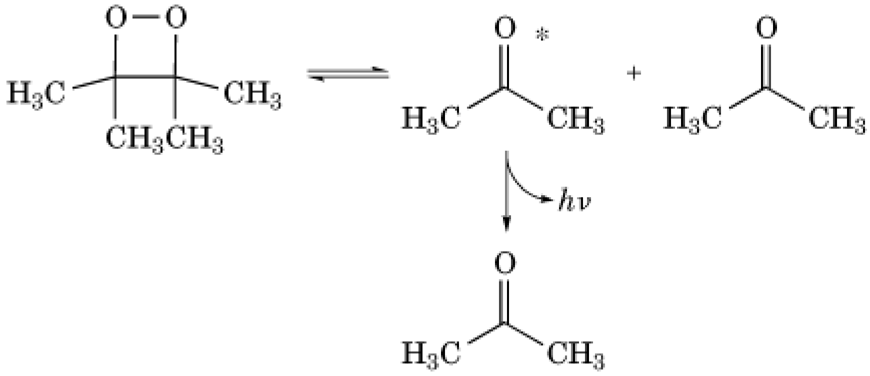
Chemiluminescence

Chemiluminescence is the production of light via a chemical reaction. As in all luminescence, the source of the light is the decay of an electron from a higher energy excited state to the ground state. In chemiluminescence, the reactants are generally in their ground-state configuration, but one or more of the products is formed with an electron in a high-energy orbital (the product molecule is formed in an excited state). Thus, chemiluminescence is the conversion of chemical energy (Gibbs **free energy**) to radiant energy (light). A necessary precondition for chemiluminescence is that the change in free energy for the reaction be sufficiently large to produce one of the products in an excited-state configuration.

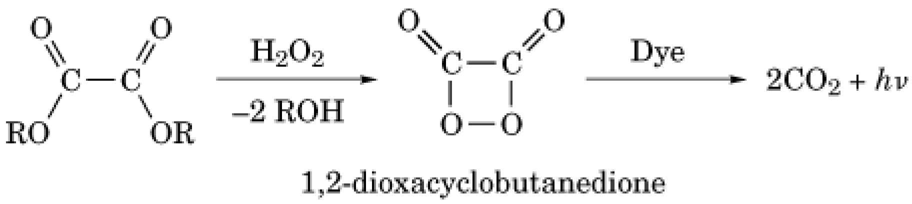
Perhaps the simplest example of a chemiluminescent reaction is the thermal dissociation of the cyclic peroxide tetramethyl 1,2-dioxetane to two molecules of acetone (Fig. 1). The free energy of the transition state of the reaction is about 90 kcal/mol above the ground state for the acetone products. This is sufficient energy for one of the acetone molecules to be produced in an electronically excited state. When this molecule decays to the ground state, a photon of light is emitted.

Figure 1. Simple example of a chemiluminescent reaction, the thermal dissociation of the cyclic peroxide tetramethyl 1,2-dioxetane to two molecules of acetone.



In many cases, a chemiluminescent reaction is carried out in the presence of a dye. The energy from the excited state of the reaction product is transferred to the dye, so that the reaction product is in the ground state and the dye is now in an electronically excited state. The dye will then decay to the ground state and emit a photon of a different color, depending on the chemical structure of the dye. Thus, a reaction that produces UV light may be coupled with a dye that emits in the visible region in order to provide useful illumination. A second reason for coupling a chemiluminescent reaction with a dye is to increase the lifetime of the light emission. Many chemiluminescent reactions are over quickly, and the light is released in a brief, intense flash. If, however, the reaction is coupled with a phosphorescent dye (see Luminescence), the radiant energy is transferred to the dye and is then released at a much slower rate, producing a longer-lasting, but less intense glow. This is the basis of such commercial products as the glow-stick for emergency lighting, as well as the luminescent novelty necklaces or other items often seen at carnivals. An example of the of reaction used in these devices is shown in Figure 2.

Figure 2. Chemiluminescent reaction coupled with a phosphorescent dye. The radiant energy from the chemical reaction is transferred to the dye and is then released at a much slower rate, producing a longer-lasting, but less intense glow. This is the basis of such commercial products as the glow-stick for emergency lighting and luminescent necklaces and other novelty items.



Chemiluminescent reactions are common in living organisms, where they are known as bioluminescent reactions. In some natural systems, energy from the chemical reaction will be passed to "antenna proteins," which serve the same functions as dyes in the strictly chemical reaction (see Luciferases And Luciferins).

Chemiosmotic Coupling

Many forms of energy are interconverted by living systems. Chemical energy may be used to drive mechanical processes, to generate osmotic and electrical gradients, and even to emit light. In photosynthesis, light energy is converted to chemical energy and is used indirectly to drive the thermodynamically unfavorable synthesis of ATP from ADP and P_i. In oxidative metabolism in mitochondria and some bacteria, ATP synthesis is driven by the energy released by oxidation of metabolites. During the 1950s, it was clearly established that both oxidative phosphorylation and photosynthetic phosphorylation are dependent on electron transport. How electron transport could be linked to the formation of a phosphoanhydride bond in ATP was a major question in bioenergetics for the next two decades.

Oxidation–reduction reactions are clearly quite different in character from the removal of the elements of water from ADP and P_i to form ATP. Yet, there is not doubt that these two processes are coupled to one another. In biochemical parlance, two reactions are said to be coupled when they share a common intermediate. The nature of the intermediate common to electron transfer and to ATP synthesis was elusive. In 1961 in a short, entirely theoretical article, Peter Mitchell proposed a radically different idea for coupling (1). Rather than a chemical intermediate linking electron transport and phosphorylation, as was then generally thought, Mitchell suggested that transmembrane electrochemical proton potentials $\Delta\tilde{\mu}_{H^+}$could couple the two reactions. In addition, Mitchell realized that specific **active transport** systems could be linked to $\Delta\tilde{\mu}_{H^+}$.

1. The Chemiosmotic Hypothesis

The postulates of the chemiosmotic hypothesis (1-3) in brief are as follows:

1. Membranes that catalyze oxidative phosphorylation (the inner mitochondrial membrane and some bacterial plasma membranes) and photosynthetic phosphorylation (chloroplast thylakoids and plasma membranes of some bacteria) are poorly permeable to protons.
2. Electron transport generates $\Delta\tilde{\mu}_{H^+}$by vectoral transport of electrons and protons.
3. An ATPase is driven in reverse (ATP synthesis) by the energetically favorable flow of protons down their electrochemical potential.
4. Coupling membranes contain specific exchange metabolite transport systems that may be linked to the $\Delta\tilde{\mu}_{H^+}$.

Before considering these postulates in further detail, we will define $\Delta\tilde{\mu}_{H^+}$. The chemical potential of a substance, m, is the free energy of a system per mole. The energetics of the movement of an ion across a membrane has two components: chemical (osmotic) and electrical. Chemical work must be done to generate a concentration (actually activity) gradient and electrical work, to generate the charge imbalance (the membrane potential). The combined electrochemical potential is $\tilde{\mu}$. Just as is the case for Gibbs free energy, *G*, it is the change in electrochemical potential ($\Delta\tilde{\mu}$) that is of interest. In general, at constant temperature and pressure

$$\Delta\tilde{\mu} = RT\ln[x^{z+}]_a/[x^{z+}]_b + zF\Delta\psi \qquad (1)$$

where R is the gas constant (8.3 kJ K^{-1} mol^{-1}); T, the absolute temperature; ln, $\log_e$; x^{z+}, a cation of z positive charges; a and b, two compartments separated by a membrane; z, the charge on the cation; F, Faraday's constant (96.5 kJ mol^{-1} V^{-1}); and Dy, the membrane potential. For protons, $z = 1$, and Equation 1 becomes

$$\Delta\tilde{\mu}_{H+} = RT\ln[H^+]_a/[H^+]_b + F\Delta\psi \tag{2}$$

or

$$\Delta\tilde{\mu}_{H+} = 2.30RT\log[H^+]_a/[H_+]_b + F\Delta\psi \tag{3}$$

or, since pH = –log[H^+],

$$\Delta\tilde{\mu}_{H+} = 2.30RT(pH_b - pH_a) + F\Delta\psi \tag{4}$$

or

$$\Delta\tilde{\mu}_{H+} = 2.30RT(\Delta pH) + F\Delta\psi \tag{5}$$

Mitchell preferred to express Equation 5 in electrical units and coined the term "proton motive force" (pmf or Dp), which is simply $\Delta\tilde{\mu}_{H+}$ divided by F:

$$\Delta p = \Delta\tilde{\mu}_{H+}/F = 2.30RT/F(\Delta pH) + \Delta\psi \tag{6}$$

As forms of energy may be interconverted, so may their units. In some ways it makes sense to consider the energetics of proton gradients in electrical units. Proton fluxes across energy-coupling membranes are analogous to electric circuits. Some people prefer to use $\Delta\tilde{\mu}_{H+}$, others Dp. Since the two terms are readily interconvertible, this usage, although potentially confusing, is not a problem. At 25°C, Equation 5 may be written

$$\Delta\tilde{\mu}_{H+} = 5.69\,\Delta pH + 96.5\Delta\psi \tag{7}$$

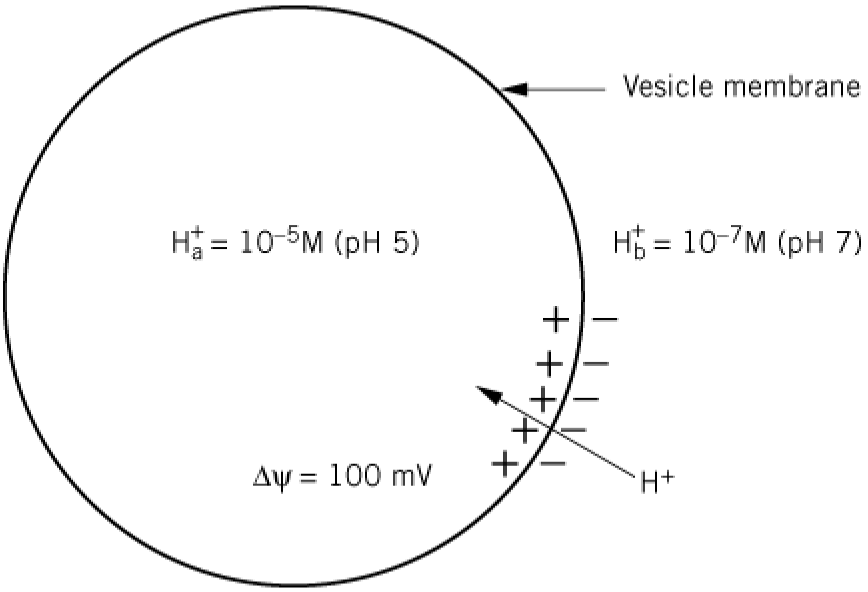
where $\Delta\tilde{\mu}_{H+}$ is also given in kilojoules per mole and Dy is expressed in volts. The proton motive force (in millivolts) may be expressed as

$$\Delta p = 59\,\Delta pH + \Delta\psi \tag{8}$$

where Dy is also given in millivolts.

As in any thermodynamic analysis, sign conventions are very important to keep straight for $\Delta\tilde{\mu}_{H+}$. Consider a topologically closed phospholipid bilayer vesicle (Fig. 1). This vesicle has an inside aqueous compartment, a, and an external compartment, b, the suspending medium. DpH is defined as $pH_{out} - pH_{in}$, which is 2.0 units for the case shown in Figure 1. A charge difference (Dy) where the inside of the membrane is more positive than the outside is defined as having a positive sign. Suppose Dy is +100 mV. From the data given in Figure 1. the $\Delta\tilde{\mu}_{H+}$ or Dp may be calculated as $\Delta\tilde{\mu}_{H+}$ = 5.69(2) + 96.5(0.1) = 21.0 kJ mol^{-1} or Dp = 59(2) + 100 = 218 mV. Notice the sign of the answers, which are positive numbers. These values give the energy cost per mole ($+\Delta\tilde{\mu}_{H+}$ or +Dp) to generate the electrochemical protein potential or Dp. The flow of protons down their electrochemical potential is exergonic, and the absolute magnitudes of $\Delta\tilde{\mu}_{H+}$ and Dp are the same, but the sign changes. This statement is equivalent to saying that if a chemical reaction has a positive DG value in the forward reaction, the reverse reaction must have a negative DG of the same absolute magnitude.

Figure 1. $\Delta\tilde{\mu}_{H^+}$Across a vesicular membrane. DpH is defined as pH_{out} (compartment *b*) $-pH_{in}$ (compartment *a*), and Dy as positive since the inside of the membrane is more positive than the outside.



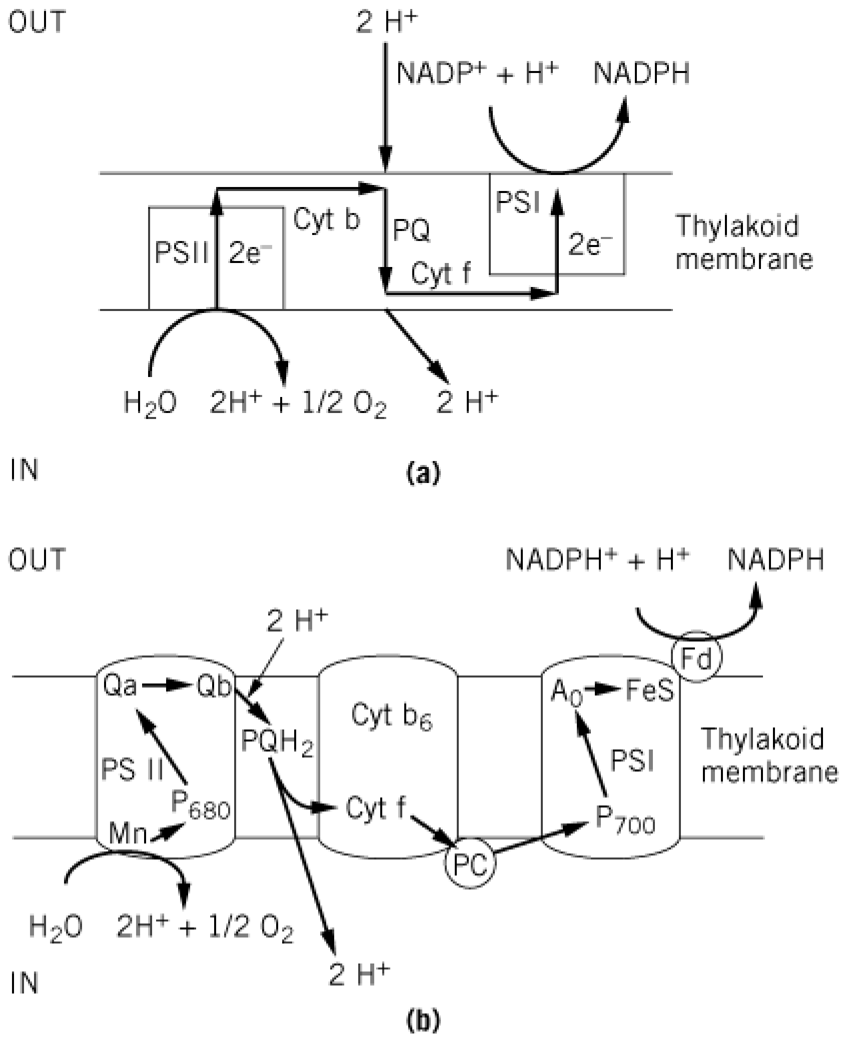
The essence of chemiosmotic coupling is that exergonic electron transport by the respiratory and photosynthetic electron chains is obligatorily linked to transmembrane proton flux, resulting in the generation of $\Delta\tilde{\mu}_{H^+}$. The flow of protons down their electrochemical potential provides the driving force for ATP synthesis. There is compelling evidence in support of these proposals.

2. Evidence in Support of the Chemiosmotic Coupling Hypothesis

As Mitchell predicted (1-3), the mitochondrial, bacterial, and chloroplast membranes that couple ATP synthesis to electron transport are poorly permeable to protons, except when proton-linked processes, such as ATP formation, occur at high rates. Proton transport was shown to be linked to electron transport in mitochondria (4), chloroplasts (5), and bacteria (6). The measurements of the magnitudes of $\Delta\tilde{\mu}_{H^+}$across these membranes turned out to be difficult, but in most instances, $\Delta\tilde{\mu}_{H^+}$values approaching 20 kJ mol^{-1} (Dp ~ 200 mV) have been measured during steady state, rapid electron transport. As predicted by Mitchell, lipophilic weak acids (eg, 2,4-dinitrophenol) could collapse the $\Delta\tilde{\mu}_{H^+}$by shuttling protons across the membrane. ATP synthesis is also inhibited by these reagents, which are termed “uncouplers” because they uncouple electron flow and ATP synthesis.

When Mitchell proposed the chemiosmotic hypothesis, the understanding of biological membrane structure, especially how proteins may be integrated into membranes, was rudimentary. We take for granted today that membrane proteins may be plugged into the lipid bilayer in an asymmetric manner (see Membranes). But in the 1960s Mitchell's proposals for membrane protein asymmetry, transmembrane electron transport, and membrane sidedness were novel. Although not all of Mitchell's predictions turned out to be correct (cytochrome oxidase, for example, translocates protons via a mechanism that Mitchell did not foresee), many were. His model for proton and electron transport in thylakoid membranes is compared to a much more recent view in Figure 2. There is a remarkable similarity between the two schemes.

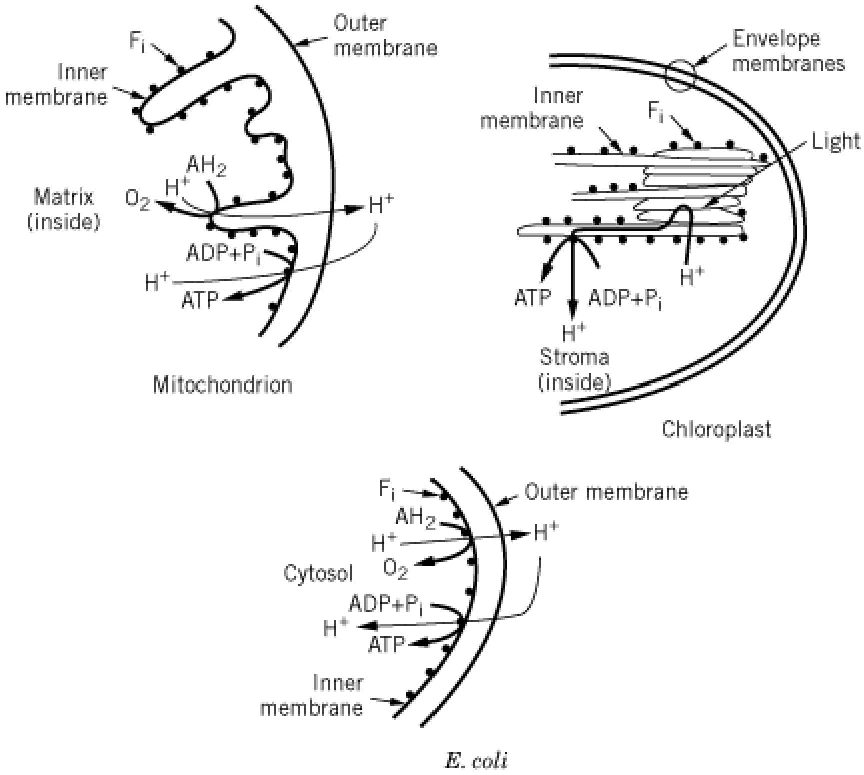
Figure 2. Schemes for electron and proton transport in chloroplast thylakoid membranes. In (**a**) Mitchell's early scheme (2) is illustrated with the membrane in the horizontal position more commonly used by others. In (**b**) a modern interpretation of electron and proton transport in thylakoids is given. The similarity between the two schemes is remarkable. Note in particular the transmembrane electron transport by photosystem II (PS II) and photosystem I (PS I), the oxidation of water to $2H^+$ and 1/2 O_2 inside (the thylakoid lumen) and proton translocation coupled to plastoquinone (PQ) oxidation/reduction. These elements are essentially the same in the two schemes. Cytochrome *b* (Cyt b) was not properly placed by Mitchell. In (**b**) Mn stands for the manganese of the oxygen evolving complex, Qa and Qb, for the bound plastoquinone electron acceptors of PS II; P_{680} and P_{700}, for the reaction center chlorophylls; Cyt f, for cytochrome f; PC, for plastocyanin; A_0, for the primary electron acceptor in PSI; FeS, for iron–sulfur electron transport proteins; Fd, for ferredoxin. Ferredoxin–$NADP^+$ oxidoreductase and the FeS protein of the cytochrome b6f complex were omitted for clarity.



As illustrated in Figure 3 (7), the sidedness of the chloroplast thylakoid membrane is opposite that of mitochondria and bacteria (8). As a result of photoelectron transport, thylakoids accumulate protons from the stroma. In contrast, oxidative electron transport in mitochondria and bacteria cause protons to be ejected from the mitochondria or bacteria. The steady state Dy across the thylakoid membrane is very low, and the DpH is high (as much as 3.5 units). The DpH component of the $\Delta\tilde{\mu}_{H^+}$ in mitochondria and bacteria is, however, usually small, and Dy is high. These observations make sense when it is realized that the mitochondrial matrix and bacterial cytoplasm are the internal compartments bounded by the coupling membranes. The pH of these compartments must be controlled to allow the numerous enzymes they contain to function. In contrast, the thylakoid lumen contains no metabolic enzymes. Electrical neutrality in thylakoids is maintained by Cl^- flux.

Essentially, thylakoids accumulate HCl in the light.

Figure 3. Sidedness of coupling membranes. Mitochondrial and bacterial (*E. coli*) electron transport is coupled to the ejection of protons, whereas in thylakoids, protons are accumulated. Note that, in bacteria and chloroplasts, ATP is generated within the same compartment in which it is used. In contrast, most of the ATP synthesized within mitochondria is exported to the cytoplasm. From Ref. 47, with permission.



Dramatic evidence in favor of the chemiosmotic hypothesis was obtained in André T. Jagendorf's laboratory during the mid-1960s (9, 10). Simply by adjusting the pH of thylakoid suspensions to pH 4 and rapidly raising the pH to 8.0 in the presence of ADP + P_i, relatively large amounts of ATP are formed *in the dark.* ATP synthesis induced by acid to base transitions is abolished by uncouplers and reagents that block ATP synthesis. Later, it was shown (11) that artificially generated electric fields could also generate ATP. In mitochondrial vesicles, Thayer and Hinkle (12) showed that the rate of D*p*-driven ATP synthesis is as fast or faster than that coupled to electron transfer.

The membrane of the halophilic bacterium, *Halobacter halobium* (*salinarium*) elaborates purple patches composed entirely of bacteriorhodopsin. Bacteriorhodpsin is a light-dependent proton pump that, when incorporated into lipid membranes, can generate substantial $\Delta\tilde{\mu}_{H^+}$(12). When the enzyme from bovine heart mitochondria that catalyzes ATP synthesis was coreconstituted with bacteriorhodopsin, vesicles were obtained that catalyzed light-dependent, uncoupler-sensitive ATP formation (14).

Mitchell's proposal that ATP synthesis is accomplished by driving a proton-linked ATPase in reverse was also novel. By the time Mitchell was developing the chemiosmotic hypothesis, it had been clearly established that the energy of ATP hydrolysis could be used to generate ion gradients. For example, the Na^+ and K^+ concentration gradients and Dy across mammalian plasma membranes are generated by an ATPase, the Na^+,K^+-ATPase. If, Mitchell reasoned, an ATPase acts as an ion pump, might an ATPase operate in reverse to utilize the $\Delta\tilde{\mu}_{H^+}$generated by electron transport to drive ATP synthesis? Work on “coupling factors” during the 1960s established that mitochondria and chloroplasts contain an enzyme that is required for ATP synthesis that could under appropriate conditions also hydrolyze ATP (15). The catalytic part of what is now known as “ATP synthase” is called “F”$_1$ and is an extrinsic membrane protein. F_1 may be removed from the membrane and is very water-soluble. (See article on ATP Synthase.)

Mitochondrial ATP synthesis and hydrolysis are strongly inhibited by the antibiotic, oligomycin. The ATPase activity of F_1, after its removal from the inner mitochondrial membrane, is insensitive to oligomycin—an observation that seemed incompatible with a role of F_1 in oxidative phosphorylation. Racker then showed that a crude detergent fraction of mitochondrial inner membranes contain a factor that confers sensitivity to oligomycin to F_1. This factor was called “F_0”; F_0 is not a coupling factor, and it is improper to denote F_0 as “F zero” or “F naught.” Kagawa and Racker (16) pioneered the isolation and purification of the entire ATPase complex, $F_1 - F_0$, which could be incorporated into phospholipid vesicles that catalyzed energy-linked activities. Similar studies were carried out with the chloroplast ($CF_1 - CF_0$) and bacterial enzymes.

Mitchell predicted that F_0 contains a mechanism for transmembrane proton movement. Removal of CF_1 was shown (17) to greatly enhance the proton permeability of the thylakoid membrane. *N*,*N*′-Dicyclohexylcarbodiimide (DCCD) at low concentrations inhibits ATP synthesis and ATP hydrolysis by $F_1 - F_0$ (17). DCCD acts by blocking proton conductance by F_0 and, in thylakoids, restores net light-dependent proton uptake and high $\Delta\tilde{\mu}_{H^+}$ to membranes from which CF_1 had been removed. The DCCD reacts with an Asp or Glu residue in a very hydrophobic, 8-kDa polypeptide of F_0 (18).

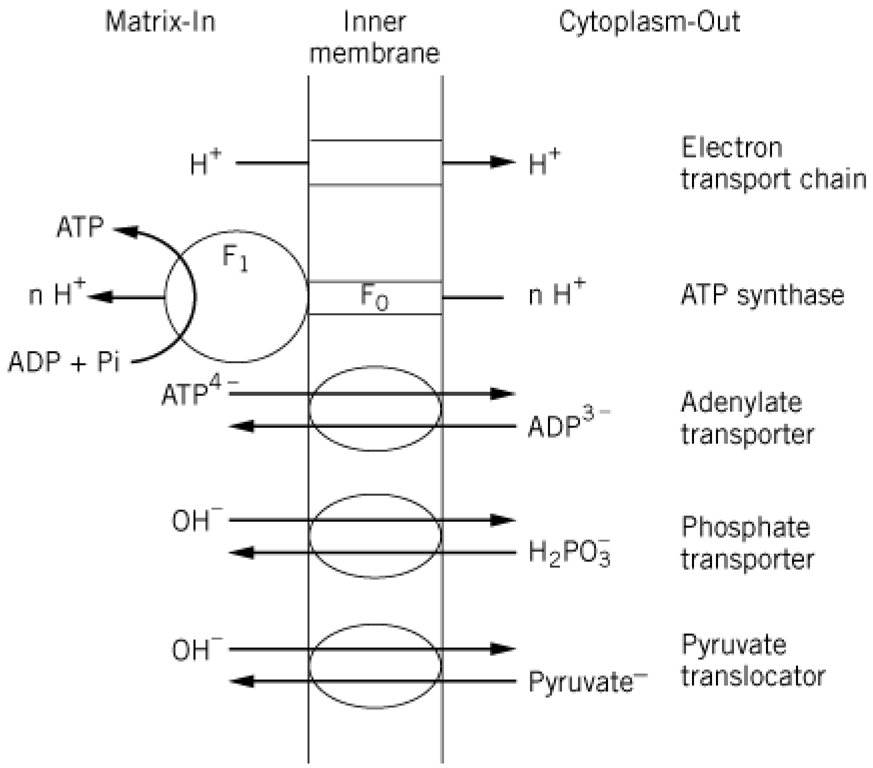
The evidence that $F_1 - F_0$ is a proton-translocating ATPase/ATP synthase is overwhelming. Phosphorylation driven by imposed DpH or Dy is abolished by specific inhibitors of either F_1 or F_0 function. As described above, F_0 conducts protons rapidly, and blocking F_0 proton transport also inhibits ATP synthesis. ATP hydrolysis by $F_1 - F_0$ is linked to proton translocation. In thylakoids ATP hydrolysis in the dark can generate $\Delta\tilde{\mu}_{H^+}$ values of significant magnitude to drive some ATP synthesis. This ATP-dependent ATP synthesis is very sensitive to inhibition by uncouplers. The $\Delta\tilde{\mu}_{H^+}$ generated by ATP hydrolysis can drive electron transport in reverse (19), a process that is blocked by ATP synthase inhibitors and uncouplers. Other evidence that the electron-transport chain and ATP synthase are linked via $\Delta\tilde{\mu}_{H^+}$ includes the facts that phosphorylation decreases the magnitude of $\Delta\tilde{\mu}_{H^+}$ and stimulates the rate of electron transport. Specific inhibition of ATP synthesis increases the $\Delta\tilde{\mu}_{H^+}$ and slows electron transport. Uncouplers strongly decrease $\Delta\tilde{\mu}_{H^+}$ and inhibit ATP synthesis, but stimulate electron transport. An extensive analysis of the coupling between photosynthetic electron transport and ATP synthesis in the steady state gave results strongly indicating that $\Delta\tilde{\mu}_{H^+}$ is the intermediate linking the two processes.

3. Metabolite Transport and Motility

Mitchell's fourth postulate, that coupling membranes contain specific exchange transport systems, has also received broad experimental support, especially for mitochondrial and bacterial coupling membranes. The chloroplast thylakoid membrane does not appear to contain metabolite transporters. ATP is synthesized in chloroplasts within the same compartment (the stroma) in which it is utilized in photosynthesis (see Fig. 3). The inner membrane of the envelope, not the thylakoid membrane, is the permeability barrier of the chloroplast. In contrast, the inner membrane of the mitochondrion and the plasma membrane of bacteria are both coupling membranes and permeability barriers. In these membranes, transport must coexist with ATP synthesis.

Most of the ATP generated by oxidative phosphorylation in mitochondria is exported to the cytoplasm and is hydrolyzed to drive cellular processes. Mitochondria must contain mechanisms to export ATP and import ADP and P_i. In addition, mitochondria will take up pyruvate, di- and tricarboxylic acids, and some amino acids. Cation exchangers are also present. Many of these transporters utilize the $\Delta\tilde{\mu}_{H^+}$established by the electron transport chain (Fig. 4). A few transporters will be briefly considered in this article, with emphasis on ADP/ATP and P_i transporters in mitochondria. (see Mitochondria).

Figure 4. Proton circuits in the mitochondrial inner membrane. Electron transport ejects protons from the mitochondrion, resulting in the formation of $\Delta\tilde{\mu}_{H^+}$. A number of processes including ATP synthesis, ADP/ATP exchange transport, P_i – OH^- exchange transport, and the uptake of certain metabolites (illustrated by pyruvate uptake in exchange for OH^-) are linked to the $\Delta\tilde{\mu}_{H^+}$.



At physiological pH, ADP exists as ADP^{3-}, and ATP as ATP^{4-}. The inner membrane contains a well-characterized transporter, known as the *adenine nucleotide translocator* (20). This transporter catalyzes the counterexchange translocation of ADP^{3-} and ATP^{4-}. The one-for-one exchange transport (**antiport**), with ATP^{4-} exported from the mitochondrion and ADP^{3-} imported, is electrogenic; there would be the net transfer of one negative charge out of the mitochondrion per transport event. The Dy across the mitochondrial inner membrane is outside positive. Thus, ATP^{4-}/ADP^{-3} exchange transport would be promoted in the direction of ATP export and ADP import by the Dy generated by electron flow.

P_i accumulation by mitochondria is also catalyzed by a transporter. P_i is either cotransported with H^+ or counter-exchanged for OH^-. Since the form of P_i that is preferentially transported is $H_2PO_4^-$, one-for-one transport of P_i with either H^+ (**symport**) or OH^- (antiport) is electrically neutral and is not affected by Dy. P_i transport is, however, linked to DpH. The pH of the matrix of respiring mitochondria is about 0.5 unit more alkaline than that of the cytoplasm. Either OH^- antiport or H^+ symport would favor P_i uptake into mitochondria. This mechanism and the rapid utilization of P_i by oxidative phosphorylation assure that the P_i is delivered to the mitochondrial matrix from the cytoplasm. The transport of ATP/ADP and P_i by mitochondria costs the equivalent of one proton/ATP synthesized. Pyruvate, the end product of aerobic glycolysis, is transported into mitochondria via an electrically neutral counterexchange with $OH^{-\prime}$, and its transport, like that of P_i, is linked to DpH.

Bacteria have the potential to carry out the active transport of a large number of compounds, including sugars and amino acids (21). Transport may be linked to the $\Delta\tilde{\mu}_{H^+}$generated by electron transport, or, under anaerobic conditions, by ATP hydrolysis by $F_1 - F_0$. The best-studied example of $\Delta\tilde{\mu}_{H^+}$-dependent active transport in bacteria is the lactose transporter (lac **permease**) of *Escherichia coli* (22). Lactose uptake is obligatorily linked to H^+ uptake into the cell, at a probable stoichiometry of one lactose to one proton. The bacterium maintains, by either electron transport or ATP hydrolysis, a negative Dy (outside positive), and, depending upon the conditions, a negative DpH (inside alkaline). The flow of protons down the $\Delta\tilde{\mu}_{H^+}$provides the driving force for the accumulation of lactose to concentrations in excess of 1,000 times that of the medium. In addition to proton-linked transport systems, bacteria contain ABC (ATP binding cassette) transporters (23) that utilize ATP for transport to metabolites or ions directly, as well as the phosphotransferase system (24) that utilizes phosphoenolpyruvate as both an energy source and a source of phosphate for the transport and concurrent phosphorylation of some sugars.

The concepts developed by Mitchell for metabolite and ion transport were subsequently found to apply to membranes other than coupling membranes. The plasma membranes of higher plant cells, yeast, and fungi contain an enzyme that is structurally, functionally, and mechanistically related to the Na^+, K^+-ATPase of animal cell plasma membranes. This enzyme, the H^+-ATPase (25), is the primary ion pump in plant, yeast, and fungal plasma membranes. ATP hydrolysis pumps protons out of the cells, generating the transplasma membrane $\Delta\tilde{\mu}_{H^+}$. The DpH component in plant cells is 1.0–2.0 pH units, whereas Dy may be in excess of –200 mV. The active transport across the plasma membrane is driven by the energetically favorable flow of protons down the $\Delta\tilde{\mu}_{H^+}$. As is the case for lactose transport in *E. coli*, specific transporters that mediate the translocation of metabolites across the membrane are obligatorily coupled to H^+ transport. An important example of H^+: metabolite cotransport (symport) in plants is the active loading of sucrose (26) into the phloem. As a consequence of sucrose: H^+ cotransport, the sucrose concentration within the phloem may be as high as 0.5 *M*.

An entirely new class of H^+-ATPases was discovered during the 1980s and characterized in the 1990s (27). The members of this class are called “V-ATPases,” in which the V stands for *vacuolar*. All eukaryotic cells contain V-ATPases. In plant and yeast cells, the V-ATPase is present on the vacuolar membrane and in the Golgi apparatus. In animal cells, V-ATPases are present in **clathrin**-coated vesicles, chromaffin granules (adrenal medulla), Golgi membranes, **lysosomes**, synaptic vesicles, and, in some specialized cells, the plasma membrane. The V-ATPases are structurally much more complex than plasma membrane H^+-ATPases, and, although the V-ATPases large subunits have some sequence similarity to the a and b subunits of F_1, V-ATPases and $F_1 - F_0$ ATPases are distinct.

The function of V-ATPases is to hydrolyze ATP and to pump protons from the cytoplasm into the internal aqueous compartment of endomembranes. The interiors of vacuoles and lysosomes are more acidic than that of the cytoplasm. Metabolite and ion fluxes are linked to the $\Delta\tilde{\mu}_{H^+}$generated by the V-ATPase. A Ca^{2+}/H^+ exchange transporter has, for example, been found in the vacuolar membrane of higher plants (28). Acidification of the vesicles that are formed by receptor-mediated endocytosis is required for dissociation of the ligand from its receptor (29).

The V-ATPase of eukaryotes never functions as an ATP synthase. Even in the best of conditions *in vitro*, imposed proton gradients will not cause the pump to reverse. The H^+-ATPase of **archaebacteria** (eg, *Halobacter salinarium* [*halobium*], (30)) more closely resembles V-ATPases than $F_1 - F_0$. Yet, the V-ATPase (sometimes called "A-ATPase" for Archeon), of the archeon can make ATP at the expense of the $\Delta\tilde{\mu}_{H^+}$generated by the light-dependent bacteriorhodopsin proton pump. Eukaryotes tailored the V-ATPase to fit their needs.

In addition to its utilization in ATP synthesis and membrane transport, $\Delta\tilde{\mu}_{H^+}$can be converted to mechanical energy in the form of motility of bacteria with **flagella** such as *E. coli* and *Bacillus subtilis*. Flagellar rotation is driven by $\Delta\tilde{\mu}_{H^+}$, rather than directly by ATP. Starved *B. subtilis* is immotile, but motility may be restored in transient manner by the artificial imposition of Dy. DpH (inside alkaline) is also capable of driving flagellar motion (31).

4. Sodium Electrochemical Potential

The electrochemical sodium ion potential, $\Delta\tilde{\mu}_{Na^+}$, is given by

$$\Delta\tilde{\mu}_{Na^+} = RT\ln[Na^+]_a/[Na+]b + F\Delta\psi \qquad (9)$$

where *R*, *T*, ln, Dy, and *F* are as defined in Equation 1. In some bacteria, $\Delta\tilde{\mu}_{Na^+}$is exploited for ATP synthesis, active transport, and motility. In addition, Na^+/metabolite cotransport systems are present in animal cells. Transporters within the plasma membrane of these cells link the translocation of the substrates (eg, amino acids) to the flux of Na^+ down the $\Delta\tilde{\mu}_{Na^+}$generated by the Na^+, K^+-ATPase (32). In bacteria, part of the $\Delta\tilde{\mu}_{H^+}$generated by respiration may be converted to $\Delta\tilde{\mu}_{Na^+}$by counterexchange transport of Na^+ for H^+. In some bacteria, Na^+ translocation may be linked to metabolism or electron transport without the involvement of $\Delta\tilde{\mu}_{H^+}$. For example, in *Propionigenium modestum*, the anaerobic decarboxylation of succinate to form propionate is coupled to the transport of Na^+ out of bacterium, generating a $\Delta\tilde{\mu}_{Na^+}$(33). In **halophiles**, Na^+ transport has been shown to be driven by electron transport through the NADH dehydrogenase region of the electron transport chain.

Vesicles of the *P. modestum* plasma membrane catalyze ATP-dependent Na^+ transport, and an imposed $\Delta\tilde{\mu}_{Na^+}$drives ATP synthesis (34). The membrane contains a Na^+-ATPase (ATP synthase) that is analogous to the $F_1 - F_0$ ATP synthase of coupling membranes. It is interesting to note that F_0 subunits of the *P. modestum* Na^+-ATPase confer to F_1 from *E. coli* the ability to translocate Na^+ (35). One archeon, *Methanosarina mazei* Gö 1, contains an $F_1 - F_0$ that uses $\Delta\tilde{\mu}_{Na^+}$and a V-ATPase ($V_1 - V_0$) that uses $\Delta\tilde{\mu}_{H^+}$(36). It is clear, therefore, that proton transport per se is not required for ATP synthesis by $F_1 - F_0$. This observation makes mechanisms of ATP synthesis in which translocated protons are directly involved in catalysis very unlikely. $\Delta\tilde{\mu}_{Na^+}$may also be the driving force for motility in some marine bacteria.

5. Pyrophosphate and Energy Coupling

Pyrophosphate (PP_i) is merely two P_i molecules joined by an anhydride bond:

$$2\ HPO_4^{2-} + 2H^+ \leftrightarrow H_2P_2O_7^{2-} + H_2O$$

The equilibrium for this reaction lies far to the left; at pH 7 and 25°C, the standard free-energy change for (PP_i) synthesis from 2 P_i is about +16.7 kJ mol^{-1}. PP_i is a product of several biosynthetic reactions, including aminoacyl tRNA synthesis, fatty-acid activation, and DNA and RNA synthesis. These reactions occur with equilibrium constants close to 1 and are freely reversible. By coupling these reactions to PP_i hydrolysis, the reactions are pulled in the synthetic direction. Cells contain soluble pyrophosphatases that hydrolyze PP_i to 2 P_i.

Other roles for PP_i in plants have recently been elucidated. The vacuolar membrane contains a pyrophosphatase (37) that couples pyrophosphate hydrolysis to inward proton translocation. Both the V-ATPase and the pyrophosphatase contribute significantly to the $\Delta\tilde{\mu}_{H^+}$ across the vacuolar membrane. Thus, some of the energy of PP_i hydrolysis is conserved by generation of the $\Delta\tilde{\mu}_{H^+}$. In addition, PP_i may be utilized as a phosphoryl donor, as an alternative to ATP, in glycolysis.

In the photosynthetic bacterium, *Rhodospirillum rubrum*, a pyrophosphatase, and $F_1 - F_0$ ATPase (ATP synthase) exist within the same membrane (38). Net PP_i synthesis driven by the photoelectron transport chain of the bacterium has been observed. PP_i synthesis is inhibited by proton ionophores (uncouplers), but not by reagents that block ATP synthesis by interacting with F_1. Membrane vesicles (chromatophores) from *R. rubrum* are oriented so that the catalytic sites of both the ATP synthase and the pyrophosphatase face the outside. ATP hydrolysis by these vesicles in the dark is coupled to inward H^+ translocation, resulting in the generation of substantial $\Delta\tilde{\mu}_{H^+}$ values. It is even possible to detect ATP-dependent pyrophosphate synthesis that is also uncoupler-sensitive. ATP hydrolysis and pyrophosphate synthesis are linked by the $\Delta\tilde{\mu}_{H^+}$.

6. Concluding Remarks

The four postulates of the chemiosmotic coupling hypothesis have received broad experimental support. Coupling membranes are poorly permeable to H^+. Electron transport results in the generation of $\Delta\tilde{\mu}_{H^+}$ at values that are consistent with the energetic demands of ATP synthesis. An ATPase is present that is reversible and can make ATP, provided the magnitude of $\Delta\tilde{\mu}_{H^+}$ is sufficient, or hydrolyze ATP if the $\Delta\tilde{\mu}_{H^+}$ is low. Artificially imposed $\Delta\tilde{\mu}_{H^+}$ can drive ATP synthesis at rates as least as fast as in oxidative or photosynthetic phosphorylation. $\Delta\tilde{\mu}_{H^+}$ is energetically and kinetically competent to be the intermediate common between electron transport and ATP synthesis. The fourth postulate, the existence of exchange transporters and their possible coupling to the $\Delta\tilde{\mu}_{H^+}$, has had a tremendous impact on the field of metabolite transport, not only in mitochondria but also in many other membranes. In part, the chemiosmotic hypothesis had its origins in Mitchell's long-standing interest in active transport in bacteria. The chemiosmotic hypothesis provided a new theoretical basis for the interpretation of transport experiments. Very early on, Mitchell proposed that membrane proteins may be organized in specific orientations within membranes and that electron transfer may in part occur across membranes. For his remarkable insights and experimental contributions, Peter Mitchell was awarded the Nobel Prize in Chemistry in 1978.

That H^+ (or Na^+) translocation is coupled to ATP synthesis and hydrolysis is generally accepted. Some evidence suggests that under some circumstances, the protons translocated during electron transport need not equilibrate with the bulk aqueous phase prior to their passage through $F_1 - F_0$ to make ATP. Because of the high buffering capacity of the interior of thylakoids, 50 ms or more of illumination may be required to generate DpH values of magnitudes sufficient to drive ATP synthesis. When the generation of Dy by proton transport is prevented, permeant buffers should delay the onset of ATP synthesis by increasing the internal buffering capacity. The delay is not as long as it should be, if it is assumed that the added buffer is uniformly distributed throughout the internal volume of the thylakoids (39, 40). These and other observations kept alive the localized proton theory of R. J. P. Williams (41). According to this theory, dubbed "microchemiosmosis" by Mitchell, protons are trapped in localized regions of the membrane that are not necessarily in equilibrium with each other. The transmembrane bulk phase $\Delta\tilde{\mu}_{H^+}$ was proposed to be used only for energy storage.

It is difficult to design experiments that provide unequivocal support for the localized proton hypothesis. If protons may be delivered to the ATP synthase without equilibrating with the bulk aqueous phase, some barrier must exist to prevent equilibration. Disruption of thylakoid structure has been suggested to convert the coupling mechanism from localized to delocalized (ie, chemiosmotic). It would thus be very difficult to establish the nature of the barrier. Results of a number of other reported experiments at first glance seem at odds with the chemiosmotic hypothesis. In most cases, flaws in the methods used or in the interpretation of the results can explain the apparent discrepancy.

The chemiosmotic hypothesis has stood the test of time. During the past few years, much has been learned about the structure of some of the proton and electron translocators of coupling membranes. Yet, we know little about how cytochrome oxidase pumps protons or how the ATP synthase exploits the $\Delta\tilde{\mu}_{H^+}$ to drive ATP synthesis. The emphasis of bioenergetics has shifted away from *what* couples electron transport to ATP synthesis to *how* the proton translocating elements work.

Chemokines

Chemokines are small secreted proteins, generally 8 to 15 kDa in mass, that were originally identified by their ability to stimulate chemotaxis and/or activate leukocytes (lymphocytes, neutrophils, eosinophils, mast cells, monocytes, and macrophages). They are now known to be multifunctional and to be secreted by many different cell types in response to various stimuli (for reviews see Refs. 1-5). In inflamed tissues, they may induce effector functions such as the generation of an oxidative burst or the secretion, from storage granules, of proteinases (by neutrophils and monocytes), histamine (by basophils), and cytotoxic proteins (by eosinophils). Chemokines activate **cell-surface receptors** to promote adhesion of circulating leukocytes to the vascular endothelium and subsequently to facilitate extravasation (diapedesis) of the adherent leukocyte into adjacent tissue, the source of the chemokine. They have proinflammatory effects and can give rise to acute or chronic inflammatory responses; some have been shown to be involved in movement and activation of cells in both angiogenesis/vasculogenesis and neural pathfinding, thus implicating them in aspects of development not directly involved in the immune response.

1. Chemokine Structure and Chromosome Location

The chemokine family (at least 40 members have been identified in humans) consists of four classes distinguished by the positioning of four conserved cysteine residues near the N-terminus of the protein. These four cysteine residues define a distinct structural motif based on the two disulfide bonds (C16C3, C26C4) that they form. All the chemokines possess a central b-pleated sheet region consisting of three antiparallel beta-strands (a Greek key motif) followed in most cases by a C-terminal alpha-helix. There is evidence that the chemokines can form dimers and higher oligomers, but whether this is important for their function is controversial (2). The N-terminal sequence of the chemokines is of particular importance in determining their specificity. Alteration or removal of one or a few amino acid residues can dramatically affect their activity or target cell specificity. This provides the opportunity for the specificity of a chemokine to be altered by local factors subsequent to its secretion.

The CXC or a-class chemokines possess a single residue between the first and second cysteines. This family can be further subdivided by the presence or absence of the amino acid sequence Glu-Leu-Arg (ELR) preceding the first cysteine. This sequence is recognized by chemokine receptors on specific cell types, and thus, has functional implications. The CC or b-class chemokines have no residues between the first and second cysteines. Some members of this group have two additional cysteine residues that form a third disulfide bond (6).

Two additional chemokines have been identified that do not fit into either the CC or CXC classes. The g class is missing both the first and third cysteines. This C chemokine has lymphotactin as its prototype member. The d class possesses a CXXXC motif, and thus far is represented only by fractalkine/neurotactin. This atypical membrane-bound CXXXC chemokine has, on the C-terminal side of the b-sheet sequences, a long glycosylated mucin structure, followed by a transmembrane segment and a short C-terminal cytoplasmic **domain**. The chemokines, with their alternative names, are listed in Table 1 by class.

Table 1. Human Chemokines and Their Receptors

Chemokine (and Alternative Names)	Receptors
ELR + CXC	
IL-8	CXCR1, R2
GROa (MGSA-a)	CXCR2, R1
GROb (MGSA-b,MIP-2a)	CXCR2
GROg (MIP-2b)	CXCR2
ENA-78	CXCR2
LDGF-PBP	CXCR2
GCP-2	CXCR2
Non-ELR CXC	
PF4	Unknown, GAGs[a]
Mig	CXCR3
IP-10	CXCR3, GAGs[a]

ITAC	CXCR3
SDF-1a/b	CXCR4
BCA-1/BLC	CXCR5
CC	
MIP-1a (LD78a)	CCR1, CCR5, CCR9
MIP-1b (Act-2, HC21)	CCR1, CCR5, CCR9
MDC (STCP-1)	CCR4
TECK	Unknown
TARC	CCR4
RANTES	CCR1, CCR3, CCR4, CCR5
HCC-1	CCR9
HCC-4 (NCC-4, LEC)	Unknown
DC-CK1 (PARC, MIP-4, AMAC-1)	Unknown
MIP-3a (LARC, Exodus)	CCR6
MIP-3b (ELC)	CCR7
MCP-1	CCR2, CCR9
MCP-2	CCR2, CCR9
MCP-3	CCR2, CCR9
MCP-4	CCR2, CCR3, CCR9
Eotaxin	CCR3, CCR9
Eotaxin-2/MPIF-2	CCR3
Six CysteineCC	
I-309	CCR8
MIP-5/HCC-2(Lkn-1)	CCR1, CCR3
MPIF-1 (CKb-8)	Unknown
6Ckine (SLC,Exodus-2, TCA-4)	CCR7, CXCR3
Others	
Lymphotactin (SCM-1)	XCR1
CX3C (Fraktalkine, Neurotactin)	CX3CR1
Multiple Chemokines	DARC (Duffy antigen)

[a] GAG = Glycosyl amino glycan.

Members within a class are linked both by their structural similarities and by their location in the human genome. Although there are exceptions in each class, members of the CXC group generally map to the chromosomal locus 4q13. CC chemokines are found primarily on chromosomes 7, 8, 9, and 17. Chromosomal location may provide a useful tool in identifying new members of the g and d classes.

2. Chemokine Expression

Chemokines are expressed by virtually all cell types. Regulation of chemokine expression is complex and highly dependent on specific signaling pathways. Cells can express chemokines constitutively or in response to stimulation by, for example, **interleukin**-1 (IL-1), interleukin-4, tumor necrosis factor a, **interferon**-g (IFN-g), or pathogenic agents such as endotoxin (lipopolysaccharide). Low molecular-weight fragments (200 kDa) of the glycosaminoglycan hyaluronan (resulting from tissue destruction, for example) can enhance expression of some chemokines (eg, MIP-1, RANTES, or MCP-1) in specific macrophage types (eg, bone marrow-derived macrophages or elicited peritoneal macrophages) (7). Depending upon the situation, the expression of these same chemokines can be either suppressed or enhanced by inflammatory mediators, such as IL-10 or IFN-g (8).

One well-characterized example of induction of chemokines is provided by the macrophage. Macrophages can be stimulated to produce-chemokines during T cell-directed delayed type hypersensitive reactions in tissues by contact with activated T cells displaying CD40L. Kornbluth et al. (9) found that, although LPS was also a potent inducer of chemokines, the macrophage-stimulating lymphokines IFN-g and GM-CSF (granulocyte macrophage colony stimulating factor) produced by activated T cells were not good inducers.

3. Chemokine Receptors

Chemokines bind to seven-transmembrane-spanning G-protein-coupled receptors (see Heterotrimeric G Proteins) whose sequence homology is distinct from that of other such receptors. The interaction of a chemokine with its receptor can activate diverse signaling pathways, depending upon the specific signaling elements expressed by the target cell. Chemokine receptors are named on the basis of the cysteine motif that they recognize, and most will bind more than one chemokine ligand in that group. Likewise, a particular chemokine can interact with more than one receptor. Table 1 lists the chemokines and their respective receptors. Some receptors are expressed constitutively by particular cell types, whereas the expression of others may require an inducing signal. Thus CCR1 and CCR2 are constitutively expressed by monocytes, but are expressed by lymphocytes only after stimulation by IL-2 (10). Some chemokine receptors are expressed by nonhematopoietic cells, eg, endothelial cells, neurons, astrocytes, and epithelial cells. This emphasizes recent findings that chemokine receptors may have other important functions besides that of leukocyte chemotaxis. The Duffy antigen receptor, the determinant of the Duffy blood group, is found on a variety of cells, including erythrocytes and endothelial cells, as well as cells of the nervous system. It is unusual in its ability to bind both CC and CXC chemokines without eliciting any known biologic response. Possibly it serves to store or scavenge chemokines (11).

Specific chemokines generally act on specific subsets of leukocytes as a function of the receptors expressed by the cell (Table 2). Most CXC chemokines containing the ELR sequence are chemotactic for neutrophils, whereas non-ELR chemokines generally attract lymphocytes. Neutrophils express the CXCR1 receptor, which is stimulated by IL-8 and granulocyte chemotactic protein-2 (GCP-2), and the CXCR2 receptor, which responds to IL-8, GCP-2, the LPS-induced CXC chemokine (LIX), the neutrophil-activating peptide-2 (NAP-2), the epithelial cell-derived neutrophil activating peptide 78 (ENA-78), and the growth-regulated oncogenes, GRO-a, GRO-b and GRO-g. IL-2-stimulated lymphocytes express CXCR3, the receptor for MIG, IP-10, ITAC, and 6Ckine.

Table 2. Primary Expression of Chemokine Receptors[a]

Receptor (Alternative Names)	Primary Expression
CCR1	Monocytes, eosinophils, activated T cells
CCR2	Monocytes, eosinophils, activated T cells
CCR3	Basophils, eosinophils, subset of Th2, monocytes
CCR4	Activated T lymphocytes

CCR5	Monocytes, T lymphocytes
CCR6 (GPR-CY4, DRY6, CKR-L3)	T and B lymphocytes, bone marrow-derived dendritic cells
CCR7 (EBI1)	Activated T and B lymphocytes
CCR8 (Ter1, CemR1)	Monocytes, T lymphocytes
CCR9 (D6)	Bone marrow, T lymphocytes, monocytes
CXCR1 (IL-8RA)	Polymorphonuclear cells (PMNs, neutrophils)
CXCR2 (IL-8RB)	Polymorphonuclear cells (PMNs, neutrophils)
CXCR3	Activated T lymphocytes
CXCR4 (LESTR,HMSTR,Fusin)	Monocytes, T lymphocytes, PMNs
CXCR5 (BLR-1)	B cells
XCR1 (GPR5)	Unknown
CX3CR1 (V28)	Neurons, endothelial cells
DARC (Duffy antigen)	Red blood cells, postcapillary endothelial cells

[a] This table lists cell types that have been widely accepted as expressors of chemokine receptors. It should be noted that many other cell types express these receptors as well.

Eosinophils, basophils, monocytes, NK cells, and T cells respond to members of the family of CC chemokines. These include monocyte chemoattractant proteins (MCP-1, -2, -3, -4, and -5), macrophage inflammatory protein-1a and -1b (MIP-1a, MIP-1b), RANTES (regulated on activation, normal T expressed and secreted), eotaxin-1 and -2, and I-309. Receptors for these chemokines expressed by eosinophils are CCR1 (recognized by MCP-3 and -4; MIP-1; RANTES) and CCR3 (recognized by MCP-3 and -4; eotaxin-1 and -2; RANTES). Basophils express CCR3 and CCR2, which is activated by all the MCPs. Receptors expressed on monocytes are CCR1, 2, 5, and 8. Ligands for CCR5 include MIP-1a, MIP-1b, and RANTES, whereas the ligand for CCR8 is I-309. Activated T cells express CCR1, CCR2, CCR4 (recognized by TARC, the thymus and activation-regulated chemokine), CCR5, and CCR7, whose ligand is MIP-3 and 6Ckine (3, 4).

4. Chemokine Signaling

The ability of pertussis toxin to suppress many of the chemokine-induced signals suggests that the heterotrimeric G_{abg} proteins mediating chemokine signaling belong to the G_i group, which is defined by their ability to inhibit adenylate cyclase. Activation of the G_i protein leads to replacement of GDP with GTP and dissociation into a_i•GTP and bg subunits, both membrane-associated. Downstream mediators of general G_{abg} signaling may include the ***src*** of nonreceptor protein **tyrosine kinases**, phosphatidylinositol 3-kinase (PI3-K), phospholipase C, protein kinase C species, and the Ras-Raf-MEK-ERK kinase cascade (12, 13). Phospholipase C hydrolyzes phosphatidylinositol 4,5-bisphosphate to produce inositol trisphosphate, a mobilizer of intracellular Ca^{2+}, and **diacylglycerol**, which, together with Ca^{2+}, activates protein kinase C (see Second Messengers and Calcium Signaling). Activation of phospholipase D, which generates phosphatidic acid, and phospholipase A2, which releases **arachidonic acid**, may be direct or indirect downstream effects of chemokine stimulation. Immediate effects (within seconds) on cell behavior are generally mediated by reversible changes in protein **phosphorylation** of **cytoskeletal** proteins, directed in part by the small Gtpases Rho, Rac and Cdc42, thereby affecting the polymerization and depolymerization of actin, which underlies the extension and retraction of lamellipodia, implementors of leukocyte migration (3). Longer term changes are effected by **transcriptional** or **posttranscriptional** changes in gene expression.

Evidence for specific signaling intermediates includes the following: The response of neutrophils to chemoattractants can be suppressed by inhibitors of tyrosine phosphorylation, possibly acting on members of the *src* of nonreceptor protein tyrosine kinases (12). In human T lymphocytes, RANTES induces PI3-K; also, wortmannin, which is a potent PI3-K inhibitor, can inhibit RANTES-induced T-lymphocyte responses (14). In a T-cell hybrid, MCP-1 mobilized intracellular Ca^{2+} concentrations, stimulated Ca^{2+} import, and transiently increased tyrosine phosphorylation of the ERKs by a pertussis toxin-sensitive process (15). In human monocytes, Yen et al. (16) obtained evidence for a putative G_q-mediated pathway, distinct from the pertussis toxin-sensitive G_i-dependent pathway, which activated ERK2 via a protein kinase C-dependent process that probably did not require Ras. Both the G_i and the proposed G_q pathways were required for a chemotactic response to MCP-1. MIP-1 activation of the CCR5 receptor expressed in a transfected murine pre-B lymphoma cell line led to phosphorylation and activation of a protein **tyrosine kinase**, known variously as RAFTK, Pyk2, or CAK-b, that is related to focal adhesion kinase (17). The cytoskeletal protein paxillin became phosphorylated and associated with RAFTK, and the downstream signaling kinases JNK/SAPK and p38 also appeared to be stimulated. Thus, chemokines have the ability to activate a variety of signal transduction mechanisms that connect the extracellular environment with the cytoskeleton.

5. Chemokine Functions

As part of the immune defense system, lymphocytes patrol the body, continually surveying it for pathogens or cells expressing abnormal surface antigens (11, 18). They move from the blood stream into tissues and then back into the blood stream via the lymphatic circulation. Granulocytes and monocytes exit the blood stream, but cannot recirculate. Extravasation is a coordinated multistep process that requires a series of complex changes in the activity of molecules on the cell's surface as it undergoes the transition from a freely floating cell to a weakly adherent rolling cell, and then to a strongly adherent stationary cell able to insinuate itself between the endothelial cells and penetrate the underlying stroma. Chemokines help drive this process and, as noted in Table 3, determine what types of cells infiltrate into the tissues in various inflammatory diseases. Imai et al. (19) report that the MDC and TARC chemokines, which are produced by dendritic cells in the thymus, act via the CCR4 receptor to recruit and activate T lymphocytes in the thymus. DC-CK1, another C-C chemokine derived from dendritic cells, is a chemoattractant for naive T cells (20). In allergic diseases such as asthma, expression of eotaxin and monocyte chemoattractant proteins appear particularly important in stimulating the accumulation and activation of eosinophils and mast cells, leading to histamine release and the allergic response (21). Similar events are thought to occur in rhinitis and atopic dermatitis.

Table 3. Chemokine Involvement in Inflammatory Diseases

Inflammatory Disease	Infiltrate	Chemokines Involved
Acute respiratory distress syndrome	Neutrophils	IL-8, GRO-a,b,g, ENA-78
Asthma	Eosinophils, T-cells,	MCP-1,4, MIP-1a,

	monocytes, basophils	Eotaxin, Rantes
Bacterial pneumonia	Neutrophils	IL-8, ENA-78, GRO-a,b,g
Sarcoidosis	T-cells, monocytes	IP-10, MIP-1a, MCP-1, Rantes
Glomerulonephritis	Monocytes, T-cells, neutrophils	MCP-1, GRO
Rheumatoid arthritis	Monocytes, neutrophils	IL-8, MCP-1, IL-8, ENA-78
Osteoarthritis	Monocytes, neutrophils	MIP-1b, IL-8
Atherosclerosis	T-cells, monocytes	IL-8, IP-10, Rantes, MCP-1
Inflammatory bowel disease	Monocytes, neutrophils, T-cells, eosinophils	MCP-1, IL-8, ENA-78, Eotaxin
Psoriasis	T-cells, neutrophils	MCP-1, MIG, IL-8, Rantes, MIP-1
Bacterial meningitis	Neutrophils, monocytes	IL-8, GRO-a, MCP-1, MIP-1a,b
Viral meningitis	T-cells, monocytes	MCP-1, IP-10
Multiple sclerosis	T-cells	Rantes, IP-10, MIP-1a
Seasonal allergic rhinitis	Eosinophils	Eotaxin, Rantes, IL-8, MIP-1, MCP-1
Periodontal disease	Monocytes, PMNs	IL-8, MCP-1

Subsets of lymphocytes express different surface molecules that allow them to target different tissues in the body. Extravasation of the lymphocyte from the blood stream is initiated when a free flowing lymphocyte becomes tethered to the endothelium such that it can still roll in the direction of flow. Rolling of leukocytes is controlled in part by the interaction of selectins with specific sialylated carbohydrate determinants. L-selectin, expressed by lymphocytes, monocytes, neutrophils, and eosinophils, interacts with receptors such as CD34 on the activated endothelium. P-selectin and E-selectin molecules are expressed by activated endothelial cells and bind structures related to the tetrasaccharide sialyl Lewis antigens on the leukocyte surface. Thrombin and histamine can mobilize P-selectin from intracellular stores, whereas up-regulation of E-selectin requires induction by inflammatory agents such as IL-1, tumor necrosis factor, or LPS. This interaction appears to result in activation of leukocyte 1 and 2 integrins, enabling them to bind to ligands of the immunoglobulin superfamily (eg, VCAM-1, the ICAMs; see Cell Adhesion Molecules) either expressed constitutively by the endothelial cells or induced by inflammatory agents. Various subsets of lymphocytes rolling on an ICAM-1 monolayer can be induced to arrest within one second by SDF-1, 6Ckine, MIP-3, or MIP-3; adhesion, which can be prevented by pertussis toxin, is transient, lasting some 5 to 8 minutes (22).

In inflammatory diseases, it is likely that sentinel cells at the site of inflammation produce chemokines that induce the strong interactions required to elicit leukocyte invasion. Chemokine expression has been demonstrated in glomerulonephritis, asthma, inflammatory bowel disease, and allogenic transplant rejection (2, 4). Because multiple inflammatory mediators are generally elaborated at sites of inflammation, the task of determining which is responsible for any particular pathogenic response is difficult. Although there is considerable redundancy built into the system, some chemokines predominate in some forms of injury. For example, IL-8 is a major causative factor associated with reperfusion injury and acid-induced pneumonitis, which is the consequence of neutrophil invasion and the release of inflammatory mediators (23).

Angiogenesis (see Angiogenin), the induction of synthesis of new blood vessels, typically with reference to the vascularization of a tumor, is a complex response affected by many factors, including chemokines. Although the specific role of chemokines in angiogenesis is unclear, evidence has suggested that CXC chemokines possessing the ELR motif generally promote angiogenesis, whereas those lacking the ELR motif tend to inhibit it (24). Mice lacking either SDF-1 or the counterpart receptor CXCR4 are defective in formation (vasculogenesis) of the large vessels supplying the intestinal tract (25). Vessels supplying the small intestine were missing major branches, and this led to hemorrhaging. Likewise, the vascular supply to the stomach in these mice was bereft of all large arteries and veins.

Many functions regulated by chemokines in the immune system, including cell migration and adhesion, as well as cytoskeletal reorganization, are important in the development and function of the nervous system. Defects in brain development in the CXCR4-deficient mouse (and its counterpart, the SDF-1 deficient mouse) are likely to be harbingers of other developmental and brain-specific functions of chemokines (26). The CXCR4-deficient mouse is embryonic-lethal, although with some animals surviving to term. The most prominent defects are found in the development of the cerebellum, where the granule neurons migrate prematurely. Since the radial glial cells are preserved in these animals, the evidence is consistent with an inhibitory role of SDF-1 on granule cell migration. This inhibition could occur by blocking the action of a migratory-promoting substance, or by altering adhesion molecules on the cell surface of the radial glial cell or the granule neuron. Since some of the guidance cues for this migratory process have been identified, it is of obvious importance to investigate if SDF-1 has any action to modulate the expression or conformation of these proteins.

Additional evidence for central nervous system actions of chemokines has been provided by the **transgenic** (see Transgenic Technology) expression of chemokines under the influence of the myelin basic protein **promoter**. Directed expression of the murine chemokine KC stimulated neutrophil infiltration of the brain at various sites (27). Likewise, overexpression of MCP-1 in both thymus and brain led to infiltration of either MAC-1, F4/80, or macrophages and monocytes, respectively (28). These studies demonstrate that each organ is capable of recruiting mononuclear cells under specific conditions.

6. Viral Adaptation to Chemokines

Viruses often exploit endogenous cell surface receptors, including chemokine receptors, in the initial stages of infection. For example, mice deficient in MIP-1 as the result of a targeted gene disruption (**knockout** mice) exhibit attenuated responses to certain viral infections (Coxsackie virus, influenza virus). Several of the chemokine receptors serve as entry mechanisms for various strains of HIV. Roger (29) has reviewed the role of chemokine receptors and the HLA **haplotype** in the development of AIDS. The CCR5 receptor appears to be the preferred coreceptor for macrophage-tropic, nonsyncytium-forming HIV-1 strains, whereas the CXCR4 receptor (fusin) primarily services the syncytium-inducing, T-cell-line-tropic HIV-1 strains (30). Some HIV isolates can utilize both receptors, while a few other variants appear to have acquired the ability to co-opt other chemokine receptors as coreceptors for virus infection. Individuals with mutations in chemokine receptors may exhibit considerable resistance to infection or to progression of the disease. One mutation in particular should be noted. People homozygous for a deletion mutation in the CCR5 gene (CCR5 d32) are resistant to infection by the virus; heterozygotes for the same mutation had a significantly slower onset of disease (31). Chemokines can also affect the progression of an HIV infection. SDF-1, a ligand for CXCR4, inhibits HIV entry into cells (32, 33), and the CC chemokines MIP-1a, MIP-1b, and RANTES, all ligands for CCR5, likewise seem to retard HIV-1 infection (34).

7. Conclusion

The chemokine field is evolving rapidly. Although the initial focus has been on the role of chemokines in the immune system, future directions for chemokine research lie in elucidating chemokine expression and function in other organs and during development. Importantly, the involvement of chemokines and their receptors in many disease processes makes them primary targets for drug development.

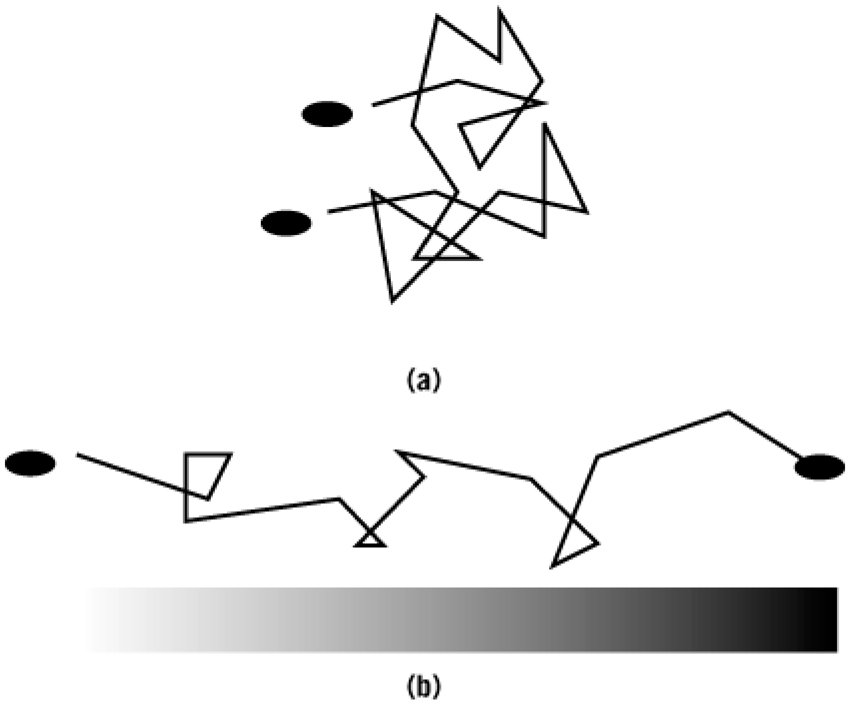
Chemotaxis

Chemotaxis is the movement of a motile cell in response to chemical changes in the environment, and it implies a directional sense. In most cases where **bacteria** migrate up concentration gradients of attractants, direction is not sensed directly. The small size of bacteria would make spatial comparisons of concentration unreliable. Instead, bacteria usually sense temporal changes in concentration by using chemoreceptors, **transducer proteins** that bind or release attractants and repellents. This temporal measurement allows the cells to alter motion of their **flagella** briefly so that a "biased random walk" brings the bacteria to the right destination (1, 2) (Fig. 1). Eukaryotic cells carry out chemotaxis by an unrelated mechanism, and they are much larger and probably do sense direction.

Figure 1. Motion of peritrichous bacteria. (**a**) Random walk in an isotropic medium. (**b**) Biased random walk in a gradient of an attractant or repellent.



1. Bacteria

There are three main types of motile bacteria: 1) the peritrichous (flagella over the surface), 2) the polar (flagella at one or both poles), and 3) the gliding bacteria, which lack flagella.

The peritrichous bacteria, such as ***Escherichia coli*** and ***Bacillus** subtilis*, normally swim smoothly by rotating their flagella counterclockwise (looking along the flagella toward the cell body) and tumble by rotating their flagella clockwise, which discoordinates the bundle of flagella. Chemotaxis in *E. coli* occurs when the cell happens to move toward higher attractant concentrations. It decreases the probability of tumbling and, thus, increases the tendency to travel up the attractant gradient (1).

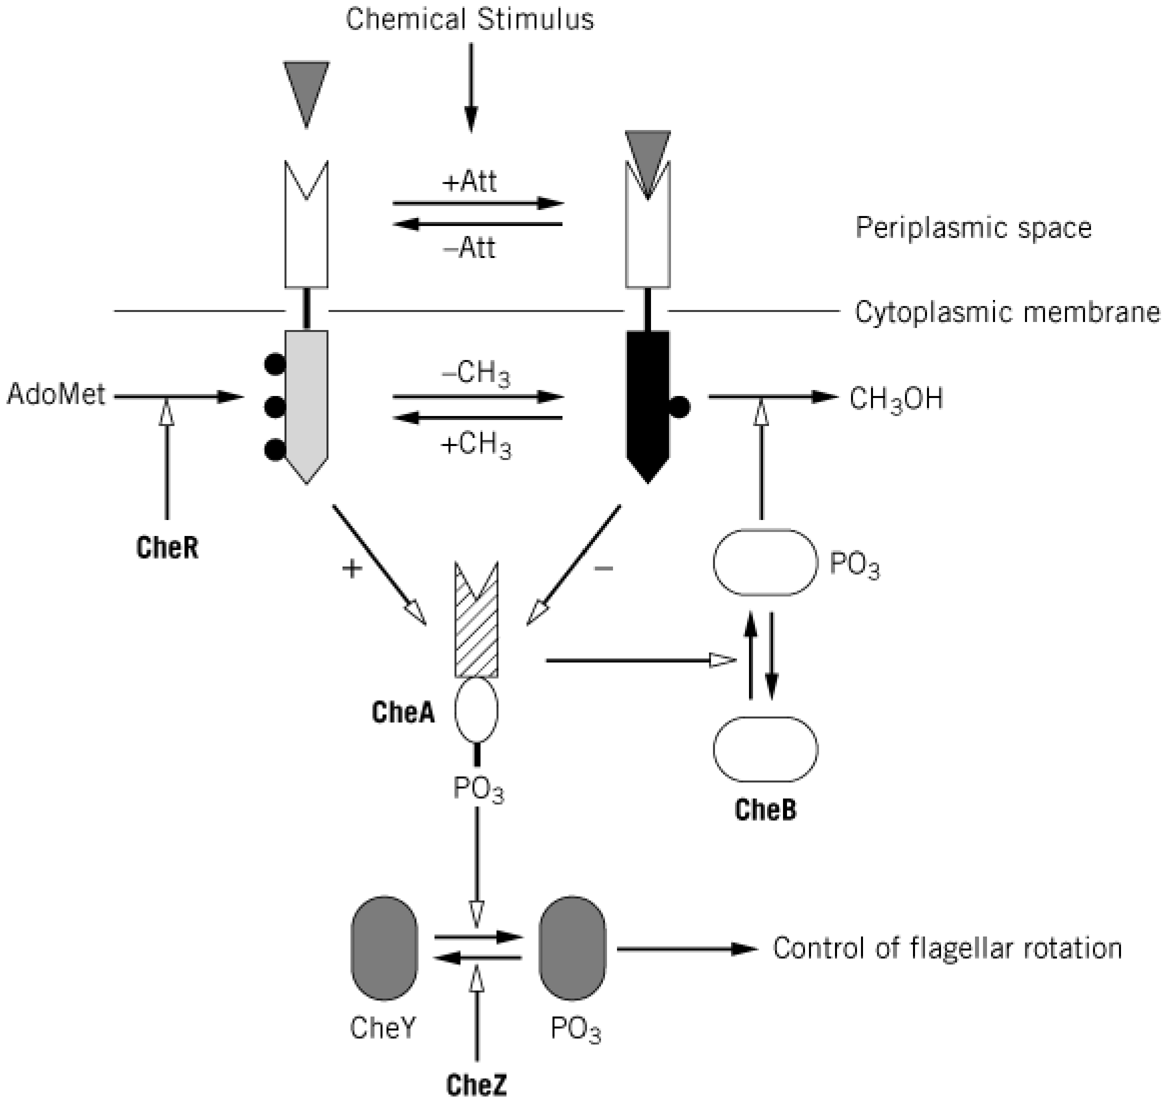
This decreased probability of tumbling results (Fig. 2) because the attractant molecules bind to methylated chemoreceptors to cause a brief inactivation of the cytoplasmic CheA **kinase** (see **Transducer proteins**). Consequently, there is less phosphorylated CheA (CheA-P) and less CheY-P (2) (see **Phosphorylation**). CheY-P dissociates from the switch that controls flagellar rotation, so that smooth swimming ensues. The enhanced smooth swimming is short-lived because CheZ hydrolyzes the phosphoryl group from CheY, and the CheR **methyltransferase** increases the degree of methylation of the chemoreceptor and restores the prestimulus activity of CheA (3) (see also Methylation, Protein). Thus, there is an inverse relation between the levels of CheY-P and termination of a smooth swimming event.

Logically, it seems plausible that bacteria moving by chance toward *lower* attractant concentrations would show an increased tendency to tumble and, hence, to begin heading in another direction. In the case of *E. coli*, however, there is no demonstrable increased tendency for these bacteria to tumble compared with bacteria in an isotropic medium (1). Interestingly, CheY-P cannot affect rotational direction of the flagella by itself. Fumarate needs to be released or synthesized for switching to occur (4) and also promotes tumbling (5). The connection between CheY-P and fumarate in controlling direction of flagellar rotation has not been elucidated.

The role of CheY-P is less clear in the case of polar bacteria, such as *Caulobacter crescentus* and ***Pseudomonas*** *aeruginosa.* When these bacteria move by chance toward lower concentrations of attractant, they reverse motion by rotating their flagella in the opposite direction, to head back up the gradient. If repellent is added, however, they show a series of reversals of motion. This result implies that CheY-P does not govern the *direction* of rotation of the flagella but instead causes repeated reversals of behavior. Such an event might ensue if binding of CheY-P to the switch reduces the energy of activation of switching the flagellar rotational direction. In the absence of binding, the energy of activation is presumed to be so high that reversals are very infrequent. In the case of *Halobacterium salinarium,* negative stimuli cause significant increases in the concentrations of free fumarate in the cytoplasm (4).

Other bacteria, like *Sinorhizoboium meliloti,* a **Gram-negative** bacterium phylogenetically rather distant from *E. coli*, rotate their flagella unidirectionally. In this case, the CheA/CheY system also exists with the complication that there are two species of CheY. CheY2-P is the major species that affects flagellar movement, and it acts by slowing flagellar rotation (6). Some bacteria, such as *Rhodobacter sphaeroides*, have multiple copies of many of the *che* genes (7).

Figure 2. Diagram of the mechanism of chemotaxis in *Escherichia coli*. Open arrows indicate control of the designated reaction or signaling step. At the *top*, the attractant (Att) binds to its transmembrane chemoreceptor, which is methylated on Glu residues. The methyl groups are depicted as closed black circles. This binding decreases the phosphorylated form of the protein CheA (*center*), which decreases phosphorylation of the proteins CheY and CheB. Dephosphorylated CheB is much less active in removing the methyl groups from the chemoreceptor, so CheR restore them. Phosphorylated CheY dissociates from the switch that controls flagellar rotation, and smooth swimming ensues. CheZ hydrolyzes the phosphoryl group from CheY, ending the response to the attractant.



Thus, it appears that the basic system involving the two-component couple CheA and CheY is universal, but how it functions varies for different groups of organisms.

The potential role for CheY-P is still less clear in the case of the gliding bacteria. One of them, *Myxococcus xanthus*, has two motility systems, the S (social) system powered by extrusion and retraction of pili from the ends and the A (adventurous) system, powered by a mechanism of unknown structure along the sides. The former coordinates cells and, unless the agar concentration is quite low, requires cell contact for movement. The frequency and pole at which pili activity occurs is governed by the Frz proteins, which are homologous to the chemotaxis proteins in flagellated cells. However, none of the genes encode a single-domain CheY (8, 9).

One issue that has existed for many years has been whether the rotation of multiple flagella are coordinated or independent. The finding that bundles of flagella located 50 mm apart on *Spirillum volutans* were observed switching synchronously within 10 ms implies electrical coordination of direction of the flagellar rotation (1). In contrast, certain mutant strains of ***Salmonella*** *typhimurium* show random and uncorrelated switching of their flagellar direction when observed under partially de-energized conditions (10). *E. coli* filamentous cells switch their flagella asynchronously although biases of nearby, but not distant, motors were correlated (11). In *H. salinarium*, an **archaeon,** the rotational direction of flagellar bundles on each end is also uncoordinated, and cells were frequently observed to be immobilized because the bundles at both ends worked against each other. Thus, there is no general rule governing flagellar coordination. Indeed, the mechanism by which an electrical connection could work, as in *S. volutans*, is obscure.

2. Eukaryotes

Chemotaxis in eukaryotes occurs by an unrelated mechanism. The process is best known from studies in the aggregating slime mold ***Dictyostelium*** *discoidium* and in leucocytes; it is probably quite similar in both. In the slime mold, chemotaxis plays a role in feeding and in the aggregation that precedes **differentiation** and **sporulation**. Chemotaxis in *Dictyostilium* involves apparent polarization of the cell to form pseudopodia or lamellipodia at the leading edge at the highest concentration of attractant molecules. Polarization and formation of pseudopodia are concerted events regulated by G protein-coupled/serpentine **cyclic AMP** (cAMP) receptors (cARs) along the surface of the organism. During aggregation, cAMP is produced and binds to a cAR, which activates a heterotrimeric **G-protein**. **Guanylate cyclase** is activated by operation of this G-protein, thereby producing cGMP. cGMP activates a cGMP-dependent protein kinase, which regulates myosin II heavy and light chain kinases and may also help regulate the actin cytoskeleton. Phosphorylation of the myosin heavy chain causes it to depolymerize so that pseudopod extension can only occur locally. Posteriorly, contraction occurs and pseudopod formation is blocked. At the same time cAMP binding to its receptor leads to activation of phosphatidylinositol-3 kinase. The product, phosphoinositol-3,4,5-triphosphate, attracts PH (pleckstrin homology) proteins, including the kinase Akt/PKB, to the localized region where the local amount of cAMP-bound receptor is highest. Another PH domain protein is CRAC. It is required for receptor activation of adenylyl cyclase (see below), which then propagates the cAMP signal to neighboring cells. This membrane localization lasts only 5 to 8 s; however, that is long enough to produce an "activation domain" as a focus for multiple pathways needed for chemotaxis, pseudopod extension, and cell polarization. F-actin is assembled primarily there. Actin polymerization is activated by formation of an Arp2/3 protein complex. Nucleation is induced by Arp2/3 interaction with WASp and Scar adaptor proteins. These proteins provide the structural linkage to the activated cAR through the activated form of Rac and Cdc42, which are regulated by the G protein G_{bg}. Pseudopod formation also requires actin crosslinking and filament growth regulated by actin binding proteins (12, 13).

Binding of cAMP to the receptors transiently activates both adenylyl cyclase and ERK2 MAP kinase. A rise in internal cAMP activates protein kinase A such that it inhibits ERK2 and leads to loss of ligand binding by the receptor. ERK2 also phosphorylates the cAMP diesterase REG A that reduces the internal concentration of cAMP. A secreted membrane-associated phosphodiesterase reduces the external cAMP concentrations, and the cells become sensitive again. These features account for spontaneous oscillations of external cAMP production of about 6 min that permit chemotactic migration of cells toward centers during the aggregation process (14).

Chimera

Spemann (1, 2) was the first to employ the term "chimera" and to consider the great potential for surgically created chimeric embryos in the analysis of **developmental** mechanisms. The chimera method has frequently involved imaginative experimental procedures by which cells of one species are grafted into another. Any animal thus composed of different cell populations that derive from more than one fertilized egg should be considered as a chimera. This type of animal can currently be constructed in amphibians, birds, and mammals.

Many fundamental concepts of embryology have been at least partly formulated on the basis of results of cell or tissue transplants between two different embryos, usually separate species of amphibians. The most spectacular transplantation experiments, published by Spemann and Mangold in 1924 (3), demonstrated the organizing power of the dorsal lip of the blastopore during gastrulation by interspecific transplantations of this area. More recently, a model of lens induction was developed by using chimeric eyes (4). The technical advantages of producing amphibian chimeras are straightforward, owing to the independence of the embryos from their parents. They are easily accessible and receptive to foreign tissue, even across species barriers. All these qualities are not shared by higher vertebrates, such as birds and mammals. Nonetheless, bird embryos have several advantages over other vertebrate embryos, making certain interesting approaches feasible. The greatest advantage is continual accessibility within the egg throughout the developmental period. Another is the ease with which the various rudiments can be delineated, and thus removed and replaced, with extreme precision. An avian chimera obtained by combining quail and chick cells has been the most successful method, having provided a continual source of new data about developmental mechanisms for almost 30 years (5, 6). With the advent of the quail-chick nuclear marker, which is particularly simple to employ, easy to identify, and endowed with great resolving power, avian chimeras have been used to study the ontogeny of the nervous system, the development of the hematopoietic and immune systems, and the formation of muscles and skeleton. Quail heterochromatin in the nucleus is concentrated around the nucleolus. This creates a large, deeply staining mass that is easily distinguishable from the diffuse heterochromatin of chick cells. Moreover, there are some antigens that are quail-specific and not detectable in chick cells. These phenomena allow individual quail cells to be readily distinguished, even when most of the cell population is chick.

Although the avian embryo is a practical model, perfectly suitable for tissue graft experiments after the incubated egg is opened, it is difficult to undertake this type of investigation in the mammalian fetus *in utero*. Nonetheless, it has become routine to remove postimplanted mammalian embryos from the uterus, manipulate them, and return them to a foster mother for further development. Thus, chimeric mice are the result of two or more early-cleavage (usually 4- or 8-cell) embryos that have been artificially aggregated to form a composite embryo. Since each cell is able to produce any component of the body, the construction of the chimeric mouse has very important consequences for the study of mammalian ontogeny. A very powerful application of this technique is the transfer of genes into every cell of the mouse embryo. During mouse development, there is a stage when only two cell types are present: outer cells, which will form the fetal portion of the placenta, and inner cells, which will give rise to the embryo itself. These inner cells are known as embryonic stem cells because each in isolation can generate all the cells of the embryo (7, 8). These cells can be grown in culture, where they are treated to incorporate new DNA. The new embryonic stem cells can then be injected into another early-stage mouse embryo, resulting in a chimeric mouse. Mice that derive from these animals are **transgenic** mice. Our understanding of regulatory mechanisms in mammalian development is improving increasingly rapidly as a result of the construction of these genetically modified mice. A combination of the tools of developmental genetics with those of embryology should lead to real advances in the study of such mechanisms. In this field, our group has pioneered the grafting of embryonic tissues from transgenic mice into the chick embryo (9, 10). Owing to these interspecies grafting experiments, it is possible to monitor factors that regulate the expression of a particular gene *in vivo*. The value of this technique is greatly increased when a reporter gene is used to follow the changes in gene expression of the grafted cells. The possibility of conducting grafts until late stages of *in vivo* development allows the behavior of wild and mutant mouse cells to be observed at any developmental stage and location.

1. Amphibian Chimera

Using amphibians, Spemann and Mangold (3) improved our understanding of the specification of the nervous system by transplanting dorsal blastopore lip tissue from an early gastrula into the ventral ectoderm of another gastrula. They used differently pigmented embryos from two species of newt: darkly pigmented *Triturus taeniatus* and nonpigmented *Triturus cristatus*. On the basis of color, it was easy to distinguish host and donor tissues. The dorsal blastopore lip tissue from early *Triturus taeniatus* gastrula, once transplanted into an early *Triturus cristatus* gastrula in the region, would normally become ventral epidermis. In fact, the donor tissue did not become belly skin but invaginated and formed a secondary embryo, face to face with its host. The more recent use of nuclear markers has allowed Spemann's results to be confirmed (11). Such chimeras elegantly demonstrate the organizing power of the dorsal lip of the blastopore in amphibian gastrula, since whole secondary embryos formed under the influence of the transplanted tissue.

Considerable advances have also taken place in the field of differentiation and organogenesis through the use of amphibian chimeras. The more common examples are those involving the interaction of epithelia with adjacent mesenchyme. After being separated, embryonic epithelium and mesenchyme can be recombined in different ways (12). In a classic experiment, Spemann and Schotté (13) transplanted flank ectoderm from an early frog gastrula into the region of newt gastrula destined to become part of the mouth. Similarly, the presumptive flank ectodermal tissue of newt gastrula was placed into the presumptive oral regions of frog embryos. The structures of the mouth region differ greatly between salamander and frog larvae. The *Triturus* salamander larva has club-shaped balancers beneath its mouth, whereas frog tadpoles produce mucus-secreting glands and suckers. Frog tadpoles also have a horny jaw without teeth, whereas the salamander has a set of calcareous teeth in its jaw. The larvae resulting from the transplants were chimeras. The salamander larvae had froglike mouths, and the frog tadpoles had salamander teeth and balancers. In other words, the mesodermal cells instructed the ectoderm to make a mouth, but the ectoderm responded by making the only mouth it “knew” how to make. Thus, instructions sent by mesenchymal tissue can cross species barriers, although the response of the epithelium is species-specific. Thus, organ-type specificity is usually controlled by the mesenchyme within a species, but species specificity is usually controlled by the responding epithelium.

The cells that form the lens are derived from a region of head ectoderm in contact with optic vesicles of the anterior neural plate. Servetnick and Grainger (14) removed animal cap ectoderm from various gastrula stages and then transplanted them into the presumptive lens region of neural-plate-stage embryos. Ectoderm from early gastrula showed little or no competence to form lenses, but ectoderm from slightly later stages was able to. By the end of gastrulation, this ability to respond to the neural plate signal had been lost. This competence was found to be inherent within the ectoderm itself and not induced by other surrounding tissues. These observations showed that only mid- to late-gastrula ectoderm is able to respond to signals from the anterior neural plate. It has recently been demonstrated that the transcription factor Pax6 may play a role in the determination processes of eye tissue (see Pax Genes).

2. Avian Chimera

When portions of quail embryo are grafted into a similar region of chick embryo, the cells become integrated into the host and participate in the construction of the appropriate organs. This grafting is done while the embryo is still inside the egg, and the chick that hatches is a "chimera," having a portion of its body composed of quail cells (15). The quail is usually chosen as a donor because it is easier to identify quail cells among chick cells than the reverse.

The ontogeny of the peripheral nervous system is one of the fields in which the use of avian chimeras is the most fruitful. This system arises almost entirely from the neural crest, a transient structure that develops at the neural tube apex. To follow the fate of chick neural tube-bearing neural crests, a segment is replaced by a homologous quail fragment. This method has permitted the diverse range of neural crest potentialities to be well-described, and the list of neural crest derivatives well-defined (6).

In relation to its origin, neural crest not only participates in the formation of spinal and cranial sensory ganglia, sympathetic and parasympathetic ganglia and plexuses, and Schwann cells of the peripheral nerves, but it also gives rise to endocrine and paraendocrine cells (calcitonin-producing cells, carotid body type-I cells, adrenomedullary cells) and pigment cells. The construction of an avian chimera has demonstrated the contribution of the cephalic neural crest to mesectodermal derivatives. For example, nasal and maxillary processes are built up partly by crest cells of mesencephalic origin. The mesencephalic crest cells also form the cephalic skeleton, the upper and lower jaws, the palate, and the tongue. The rhombencephalic crest participates in formation of the pre-optic region and the hyoid arch skeleton. In addition to cartilage and bone, the cephalic neural crest takes part in other derivatives of the head and neck, such as dermis and connective tissue.

Brain development has also been characterized by the use of the quail-chick chimera technique (16). Quail-chick brain chimeras can hatch and survive without showing impaired movement or locomotion, which indicates that functional synapses have been established between host and donor neurones, as well as between donor neurones and host muscles. Moreover, the normal behavior of the chimeras demonstrates that proper neuronal connections develop in the brain, which means that quail axons recognize local signals for growth and directionality in the chick environment, as they do in normal development. An interesting application of the chimeras is illustrated by chicks with transplanted quail mesencephalic-diencephalic brain areas, which then exhibit quail vocalization (17). Another important issue is the elucidation of when and where groups of cells in the brain make commitments to particular development pathways. Genes with spatially restricted expression are of particular interest, since they may indicate the existence of committed groups of cells that are important in pattern formation, but are not discernible on the basis of morphology. An example is provided by the **zinc-finger** gene *Krox-20*, which has restricted domains of expression in the early neural plate. *Krox-20* is expressed in the early neural epithelium, first in one stripe, and then in two stripes in the hindbrain. Subsequently, *Krox-20* is expressed in two alternating segments (rhombomeres) in the hindbrain. The generation of stripes of *Krox-20* expression in the early neural plate suggests that rhombomeric precursor cells are committed prior to the morphological appearance of the rhombomere.

Hox homeotic gene expression is seen along the dorsal axis, from the anterior boundary through to the tail. Direct evidence for hindbrain plasticity comes from quail-chick chimera experiments showing that anterior-to-posterior transpositions can reprogram Hox expression and induce a transformation in cell fate (18). The quail-chick system has also shown that environmental cues play a significant role in maintaining the Hox code in the neuroepithelium.

Chimeric experiments involving the muscles of the body, limbs, and skeleton have also been carried out in birds. For development, somites are the primitive metameric structures of the vertebrate body from which arise the vertebrae that surround the spinal cord, the muscles and connective tissue holding the vertebrae, the dermal layer of the skin of the back, and the limb musculature. All these data were obtained by constructing a chimeric embryo after interspecific grafts of somites between quail and chick embryos (19, 20). The somites appear as pairs of epithelial spheres that bud off from the unsegmented paraxial mesoderm in a craniocaudal direction. They become polarized into a ventral mesenchymal compartment, the sclerotome, which yields the dorsal skeleton, and a dorsal epithelial component, the dermomyotome, from which striated muscle and dermis arise. By constructing a quail-chick chimera after interspecific exchanges of medial or lateral halves of newly-formed somites, Ordhal and Le Douarin (21) determined that, regardless of the somites, cells farthest from the neural tube (ie, lateral) migrate to form the body wall and limb musculature.

The interspecies graft method in birds has contributed considerably to understanding the control mechanisms of somite patterning. This method demonstrates that specification of the somite is accomplished by the interaction of different tissues that form its environment. In fact, the newly formed somite is composed mostly of unspecified cells, and the determination of somite compartments toward the different lineages is regulated by environmental cues. The ventral-medial portion of the somite is induced to become the sclerotome by factors, especially *Sonic hedgehog* protein, that are secreted from the notochord and neural tube floor plate. If portions of the notochord, the source of Sonic **hedgehog**, are transplanted next to other regions of the somite, those regions also become sclerotome cells. These sclerotome cells express a new transcription factor, Pax1, which activates cartilage-specific genes and is necessary for the formation of vertebrae (22). In similar ways, the myotome is induced by two distinct signals. The muscles surrounding the body axis, which arise from the medial portion of the somite, are induced by factors from the dorsal neural tube, probably members of the *Wnt* family (23, 24). The muscles derived from the lateral portion of the somite, which form the musculature of the limbs and body wall, are probably induced through the combination of Wnt proteins from the epidermis with bone morphogenetic protein-4 (BMP4) protein from the lateral plate mesoderm (25). These factors cause the myotome cells to express particular transcription factors, MyoD and Myf5, that activate muscle-specific genes. The dermatome differentiates in response to another factor secreted by the neural tube, neurotrophin 3 (NT-3) (26).

3. Mammalian Chimera

The laboratory mouse is by far the most popular mammal used to construct chimeras for developmental studies. Mice offer a large variety of genetically well-characterized strains that provide scope for using genetic markers. Moreover, they breed throughout the year and thus continually supply embryos. The most convenient time for manipulation of a mammalian embryo is before its implantation. During the first three to four days of gestation, mouse embryos have not yet formed an attachment in the mother's reproductive tract and can thus be explanted, manipulated, and then retransplanted into another mouse to continue their development. Chimeric mice are generally formed by the fusion of two early embryos that organize to produce a single mouse with two distinct cell populations.

A skeletal muscle cell (myotube) is an elongated cell containing many nuclei. It has been widely debated whether this cell is derived from the fusion of several mononucleated precursor cells (myoblasts) or from a single cell that undergoes nuclear division without cell division. Evidence for the fusion process has been provided by mouse chimeric constructions. Mintz and Baker (27) fused mouse embryos from two strains that produce different types of the dimeric enzyme isocitrate dehydrogenase: one strain makes the A subunit and the other B. If myotubes are formed from one cell whose nuclei divide without cytokinesis, the dimeric enzyme will be purely AA or BB. If, however, myotubes are formed by fusion between cells, some might code for the B subunit and others for A, in which case the molecules of the enzyme will be hybrid (AB). Electrophoresis can separate these three types (see Isozyme, Isoenzyme). The presence of the hybrid AB enzyme in extracts of skeletal muscle tissue confirms the fusion model.

The study of mutations that impair development or function has long been recognized as a valuable means of elucidating the normal role of genes in such processes. Genetically chimeric animals consisting of mixtures of mutant and wild type cells can be of considerable value for studying the genes that are primarily implicated in developmental mechanisms. Methods of manipulating mouse embryos and transferring genes into every embryonic cell are now standard procedures. In recent years, an extraordinary increase in the use of these methods has led to numerous exciting prospects.

The most widely used method to produce transgenic mice is to inject **cloned** DNA into a pronucleus of a fertilized egg. Although this method has been used primarily for studies of **gene expression**, an unexpected benefit is the frequent integration of the injected DNA into genes, causing insertional mutations. Experimental infection of embryos by retroviruses has also been developed as a method for gene transfer. As in the case of spontaneous infection, this approach has resulted in insertional mutations. An additional approach to producing transgenic mice involves genetic modification of tissue culture lines of embryonic stem cells, followed by their re-incorporation into growing embryos. By applying somatic cell genetic techniques to these cells while in culture, both random and selected insertional mutations have been produced. Another method for assaying the function of a gene is to eliminate it from the genome of the whole organism. Very recent studies, using strategies to inactivate genes by homologous recombination in embryonic stem cells, with the subsequent generation of germ-line chimeras, have made this scenario possible and thereby initiated a new era in mammalian developmental biology.

The power of this technology can be illustrated by the *int-1* gene, which is expressed during central nervous system development in a temporally and spatially restricted fashion. Following inactivation of the gene by homologous recombination in embryonic stem cells, germ-line chimeras were obtained and bred to derive homozygous *int-1*-deficient mice. These homozygous mice were not viable, because specific regions of the brain were missing. This experiment indicates that *int-1* is an essential gene for early development and suggests that its expression might determine the fate of a cell. The *Hox a-3* gene has been found to control segment-specific gene expression in Drosophila, but what is its role in mammals? Chisaka and Capecchi (28) used gene targeting to determine the function of *Hox a-3* in the development of the mouse. Homozygous mutants of *Hox a-3* were found to have severe anomalies in development of the hindbrain and in mesectodermal neural crest derivatives and to lack thyroid, parathyroid, and thymus glands. These studies clearly open up new avenues for the study of mammalian development at the molecular level and will certainly be instrumental in unraveling the molecular networks responsible for the functioning of a multicellular organism.

4. Mammalian Avian Chimera

In chimeras, the analysis of cell lineages depends on the ability to distinguish between cells of different origins. Markers are required to trace the developmental fate of cells and to recognize them at all ages in chimeric embryos. In mammals, genetic manipulations appear to be valuable means of elucidating the normal role of genes and identifying altered cells. Furthermore, the environment of the chimera allows these cells to survive and to display their phenotype. In chimeras, identification of all the descendants of genetically modified cells has thus far provided a reliable and sensitive means of measuring alterations in embryogenesis. In conjunction with an *in situ* marker, this may help in determining the cell type and the nature of the functions affected by the particular mutant. Extremely sensitive labeling is possible with transgenic mouse lines since cells that integrate foreign DNA, such as a reporter gene encoding for *Escherichia coli* b-galactosidase, are detectable by simple histochemical revelation, which can be used to differentiate grafted cells from host cells. Currently, the major means of exploring this genetic tool is by *in vitro* experiments in which mutant-induced tissue is cultured with wild-type tissue. The culture system is efficient in tissue development for only limited periods, however, and the media used may affect the tissue outcome. *In vivo* micromanipulation remains the most powerful means of studying the fates of cells, their origins, and the cell-cell interactions that govern development. Since implantation of mouse embryo is particularly unsuitable for *in vivo* manipulation, chick embryo is used as the site for developing mouse embryonic cells. Studies in such chimeras provide considerable information on the lineage and the differentiation of mouse embryonic cells, since *in ovo* grafted mouse cells are accessible throughout chick host embryogenesis. Moreover, these results are indicative of the information to be obtained through genetic manipulations in conjunction with embryonic tissue transplantation. It has been clearly demonstrated that *in ovo* transplantation provides a suitable environment for the development of mammalian cells and that the information supplied by this environment is capable of promoting mouse cell differentiation.

Chimeras were prepared by transplanting somites from nine-day postcoitum mouse embryos into two-day-old chick embryos at different axial levels. Mouse somitic cells then differentiated *in ovo* into dermis, cartilage, and skeletal muscle, as they normally do in the course of development, and were able to migrate into chick host limb. To trace the behavior of somitic myogenic stem cells more closely, somites arising from mice bearing a transgene of the desmin gene linked to a reporter gene coding for *E. coli* b-galactosidase were grafted *in ovo*. Interestingly, the transgene was rapidly expressed in myotomal muscles derived from implants. In the limb muscle mass, positive cells were found several days after implantation. This method facilitates investigation of the mechanisms of mammalian development, allowing the normal fate of implanted mouse cells to be studied and providing suitable conditions for identification of descendants of genetically modified cells.

Chimeras were also prepared by transplanting fragments of neural primordium mouse embryos into chick embryos at different axial levels. Mouse neuroepithelial cells differentiated and organized to form the different cellular compartments normally constituting the central nervous system. The graft entered into the development of the peripheral nervous system through migration of neural crest cells associated with mouse neuroepithelium. Depending on the graft level, mouse crest cells participated in the formation of various derivatives, such as head components, sensory ganglia, orthosympathetic ganglionic chain, nerves, and neuroendocrine glands. Knock-out mice with the tenascin genes inactivated, which express LacZ instead of tenascin and show no tenascin production (29), were used specifically to follow Schwann cells lining nerves derived from the implant. Together with the previous results on somite development, this study shows that the chick embryo constitutes a privileged environment, facilitating access to the developmental potentials of normal or defective mammalian cells. It allows study of the histogenesis and precise timing of formation of a known structure, as well as the implications of a given gene at all equivalent mammalian embryonic stages.

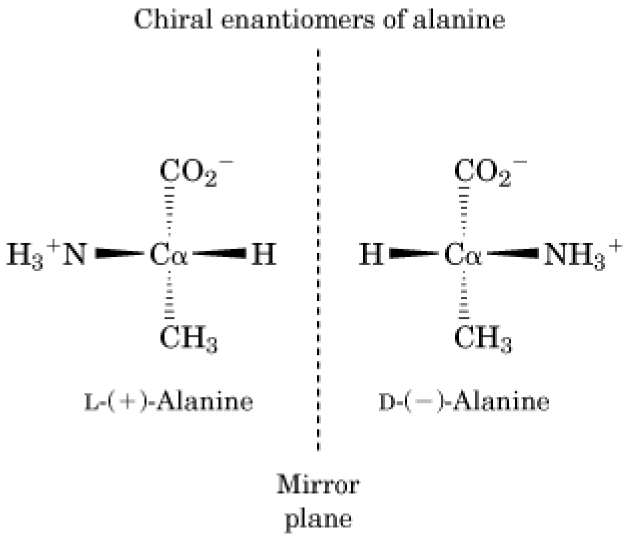
Chiral and Chiral Center

The word chiral is derived from the Greek word "cheir" for "hand." It was first used to describe any molecule that could not be superimposed on its mirror image, like left and right hands, by Lord Kelvin (1). This supplanted the less precise term dissymetrical used by Pasteur (2). The nonsuperimposable mirror image isomers are enantiomers. The physical property that differentiates enantiomers is the direction that they rotate plane polarized light. Thus, the two enantiomers are differentiated as either dextro(+) or levo(–) rotatory, depending on whether the rotation of the polarized light is clockwise or counterclockwise, respectively. Solutions containing an excess of one of the enantiomers are said to be optically active. A solution containing exactly equal concentrations of both enantiomers is called racemic (see Racemic And Racemization).

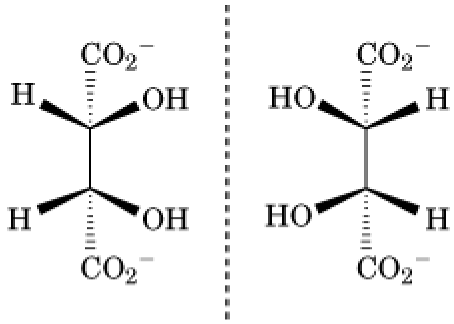
The most common structural element that generates chiral molecules is the presence of a tetrahedral atom with four different substituents, by definition a chiral center. The a-carbon of the a-amino acids (Fig. 1), except for glycine, and the hydroxymethylene carbons of carbohydrates are all chiral centers. The mirror images of chiral molecules have different absolute configurations, which are uniquely identified by the rules proposed by Cahn et al. (3) (see Configuration).

Figure 1. The enantiomers of alanine, which are mirror images. Note that the a-carbon is chiral because of the four different substituents. The (L) and (D) designate the absolute configuration of the chiral center, whereas the (+) and (–) indicate which direction an aqueous solution of the enantiomer will rotate the plane of polarized light.



Possessing a tetrahedral chiral center is not required for chirality, nor is the presence of a chiral center proof that the molecule will be chiral. Other arrangements of atoms can generate nonsuperimposable mirror images. One example of biochemical importance is the hexacoordinate complexes of metal ions, such as the Mg ATP complex (4). Other chiral molecular structures have been surveyed by Testa (5). A molecule with an internal mirror plane may have chiral centers but not be chiral. These are meso compounds. Because of their internal symmetry, these molecules can be superimposed on their mirror image. The **diastereomeric** form of tartaric acid, which has two chiral centers, but a mirror plane between C2 and C3, provides an example of a meso compound (Fig. 2).

Figure 2. Meso tartrate, which contains two chiral centers C2 and C3, but is not chiral because there is an internal plane of symmetry. Note that, unlike the enantiomers of alanine, these mirror images can be superimposed by a 180° rotation.



Meso form of tartrate

Chironomus

The subfamily chironomini includes Chironomus and related genera that by some estimates contain over 5000 species. Because of this diversity, many studies of chironomids focus on environmental biology and systematics. But it was the giant polytene chromosomes of salivary gland cells and the bright red color of the larvae of these ubiquitous flies that first drew the attention of experimental biologists more than 100 years ago.

The alternating dark bands (chromomeres) and light bands of the polytene chromosomes are punctuated by puffed regions, the largest of which were named Balbiani rings to honor their discovery by E. G. Balbiani in 1881. The possible relationship between chromomeres and genetic loci on the one hand, and between puffs and gene activity on the other, excited the interest of cytologists and geneticists. One of these, W. Beermann, examined the morphology of chromosomes in four cells in the “special lobe” of the salivary glands of larvae that were derived from a cross between *C. tentans* and *C. pallidivitattus*. He was able to correlate the production of prominent secretion granules by these cells with the presence of a specific chromosome puff in both the hybrid and in *C. pallidivitattus*, and showed that the puff was absent from the special cell chromosomes in *C. tentans*, which do not contain the secretion granules. C. Pelling later demonstrated that polytene chromosome puffs selectively incorporated radioactive uridine, firmly establishing that they are sites of active gene transcription. The sequential appearance of some, and the disappearance of other chromosome puffs during development could be mimicked by treating cultured late-stage larval salivary glands with the steroid hormone, 20-hydroxyecdysone. Thus, the same hormone that signals molting and metamorphosis in insects also controls the differential transcription of genes encoded by responsive puffs (see Ecdysone).

In a prodigious feat of molecular isolation that predates molecular cloning by almost a decade, J. E. Edstrom and his colleagues used micro manipulation to dissect individual Balbiani rings. A very large (75S) mRNA (messenger RNA) encoding a polypeptide of about 850 kDa was extracted from pooled Balbiani ring 2 isolates. This and other salivary gland secretory proteins encoded by the major Balbiani rings are extruded through the larval mouth and spun together with benthic detritus to make tabular houses. The stickiness of *Chironomus* “silk” results from the aggregation properties of interacting secretory polypeptides from the major Balbiani rings, and several studies focus on those aspects of structure that could explain the adhesive properties of these unusual biopolymers. In *C. tentans*, each major Balbiani ring encodes polypeptides with internal repetitive domains. The core repeat of one of these domains has four cysteine residues in invariant positions; a subrepeat region contains tandem *basic-pro-acidic* residue motifs. This arrangement might encourage protein strand alignment and polymerization of the “silk”. In other studies, B. Daneholt and colleagues have capitalized on the large size of the Balbiani Ring gene transcripts to investigate messenger ribonucleoprotein (mRNP) assembly and transport through nuclear pores; polytene chromosome centromere and telomere evolution, replication, and function are also areas of active research.

Recent studies have used expression of a chironomid/drosophilid ecdysone receptor (ultraspiracle) gene to understand hormone receptor domain function. Still other seek to define sex-determining genes and proteins, and to characterize diverse transposable elements in chironomids. A significant number of reports have focused on *Chironomus* globin gene structure, polymorphism, and evolution. The rest of this article deals with developmental and functional studies of *Chironomus* hemoglobins and with the structure, organization, and evolution of the many globin genes in this large multigene family.

1. *Chironomus* Hemoglobin Structure and Function

The red pigment so visible through the larval integument was identified as hemoglobin by E. R. Lankester in 1872. In 1932, T. Svedberg et al. used their then-new technique of sedimentation velocity ultracentrifugation to estimate the molecular weight of hemoglobin from *Chironomus* (and other invertebrates); chironomid hemoglobins “weighed in” at 32 kDa. Physiological studies focused on the unusually high oxygen affinity of the hemoglobin (compared to its vertebrate counterparts) and on how it facilitated oxygen supply to larval tissues in a relatively hypoxic benthic habitat.

Chironomus hemoglobin is actually a mixture of many hemoglobin proteins synthesized and secreted by larval fat body. Long before the first chironomid globin gene was cloned, much was known about the structure of these proteins. In contrast to the tetrameric vertebrate hemoglobins (see Hemoglobin), chironomid hemoglobins do not show cooperative binding of oxygen, existing either as monomers or homo-dimers under physiological conditions (Svedberg’s 32 kDa “hemoglobin” was presumably a mixture of homodimers). Over the course of a decade, the amino acid sequences of 12 *C. thummi* globins were determined in the laboratory of G. Braunitzer. Since none is truly similar in sequence to its vertebrate counterparts, alignments of chironomid and vertebrate globin sequences were only possible because they share several amino acids at crucial positions known to be involved in binding the heme group. On the other hand, comparison of the three-dimensional structure of a monomeric chironomid hemoglobin (determined by X-ray crystallography) with that of vertebrate globins reveals many shared structural features, including similarly organized a-helical domains and a characteristic hydrophobic heme pocket. These observations clearly indicate that similar molecular functions and three-dimensional structures can be attained in different proteins despite considerable differences in primary structure. The differences in primary structure between globins of very different organisms reflects adaptation to species-specific oxygen requirements over long evolutionary periods.

Whereas at least two *C. thummi* globin genes encode identical polypeptides (1), pairwise comparisons of amino acid sequences reveal remarkably dissimilar globins. These differences have also been ascribed to evolutionary specialization of different hemoglobins that now serve different respiratory functions (2). However, the physiological roles of individual hemoglobins are at best only poorly understood. *In vivo* determinations of larval O_2 binding and storage abilities under different conditions of oxygen tension necessarily represent a function of the aggregate set of hemoglobins present at the time of measurement. As expected, the O_2 affinities determined for purified hemoglobins that are present in different proportions in the hemolymph are not easily related to the aggregate *in vivo* data. What does emerge from such experiments is a loose correlation of the generally high oxygen affinities of the hemoglobins and the benthic, often oxygen-depleted habitat of larvae.

Larvae live in the mud at the bottom of freshwater ponds and lakes, developing in burrows constructed to detritus cemented by the sticky secreted salivary gland proteins discussed above. Moreover, chironomids can withstand the oxygen stress of polluted or eutrophic waters, often comprising more than 80% of all animal individuals. This tolerance is due in part to the high concentrations of hemolymph hemoglobin. Zebe (3) suggested that hemoglobins of *C. thummi* may not be required for oxygen delivery at higher partial pressures (oxygen needs under these conditions are presumably satisfied by diffusion). Rather, because they can bind O_2 at low partial pressures (50 to 10 torr), the hemoglobins allow continued respiration in times of severe oxygen deficit, when they become physiologically significant. From this, one might predict that oxygen stress will favor larval production of hemoglobins with particularly high O_2 binding affinities. Homodimeric hemoglobins have higher O_2 affinities than the monomeric hemoglobins and do indeed rise in concentration in response to circadian and seasonal declines in O_2 availability and water quality, where they may be more involved in O_2 transport under these conditions than monomeric hemoglobins. With a more pronounced Bohr effect than monomeric hemoglobins, dimeric hemoglobins may also allow response to more immediate changes in oxygenation conditions due to local fluctuations in pH.

Overall hemoglobin levels reach their highest concentrations in the hemolymph of *C. thummi* in the fourth, or last larval stage (instar). Although it is likely that newly synthesized hemoglobins function mainly in respiration, hemolymph hemoglobin is also taken up by developing oocytes and deposited in yolk granules during oogenesis in pupae (4, 5). This hemoglobin undoubtedly serves a nutrient rather than a respiratory function during embryogenesis. At the same time, developing eggs may contain hemoglobins of their own making. Cross-reactive antihemoglobin antibodies tagged with colloidal gold particles are localized over rough endoplasmic reticulum in young embryos, suggesting that hemoglobin synthesis begins at embryogenesis (6). Hemoglobins first accumulate sufficiently to become visible as a red pigment in the blood of second instar larvae. Thereafter, hemoglobin synthesis is cyclic, being high during the instar and declining at each molt. Hemoglobin synthesis occurs for the last time just after pupariation, ceasing sometime in the pupal stage, by which time most existing hemoglobins are degraded. Hemoglobins have disappeared and are virtually undetectable several hours after adult emergence, at which time the adult flies have a fully developed tracheal respiratory system. Once again, in spite of these observations, it is not possible to state with certainty the physiological role played by any given hemoglobin at any given moment. As we will see, this issue may be moot for many of the hemoglobins, since there is reason to believe that much of the structural variation between hemoglobins has not been selected to perform a unique physiological function, but instead is the result of neutral evolution.

2. Developmental Regulation of *Chironomus* Hemoglobin Synthesis

While cyclic hemoglobin production is tied to molting, it should also come as no surprise that the synthesis of individual members of such a large family of hemoglobins is regulated differentially during development. For example, polyacrylamide gel electrophoresis (PAGE) of *C. thummi* fourth instar hemolymph reveals two hemoglobins that are absent in electrophoretic separations of third instar larval hemolymph. Another hemoglobin, detectable in embryo homogenates by electrophoresis and immunoblotting, is undetectable in last instar larval hemolymph. In S1 nuclease protection assays performed to follow specific globin gene expression during development, transcripts of the ct-1, ct-4, ct-7B4, and ct-7B5 globin genes (ct-, ctp-, ctn-, and kc- are prefixes for *C. thummi, C. piger, C. tentans,* and *K. cornishi* globins and globin genes.) are detected at high levels in 3rd instar *C. thummi* larvae (7). Transcripts of each of these globin genes decline to undetectable levels immediately after molting to the fourth instar, reappearing 24 hr later, along with two new fourth-instar–specific globin transcripts (ct-3, ct-6). The expression of each of these globin mRNAs was tracked further during fourth instar development. The results of these experiment indicate that globin transcript steady-state levels follow one of two kinetic patterns. Transcripts of the ct-3 and ct-6 genes rise from very low or undetectable levels after the molt, and then remain elevated through 8 days of the instar. Globin mRNAs expressed in both instars also rise from low or undetectable levels just after the molt. But unlike the specific globin mRNAs, they reach maximum levels after 2 to 3 days and then decline to near basal levels. The absence of detectable globin transcripts just after the third to fourth instar molt is consistent with the observation that the rate of synthesis of hemoglobins of cultured larval tissues exposed to the molting hormone 20-hydroxyecdysone (20HE) is very much reduced. Like other steroid hormones, 20HE binds to an intracellular receptor, which then binds to a hormone response element(s), directly controlling the transcription of adjacent genes. Such direct action on globin is unlikely, since a search in DNA lying between or flanking any *C. thummi* globin gene sequences published or recorded in international DNA sequence databases failed to detect 20HE response elements. As yet unidentified factors must mediate the hormone-induced repression of hemoglobin synthesis during molting. There is no evidence at all for a role for 20HE in the selective repression of "non–stage-specific" globin mRNA levels during the fourth instar, indicating the action of still other factors in the selective silencing of some but not all globin genes.

3. *Chironomus* Globin Gene Structure and Organization

At the same time as the differential expression of hemoglobins or globin transcripts was being described, many more globin genes were being characterized. Known *C. thummi* genes exceed the number needed to account for the 12 hemoglobins that were first isolated. The loci of individual and clustered globin genes were mapped by *in situ* hybridization of cloned DNAs to polytene salivary gland chromosomes, and as noted, the expression of many globin genes including several for which no protein product has yet been isolated, has been shown. Table 1 summarizes some key properties of cloned globin genes characterized thus far. Genes that are clearly inactive include ct-13RT (which suffered insertion of a retroposon in coding DNA; see Fig. 1), ct-V (with an inappropriately located stop codon), and ctn-ORFB (with its coding region truncated at the 5' and 3' ends). With these exceptions, all of the known chironomid globin genes possess the structural prerequisites of active genes, including appropriately located TATA (promoter)and AATAAA (polyadenylation) signals, an open reading frame, and a stop codon. In addition to the first of full-length globin genes in Table 1, many partial genes (8, 9) amplified by PCR from numerous species (eg, for globins 2b, 7, and 9) are probably active. When compared to vertebrate (eg, human) globin genes, a striking difference is that the latter are separated by thousands of nucleotides, whereas chironomid globin genes are often separated by less than 500 nucleotides. Another difference is that chironomid globin genes lack the hallmark structure of three exons separated at conserved positions by two introns that characterize vertebrate (and even plant) globin genes. Instead, different chironomid globin genes are either intronless or contain a single introns at divergent locations. The growing database of chironomid globin genes from several species, their unusual structure, and their organization have sparked considerable interest in the evolution of this unique multigene family.

Figure 1. Intron acquisition by chironmid globin genes. Relative times of independent acquisition of introns at different locations ("type 1" vs "type 2") by ancestral globin genes in the "*pseudothummi*" and "*plumosus*" phylogenetic groups are suggested. Only *C. dorsalis*, the oldest member of the "*pseudothummi*" group, has intronless orthologues of the

intron-bearing genes. Phylogenetic clusters are taken from Guryev et al. 2001 (9). The evolutionary history of intron-bearing and intronless orthologous gene clusters *C. thummi* and its distant relative, *C. tentans* is also shown. ct-, ctn-, and ORF ("open reading frame") designations are deleted to save space. Arrows above the genes indicate direction of transcription. Ancestral genes are designated in italics. Details are explained in the text.

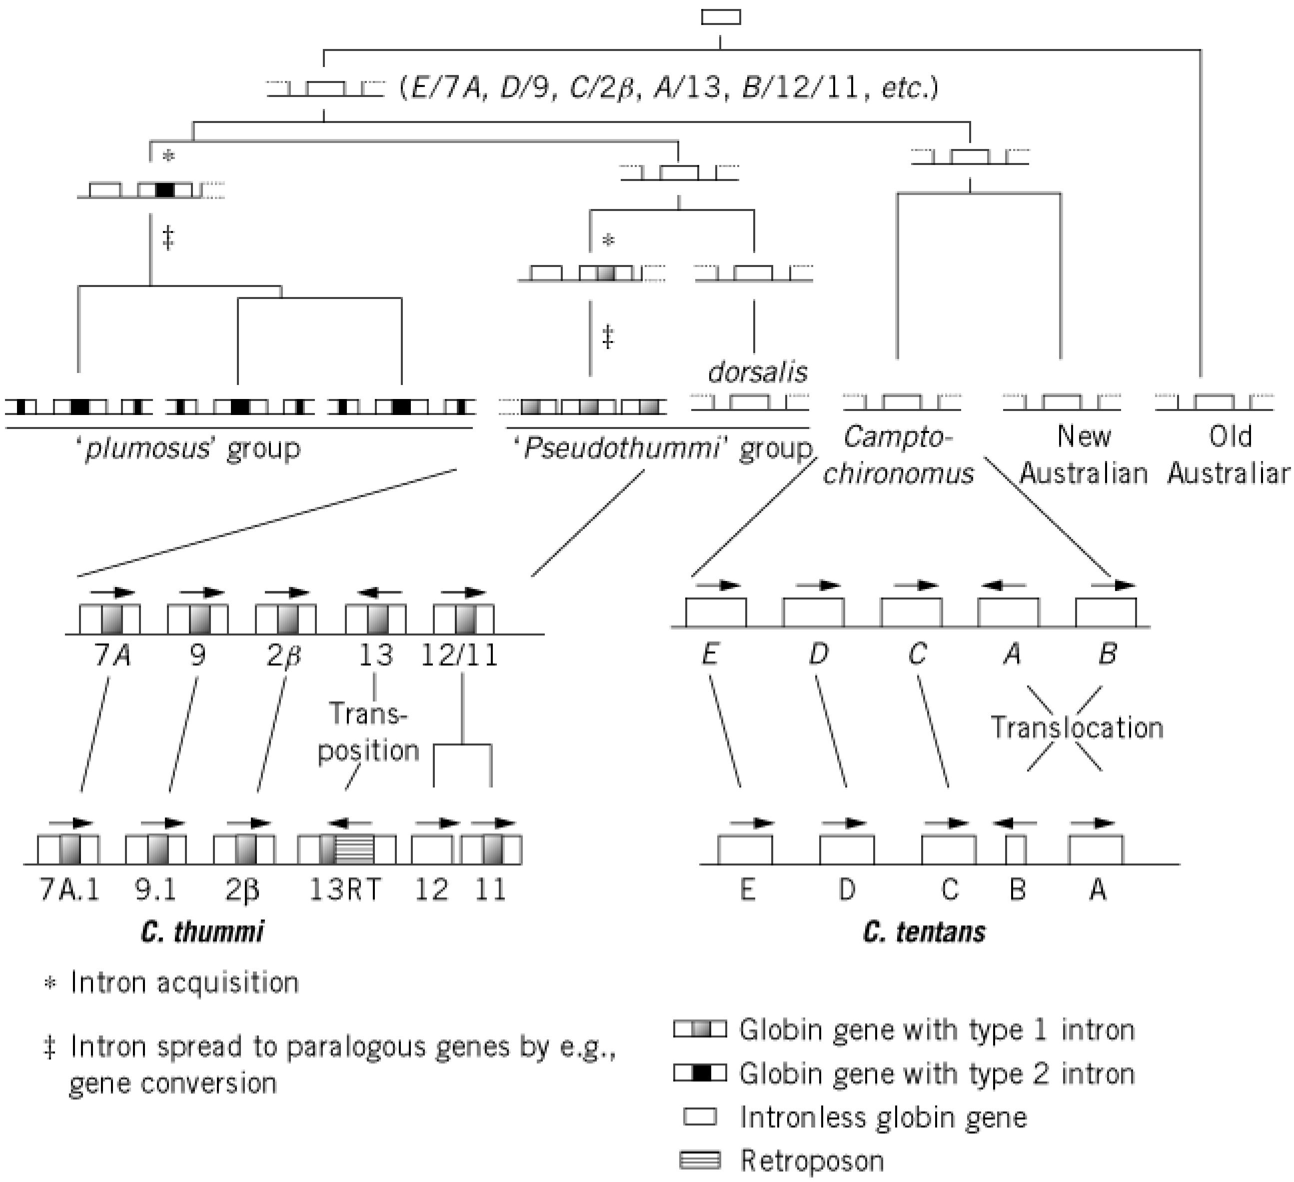

Table 1. Chironomid Globin Genes

Organism	Gene	Protein Product	Status[a]	Homologues	locus[b]	Comments
C. thummi	ct-1	I	active	—	F2b3	Allele of ct-1A; intronless; aa sequence avail.
	ct-1A	IA	active	—	F2b3	Allele of ct-1;

[a] Active genes have been shown to be transcribed and/or translated, or to correspond to an identified globin polypeptide.

[b] Positions mapped to polytene salivary gland chromosomes of *C. thummi*; See Ref. 44 for the mapping of the same genes to the salivary gland chromosomes of other chironomid species.

4. Evolution of *Chironomus* Globins

Phylogenetic analyses support an early origin of monomeric hemoglobins about 500 million years ago and the appearance of homodimeric hemoglobins about 250 to 300 million years ago, corresponding roughly with the origin of Diptera. Recently, a search of the *Drosophila* genome database using a chironomid globin gene query found a distant relative, designated a neuroglobin because it was expressed in brain tissue in *D. melanogaster*; and mouse and human neuroglobins have since been characterized (10-13). The chironomid globin gene family has experienced many of the same evolutionary events as their multigene families, such as point-mutational inactivation, translocations, gene loss, gene conversion, etc. They also support two somewhat unorthodox hypotheses. One that has received much attention in recent years, is that eukaryotic genes can acquire introns, complete with correctly placed intron/exon junctions and splicing signals. The other hypothesis is that much of the diversity of hemoglobin structure in *Chironomus* has arisen by neutral evolution rather than by functional adaptations of the proteins. There is resistance to ascribe to neutral evolution those mutations causing even minor differences in amino acid sequence between the products of homologous genes in different species or paralogous genes in the same organism. Such differences between globin genes in *Chironomus*, and between the products of multigene family members in general, are widely thought to be the result of adaptive selection. However, evidence from the different chironomid globins and globin genes suggest that many were not selected for their adaptive value, but exist instead as a neutral consequence of positive selection of the expression of high levels of hemoglobin from multiple genes.

4.1. Origin of A Central Intron

By the time the first chironomid globin genes were cloned in 1984, the sequencing of vertebrate globin genes had become a cottage industry. Each new report presented a globin gene with the same mosaic structure: three exons and two introns, the latter always interrupting the coding DNA at the same location. In a prophetic para (14), Go analyzed X-ray diffraction data for a vertebrate globin and concluded that in addition to the outer introns, the ancestral globin gene had a third intron in the center of the gene such that the entire gene was separated into four exons of similar length, each coding for a separate structural domain. Go's prediction was fulfilled shortly thereafter with the report of the first plant (legume) globin gene, which had a centrally located intron in addition to two introns at the same position as those in the vertebrate globin genes. Apparently the structure of plant globin genes represents the ancestral state. Many of the first chironomid globin genes to be reported were intronless, a condition presumably due to the reverse transcription of a completely processed transcript and reinsertion of the complementary DNA into the genome. The discovery of the *C. thummi* ct-2b and ct-9.1 genes (15), and of several other invertebrate globin genes with a central intron, however, raised questions about the origin of chironomid globin gene introns. Unlike the conservation of location of the outer vertebrate globin gene introns, the location of central introns is not conserved across kingdoms or phyla, and none is at the position predicted by Go. Could they, like the outer introns in globin genes, still be descendants of an ancestral intron? Gilbert suggested that introns at nonconserved locations have moved by "intron sliding." Others have argued that the discordant location of nitrons is more easily explained if introns can be acquired by previously uninterrupted genes. Hankeln et al. (8) reported that the globin genes of some species have a "central" intron at a slightly different location that those of other species. A chironomid mitochondrial gene phylogeny groups flies with an intron at one location ("type 1") on the "*pseudothummi*" branch, and groups those with an intron at the other location ("type 2") on a separate "*plumosus*" evolutionary branch (8, 16, 17). The phylogeny supports the separate acquisition of an intron by the homologous genes after divergence of the two lineages (Fig. 1). Several plausible mechanisms for intron acquisition have been suggested. In considering these, Kao et al. (15) offered a mechanism whereby a chironomid globin gene containing a centrally located ¼AGGT¼ tetramer (to provide donor and acceptor splice sites) could have acquired a central intron by a simple gene duplication, accompanied (or followed) by deletion of all but the DNA presently found in the intron. A mechanism proposed by Hankeln et al. (8), where introns are acquired by a reversal of the splicing reaction, might explain intron insertion in globin genes lacking these AGGT splice site precursors. An intron once acquired by a single gene might spread to nearby related genes by gene conversion (8); see Fig. 2).

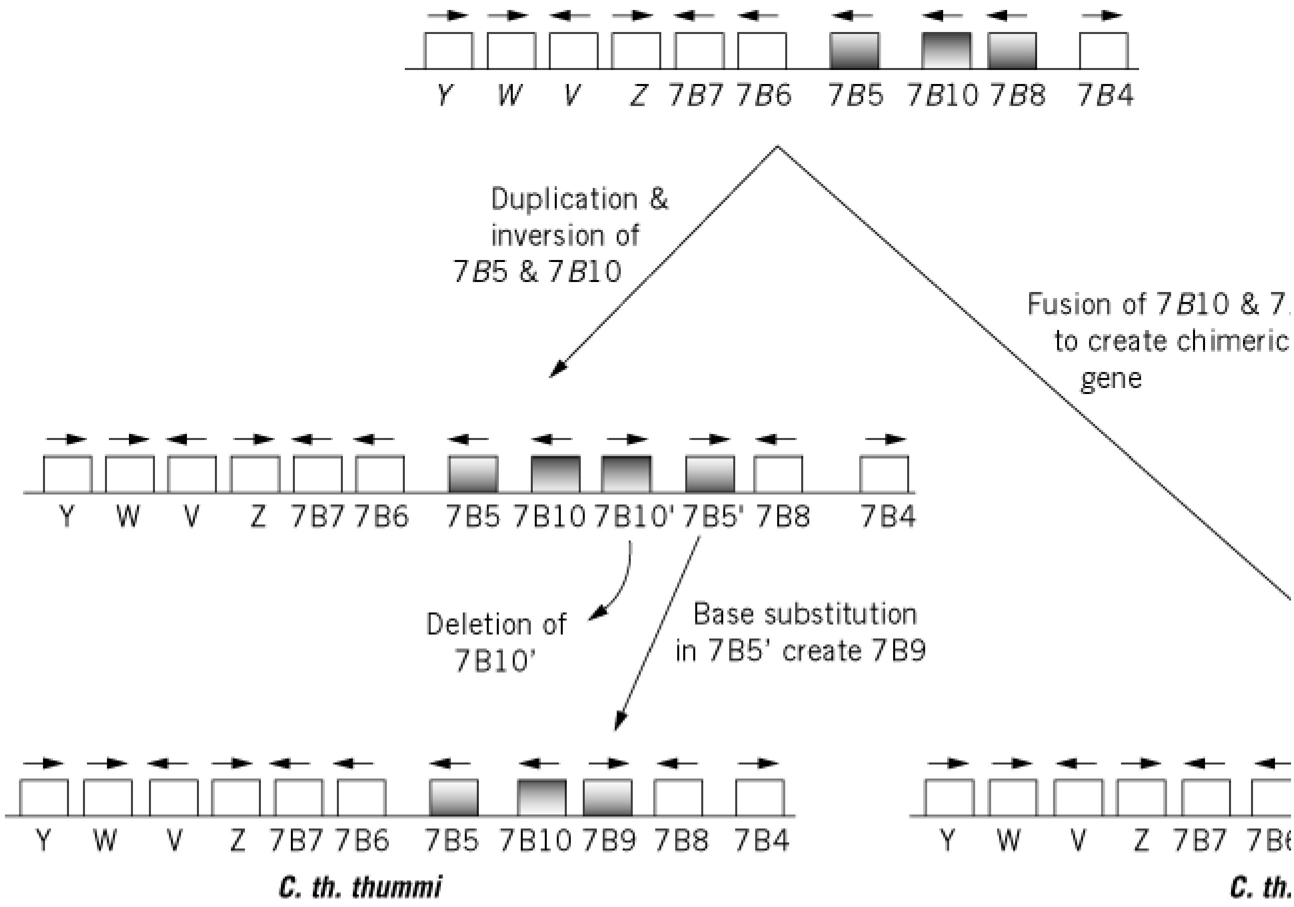
save space. Arrows above the genes indicate direction of transcription. Ancestral genes are designated in italics. Shaded
recent duplications, losses, and fusions.



4.2. Evolution of a Globin Multigene Family

The DNA sequences of orthologous globin gene clusters in different chironomid species support the adaptive selection of a high globin gene copy number and the essentially neutral evolution of individual globin genes. The ctp-Y, ctp-W, ctp-V, and ctp-Z genes, and five ctp-7B genes in *C. piger* (18), and the ctp-Y, ctp-W, ctp-V, and ctp-Z genes, and seven ctp-7B genes of sibling species *C. thummi* (1) are a case in point. The phylogenetic study summarized in Figure 2 traces the evolutionary history of the two clusters, showing the seven genes that are clearly homologous, and a series of gene duplications and deletions necessary to explain the current sequence and organization of the clusters. Pairwise comparisons show that at the nucleotide level, homologous globin genes or logical gene pairs (ie, genes of indeterminate orthology, but sharing immediate common ancestry) in the two species share from 96.7% to 99.2% identity. In three cases, homologous genes in each species code for identical polypeptides, despite several millions of years of species divergence. Within *C. thummi*, the ct-7B5, ct-7B6, ct-7B9, and ct-7B10 paralogous genes are also very similar, as shown by the amino acid differences in the pairwise comparisons shown below:

	7B6	**7B10**	**7B5**	**7B9**
7B8	6	4	6	6
7B6		2	1	1
7B10			2	2
7B5				0

In addition to identical paralogues (ct-7B5, ct-7B9), sequencing of an independent genomic clone revealed a gene identical ct-7B5 (19). Designated ct-7B9/5 because its 5’ and 3’ flanking DNA are similar to the 5' and 3' regions of ct-7B9 and ct-7B5, respectively, it probably arose by intrachromosomal crossing over between oppositely oriented ct-7B9 and ct-7B5 in a looped (bent) chromosome structure (with deletion of most or all of ct-7b10). Since the recombination point is in fact external to the transcribed region of the gene, 7B9/5 must simply be another ct-7B5 gene or allele. The recombined region (without ct-7B10) may be an independent gene locus or an allelic haplotype. Clearly the 7B globin gene subfamily predates the *thummi/piger* divergence. The ability of *C. thummi* and *C. piger* to lose different descendants of an ancestral cluster by gene fusion, and the overall similarity of paralogous genes, implies that any small differences that accumulate in the genes before or after fusions and corrections are evolutionarily inconsequential. The 7B gene cluster seems to have undergone periodic expansion and contraction (gene duplication, deletion), while maintaining the ability to encode identical or nearly identical globins for millions of years. The best explanation for this phenomenon is that the few differences that accumulate between 7B genes are the result of random drift (neutral evolution), but that the cluster itself has experienced positive selection of a high number of copies of globin genes as a means to ensure the synthesis of large amounts of hemoglobin.

Whereas the orthologous globin gene clusters in *C. thummi* and *C. piger* illustrate early evolutionary events in the life of a multigene family, globin gene clusters in *C. thummi* and *C. tentans* are separated by 60 million years of evolution (16, 20). The extent paralogous and homologous genes sequences are much less similar to each other (except for a region of the ct-2b and ct-9A genes that underwent partial gene correction, homogenizing intronic and exonic DNA in the middle of the two genes). The divergence of the *C. thummi* and *C. tentans* gene clusters offers a wider window through which to test the concept of gene copy number selection. Figure 1 summarizes evolution of these genes after acquisition and spread of a "type 1" intron in one of the clusters. The ancestral *C. thummi* gene cluster must have had five intron-bearing genes before a gene duplication created ct-11 and ct-12. ct-12 has since lost its intron, and both ct-11 and ct-12 have been diverging for some time (16). In contrast, the *C. tentans* cluster contains only intronless homologues, originally ascribed to multiple intron losses from intron-bearing ancestors (16, 20). Figure 1 reflects more recent phylogenetic evidence that some or all of the genes in these clusters arose early in the genus, and that the *C. tentans* genes never acquired an intron in the first place (9). A difference in the organization of the orthologous genes between *C. thummi* and *C. tentans* is explained if a translocation is assumed between ctn-A and ctn-B (or vice-versa in *C. thummi*). Of special note, the recent inactivation of a different (non homologous) gene in each cluster suggests that not all globin genes in a cluster are indispensable, even after 60 million years of evolution. In *C. thummi*. ct-13RT suffered the insertion of a retroposon into coding DNA in exon I. This occurred very recently, because the rest of the coding region, the intron, and the flanking DNA containing promoter and polyadenylation motifs are all still intact. Recent retroposition is supported by the observation that ct-13RT is actually an allele coexisting with a normal, uninterrupted ct-13 allele (17). In *C. tentans*, the ctn-ORFB gene was truncated at both the 5' and 3' ends. Again, this event must have occurred very recently, because the gene retains all other attributes of a viable, transcribable gene. The phylogenetic analyses of the orthologous *C. thummi* and *C. tentans* gene clusters supports the recent inactivation of the ct-13RT allele and the ctn-ORFB genes, and the likelihood that accumulated amino acid differences between many (if not all) homologous and paralogous genes are the result of neutral evolution. If the greater diversity of the *tentans* and *thummi* genes cannot be completely explained as the positive adaptation of structurally diverse hemoglobins, then their maintenance, like that of the large number of 7B genes in *thummi* and *piger*, must be the result of positive gene copy number selection favoring high levels of hemoglobin synthesis.

In sum, the evolution of *Chironomus* globin genes spans more than 250 million years, in which time individual sequences within and across species have accumulated many amino acid substitutions. Some especially diverged hemoglobins may have evolved to serve unique functions, for example in environments that undergo cyclic changes in oxygenation. The specific expression of some globins during development might reflect habitant (and therefore, oxygenation) differences as larvae first descend from the waters' surface to the benthos, and later ascend to the surface at the time of eclosion. On the other hand, differences between many of the globin genes may be neutral, selection favoring the proliferation of a large family of genes encoding proteins of physiologically similar function. Kimura (21) suggested that duplicated genes accumulating neutral change are preadapted, later becoming substrates for positive adaptation after speciation. A consequence of high gene copy number selection is that some of the many functionally redundant globin genes can serve as raw materials for Darwinian selection, which could explain the evolution and spread of more than 5000 species of Chironomous to diverse habitats.

Chloramphenicol

Chloramphenicol is a bacteriostatic agent that inhibits the growth of many species of Gram-positive and Gram-negative bacteria; it was the first broad-spectrum antibiotic to be used clinically. Originally obtained from cultures of the soil bacterium *Streptomyces venezuelae*, chloramphenicol inhibits bacterial **protein biosynthesis** by interfering with the intrinsic catalytic activity of the peptidyl-transferase of the ribosome during the elongation phase of translation.

Eukaryotic cells are generally not affected by chloramphenicol. Nevertheless, the clinical application of this drug for the treatment of systemic infections has been severely curtailed, primarily because of the haematotoxicity associated with its use. Chloramphenicol continues to be used topically, particularly in the treatment of eye infections. The emergence of chloramphenicol-resistant bacteria, apparently in response to the selective pressure exerted by the drug (see Antibiotic Resistance), has also restricted the use of chloramphenicol in the treatment of bacterial infections.

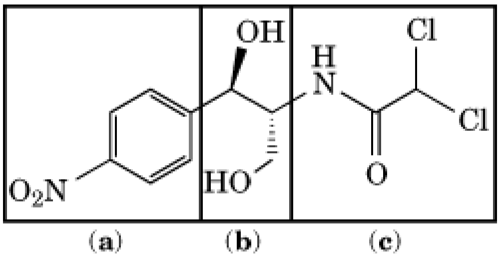
Chloramphenicol resistance is frequently encountered in many genera of bacteria. Several mechanisms of resistance have been described: (i) modification of the target, the bacterial ribosome; (ii) alteration in the permeability of the bacterial cell, leading to low intracellular antibiotic concentrations; and (iii) enzymatic modification of the antibiotic. Resistance most commonly occurs as the result of inactivation of chloramphenicol by chloramphenicol acetyltransferase (CAT). This enzyme is of value to molecular biologists, because it can be assayed with specificity and sensitivity.

Chloramphenicol is used today in molecular biology primarily as a component of selective media for genetic studies, to distinguish chloramphenicol-resistant from chloramphenicol-susceptible bacteria. Chloramphenicol is also an essential component of CAT assays, which are used to study gene regulation, generally in eukaryotic cells. Finally, chloramphenicol provides a tool with which to investigate the peptidyl-transferase center of the bacterial ribosome.

1. Chemistry

Chloramphenicol [D(–)-*threo*-2-dichloroacetamido-1-*p*-nitrophenyl-1,3-propanediol; Fig. 1] has two asymmetric carbon atoms. Of the four stereoisomers, only one, the D-threo isomer, has antibacterial activity. This compound can be produced on an industrial scale by chemical synthesis or by fermentation. Chloramphenicol is poorly soluble in water, but dissolves readily in organic solvents (eg, methanol).

Figure 1. Chemical structure of chloramphenicol [D(–)-*threo*-2-dichloroacetamido-1-*p*-nitrophenyl-1,3-propanediol].



Derivatives having a wide range of para substituents are active; therefore, this part of the molecule is not involved in specific drug–target interactions. The propanediol moiety, the site of the D-threo configuration, is essential for activity. Acetylation of one or both hydroxyl groups inactivates the drug. Removal of the dichloroacetamido side chain virtually eliminates biological activity, although substitution by a number of groups does not render the drug inactive. Some substituents reduce activity against intact bacteria, but enhance the inhibition of cell-free protein synthesis (1). Apparently, these derivatives are not taken up by the bacterial cell as efficiently as the parent compound.

2. Antibacterial Spectrum

Chloramphenicol is a broad-spectrum antibiotic, active against archaebacteria and both gram-positive and gram-negative bacteria. Organisms that fall within its spectrum include *Bacillus anthracis*, *Brucella abortus*, *Corynebacterium diphtheriae*, *Escherichia coli*, *Hemophilus influenzae*, *Klebsiella pneumoniae*, *Neisseria meningitidis*, *Salmonella* spp., *Serratia marcescens*, *Staphylococcus aureus*, *Streptococcus* spp., and so on (2).

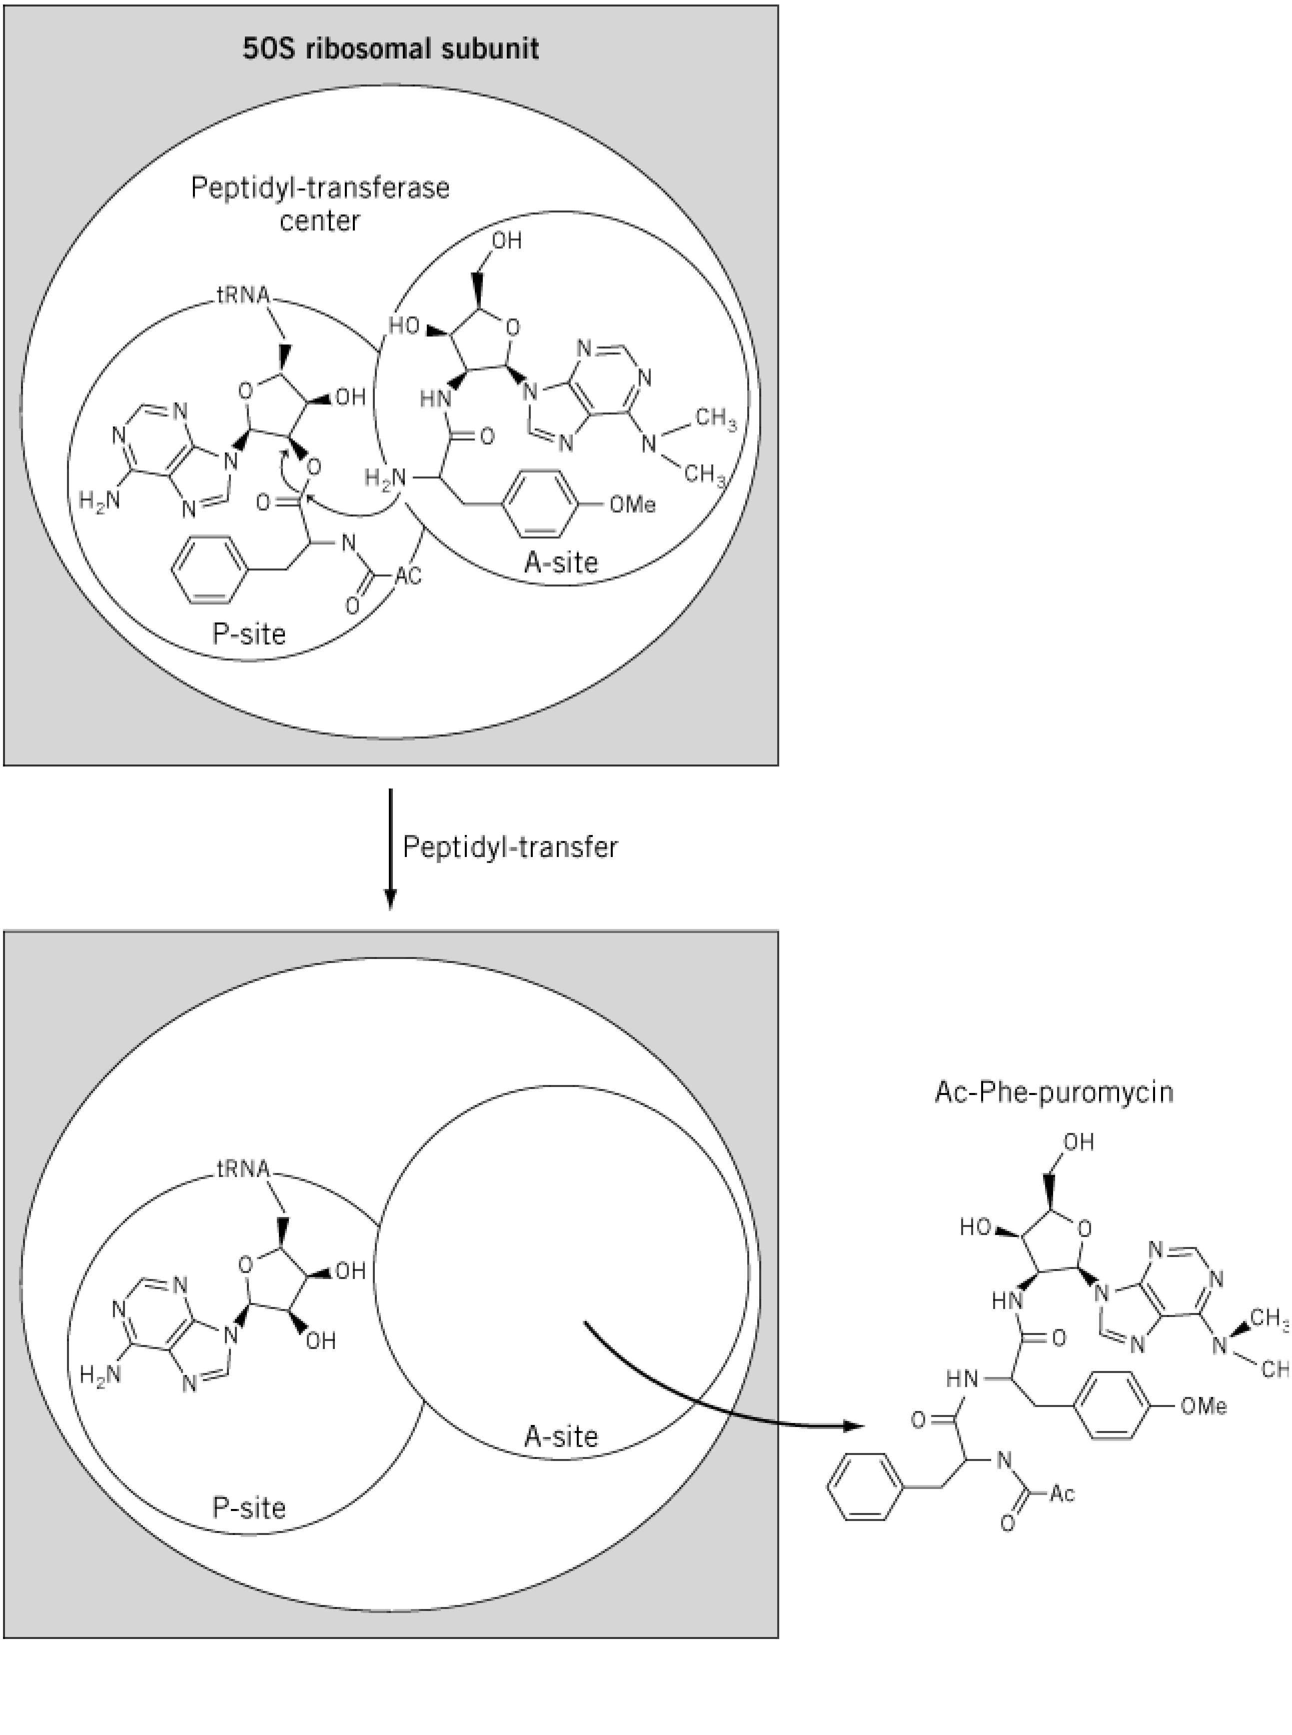
Chloramphenicol inhibits translation in bacterial cells, intact chloroplasts, and intact mitochondria. Some of the toxic side effects associated with chloramphenicol may arise from the effect of the drug on mitochondrial metabolism. Translation by mammalian cells, yeast, and protozoa is not inhibited by chloramphenicol.

3. Mode of Action

Chloramphenicol inhibits bacterial peptidyl-transferase, the enzymatic reaction by which one more amino acid is added to the growing polypeptide chain. During the elongation phase of protein biosynthesis in bacteria, chloramphenicol "freezes" **polysomes** on the messenger RNA, thereby fixing the peptidyl-tRNA to the ribosomes (3). Chloramphenicol competes for binding to the 50S subunit of the bacterial ribosome with molecules that specifically bind to the A site of the peptidyl-transferase center (aminoacyl-tRNA and its analogues, eg, CACCA-Leu) and is, therefore, thought to bind next to, or within, the A site of the peptidyl-transferase center (4). In contrast, no competition is observed with substrates that bind at the P site (peptidyl-tRNA analogues, eg, CACCA-LeuAc or AcPhe-tRNA). Furthermore, neither the dinucleotide ApC nor amino acids block the binding of chloramphenicol, whereas both puromycin and the dinucleotide CpA do (5). Thus, the drug presumably binds in the same region of the A site as the universally conserved CCA part of aminoacyl-tRNA.

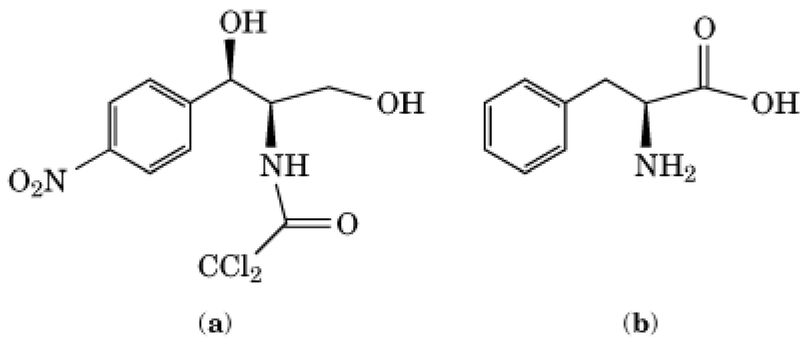
The peptidyl-transferase assay in which peptide bonds are formed between a peptidyl-tRNA and puromycin on the 50S subunit (the "puromycin reaction") has been used to unravel the mechanism of action of chloramphenicol (6) (Fig. 2). Chloramphenicol blocks this reaction, provided that the donor peptidyl-tRNA, bound at the P site, is short (eg, AcPhe-tRNA). In this case, chloramphenicol appears to disturb the correct positioning of the nascent peptide during its synthesis, thereby causing the premature release of the peptidyl-tRNA from the ribosome. Chloramphenicol does not, however, affect the puromycin reaction when a larger peptidyl-tRNA—for example, Ac(Phe)$_2$-tRNA—is used as donor (7). It is likely, therefore, that chloramphenicol interferes with the binding of the terminal CCA of the aminoacyl-tRNA at the A site and also interferes with the entry of the nascent polypeptide into the "tunnel" that normally guides it away from the peptidyl-transferase center.

Figure 2. The puromycin reaction. A peptidyl-tRNA analogue [eg, Ac[^{14}C]Phe-tRNA) bound to the ribosomal P site of 50S ribosomal subunit reacts with puromycin (an aminoacyl-tRNA analogue) bound to the A site of the peptidyl-transferase center. The resulting peptidyl-puromycin (eg, Ac[^{14}C]Phe-puromycin) is falling of the 50S subunit and can b separated from the substrate (Ac[^{14}C]Phe-tRNA) by extraction.



Chloramphenicol inhibits protein synthesis in bacterial extracts with varying potencies depending on the template employed. In particular, synthesis promoted by poly(U) is markedly more resistant to chloramphenicol than that promoted by poly(C) or poly (A) (8). Synthesis occurring with a natural mRNA (eg, MS2 phage RNA) is usually very sensitive to chloramphenicol. The precise reason for the template-dependence is not known. Chloramphenicol may inhibit poly(U)-dependent poly(Phe) synthesis less than it does the synthesis of other polypeptides because the structures of D-threo chloramphenicol and L-phenylalanine are similar (Fig. 3). Competition between these molecules during poly(Phe) synthesis may involve steric hindrance between their phenyl groups and, consequently, chloramphenicol may be chased from the ribosome. Nevertheless, this does not explain why the same template dependence is also observed with several other peptidyl-transferase inhibitors that differ chemically from chloramphenicol and, in particular, that do not have a phenyl group (e.g, the group B streptogramins and the macrolides). Further experiments are needed to elucidate this phenomenon in greater detail.

Figure 3. Structural similarity of D(–)-*threo* chloramphenicol and L-phenylalanine. Competition between these molecules during poly(Phe) synthesis may involve steric hindrance between their phenyl groups.

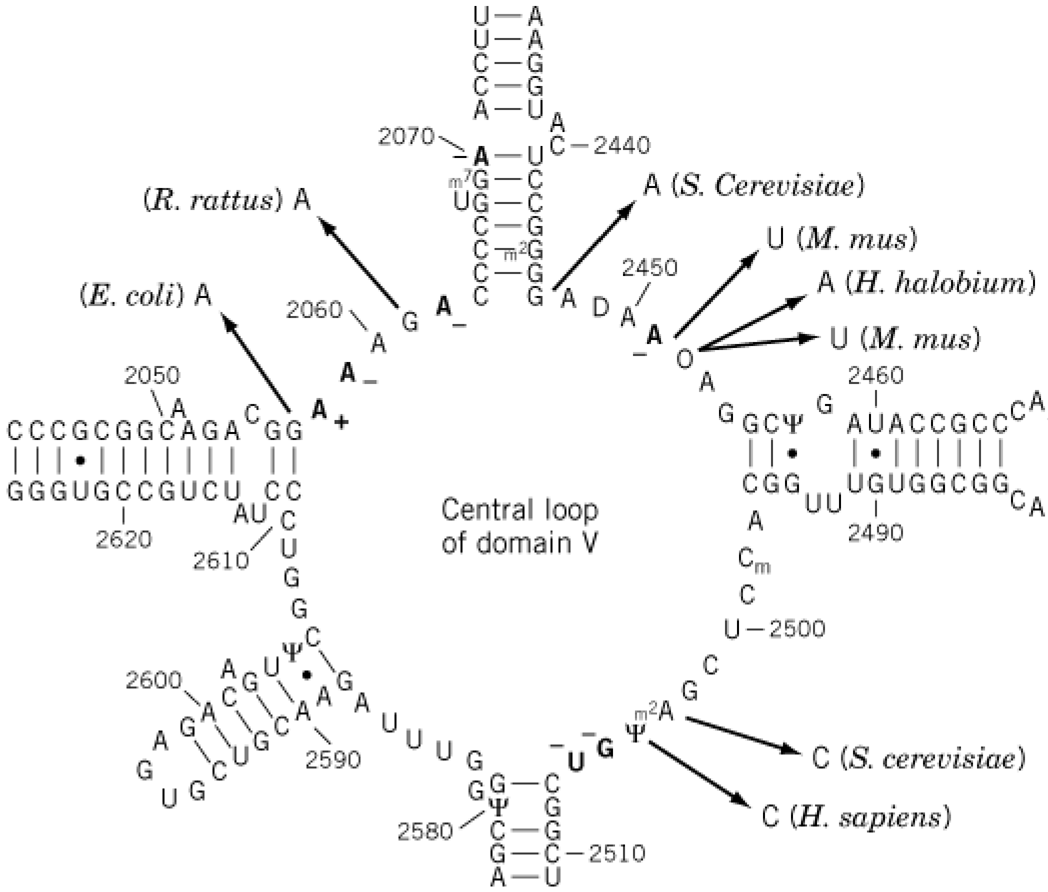


4. Ribosomal Binding Site

Chloramphenicol has a single high-affinity binding site located on the 50S ribosomal subunit ($K_d = 2 \times 10^{-6}$ M), as well as one or more low-affinity sites, at least one of which is located on the 30S subunit ($K_d = 2 \times 10^{-4}$ M) (9). A number of 50S proteins were labeled in affinity-labeling experiments, including L1, L2, L11, L16, L19, and L27 (10). Most of these proteins are located in or next to the peptidyl-transferase center of the ribosome, and several can be affinity-labeled with other antibiotics that interact with this center (**erythromycin**, puromycin, lincosamides, streptogramins).

That the peptidyl-transferase domain is the primary binding site of chloramphenicol was confirmed by RNA footprinting experiments, in which bases of 23S rRNA were compared in antibiotic-free or chloramphenicol-bound ribosomes for their reactivity to chemical probes. Chloramphenicol protected bases A2059, A2062, A2451, and G2505 and enhanced the reactivity of A2058 (11). Protection of A2070 and U2506 has also been observed (12). All these nucleotides are located in the central loop of domain V of 23S rRNA (Fig. 4). Additionally, several mutations of RNA that confer resistance to chloramphenicol have been identified in the same domain (Fig. 4; see references in Ref. 12).

Figure 4. Interaction of chloramphenicol with the central loop of domain V of 23S rRNA. The secondary structure of the central loop of domain V in *E. coli* 23S rRNA is derived from phylogenetic sequence comparisons. Differences in the accessibility of bases to chemical reagents in the presence and absence of chloramphenicol (footprints) are shown in red (–, protection of base; +, enhanced activity). Mutations leading to chloramphenicol resistance are indicated by arrows, and the corresponding organisms are indicated in brackets. All of the eukaryotic mutations were characterized for mitochondrial rRNA. (Figure derived from Refs. 11 and 12.)



5. Cold-Shock Induction

Shifting growing *E. coli* from 37°C to 20°C inhibits cellular growth and shuts down protein biosynthesis. To compensate for the stress produced by the temperature shift, the levels of (p)ppGpp drop and the synthesis of a subset of proteins is induced; this induction is known as **cold-shock**. Certain inhibitors of protein synthesis, including chloramphenicol, specifically induce the synthesis of the cold-shock proteins in the absence of a temperature shift (13). Ribosomal inhibitors have, in fact, been classified according to their ability to elicit a cold-shock- or a heat-shock-like response. Inhibitors in whose presence the A site of the peptidyl-transferase center is occupied, either by the antibiotic or by an aminoacyl-tRNA (chloramphenicol, erythromycin, fusidic acid, spiramycin, **tetracycline**), produce a cold-shock-like response. In contrast, inhibitors in whose presence the A site of the peptidyl-transferase remains empty (kanamycin, streptomycin) produce a heat-shock-like response.

6. Chloramphenicol Resistance

6.1. Modification of the Bacterial Ribosome
Several mutations in 23S rRNA confer resistance to chloramphenicol. The residues at which these mutations occur (residues G2057, G2061, G2447, A2451, C2452, A2503, U2504; *E. coli* numbering) are located in the peptidyl-transferase loop of 23S rRNA (Fig. 4), which is in accordance with their proposed binding site.

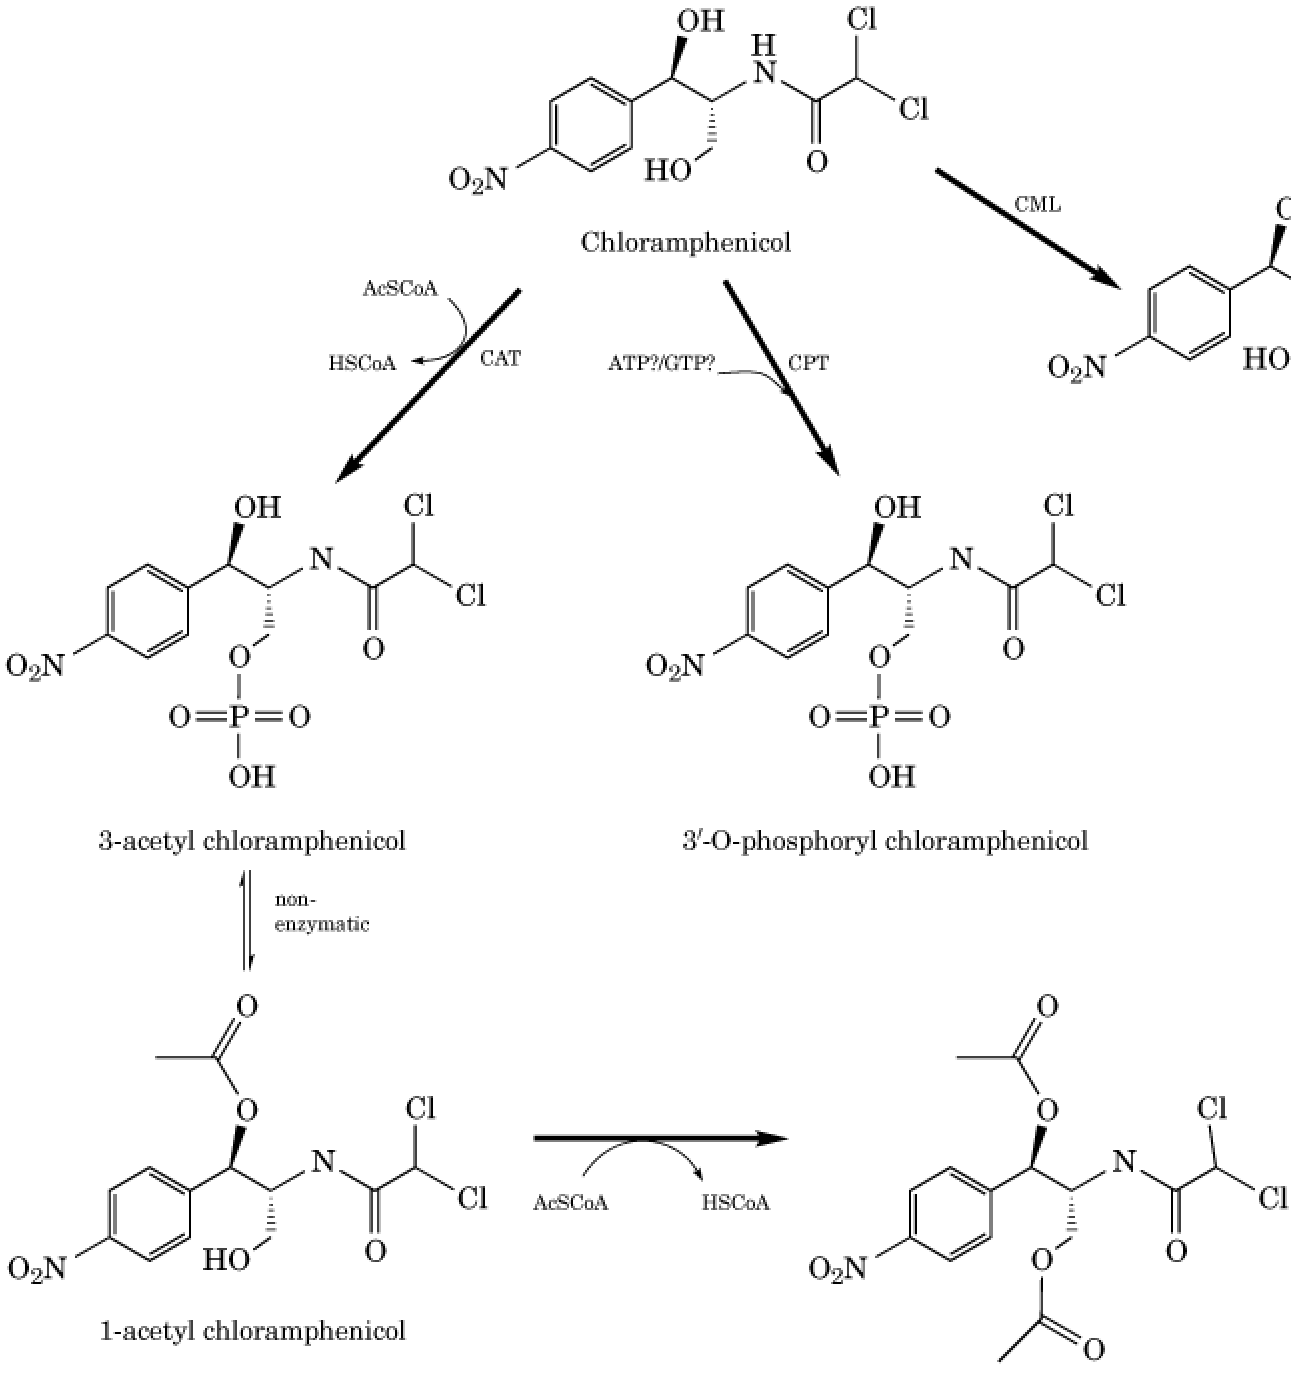
6.2. Alteration in Permeability to Chloramphenicol
Protein synthesis in *S. venezuelae* cells that have begun to produce chloramphenicol becomes insensitive to the antibiotic. There is no modification of the ribosome in these cells; instead, the antibiotic is excluded from the cytoplasm during biosynthesis. The amino acid sequence deduced

from the gene conferring resistance (*cml*) is markedly similar to those of chloramphenicol-resistance genes from *Streptomyces lividans*, *Rhodococcus fascias*, and other bacteria. These polypeptides contain 12 **hydrophobic** regions characteristic of membrane-associated **transport** proteins and are related to a known family of efflux proteins (14).

6.3. Enzymatic Modification of Chloramphenicol

The most common mechanism of chloramphenicol resistance is inactivation by the enzyme chloramphenicol 3′-*O*-acetyltransferase (CAT), encoded by the *cat* gene. The biological and immunological properties of three types of CAT (I, II, III) have been described. The structure of CAT III has been determined by X-ray crystallography, as well as its tertiary complex with chloramphenicol and CoA (15). The enzyme is a trimer; its active sites lie at each of the interfaces between adjacent subunits. CAT catalyzes the transfer of an acetyl moiety from acetyl-CoA to the 3′-hydroxyl of chloramphenicol. The initial product of the reaction, 3-acetyl chloramphenicol, can undergo nonenzymatic intramolecular rearrangement to 1-acetyl chloramphenicol. The latter compound is a substrate for a second round of enzymatic acetylation at the 3-hydroxyl, which yields 1,3-diacetyl chloramphenicol as the final product (Fig. 5). Neither the monoacetylated nor the diacetylated derivative binds to the bacterial ribosome; both, therefore, are devoid of antibiotic activity.

Figure 5. Enzymatic inactivation of chloramphenicol. CAT, chloramphenicol 3′-*O*-acetyltransferase; CPT, chloramphen
CML, chloramphenicol hydrolase.



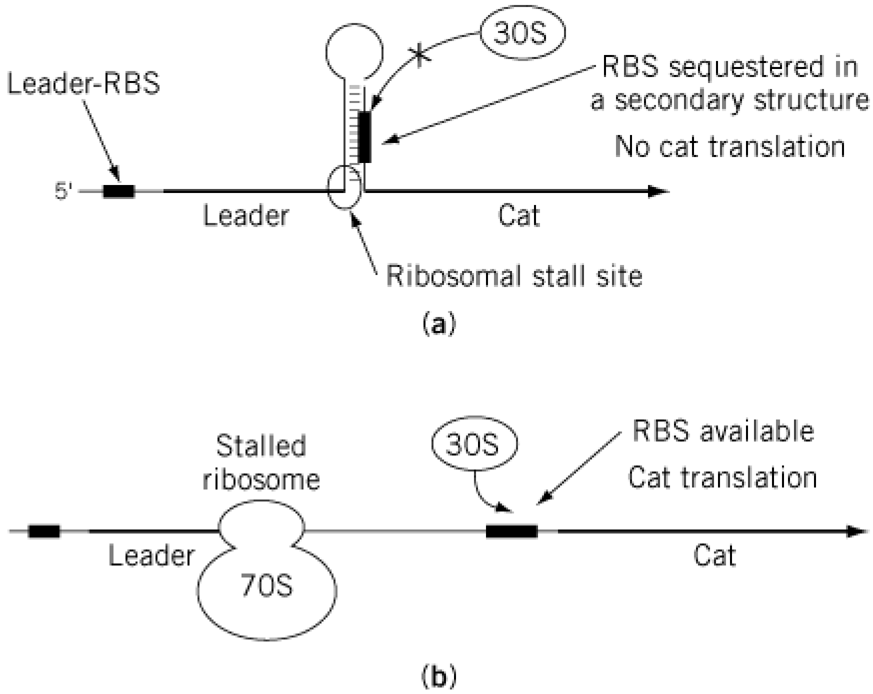
Recently, a second chloramphenicol 3′-*O*-modifying gene was discovered (16). This enzyme, chloramphenicol 3′-*O*-phosphotransferase (CPT) phosphorylates chloramphenicol, yielding 3′-*O*-phosphochloramphenicol, which binds only very weakly to ribosomes and thus does not inhibit translation.

Chloramphenicol is also inactivated by chloramphenicol hydrolase, which hydrolyzes the amide bond (17) (Fig. 5). This enzyme, encoded by the *cml* gene, was first isolated from the mycelium of a chloramphenicol-producing strain of *Streptomyces*. A similar enzyme has been obtained from several other bacteria, including *E. coli*.

6.4. Induction of Chloramphenicol Resistance by Translational Attenuation

Chloramphenicol resistance by enzymatic modification in both Gram-positive and Gram-negative bacteria can be either constitutive or inducible. What is unusual about inducible chloramphenicol resistance is that it occurs by translational attenuation, rather than by transcriptional **attenuation**. The ribosome-binding site for the resistance determinant is sequestered in a secondary "hairpin" structure situated within the encoding mRNA; a short, translated open reading frame, termed the leader, lies upstream of this structure. In the absence of the antibiotic, the secondary structure is maintained, the ribosome does not translate the mRNA that constitutes the hairpin, and the resistance gene is not translated. In the presence of the antibiotic, the ribosome stalls at the leader sequence and the secondary structure relaxes, allowing the *cat* (or *cml*) determinant to be translated (18) (Fig. 6).

Figure 6. Chloramphenicol resistance by translational attenuation. RBS, ribosomal binding site; 30S, small ribosomal subunit; 70S, entire bacterial ribosome.



7. The Use of CAT in Molecular Biology

CAT is a gene product that can be assayed with specificity and sensitivity, and consequently it is of considerable value to molecular biologists. When the *cat* gene is fused to heterologous regulatory signals, gene expression can be determined by measuring the CAT activity. Eukaryotes lack endogenous CAT activity, and the amount of CAT activity correlates well with the amount of mRNA transcribed, so the CAT assay has proved to be a powerful tool for investigating and quantifying gene expression in eukaryotic cells. Conventional CAT assays involve the incubation of cell extracts with radioactively labeled chloramphenicol, chromatographic separation of the reaction products, and autoradiography. The recent use of **fluorescent**, rather than radioactive, substrates has dramatically speeded up and simplified the CAT assay (19).

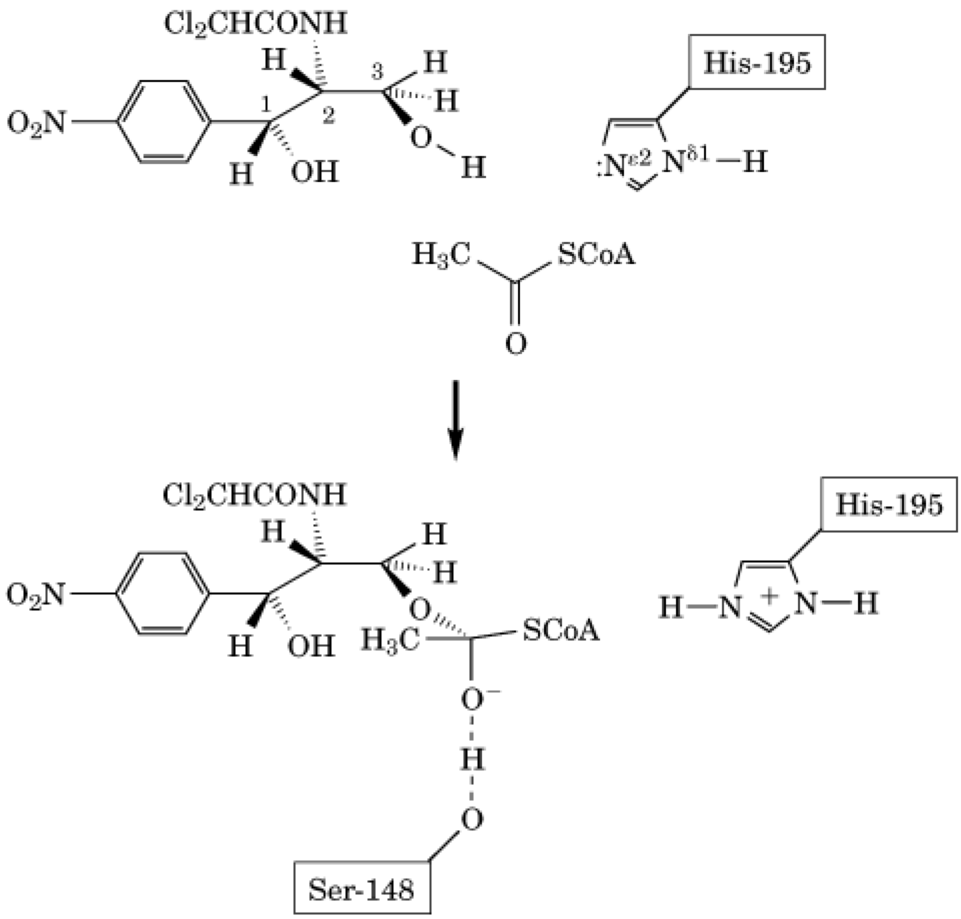
Chloramphenicol Acetyltransferase

The **enzymic** mechanisms by which bacteria modify biologically active molecules are limited by two constraints: (i) the structure–activity correlations for each class of chemical agent and (ii) the metabolic repertoire available to the bacteria. In the case of chloramphenicol (Cml), which has a number of vulnerable functional groups, there are several possibilities. Each functional group of Cml (Fig. 1) contributes to its effectiveness as an inhibitor of ribosomal peptidyltransferase activity (1), and there are examples (reviewed in Ref. 2) of enzyme-mediated resistance to Cml due to dehalogenation, nitro group reduction, hydrolysis of the amide bond, and modification of the hydroxyl groups by phosphorylation (3) or acetylation (2, 4, 5). Nonetheless, after more than four decades of medical and veterinary use, the preponderant enzymic modification mechanism for Cml resistance in bacteria of clinical importance is that of *O*-acetylation of the 3-hydroxyl group, catalyzed by chloramphenicol acetyltransferase (CAT) (Fig. 1).

Figure 1. The mechanism of acetylation of the 3-hydroxyl group of chloramphenicol by acetyl-CoA as catalyzed by

CAT. The two substrates and the His195 residue of CAT are shown (**top**). Within the transition state or tetrahedral intermediate (**bottom**), His195 has abstracted a proton from the 3-hydroxyl group, to generate an "oxyanion" intermediate that has attacked the carbonyl of acetyl-CoA. The intermediate and transition state are stabilized by hydrogen bonding with the side-chain hydroxyl group of Ser148 of CAT.



Genes for CAT are widespread among gram-positive and gram-negative bacteria; the *cat* gene in each case is either chromosomal or carried by a mobile genetic element, such as a plasmid or transposon. More important biochemically are the properties of representative variants within the CAT "family" and the pattern of conservation of the primary structure, deduced from nucleotide sequences of its genes, which in turn is related to its three-dimensional protein structure, substrate specificity, and catalysis.

All CAT polypeptide chains are in the range 24 to 26 kDa and normally exist in solution as compact and very stable *homo*-trimers. However, some CAT variants associate *in vivo* and *in vitro* to give hybrids, functional a_2b and ab_2 *hetero*-trimers with physical and catalytic characteristics reflecting the properties of the parental trimers (6). Because natural isolates of Cml-resistant bacteria may occasionally harbor more than one *cat* gene, it is possible in such instances that the intracellular CAT pool will include both parental and hybrid trimers.

The extent of structural variation within the CAT family can be appreciated from a comparison of the deduced primary structures for the products of known *cat* determinants, which yields a lower limit of 28% identity for the most divergent pair of known sequences. Only ~11% of the amino acid residues appear to be identical in all CAT variants, comprising not only residues with side chains that are involved in catalysis and substrate binding, but also those that contribute to critical structural elements necessary for the precise folding and stable packing of the polypeptide chains. A reference point for understanding the variety in primary structures of CAT variants is the type III enzyme

(CAT_{III}), for which a wealth of information is available, including the tertiary structure at high resolution (7, 8) and the structural determinants for the binding of each substrate (2, 4, 5, 7, 8). However, the type I enzyme (CAT_I) may be the most widely distributed variant, because it is specified by many "F-like" R plasmids of gram-negative bacteria, by transposon *Tn9* (9), and by promoter-less *cat* "cassettes," constructed in the laboratory for insertion "downstream" of the noncoding sequences of other genes, to study the regulation of their expression (see Reporter Genes). Type II CAT (CAT_{II}), notable among "enteric" CATs for its particular sensitivity to inhibition by reagents that react with thiol groups and by its association with *Haemophilus influenzae* (10), is less commonly encountered. CAT_I has the remarkable properties of a high affinity for triphenylmethane dyes, such as crystal violet (reviewed in Ref. 2), and the ability to bind a steroidal antibiotic (fusidic acid) both tightly and specifically (11). The latter property is sufficient to confer resistance to fusidate in mutant strains of *Escherichia coli* that were selected for their sensitivity to the antibiotic prior to the introduction of the gene for CAT_I. A plausible mechanism is the effective sequestration of fusidate by high levels of CAT_I, thereby impeding access of the antibiotic to its cellular target, ribosomal elongation factor G. The structural basis for the curious binding of fusidate, which is competitive with respect to Cml, has been deduced by protein engineering and X-ray crystallography (11). Of the eight residues in the Cml binding pocket of CAT_{III} that differ from those of CAT_I, only four appear to be responsible for the former's low affinity (K_i = 279 µM) for fusidate. Replacement of each of the four with their counterparts in CAT_I is sufficient to confer upon CAT_{III} an affinity for fusidate (K_i = 5.4 µM) that approaches that of wild-type CAT_I (K_i = 1.5 µM).

The catalytic machinery of CAT_{III} comprises a number of amino acid side chains (as well as backbone atoms and ordered water molecules) that make precise contacts with one another or with a substrate molecule. The homo-trimers have rotational symmetry at the molecular threefold axis, and consequently have three identical active sites, so only atoms in a single monomer need be addressed. Nonetheless, each of the structurally and functionally equivalent active sites lies deep in the interfacial clefts between subunits. Central to catalysis (12) is His195, which arises from one face of each cleft to supply the general base (N^{e2} in Fig. 1) to deprotonate the C3 hydroxyl of Cml, producing an "oxyanion" intermediate that in turn attacks the carbonyl (C2) carbon of acetyl CoA to yield a tetrahedral intermediate (Fig. 1). Essential for the stabilization of the latter, *en route* to the transition state for the reaction, and confirmed by site-directed mutagenesis (13), is a negatively charged hydrogen bond (Fig. 1) between the oxyanion and the hydroxyl of Ser148, another residue conserved in all CATs. A neighboring participant in catalysis is Thr174, also conserved, which is hydrogen-bonded to a water molecule that in turn probably makes two hydrogen bonds with the putative tetrahedral intermediate (Fig. 1), one to the 1-hydroxyl of Cml and the other to the 3-oxygen of the intermediate. Two additional conserved residues (Arg18 and Asp199) facilitate catalysis via a network of hydrogen bonds with His195, anchoring the side chain of the latter in a novel conformation that allows it to fulfill its general base role (7, 8, 13-15).

Chloramphenicol becomes acetylated on its 1-hydroxyl group also, albeit at a rate much slower than the 3-acetyl derivative is generated (16). The equations below, all of which are reversible, indicate the transformations involved in the two reactions, indicating that in both cases CAT acetylates only the 3-hydroxyl:

$$\text{chloramphenicol} + \text{acetyl-CoA} \rightleftharpoons \text{3-acetyl chloramphenicol} + \text{CoA} \quad (1)$$

$$\text{3-acetyl chloramphenicol} \rightleftharpoons \text{1-acetyl chloramphenicol} \quad (2)$$

$$\text{1-acetyl chloramphenicol} + \text{acetyl-CoA} \rightleftharpoons \text{1,3-diacetyl chloramphenicol} + \text{CoA} \quad (3)$$

Reaction 2 is a nonenzymic acetyl migration, slow and reversible, which yields at equilibrium a mixture of mono-acetyl products. The 1-acetyl Cml so formed is available for a second round of enzymic acetylation at the C3 position, yielding 1,3-diacetyl Cml. Reaction 3 is ~150-fold less efficient than reaction 1, almost certainly due to an unfavorable "fit" of the substrate at the active site because of the bulky 1-acetyl substituent (17). In any case, the sluggish final step (reaction 3) is of little microbiological significance, because both mono-acetyl derivatives of Cml are already devoid of significant antimicrobial activity, making the rate of reaction 1 the prime determinant of the Cml-resistance phenotype.

In summary, the precise geometry and chemical properties of both substrate binding sites (for Cml and acetyl CoA) and of the catalytic center of CAT_{III} each contribute to its extraordinary efficiency, with a turnover number of 600 s^{-1} (25°C) with a K_m for Cml of 12 μM (~4 μg/mL), reassuringly close to the concentrations at which it inhibits most bacteria of clinical importance. A derived kinetic parameter, the so-called specificity constant (k_{cat}/K_m), which combines a measure of substrate affinity with one for catalytic competence, is actually the second-order rate constant for productive collisions of an enzyme with its substrate(s). The value for CAT_{III} and Cml ($5 \times 10^7\ s^{-1}M^{-1}$) approaches that of well-characterized enzyme reactions that are limited by diffusion of the reactants (typically 10^8 to $10^9\ s^{-1}M^{-1}$) and hence at the limit of evolutionary development. By such criteria, CAT_{III} has evolved to a state approaching "perfection" in biological catalysis (18), wherein a fine balance has been struck between rate acceleration (k_{cat}) and specificity (and affinity) for substrate (K_m). Although it is not clear how the specificity and catalytic efficiency of CAT_{III} (and related variants) have evolved, the acetyltransferase (E2p) of the pyruvate dehydrogenase complex, which generates acetyl-CoA for central metabolism, has a three-dimensional structure that is virtually identical to that of CAT, as well as the same mechanism of catalysis, but the two proteins have very few identities in primary structure—only those involved with the active site (19).

It is of interest that there is a large family of "xenobiotic" *O*-acetyltransferases (XATs) with a range of specificities for natural products; several of these enzymes have a low affinity for Cml and hence were first detected as effectors of low-level resistance to the antibiotic (20). All appear to be trimeric but have no sequence homologies with members of the *bona fide* CAT family described above. One such XAT (with CAT activity) has been studied by X-ray crystallography (21) and shown to have a tertiary structure quite different from that of CAT, but the catalytic mechanism may well involve general base catalysis involving a conserved histidine residue.

Chloroplast

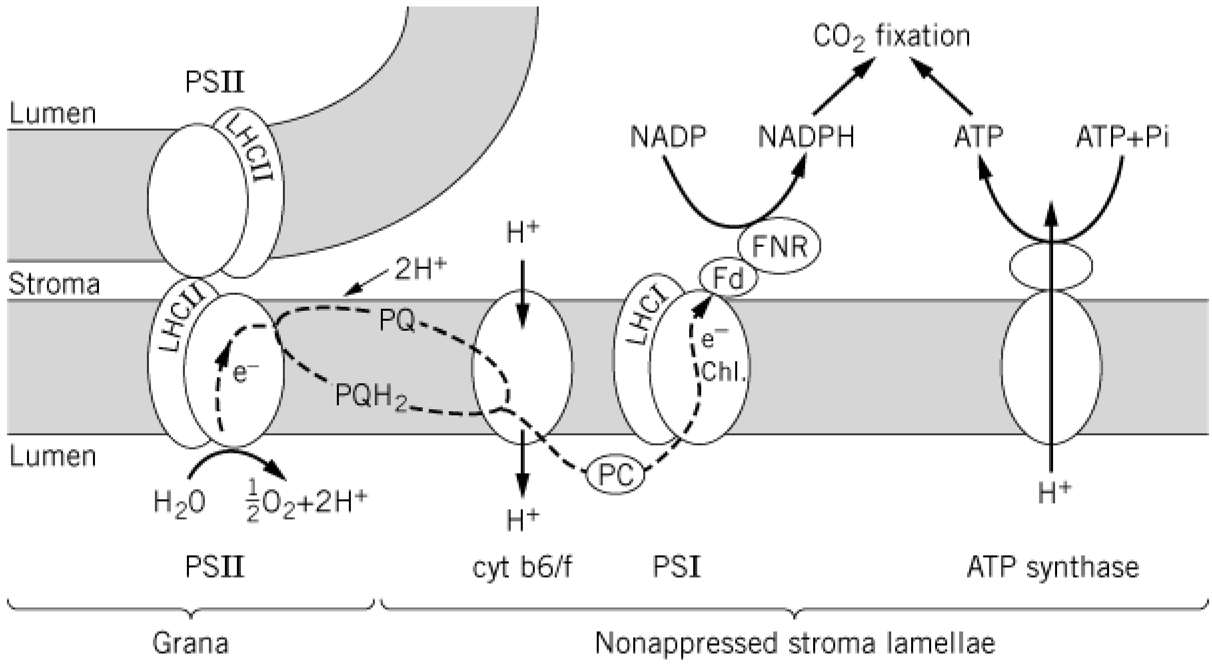
A distinctive feature of chloroplasts of **plants** and **algae** is their extensive, internal, green, chlorophyll-containing membrane system, called thylakoid membranes, where the primary reactions of photosynthesis occur. This system of photosynthetic reaction centers converts light energy into chemical energy, which is used to drive cellular metabolism. Besides their important role in photosynthesis, chloroplasts are also involved in several biochemical pathways, such as the biosynthesis of amino acids, fatty acids, tetrapyrroles including chlorophyll and heme, carotenoids, isoprenoids and pyrimidines. Chloroplasts are also involved in carbon metabolism and in nitrogen and sulfur assimilation (1). Like mitochondria, chloroplasts possess their own genetic system, which cooperates closely with the nucleus in biosynthesizing numerous organellar components. Chloroplasts represent one type of plastid derived from colorless proplastids in the meristematic cells of plant leaves and shoots, which have only a rudimentary internal membrane system (1). Light profoundly affects the development of proplastids. They differentiate into chloroplasts in the presence of light, whereas in its absence they differentiate into etioplasts, which lack chlorophyll and contain a prolamellar body. Upon subsequent illumination, the prolamellar body gives rise to lamellae of the thylakoid membrane. Depending on the plant tissues, the developmental stage, and the environmental conditions, proplastids also differentiate into chromoplasts in petals or fruits, into leucoplasts in roots, or into amyloplasts in tubers in which starch is accumulated. Proplastids also develop into elaioplasts in glands, certain fruits and seeds, where they are involved in synthesizing lipids, terpenoids, carotenoids, and carbohydrates. Although these various plastid forms have rather distinct morphologies, plastid differentiation is reversible to a large extent, because chloroplasts develop from leucoplasts or amyloplasts, and viceversa. During transitions from chloroplasts to the other plastid forms, the expression of most organellar genes is reduced, whereas specific nuclear genes encoding plastid proteins are activated (1, 2). An important point is that all plastid types contain an internal membrane system that is crucial for their interconversion.

1. Thylakoid Membranes and the Photosynthetic Apparatus

The internal thylakoid membrane system consists of appressed and non-appressed flattened membrane vesicles, called grana and stroma lamellae, respectively (Fig. 1). The primary reactions of photosynthesis are catalyzed by four major protein-pigment complexes of the thylakoid membrane:

(i) photosystem II and (ii) photosystem I, and their associated chlorophyll antennae, (iii) the cytochrome b6/f complex, and (iv) the ATP synthase (Fig. 1; see also Photosynthesis). Briefly, light energy is captured by the antennae and channeled to the reaction centers of photosystem II and photosystem I. The energy is used to energize an electron in chlorophyll and to create a stable charge separation across the membrane. This triggers a series of oxido-reductions along the photosynthetic **electron-transfer** chain. At one end of this chain, water is oxidized by photosystem II with concomitant evolution of oxygen and release of protons into the lumen. Then electrons are transferred to plastoquinone, to the cytochrome b6/f complex, which acts as a **proton pump**, and to the soluble electron carrier plastocyanin in the thylakoid lumen. At the other end of the chain, photosystem I oxidizes plastocyanin upon light absorption and transfers electrons to ferredoxin and then to NADP to form NADPH. The resulting pH gradient is used by the fourth complex, ATP synthase, to produce ATP on the stromal side. This enzyme also functions in the opposite direction by hydrolyzing ATP to pump protons into the thylakoid lumen and thus generate a pH gradient. Because the abundance of the thylakoid membrane complexes facilitates their biochemical analysis and because the state of the redox cofactors is monitored readily by **spectroscopic** techniques, the thylakoid membrane has been studied intensively and represents one of the best-studied membrane systems.

Figure 1. Photosynthetic complexes in the thylakoid membrane of chloroplasts. PSII (photosystem II) is located within the appressed grana region, whereas PSI (photosystem I) is located within the nonappressed stroma lamellae. The photosynthetic electron transfer chain is shown starting with water as electron donor to PSII, to plastoquinone (PQ), to the cytochrome b6/f complex (cytb6/f), to the soluble electron transfer protein plastocyanin (PC), to PSI, to ferredoxin (Fd), to ferredoxin-NADP oxidoreductase (FNR), and to NADP as final electron acceptor. Electron flow is coupled to proton translocation into the lumen. The resulting pH gradient across the thylakoid membrane drives ATP synthesis. Both ATP and NADPH are used for CO_2 fixation.



Each of the four photosynthetic complexes contains numerous protein subunits, some of which are encoded by the chloroplast genome, whereas others are encoded by the nuclear genome (Table 1; Fig. 2). The two principal reaction center polypeptides of photosystems I and II are highly **hydrophobic** and contain 11 and 5 transmembrane a-helices, respectively, to which most of the redox cofactors and several chlorophylls are bound with an asymmetrical distribution across the thylakoid membrane. This asymmetry is crucial for the vectorial electron transport in the membrane.

The distribution of these complexes is unequal between the appressed (grana) and nonappressed thylakoid membrane regions (3). Photosystem II is localized predominantly in the grana regions, whereas photosystem I and the ATP synthase complex are found exclusively in the nonappresssed regions. The cytochrome b6/f complex is present in both the grana and nonappressed regions. Destacking and restacking of thylakoid membranes are induced experimentally by decreasing and then increasing again the cation concentration. Remarkably, the lateral segregation of the photosynthetic complexes between grana and stromal membranes is lost upon destacking because of random mixing, but it is restored upon restacking the membranes (4).

Figure 2. Biosynthesis of the photosynthetic apparatus and protein traffic in the chloroplast. Photosynthetic complexes consist of nucleus- and chloroplast-encoded subunits. The former are synthesized as precursors on cytosolic 80S ribosomes and targeted to the chloroplast. Upon import into the organelle, the N-terminal stromal transit peptide domain is cleaved, and the protein is directed to the stroma, to the envelope, or to the thylakoids. In the latter case, the protein contains an additional cleavable thylakoid targeting domain. Several posttranscriptional steps in the chloroplast, such as RNA stability, processing, splicing, editing, and translation, plus the assembly of protein complexes, require the action of numerous nucleus-encoded factors. Chlorophyll, the major pigment of the thylakoid membrane is synthesized entirely in the chloroplast. Synthesis starts from d-aminolevulinic acid (ALA) and involves several steps in common with heme biosynthesis until protoporphyrin IX (proto IX). One of the last steps of chlorophyll synthesis, conversion of protochlorophyllide (Pchlide) to chlorophyllide (Chlide), requires light in land plants. Chlorophyll synthesis is tightly coordinated with the synthesis of its apoproteins. Expression of nuclear genes of photosynthetic proteins is strongly stimulated by light. Some of the chlorophyll precursors influence, directly or indirectly, expression of nuclear genes involved in photosynthesis.

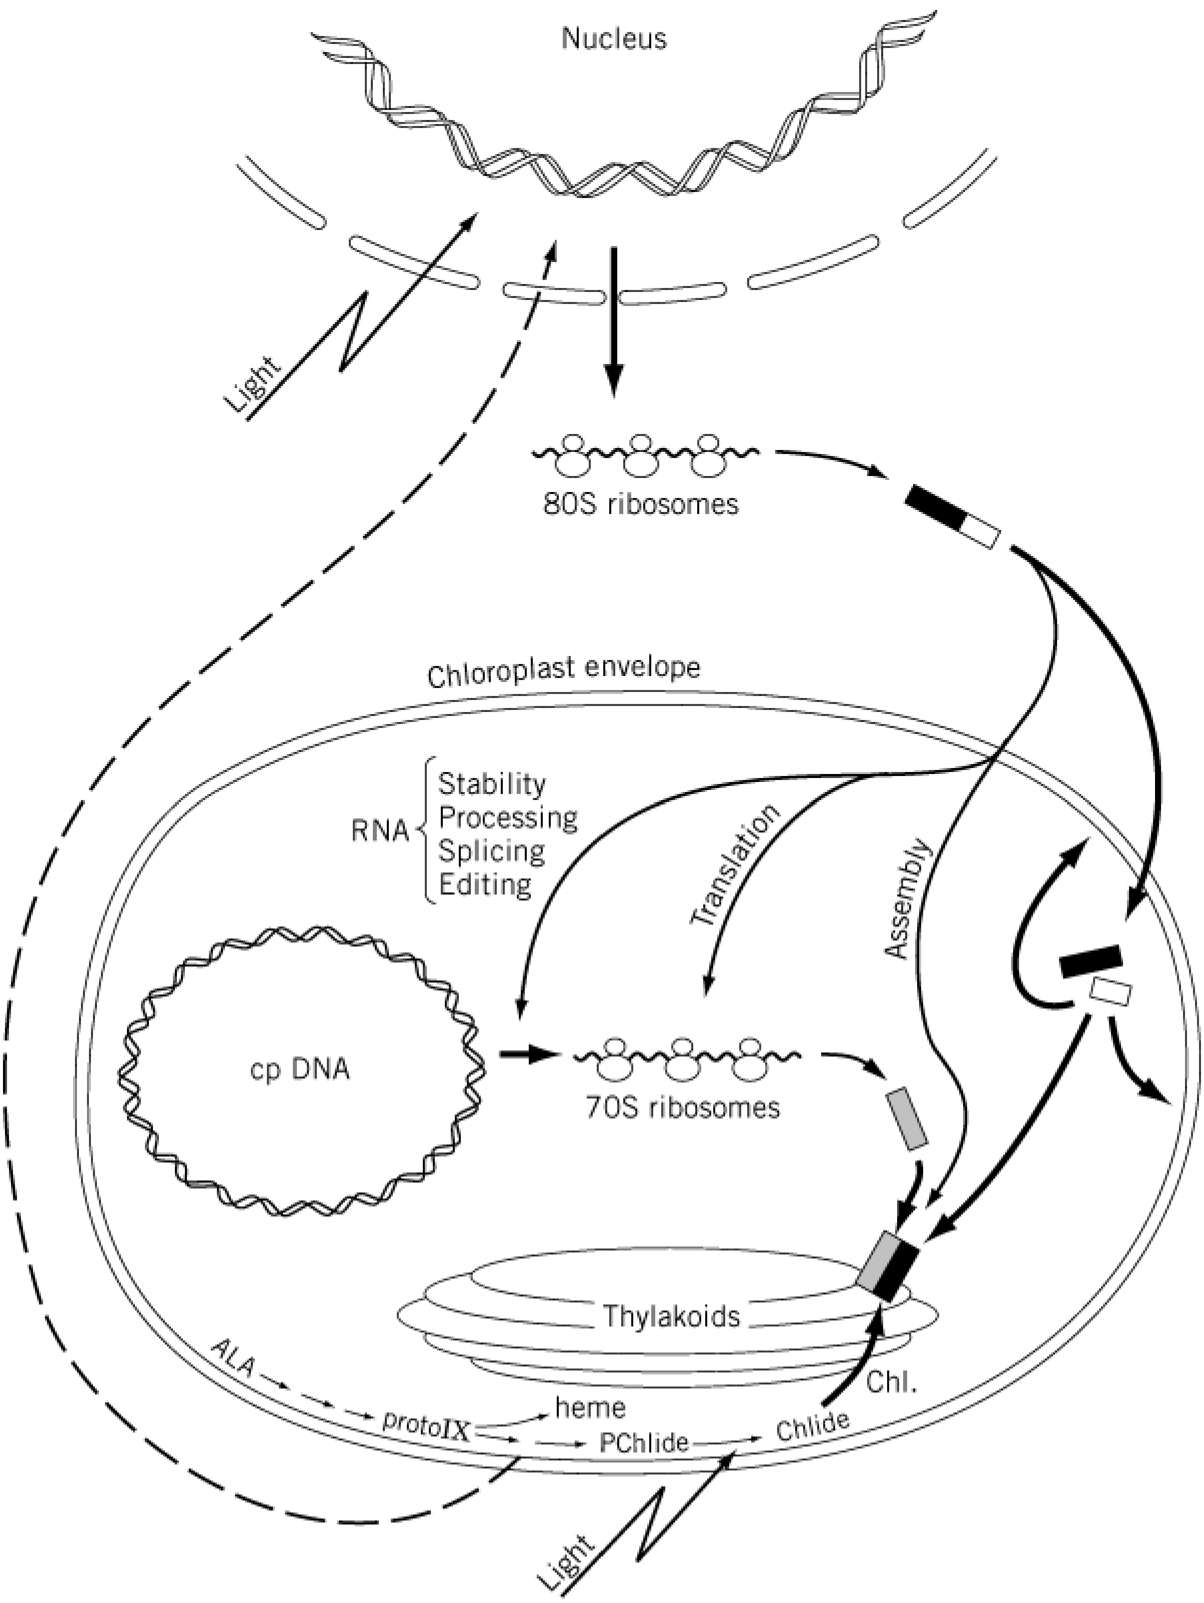


Table 1. Informational Content of Chloroplast DNA from Land Plants and Green Algae

	Number in Chloroplast

Genes Involved in	(Nucleus)[a]
Photosynthesis	
Photosystem II	14 (5)
Photosystem I	5 (8)
Cytochrome b6/f complex	5 (2)
ATP synthase	6 (3)
Ribulose biphosphate carboxlase/oxygenase	1 (1)
NADH dehydrogenase [b]	11
Light-independent chlorophyll synthesis [c]	3
CO_2 uptake[d]	1
Protein Biosynthesis	
Ribosomal RNAs	4
Ribosomal proteins	20
tRNAs	30–31
RNA polymerase subunits	4
Other Functions	
ClpP subunit of ATP-dependent protease	1
ORFs of unknown function	10–20

[a] The number of chloroplast-encoded subunits of photosynthetic complexes. The numbers in parenthesis refer to the number of nucleus-encoded subunits.

[b] These genes are found only in the chloroplast genomes of land plants.

[c] The number of chloroplast genes involved in light-independent chlorophyll synthesis and CO_2 uptake. These genes are found only in the chloroplast genomes of gymnosperms, liverwort, and Chlamydomonas.

[d] This gene is involved in CO_2 uptake.

Other dynamic changes in thylakoid membrane organization occur when plants and algae are subjected to light of different wavelengths that is preferentially absorbed by either photosystems II or I. Under these conditions, part of the chlorophyll antenna is displaced from one photosystem to the other, so as to achieve balanced light absorption and hence optimal functioning of the two photosystems (5). Thus when photosystem II is preferentially activated, the plastoquinone pool is reduced. This leads to the activation of a protein kinase associated with the cytochrome b6/f complex, to the phosphorylation of the light-harvesting complex (LHCII), and to the concomitant movement of part of the photosystem II antenna to photosystem I. If photosystem I is preferentially activated, LHCII is dephosphorylated, and it returns to photosystem II in the grana regions.

1.1. Stroma and Carbon-Fixation Cycle

The ATP and NADPH produced by the primary light reactions of photosynthesis are used as sources of energy and reducing power to drive the reactions of the carbon fixation cycle, which convert CO_2 into glyceraldehyde 3-phosphate, a precursor to sugars, amino acids, and fatty acids. Although these reactions are also called the “dark reactions,” the enzymes involved are inactivated in the dark and need to be reactivated by light through the reducing power generated by photosynthesis. The key reaction, which involves converting one atom of inorganic carbon, as CO_2, into organic carbon, is catalyzed by the enzyme **ribulose 1,5 bisphosphate carboxylase** (Rubisco), a large stromal enzyme that works only sluggishly (6). Therefore, it is required in large amounts and is thought to be the most abundant protein on earth. This enzyme also has an oxygenase activity, which predominates if the concentration of CO_2 is low. Under these conditions it catalyzes the first step of a pathway called photorespiration, which ultimately liberates CO_2 and thereby reverses the photosynthetic reaction. In addition, the stroma includes a large number of proteins involved in several important metabolic pathways (amino acid and fatty acid synthesis, sulfur and nitrogen assimilation). The chloroplast transcription and translation systems are also contained in this compartment.

1.2. Chloroplast DNA and Its Informational Content

Chloroplasts together with mitochondria, are the only cellular organelles containing their own apparatus for **protein biosynthesis**. It consists of chloroplast **DNA**, **RNA polymerase**, enzymes involved in RNA metabolism, ribosomes, transfer RNA, and several translation factors. Chloroplast ribosomes resemble those of **bacteria** and have similar ribosomal RNA and proteins and sensitivity to a similar spectrum of **antibiotics**. The circular chloroplast DNA molecules range in size between 70 kb and 400 kb (7) and are present in about 100 copies per chloroplast. A typical mesophyll cell contains close to 100 plastids and thus about 10,000 chloroplast DNA circles. A dozen chloroplast genomes from several vascular plants and algae have been sequenced. These sequences have revealed the existence of about 120 chloroplast genes in plants and green algae. They include about 50 genes that encode components of the transcriptional apparatus (subunits of RNA polymerase) and of the translational apparatus (ribosomal RNA, ribosomal proteins, transfer RNA, and translation factors). About 40 genes are involved in photosynthesis, and they encode some of the subunits of photosystems I and II, the cytochrome b6/f complex, ATP synthase and Rubisco (see Table 1). The other subunits of these complexes are encoded by the nuclear genome, translated on cytosolic ribosomes, and imported posttranslationally into the chloroplast. The genes involved in the plastid protein synthesizing system and in photosynthesis have been conserved during evolutionary **divergence** of the chloroplast genomes of plants and green algae. The remaining chloroplast genes, however, have not been universally conserved. Eleven genes encoding subunits of NADH dehydrogenase are present in the chloroplasts of plants, but not in algae. Whereas the role of the mitochondrial NADH dehydrogenase in respiration is well understood, the function of the chloroplast enzyme has not yet been elucidated. It could be involved in a chlororespiratory pathway by reducing the plastoquinone pool in the dark, which is ultimately oxidized by molecular oxygen via unknown redox components (8).

In most plants, one of the last steps of the chlorophyll synthesis pathway, the conversion of protochlorophyllide into chlorophyllide, is light-dependent. In green algae and **gymnosperms**, an alternative light-independent pathway for chlorophyll synthesis is mediated by three chloroplast genes that are absent in **angiosperms**. The sequences of chloroplast genomes have revealed additional genes whose functions are still unknown.

The chloroplast genomes of nongreen algae contain twice as many genes as those of higher plants. Additional genes include those required for photosynthesis that are nucleus-encoded in plants and green algae, genes involved in the synthesis of fatty acids, amino acids, and pigments, genes required for **protein folding** and transport, and additional genes of unknown function (9). The smallest plastid genome identified, that of the white parasitic plant *Epifagus virginiana*, is only 70 kbp in size. It has lost all the genes involved in photosynthesis, and the remaining genes encode mostly components of the plastid protein synthesizing system.

It is generally admitted that plastids originated as the result of an endosymbiotic event in which a **prokaryotic** photosynthetic organism, probably similar to a **cyanobacterium**, invaded a primitive **eukaryotic** cell. Strong support for this endosymbiotic hypothesis arises from the considerable similarity between the transcriptional and translational systems of prokaryotes and plastids. It is thought that during evolution genetic information from the intruder was gradually lost and transferred to the nucleus of the host. The question thus arises why chloroplast DNA has been maintained. One possibility is that this evolutionary plastid genome size reduction is still in progress and has not yet reached its final stage. Another possibility is that the plastid protein synthesizing apparatus is essential for synthesizing the large hydrophobic polypeptides of the photosynthetic reaction centers, which cannot be translocated across the plastid envelope membrane. A third recently advanced hypothesis is that the presence of the plastid protein synthesizing system is essential to allow a rapid response of plastid gene expression to environmental changes (10).

1.3. Chloroplast Gene Expression

Two distinct RNA polymerases are present in the chloroplasts of higher plants. One is similar to its bacterial homologue, and its subunits are encoded by chloroplast genes. This enzyme transcribes primarily genes involved in photosynthesis, which are expressed at a high level. The second plastid RNA polymerase is nucleus-encoded and is required for expressing the nonphotosynthetic plastid functions necessary for plant growth (11). Many chloroplast genes are organized in large transcription units. These units are transcribed into large precursor transcripts, which then are processed into individual messenger RNA (mRNA) molecules. Chloroplasts contain RNA **splicing** systems, because several plastid genes contain **introns**, mostly group II and group I, which have a characteristic secondary structure (12). These introns have also been found in mitochondrial genes, and some of them are **self-splicing**. Splicing in the chloroplast is rather complex, as in the case of the *psaA* gene encoding one of the reaction center polypeptides of photosystem I in the green alga *Chlamydomonas*. This gene consists of three coding regions (**exons**) that are widely separated on the chloroplast genome and are flanked by group II intron sequences (13). They are transcribed individually, and maturation of the *psaA* mRNA depends on two trans-splicing reactions in which the separate transcripts of the three exons are spliced together. A particularly intriguing feature is that one of the introns is split into three parts (14). This has interesting evolutionary implications because it is thought that group II introns represent the precursors of nuclear introns and their associated splicing factors. In this view, the split chloroplast intron may represent an intermediate between group II and nuclear introns. The chloroplast genetic system has evolved at a rather slow rate and could have therefore maintained some ancient gene organization.

Another unusual feature of chloroplast RNA metabolism is RNA **editing** in vascular plants (15). Editing in chloroplasts is a posttranscriptional process in which specific C residues of a primary transcript are changed to U. Editing has important implications for interpreting DNA genomic sequence data. As an example, an ACG triplet may be edited to AUG, thereby creating a new initiation codon, which could not be identified in the DNA sequence. Alternatively, an editing event may change an internal codon and thus change the corresponding amino acid predicted by the DNA sequence. Therefore, sequencing of chloroplast genomes may not allow identifying of all of the plastid genes.

Because the subunits, redox cofactors, and pigments of photosynthetic complexes are synthesized by two distinct genetic systems, the process has to occur in a coordinated way (Fig. 2). Genetic studies with ***Chlamydomonas*** and **maize** have indeed revealed the existence of highly complex interactions between nucleus and chloroplast (16). A large number of nuclear genes are involved in chloroplast gene expression. They encode factors targeted to the chloroplast that act at different posttranscriptional steps, such as RNA processing, RNA stability, RNA splicing, translation, and the assembly of photosynthetic complexes. Light strongly enhances some of these steps, especially translation. Several translational activators have been identified, which act at the level of initiating translation. Translation in the chloroplast occurs on chloroplast ribosomes, which are often closely associated with the thylakoid membrane. Cotranslational insertion into the thylakoid membrane has been proposed for the hydrophobic reaction center polypeptides. In addition, synthesis of chlorophyll and its apoproteins needs to be strictly coordinated, because free chlorophyll is highly photoreactive and causes serious damage to the cell.

1.4. Chloroplast-Nuclear Cross talk

Chloroplast function and development depend to a large extent on the nucleus. A large number of nuclear genes encode chloroplast structural components and enzymes and are involved in regulating chloroplast gene expression. Reciprocally, chloroplasts also influence nuclear gene activity. This is apparent in mutant plants with defective chloroplasts, where nuclear genes of proteins involved in photosynthesis are no longer expressed. As an example, when carotenoid synthesis is inhibited, chloroplasts rapidly bleach in strong light because chlorophyll is photooxidized in the absence of carotenoids (17). Under these conditions, expression of nuclear genes that code for several abundant chloroplast proteins involved in photosynthesis is specifically repressed. A block in chloroplast protein synthesis has a similar effect (18). These observations imply the existence of a plastid-derived factor that directly or indirectly influences nuclear gene activity. There are mutants of Arabidopsis in which the transduction of this plastid-derived signal to the nucleus is affected (19). The nature of the plastid factor is still unknown in plants, although studies with *Chlamydomonas* suggest that some porphyrin compounds, which act as intermediates in the chlorophyll biosynthetic pathway, are involved in this response (Fig. 2, 20).

1.5. Protein Sorting in the Chloroplast

Chloroplasts are bounded by an envelope that consists of the outer and inner membranes. The outer membrane is freely permeable to ions and small molecules, whereas the inner membrane is highly selective and contains specific translocators and **permeases** that allow regulated metabolic transport between cytosol and stroma. The envelope also contains the protein import system.

From just the modest size of the plastid genome, it is clear that the majority of the chloroplast proteins are encoded by nuclear genes and imported into the chloroplast. Six chloroplast compartments can be distinguished: (1) the outer envelope membrane, (2) the intermembrane space, (3) the inner envelope membrane, (4) the stroma, (5) the thylakoid membrane, and (6) the lumen. Nucleus-encoded proteins destined to the chloroplast are synthesized as precursor proteins containing, in most cases, a transient N-terminal transit peptide (21). Transit peptides are both necessary and sufficient to import a polypeptide into the chloroplast. Transit peptides of stromal proteins consist of 30 to 120 residues in only a poorly conserved sequence. The only distinguishing feature is that they are rich in hydroxylated amino acids and deficient in acidic residues. Recognition of the protein import **receptor** by the transit peptide is followed by translocation of the precursor protein in an extended conformation across the two envelope membranes. ATP and GTP are the sole energy sources for this process, which also requires the participation of several factors to unfold protein on the outside and to refold protein on the inside of the organelle. Several **molecular chaperones** play an important role in the proper folding of the polypeptides that enter the chloroplast (21). Translocation of the precursor of protochlorophyllide oxidoreductase, an enzyme involved in the last step of chlorophyll synthesis, also requires the presence of its substrate, protochlorophyllide, inside the plastid (22). This raises the possibility that the substrate drives the translocation by inducing or stabilizing folding of the enzyme on the stromal side of the envelope.

Thylakoid precursor proteins contain a bipartite transit peptide. The first domain targets the protein to the stroma, and the second hydrophobic domain, which resembles the **signal sequences** of **secretory proteins**, acts as the thylakoid targeting domain. Surprisingly, there are four pathways for protein translocation into or across the thylakoid membrane (21). The first corresponds to the bacterial protein secretion system and uses **Sec proteins** homologous to the bacterial SecA and SecY proteins. The second uses a system involving a signal recognition particle. The third pathway is rather unique because it uses only the trans-thylakoid pH gradient as an energy source (see Chemiosmotic Coupling). The fourth pathway involves spontaneous insertion of certain proteins into the thylakoid membrane.

Insertion of proteins into the chloroplast envelope occurs by several routes. Some nucleus-encoded polypeptide chains lack a cleavable transit peptide and are inserted directly into the outer and inner membranes. Other envelope membrane proteins containing a cleavable transit peptide use the general import pathway. At least one inner membrane envelope protein is encoded by the chloroplast genome, so it must contain an appropriate targeting signal.

1.6. Chloroplast Engineering

A major breakthrough in chloroplast research in 1988 was the development of an efficient method for genetically **transforming** chloroplasts of the green alga *Chlamydomonas* (23), which was subsequently adapted to higher plants (24). In this method, tungsten or gold particles are coated with DNA and bombarded into cells with a particle gun (see Transfection). Upon entry of the particles into chloroplasts, the DNA is released and integrated into the chloroplast chromosome by homologous recombination. The existence of an efficient chloroplast homologous recombination system and the development of selectable markers for chloroplast transformation have opened the door to manipulating the chloroplast genome. In particular, this new technology allows directed chloroplast gene disruption, a powerful tool for elucidating the role of genes of unknown function. It has also permitted site-directed mutagenesis of specific residues of photosynthetic reaction center polypeptides so as to gain new insights into their structure-function relationship, and it has been very useful for studying chloroplast gene expression. Chloroplast transformation has important applications for plant biotechnology and protein engineering. Because the chloroplast genome is present in multiple copies, up to 10,000 per cell, new genetic information introduced into plastids is amplified. In principle, this opens the possibility of expressing foreign proteins of commercial interest in large quantities. The expression of foreign genes in the chloroplast compartment offers the additional advantage of considerably reducing the risk of transfer of new genetic material to the environment because the chloroplasts from the male parent are not transmitted to the progeny in most crop plants.

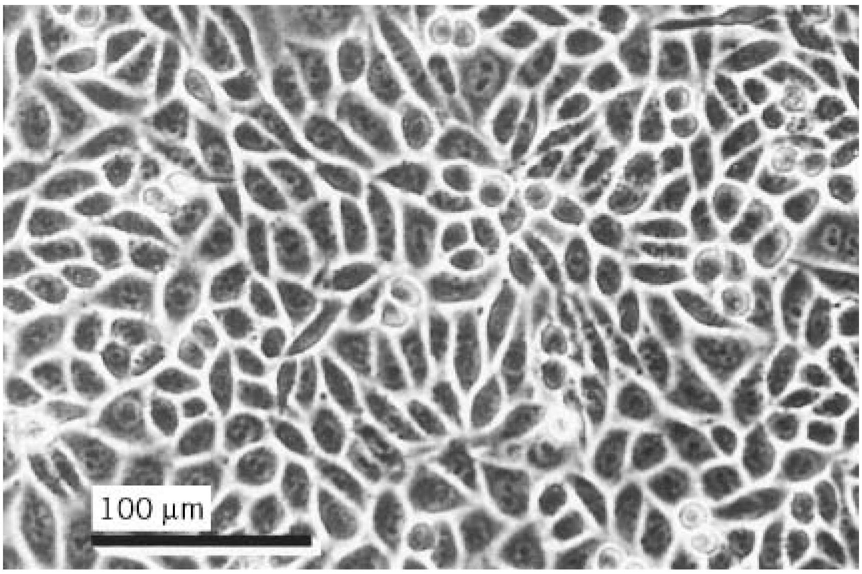
CHO Cells

1. Origin

CHO cells were originated as a cell line by Theodore Puck in 1958 (1) from the Chinese hamster, *Cricetulus griseus*. CHO/Pro cells requiring proline for growth were subsequently derived by nutritional selection. The parental cells were treated with bromodeoxyuridine (see 5-Bromouracil) in proline-deficient medium and then exposed to the near-visible UV from a fluorescent light. This killed the growing cells, but not those that required proline. Proline-requiring clones were then grown up by feeding the surviving cells with proline-rich medium. CHO/Pro^{-} was subcloned by dilution cloning, and cell line CHO/Pro-K1 was isolated. The current designation of this cell line in common use is CHO-K1, and it still has a requirement for proline, which is present in Ham's F12, the medium usually recommended for its propagation. It is listed in the American Type Culture Collection (ATCC) catalogue as CCL-61 (Fig. 1).

Figure 1. Confluent culture of CHO-K1 cells. Phase contrast, Olympus CK microscope, 20× objective.



2. Properties

CHO-K1 (Fig. 1) is a continuous cell line and near-**diploid** with 20 chromosomes ($2C = 22$). It has a very short doubling time of around 15 h, making it popular as a host for transfection and biotechnology. The plating efficiency is also very high, and can be 100% under optimal conditions, so these cells have always been popular for clonogenic survival studies of nutritional mutants and radiation survival. Chinese hamster cells originally became popular for genetic studies because of their relatively small number of readily distinguishable chromosomes, but the advent of chromosome banding techniques and chromosome painting by fluorescence in situ hybridization makes the distinction of individual chromosomes easier in many other species.

CHO-K1 cells, although transformed, still retain nutrient-dependent G_1 cell-cycle blockade. Isoleucine deprivation blocks the cells in G_1, and its restoration generates a synchronous population (2).

3. Usage

CHO-K1 cells have been used in cell-cycle control and signaling (3) and are used extensively in biotechnology (4). They are used frequently in DNA transfection (5) and virally mediated DNA transfer (6). They can be maintained in suspension culture to generate large numbers of cells or product. Using methotrexate-induced co-amplification with cotransfected dihydrofolate reductase, they have been used for production of **interferon**-g (7) and pro**thrombin**-2 (8). They have been adapted to grow in serum-free medium (9) (see Serum Dependence). Together with V79 cells, another Chinese hamster cell line, they have been used extensively in genotoxicity studies (10).

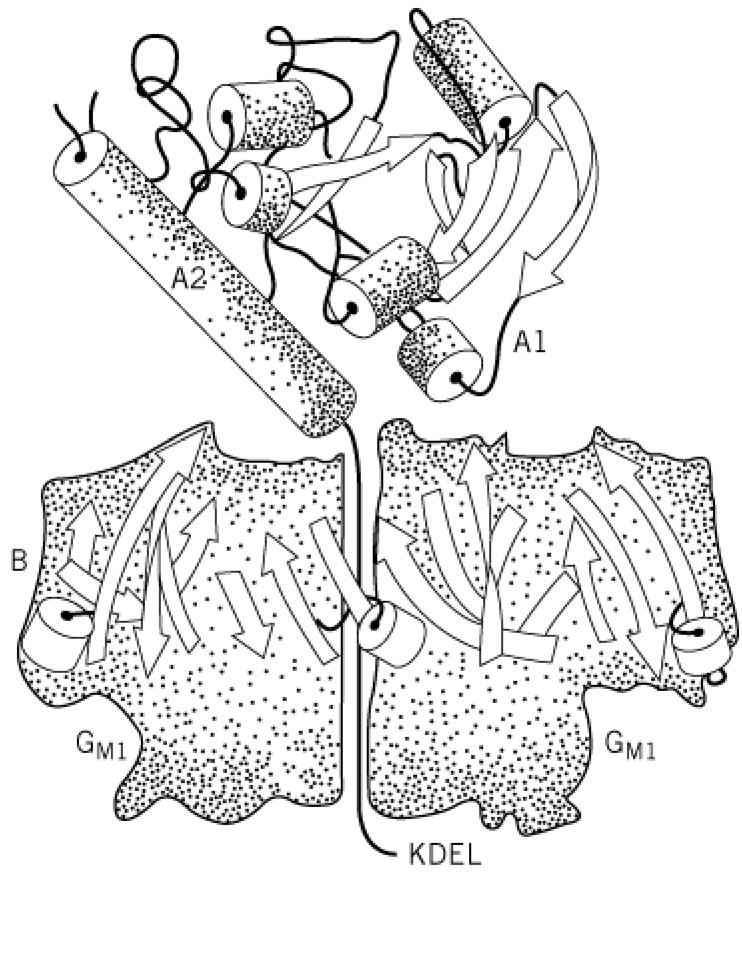
Cholera Toxin and Enterotoxins

Cholera toxin (CLT) and the closely similar heat-labile enterotoxins (LTs) are released by toxigenic strains of *Vibrio cholerae* and *Escherichia coli*, respectively, the causative agents of epidemic diarrheas (1). These bacteria attach firmly to the apical portion of the intestinal epithelium and produce several toxins, including CLT or LT, encoded by genes contained in a transferable virulence cassette (2). Five B subunits (103 residues) are secreted into the bacterial **periplasm**, where they assemble into a pentamer that binds the A chain. A is then proteolytically cleaved at a single point to generate the catalytic A1 chain (192 residues) linked via a disulfide bond to the A2 peptide (3, 4)

(Fig. 1). The structural organization of these enterotoxins is shared by *Shiga* toxins (other enterotoxins, which cause bloody diarrheas and necrosis of intestinal epithelium and are produced by *Shiga spp.* and *E. coli spp.*) and pertussis toxin (3-6). The B pentamer has the shape of an irregular cylinder with a flat surface and convoluted bottom surface. The five B monomers are arranged around a 5-fold axis in the oligomer-binding fold, recently identified in a set of oligonucleotide- and oligosaccharide-binding proteins (7). Each monomer contains five b-strands in an antiparallel beta-sheet and one alpha-helix. The five helices form a central pore hosting the carboxyl-terminal segment of A2, which emerges on the other side with a Lys/Arg-Asp-Glu-Leu motif that may be important in cell penetration (8). The amino-terminal half of A2 forms a long a-helix, rising from the flat surface, involved in interaction with A1. Thus, very few protein–protein contacts exist between A1 and B. The convoluted oligomer B surface, distal from A1, forms five sugar-binding sites on the outside edge of the cylinder (1, 3, 4).

Figure 1. Structural organization of cholera toxin and related toxins, showing a cross section of the molecule of cholera toxin and the *E. coli* heat-labile enterotoxins (1, 3, 4). A is composed of two polypeptide chains: A1, endowed with ADP-ribosyltransferase activity, and A2, which consists of a long a-helix, involved in interaction with A1, followed by a structureless segment that penetrates the small central hole of the B pentamer. Each of the five B subunits forming the B oligomer has a binding site for the oligosaccharide portion of the ganglioside G_{M1}. Thus, cholera toxin binds to the membrane via multiple interactions, with the catalytic A1 subunit pointing away from the membrane, with little protein–protein contact between A1 and B.



The structure of A1 shows a cleft where NAD binds and Arg-7 and Glu-112, two residues essential for activity, are located (9). Each B subunit of CLT or LTs possesses a single binding site specific for the oligosaccharide portion of a ganglioside (10), and one molecule of toxin binds five glycolipid molecules. Oligosaccharide binding affinity is rather low, but a high affinity of the toxin for the cell ($\boldsymbol{K_d}$ of the order of 10⁻10) is obtained because of the pentavalent binding. This strategy of multivalent binding to obtain a strong cell association is displayed by other bacterial toxins and viruses (11).

The target of CLT and LTs is localized on the basolateral membrane; therefore, these toxins have to transcytose through the cell to display their activity. Available evidence indicates that CLT and LTs are internalized inside apical endosomes that may recycle the glycolipid–toxin complex to the surface or deliver it to later endosomes. As a result of the binding of the **KDEL sequence** of the A subunit to a KDEL **receptor**, the toxin moves retrogradely through the **Golgi** cisternae, and some toxin molecules are then expected to be sorted into basolateral endosomes that fuse with the basolateral membrane (8). At some stage of this intracellular trafficking, these toxins have to be reduced and the A1 subunit has to translocate from the lumenal to the cytosolic side of the membrane to interact with their target on the cytosolic face of the basolateral membrane. Structural and membrane photolabeling data indicate that oligomer B does not penetrate the lipid bilayer (1, 10, 12), but A1 inserts in the membrane upon reduction of the A1━A2 interchain disulfide bond. Hence, it is likely that as soon as the disulfide bridge is reduced, A1 "rolls over" oligomer B and inserts into the membrane. This is at variance from postulated mechanism of membrane penetration of other toxins, whose protomer B plays an active role in the insertion of the catalytic subunit. Neither the chemical nature of the reducing agent nor the intracellular stage at which this step takes place are known.

The A1 subunits of CLT and LTs catalyze the transfer of ADP-ribose from NAD to an Arg residue present in the LRX**R**VXT conserved sequence of the a subunit of the G_S, G_t, and G_{olf} large trimeric GTP-binding proteins involved in the coupling of cell surface receptors to the adenylate cyclase (13). Such modification results in a permanent activation of this latter enzyme and a large increase in cellular cyclic AMP (cAMP) level, which initiates a cascade of signal transduction pathways. A1 ADP-ribosylating activity is enhanced by a group of cytosolic or membrane GTP-binding proteins, termed ARF (ADP-ribosylating factors), present in eukaryotic cells (14). ARF are strongly conserved from yeast to humans and are involved in the control of membrane trafficking and protein transport inside cells (15).

The increased cAMP level brought about by CLT or LTs in the enterocyte has a series of consequences, but the inhibition of a **sodium channel** and activation of a **chloride channel** localized on the apical membrane appear to be very relevant to diarrhea. In fact, a decreased sodium reabsorption and increased chloride secretion cause an osmosis-driven loss of water into the intestine. Also important in cholera is the activation of entero-chromaffim cells, which respond to the cAMP increase with release of VIP (vasointestinal peptide), which further lowers intestinal water reabsorption and inhibits muscle cells with an alteration of intestinal peristalsis.

Chorion Genes and Proteins

The outer eggshell of those numerous insects whose embryos develop externally is known as the *chorion*, and it must be mechanically robust in order to provide the environment in which the egg can develop successfully. The chorion must also have a structure that minimizes water loss, while still permitting the gas exchange vital for embryonic respiration. In ***Drosophila*** the chorion consists of an outer exochorion, an endochorion, a thin inner chorionic layer, a wax layer and the vitelline membrane. The endochorion has the most important structural and gas-transporting roles *in vivo* (1). The wax and inner chorionic layers act as the waterproofing agent for the egg. Proteins in the chorion undergo extensive post-translational modifications and consequent peroxidase-catalyzed cross-linking of two or three tyrosine residues, which results in a significant increase in the mechanical stability of the entire structure. In contrast to the chorion in the *Drosophila*, however, the gypsy moth and other Lepidoptera have a chorion with an outer “sieve” layer (30 nm thick) overlying about 50 to 60 lamellae of variable thickness (but each about 0.2 µm thick on average). The innermost region of the chorion (ie, that beneath the lamellar region) is called the *trabecular layer* and has a thickness of about 0.5 µm (2). Lamellar substructures of this general type are not found outside Ditrysia. An individual lamella consists of a fibrous layer in which fibrillar elements reported to be about 3 to 4 nm in diameter lie parallel to the surface. The orientation of the lamellae change in a relatively systematic manner from one lamella to the next, thus generating a liquid crystal-like, cholesteric phase ultrastructure. These and other observations reveal that the *Drosophila* and silk moths show remarkable similarities, but equally remarkable differences. For example, they share regulatory elements that direct chorion **gene expression** to the follicular epithelium at the end of **oogenesis** (2). In contrast, they differ in their structural **gene** sequences, their **chromosomal** organization, their chorionic ultrastructures, and their modes of morphogenesis.

The chorion in general is a very complex structure and, in some cases at least, contains a hundred or more different proteins. The proteins in silk moths, however, all have similarities in sequence and fall within either the a or b branches of the chorion superfamily. These proteins in turn are encoded by numerous duplicated genes, all of which contain a single **intron**. Fortunately, the chorion genes too fall into one of a small number of families - A, B, and C. Each family contains multiple genes that occurred during evolution by gene duplication and sequence **divergence**. The families themselves are related and constitute a superfamily with A genes in one branch and B and C in the other. The A and B genes, which exist in pairs in divergent orientation in the chromosome, are coordinately expressed and **transcribed** in opposite directions under the direction of a bidirectional **promoter**. The chorion genes in *Drosophila* are quite different from those in silkmoths with regard to sequence and organization. In particular, the *Drosophila* genes are tandemly orientated, and each has its own unidirectional promoter that is temporally unique.

Proteins in the mature silkmoth chorion are usually small (10 to 20 kDa) and have *N*- and *C*-terminal **domains** that are variable in sequence and structure. These regions endow the protein with specific functional and structural attributes. Quasi-repeats are not uncommon (3): In *Drosophila* the dipeptide (Gly━His) is repeated five times towards the *N*-terminal end of s36 and nine times in the *C*-terminal region of s38; a hexapeptide repeat based on tyrosine is found in the *C*-terminal region of s36. Peptide repeats of the form (Cys━Gly), (Cys━Gly━Gly), and (Gly━Tyr━Gly━Gly━Leu) are found in the case of silkmoths. Unlike the chorion proteins in *Drosophila*, a central domain is largely conserved in the a and b families of the silkmoth proteins. This is characterized by tandem repeats. In the case of the a family, the central domain is 52 residues in length and displays a six-residue quasi- repeat with a **consensus sequence** (Gly—X—Val/Ile—Y—Val/Ile—Z), where X is generally a charged or large polar residue, Y is variable, and Z is commonly Ala, Gly or Cys. The b family also displays a similar but different six-residue quasi-repeat. The predicted **secondary structure** of both hexapeptide repeats is that of an antiparallel b-strand terminated by a b-turn. Interestingly, the occurrence of valine and isoleucine residues two apart in the a repeat places them on the same side of the b-sheet in a manner analogous to that in feather keratin. Depending on the precise form of the b-turns, one face of the twisted b-sheet would be almost entirely apolar and could give rise to a b-barrel structure in which the apolar residues would be located internally. In the case of the gypsy moth Ld15 protein (and the 292a protein of *A. polyphemus*), both penta- and hexapeptide quasi-repeats are found with consensus sequences of (Gly—Leu—X—Pro/Gly—Tyr), (Tyr—Gly—X—X—Gly/Ala), and (Gly—X—Val—X—apolar—Ala/Gly) (2). *Drosophila* chorion proteins s36 and s38, on the other hand, contain three consecutive large apolar residues in a quasi-repeat, and these are likely to form a b-strand. They are followed by three to seven residues rich in proline and basic amino acids that are likely to form a connecting b-turn or loop. These few examples illustrate that although there are significant variations in the detail of the sequence repeats, the antiparallel b-sheet conformation that is predicted to occur in all cases would seem to be a constant feature of all the chorion proteins. The paired organization of the moth chorion genes may imply that the a and b members of the chorion superfamily interact with one another to form the core of the structure, thus leaving the *N* - and *C*-terminal regions in an external location where they are able to provide other important functional properties.

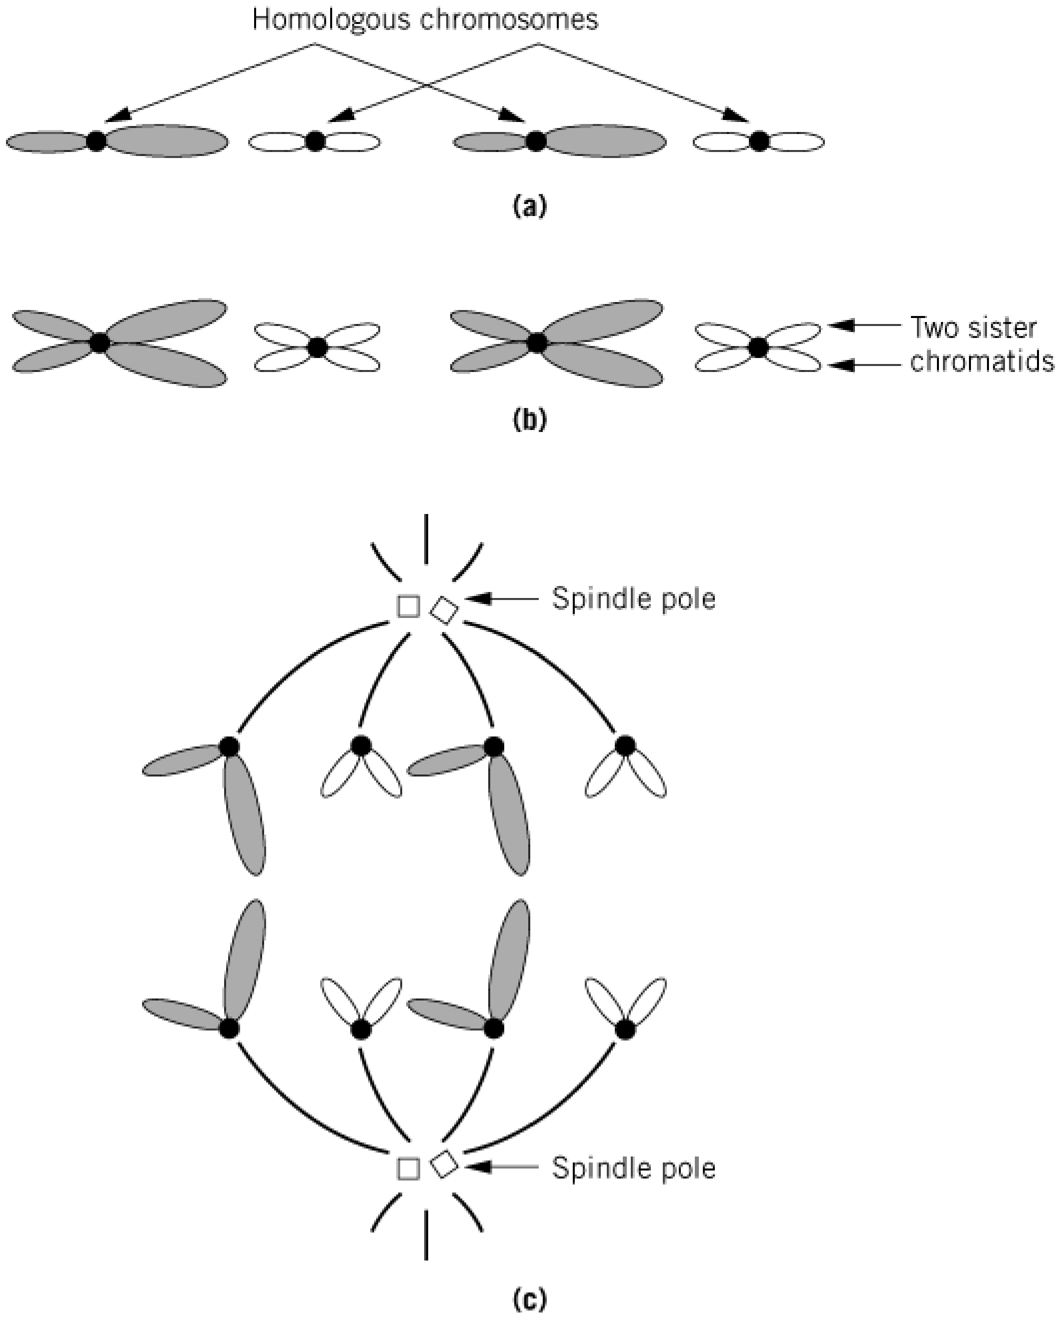
Chromatid

A chromatid is one of the two adjacent strands of a chromosome that are generated as a result of chromosomal duplication. The two chromatids are held together at the centromere and become visible during **mitosis** (Fig. 1, see top of next page). Chromosomal dynamics during the cell cycle are conveniently discussed in terms of the appearance and behavior of chromatids. It is during **interphase** that DNA is replicated (**S-phase**). Before the S-phase there is a gap known as G1, when the chromosomes are considered to be unineme, meaning that a single duplex DNA molecule runs the entire length of the chromosome (see Lampbrush Chromosomes). The amount of DNA in G1 per haploid genome is called the C-value. A **diploid** cell has a 2C DNA content. After the S-phase, in the gap known as G2, the chromosomes have duplicated and there is a 4C DNA content. Now each chromosome consists of two unineme sister chromatids. Mitosis begins at the end of G2. Whereas the chromosomes are too diffuse and decondensed to be visualized when somatic cells are in the interphase, during mitosis the chromosomes and chromatids become visible. Mitosis can be divided into four stages. During **prophase**, the chromatin in the chromosomes begins to condense so that they appear as morphologically indistinct, diffuse threads. At the end of the prophase, the chromosomes become well separated. Now each chromosome is distinctly double-stranded, consistent with two sister chromatids joined at the centromere. In the metaphase the chromosomes are maximally contracted and align on a plane, known as the metaphase plate. The metaphase plate is midway between the **spindle poles** and represents an integral component of the **mitotic spindle**. In the **anaphase**, the pairing region within the centromere dissolves (see Centromeres). This allows the mitotic spindle to pull the two sister chromatids apart. Each pole receives a complete set of chromatids, representing all of the chromosomes. Finally in **telophase** the mitotic spindle breaks down, and the nuclear membrane is reassembled around the chromosomes. The chromosomes progressively decondense and cease to be visible by light microscopy.

Figure 1. Chromosomal dynamics during the cell cycle. (**a**) At the end of mitosis and in G1, there are two copies of each chromosome, called homologous chromosomes, in a diploid cell. (**b**) At the end of the S-phase and in G2, each chromatid in each chromosome has been duplicated, creating two sister chromatids joined at the centromere. (**c**) During the anaphase of mitosis the two sister chromatids separate and move to opposite spindle poles.



Sister chromatids also interact during **meiosis**, which represents the cell division, chromosomal and chromatid segregation events associated with **gamete** formation. There are two cell divisions during meiosis. Once again chromosomal dynamics are best described in terms of the segregation of chromatids. Initially, the chromosomes replicate, then the cell enters the first meiotic cell division. Homologous chromosomes are attracted to each other, forming stable pairs held together by the synaptonemal complex (see Homologous Chromosomes). Thus each structure consists of two chromosomes, each containing two sister chromatids. Recombination occurs between the maternal- and paternal-derived chromosomes. Sites of such genetic **crossing over** are called **chiasmata**. Chiasmata represent sites of physical breakage and reunion between nonsister chromatids. They generally encompass a few hundred to a few thousand base pairs of DNA. Finally, each pair of chromosomes separates. At the start of the second meiotic cell division, each chromosome consists of two chromatids joined by a centromere. Then the chromatids are aligned on a metaphase plate attached to a spindle. The centromere splits, and the two sister chromatids move to opposite poles. Then nuclei are reformed in each of the four haploid daughter cells. Thus for both mitosis and meiosis the mechanics of chromosome condensation, recombination, and segregation emphasize the fate of individual chromatids.

Chromatin

Chromatin is the complex of histones and DNA, associated with smaller amounts of other proteins, into which the chromosomal DNA of all eukaryotes is organized. As well as being a means of packing DNA in an orderly fashion, chromatin structure plays a crucial role in the regulation of gene expression, both activation and repression. Three books contain much useful information about chromatin structure and function (1-3); for the most up-to-date information in many areas of this rapidly moving field, the reader will be referred to recent articles and reviews.

1. Overview

Chromatin has a beaded appearance in the electron microscope at low ionic strength, arising from a regularly repeating structure (4). The repeating unit is the nucleosome, which contains ~166 to 240 bp of DNA, of which ~166 bp is wound in two left-handed superhelical turns around an octameric complex of the four core histones (H3, H4, H2A, and H2B) and stabilized by one molecule of histone H1; the nucleosome also includes a variable length of linker DNA (~0 to 76 bp) that connects neighboring nucleosomes. The octamer is organized as a central $H3_2H4_2$ tetramer, which has a rather flat, twisted horseshoe shape, flanked above and below by an H2A–H2B dimer. The details of the organization of histone and DNA in the core of the nucleosome are revealed in the high-resolution structure of the 146-bp nucleosome core particle (which contains no linker DNA and no H1) recently determined by X-ray crystallography (5). The globular domain of histone H1 binds asymmetrically, bridging a point near the dyad and an entering or exiting DNA double helix (6) (see Nucleosome for further details); the basic *C*-terminal domain interacts with the linker DNA, partially neutralizing its charge. The array of nucleosomes is known as a nucleosome filament, or the 10-nm filament (10 nm being the diameter of the nucleosome). The amount of DNA contained in the repeating unit, which reflects the length of linker DNA, is determined from the sizes of the DNA in the chromatin fragments liberated by incomplete digestion with micrococcal nuclease (**Staphylococcal nuclease**), which cuts in the linker. A series of fragments, usually visualized as a "ladder" of bands in gel electrophoresis, occurs at multiples of the unit repeat size. This is commonly about 200 bp (when there is a linker length of 200 – 166 = 34 bp), but it may be as long as ~240 bp (in sea urchin sperm), or as short as ~166 bp (essentially no linker DNA) in yeast and in mammalian cerebral cortex neurons (the glial cells in the same tissue have a repeat length of about ~200 bp). The repeat length measured in this way is the average for the tissue or cell population under examination; there will be local variations about this mean (see Linker DNA). Packaging of the DNA in nucleosomes achieves about a sixfold length compaction of the DNA, and further packing is achieved by salt-dependent, histone H1-assisted folding of the 10-nm nucleosome filament into a 30-nm filament. Much evidence supports a simple helical coiling of the nucleosome filament into a "solenoid" with six nucleosomes per turn, but there are other models (see text below). Most of the chromatin in the cell is in the form of a 30-nm filament throughout most of the cell cycle, and at interphase appears to be looped onto the nuclear matrix; at mitosis, the 30-nm filament is subjected to further levels of folding to give the highly dense metaphase chromosome in which the overall length compaction of the DNA is about 10,000-fold.

The 30-nm filament is not a suitable template for transcription by the large eukaryotic **RNA polymerases** and clearly has to be unfolded first; formation of an "open" ("transcriptionally competent") chromatin state is an essential prerequisite for transcription. This involves acetylation of the basic *N*-terminal regions of the core histones, which appear to play a role in chromatin folding, and some depletion of histone H1. It has recently become clear that acetylases are targeted to particular regions of the chromosome through recruitment, directly or indirectly, by gene regulatory proteins bound to specific DNA sequences at **promoters** or upstream activating sequences. Cells appear to contain many acetylase (and deacetylase) activities, which function as components of multiprotein complexes (see Histone Acetylation). Even in the 10-nm filament form, nucleosomes may act as blocks to the formation of transcription initiation complexes by occluding promoters, which may include strategically positioned nucleosomes. It is now clear that the cell has specialized energy-dependent mechanisms that are required for "remodeling" some promoters, so that they become accessible to transcription factors, as well as mechanisms for facilitating RNA chain elongation. These mechanisms also involve multiprotein complexes, which may have subunits in common with acetylases and deacetylases. Chromatin is thus both an effective means of packing and the target for an integrated network of machines that modify it. There is a wealth of genetic evidence showing that the growing list of factors that regulate transcription includes both *bona fide* chromatin components (eg, histones) and proteins that modify chromatin (eg, acetyltransferases and deacetylases). An unexpected discovery was that a structural motif found in all the core histones is also found in a number of components of the transcription initiation factor TFIID (see Histone Fold), as well as in some histone acetyltransferase complexes (see Histone Acetylation), suggesting a structural and evolutionary link between chromatin and the assemblies that act upon it. Another surprising finding has been that histone H1 may have a specific gene regulatory role, in addition to its role in packaging and as a general repressor (see Histones).

2. Nucleosome Positioning and Mobility

Histones package the whole of the genome and therefore appear to be largely indifferent to DNA sequence. Locally, the position of a nucleosome is determined by the underlying DNA sequence and, in particular (because the DNA, which is normally rigid, is bent around the octamer surface), by the local bendability of DNA, which is sequence-dependent. Analysis of the DNA sequences of bulk nucleosome core particles shows that A and T di- and trinucleotides are likely to occur where the minor groove faces inward, and G and C di- and trinucleotides where the minor groove faces out. This is because the minor groove of AT-rich DNA is naturally narrow and so, by having A and T where the minor groove faces in, the compression of the groove that occurs on wrapping the DNA around the octamer is readily accommodated (7). The dinucleotide periodicity is on average 10.2 bp, exactly the average structural periodicity given by the X-ray crystal structure of the nucleosome core particle (see Nucleosome). The helical periodicity in solution is 10.6 bp, so the DNA is overtwisted in the nucleosome, presumably to achieve the match between the structural and sequence periodicities that underlie the rules that govern rotational positioning of the octamer with respect to the DNA sequence (the orientation of a face of the duplex with respect to the histone octamer surface). This is thus determined by the local bendability (flexibility toward curvature) of the DNA, which is determined by the properties of the individual base steps. A rotationally positioned duplex shows a characteristic 10-nucleotide pattern of nicking by DNase I, as each strand rises from the surface about every 10 nucleotides. Translational positioning, on the other hand (the basis of which is not well understood), refers to the choice of a particular stretch of DNA by the histone octamer, rather than other stretches of the same length translated forward or backward along the DNA by about 10 bp, which would allow the same rotational setting. The abundance of AA/TT dinucleotides separated by roughly 10 bp led to the construction of fragments with alternating A/T and C/C sequences [(A or T)$_3$NN(G or C)$_3$NN]$_n$—the so-called TG pentamer—that indeed formed very stable nucleosomes (8). Selection of naturally occurring 146-bp DNA sequences with a high affinity for the histone octamer revealed (in addition to the A/T, G/C periodicity) that sequences with repeated TATAAACGCC motifs ("phased TATA" sequences) formed nucleosomes that were even more stable, suggesting that high-affinity binding is aided by flexible sequences (9); selection from longer (220 bp) synthetic DNA sequences also revealed a signal (CTAG) that favored high-affinity binding (10). Such sequences, even if they occurred infrequently in the genome, could have important implications for chromatin organization and regulation, as could sequences that are refractory to nucleosome formation (eg, TGGA repeats identified in a negative-selection approach (11). It seems likely that the signals discovered for rotational positioning *in vitro* (7) also function *in vivo*, as revealed by analysis of the complete genome sequences of the yeast *Saccharomyces cerevisiae* and the nematode *Caenorhabditis elegans* (12), where dinucleotide periodicities are compatible with nucleosomal constraints. Analysis of 168-bp chicken erythrocyte chromatosome sequences [ie, containing H5(H1] shows that the statistical preferences of the octamers for particular sequences are slightly modulated (13), presumably in order to optimize the stability of the octamer–DNA–H1 ternary complex. This would be reflected in slight differences in translational positions of nucleosomes in the presence of H5(H1), which might have functional consequences (eg, in exposing or revealing short DNA sequences in an H1-dependent manner). An additional feature of chromatosomal DNA is the frequent occurrence of AGGA within half a double helical turn of one terminus, imposing asymmetry on the chromatosome. Whether this is related to the asymmetric binding of H1 to the nucleosome remains to be seen. The rules for nucleosome organization on DNA sequences have recently been reviewed (14).

Although histones can, in general, package DNA essentially irrespective of sequence, but capitalize on the local bendability of DNA to promote a better fit on the octamer surface, some DNA sequences have a particularly high affinity for the octamer, leading to a "positioned nucleosome" in which a particular translational position is preferred. Nucleosome reconstitution experiments show that the H3–H4 tetramer alone is sufficient to confer positioning on a defined DNA sequence (15, 16). Positioned nucleosomes have been identified *in vivo* by nucleosome mapping techniques and *in vitro* in nucleosome reconstitution experiments on defined DNA sequences. The rules for nucleosome positioning *in vivo* are not well understood: When the TG pentamer (see above) was introduced into yeast, it appeared to exclude nucleosomes rather than provide optimal positioning (17), showing that a strong rotational setting is not sufficient for positioning *in vivo*. Positioned nucleosomes may act as a boundary (18) and determine the positions of several neighboring nucleosomes on either side. More than one positioned nucleosome separated at less than a nucleosome's length of DNA would serve to keep the region clear of histones (eg, at promoters) for the binding of sequence-specific proteins with various gene regulatory or structural roles. At the inducible yeast *PHO5* promoter, events leading to promoter remodeling and transcription of the *PHO5* gene, which encodes a phosphatase, are initiated in response to low phosphate levels by binding of the transcription factor PHO4 to a site between two positioned nucleosomes in a set of four over the promoter (19) (see text below). Positioned arrays of nucleosomes, essential for the functioning of the promoter, are also found in many other cases—for example, the mouse mammary tumor virus (MMTV) major late promoter (20) (see also Ref. 2). It has recently become apparent (21) that nucleosome positioning is the probable explanation for the differential regulation of *Xenopus* oocyte and somatic 5S genes *in vivo* (22), where the oocyte genes are repressed and the somatic genes remain active when H1 accumulates after the mid-blastula transition. Sequence differences between the two types of gene mean that the oocyte nucleosome occludes the TFIIIA binding site and binds H1 preferentially (so the gene is turned off), whereas the converse is broadly true for the somatic gene, which remains active.

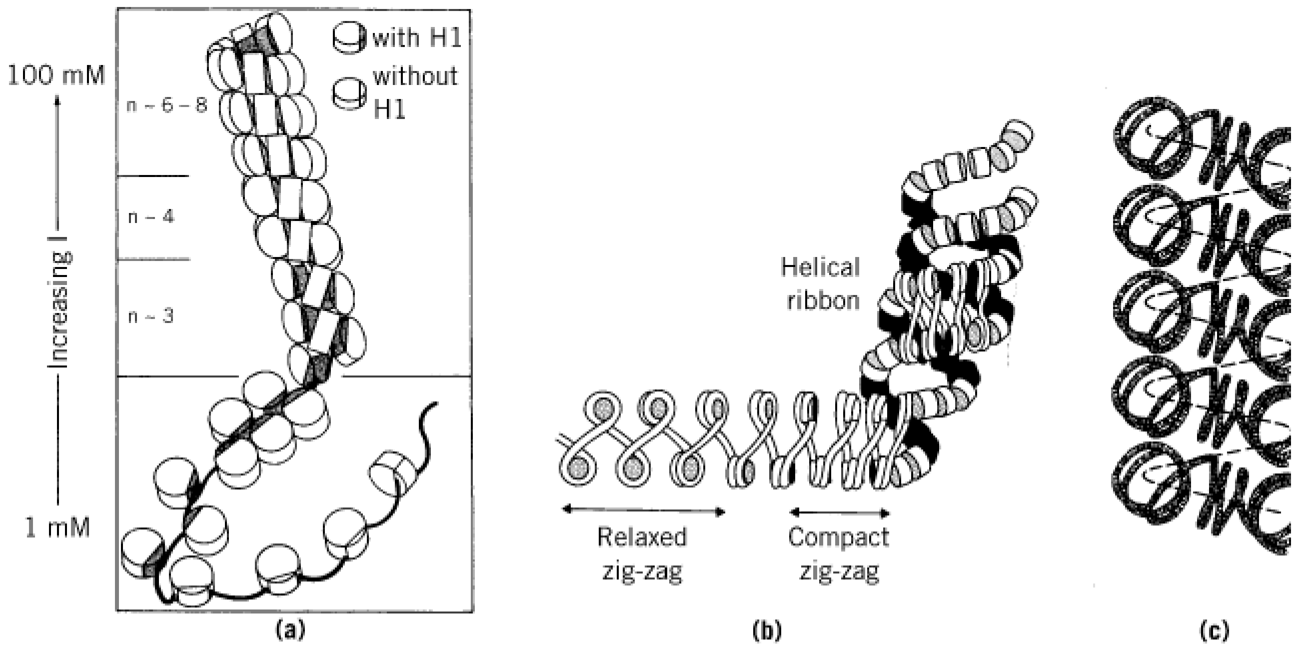
A nucleosome core can be reconstituted on to DNA *in vitro* by dialysis of an equimolar mixture of the histone octamer (or H3–H4 tetramers and H2A–H2B dimers) and DNA from high ionic strength (eg, 2 M NaCl) to low ionic strength. Even in cases where there are strong nucleosome positioning signals in the DNA, octamers on different fragments will occupy a population of less favorable minor translational positions in addition to a major position, all with the same rotational setting of the DNA. For example, on the *Xenopus borealis* somatic 5S rRNA gene, which is regarded as a strong positioning sequence, octamers can occupy 10 different positions (six being predominant), all related to each other by the 10 bp helical periodicity of the DNA, which must be caused by a strong rotational signal in the DNA sequence (21). The occupancy of less favorable octamer positions on a DNA sequence is higher at low temperatures (eg, 4°C), when the octamers are trapped, than if the temperature is then shifted to 37° (23). The change in positions populated demonstrates that nucleosomes have an intrinsic mobility, which could be useful, for example, in remodeling of promoters. In the presence of H1, nucleosome mobility is greatly reduced (24, 25); conversely, loss of H1 might enable nucleosomes to move, for example, to expose binding sites for gene regulatory proteins.

3. Higher-Order Structure: The 30-nm Filament

The 10-nm nucleosome filament, which represents the first level of chromatin structure, is the form in which chromatin exists at low ionic strength (eg, >20 mM) *in vitro*. As the ionic strength is increased, the 10-nm filament condenses into a 30-nm (diameter) filament, visible by electron microscopy. Most of the chromatin in the nucleus is in this form. The folding is a consequence of ionic-strength induced screening of the residual negative charge on the linker DNA (26), much of the charge having already been neutralized by the basic tail(s) of histone H1 and, probably, the basic *N*-terminal tails of at least some of the core histones, and results in new interactions (eg, nucleosome-nucleosome) within the higher-order structure.

Various models have been proposed for the 30-nm filament (27), some of which are shown in Figure 1. All agree on a radial distribution of nucleosomes with their faces parallel to the filament axis, but they differ fundamentally in the path taken by the linker DNA, whether bent, curved, or straight. The evidence on this point is conflicting (see Linker DNA). The evidence for the various models has been extensively reviewed (28-31). Much evidence supports the original "solenoid" model (32), which proposes a simple helical coiling of the nucleosome filament, with about six nucleosomes per turn at physiological ionic strength, and necessarily bent linker DNA (Fig. 1a). [The details are easily modified to accommodate the asymmetric, rather than symmetric, location of the globular domain of H1 near the dyad (6); see text above.] The solenoid places the dyads of the nucleosomes, histone H1, and the linker DNA between nucleosomes, on the inside of the solenoid; H1 has indeed been shown to be located within the 30-nm filament (33). However, other models have been proposed, such as the helical-ribbon model (34, 35) (Fig. 1b), which invokes straight linkers and is based on the zigzag appearance of the nucleosome filament in electron micrographs, and these too would be compatible with an internal location of H1. The coiled linker model (36), like that shown in Fig. 1c, which is related to the solenoid, is not necessarily compatible, because the dyads of the nucleosomes, and hence H1, are alternately inside and outside the solenoid for some linker lengths (eg, in chicken erythrocyte chromatin).

Figure 1. Some models of chromatin higher-order structure. The 30 filament is shown as (**a**) a solenoid (32), (**b**) a helical ribbon (34), and (**c**) as a helical conformation with coiled linkers (36). In (**a**) and (**b**) the most condensed structures are shown at the top, and the extended structures present at low ionic strength at the bottom. (From Refs. 32, 34, and 36, respectively, with permission.)



Whatever the model that best describes the spatial relationships between nucleosomes in the higher-order structure, the 30-nm filament in the cell nucleus is unlikely to be completely regular, partly because of local heterogeneity in linker length along the filament within the average value, partly due to the presence of different histone variants or subtypes, and so on. The 30-nm filament is also a dynamic structure that undergoes thermal "breathing", and this property is probably central to gene regulation through control of chromatin folding. The stability of the 30-nm filament is relevant to the ease with which it may be unpackaged for transcription and appears to be increased by special variants of H1 (such as H5 and spH1 in the condensed chromatin of nucleated erythrocytes and sea urchin sperm, respectively) (37), and it is probably decreased in regions of transcriptionally competent chromatin by (partial) loss of H1 (eg, Ref. 38) and by acetylation of the core histone *N*-terminal tails (see Histone Acetylation).

4. Chromatin and Transcription

In eukaryotes, transcription works in a chromatin context (39, 40). Some genes are active in all cell types, whereas others are active only in specific cell types. Active genes in higher eukaryotes have a chromatin structure characterized by a greater sensitivity (7- to 10-fold) to the endonuclease DNase I than the bulk of the chromatin in the nucleus (1, 2). This state precedes active transcription and marks "transcriptional competence"; it is the first step in control of transcriptional activity. DNase I sensitivity is probably due to (partial) relaxation of the 30-nm filament toward the 10-nm filament state, which is probably facilitated by partial loss of linker histones and acetylation of the core histone *N*-terminal tails (41) (see Histone Acetylation). DNase I sensitivity associated with a particular gene extends well beyond the coding region and encompasses an entire chromosomal domain (eg, tens of kilobases) and includes all the regulatory elements (eg, enhancers) for the genes (2). The boundaries of these chromosomal domains have been characterized in only a few cases, and no common feature is apparent. In at least some instances, the boundaries act as "insulators", preserving the structural and functional autonomy of the domain and also blocking the influence of regulatory elements from the outside (42). Short localized regions, termed DNase I hypersensitive sites (typically a few hundred base pairs), in the genome show a much higher sensitivity to DNase I than described above (43). These are due to the absence of a canonical nucleosome and the presence of gene regulatory (sequence-specific) proteins. They often occur within a domain of general DNase I sensitivity, coinciding with promoters or enhancers, and may also occur at the boundaries of chromosomal domains. Hypersensitive sites at promoters may be constitutive or inducible, depending on the gene, and are often flanked by “positioned nucleosomes”.

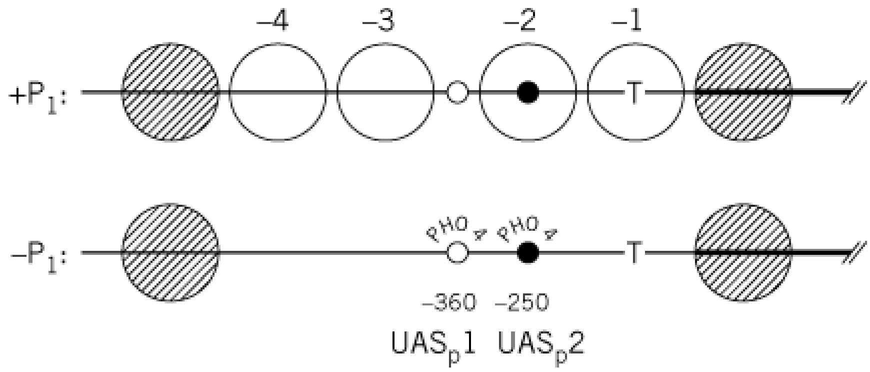
The presence of a nucleosome at a promoter generally inactivates it (39). Promoters therefore either have to be kept clear of nucleosomes, or one or more nucleosomes has to be perturbed or disrupted to permit assembly of a preinitiation complex and recruitment of RNA polymerase. Promoters may be kept clear either by flanking positioned nucleosomes or by the presence of sequence-specific proteins that bind during replication—for example, the Grf2 protein in yeast, which binds to an extended region of DNA and precludes nucleosome formation (39). The promoters that are packaged in nucleosomes have to be opened up (“remodeled”) in order to permit assembly of a preinitiation complex. The nature and extent of the disruption required to open up a promoter is unclear and may be different in different cases, perhaps depending on where the factor-binding sequences are within a nucleosome (eg, whether they can be exposed simply by loss of H1 or by loss of an H2A-H2B dimer, or whether they also require disruption of the central tetramer in the core of the nucleosome; see Ref. 2). It does not appear to result in complete histone loss. Promoter remodeling and disruption *in vivo* appears to require the action of energy-dependent “chromatin remodeling machines” (see text below) which may be recruited to particular promoters in response to the initial signal for activation, and possibly also histone acetyltransferases (see Histone Acetylation).

In vitro many transcription factors have been shown to be able to can bind to their cognate sites on the surface of a nucleosomes, albeit with lower affinity than to free DNA. The effects can be accounted for by transient “site exposure” as the interactions between the octamer and DNA fluctuate (44); this model predicts that binding of factors to multiple juxtaposed binding sites on the same nucleosome will be cooperative (45), as indeed already observed. Binding occurs without global displacement of the DNA, which will remain anchored at sites not bound by transcription factors. Consistent with this, a recent report shows that the erythroid transcription factor GATA-1 causes extensive disruption of histone–DNA contacts in nucleosome core particles containing GATA-1 sites, except over 50 bp around the dyad that serves to anchor the DNA (46). The complex is stable in solution, and the disruption is reversed on removal of GATA-1. The inherent flexibility of the nucleosome, and the fact that many promoters have clusters of factor-binding sites, suggests that this mechanism of gaining access to binding sites within nucleosomes at promoters could have physiological relevance.

At some inducible promoters, the binding site for the transcription factor that initiates the remodeling events is already exposed, in the linker between two nucleosomes in a short positioned array, rather than within a nucleosome. This is the situation at the *PHO5* promoter in yeast (19). Activation of the promoter in response to low phosphate relies on the accessibility in the uninduced state of a (weak) binding site for a transcription factor (Pho4) in the 70-bp gap between two of the four positioned nucleosomes at the promoter (Fig. 2). Binding of Pho4 leads to disruption of two nucleosomes on either side of the binding site and exposure of a second, stronger Pho4 binding site, as well as binding sites for another transcription factor, Pho2, which binds cooperatively with Pho4. The nature of the disruption is not clear but is reflected in the accessibility to a restriction enzyme of a site normally incorporated into a nucleosome and probably involves a “remodeling complex” (see text below). In other cases, a nucleosome at a promoter may be beneficial or even essential for activation of transcription. In the mouse mammary tumor virus (MMTV) long terminal repeat (LTR) promoter, six positioned nucleosomes place two glucocorticoid response elements in rotational positions (see text above) on one of the nucleosomes, such that they are accessible to glucocorticoid receptor binding in response to hormone; the two sites are also in close proximity on one face of the nucleosome. The binding site for the transcription factor NF1 is occluded until the nucleosomes are disrupted or perturbed in response to receptor binding (20). In a slightly different scenario, wrapping DNA around a nucleosome may bring into proximity two sites outside the nucleosome core, which are separated by about a nucleosome repeat length of DNA. There are several instances of this (2)—for example, the *Drosophila hsp*26 promoter (47), where a critical nucleosome upstream of the start site of transcription performs such a scaffolding role and brings binding sites for **heat shock** transcription factors into proximity with each other and with TFIID, to create a preset promoter, with bound RNA polymerase, waiting only for the binding of heat shock transcription factor to induce it.

The positioned nucleosome is flanked by binding sites for the GAGA protein, which appears to play a crucial role in the architecture of the promoter, by helping to determine the position of the nucleosome (2).

Figure 2. The yeast *PHO5* promoter: chromatin structure in the uninduced (+Pi) and induced (–Pi) states. Large open circles (–1 to –4): the four positioned nucleosomes that are disrupted and become "transparent" upon induction. Small circles: Pho4 binding sites [UASp1 (open) and UASp2 (filled)]. T: TATA box. The thick horizontal line marks the beginning of the coding sequence. From Ref. 75, with permission.



In contrast to initiation, transcriptional elongation can proceed through nucleosomes *in vivo*. In a model system using SP6 polymerase and a single nucleosome, the histone octamer is displaced during elongation (39) and then rebinds upstream of its initial position; the mechanism proposed is transferred from in front of the advancing polymerase to behind it, via a DNA loop that is displaced (48). However, no such studies have yet been carried out with the large eukaryotic RNA polymerases. The indications are that a reconstituted nucleosome array presents a block to elongation by RNA polymerase II, which may be relieved by an energy-dependent mechanism (see next section).

5. Chromatin Remodeling Machines

Exciting discoveries in the last couple of years have revealed several multiprotein complexes (molecular masses ranging from 0.5 to 2 MDa) in *Drosophila*, yeast, and human cells that are able to remodel repressive chromatin in an ATP-dependent manner to permit transcription initiation at promoters *in vitro*. These include three complexes derived from a *Drosophila* embryo extract: NURF (*nu*cleosome *r*emodeling *f*actor), CHRAC (*chr*omatin *a*ccessibility *c*omplex) and ACF (*A*TP-dependent *c*hromatin assembly and remodeling *f*actor); the S*accharomyces cerevisiae* SWI-SNF (*swi*tching-*s*ucrose *non**f*ermenting) and related RSC (*r*emodeling the *s*tructure of *c*hromatin) complexes; and SWI/SNF-related complexes in human cells and *Drosophila*. They have been comprehensively discussed in a number of recent reviews (49-53) that cite the original literature. They all contain an ATPase activity; in the case of the three *Drosophila* complexes, this is the same ISWI (*i*mitation *SWI*2) subunit. The various complexes were purified initially using a range of functional assays to follow the purification, and they appear to be functionally and mechanistically distinct; they are likely to differ in their modes of nucleosomal perturbation. NURF (four protein subunits) was purified as a factor required for ATP-dependent remodeling of chromatin templates so that the GAGA protein is able to bind (GAGA binds to GA-rich sites in several *Drosophila* heat-shock promoters, such as the *hsp*26 promoter, already mentioned); and it facilitates transcriptional activation. Interestingly, the 55-kDa subunit of NURF (which contains "WD repeats," which are protein-interaction motifs) is also found in the *Drosophila* chromatin assembly factor dCAF-1 (54), and human homologues are components of histone acetylase and deacetylase complexes (see Histone Acetylation). CHRAC (five subunits) was purified as a factor that generated ATP-dependent accessibility of sites in a chromatin template, reconstituted *in vitro*, to restriction enzymes. It is also able to generate a regular array from an irregular array of nucleosomes and has been described as an energy-dependent nucleosome spacing factor; it may therefore play a role in chromatin assembly (see text below) (where newly assembled nucleosomes are initially deposited in an irregular array that "matures" to give a regular spacing), although a spacing activity might, of course, also promote transcription factor binding. The third *Drosophila* complex, ACF (four subunits), was also purified as an ATP-dependent nucleosome spacing factor in a fractionated system and plays a role in nucleosome assembly; it can also mediate transcription-factor-mediated chromatin disruption in much the same way as NURF. SWI/SNF (9 to 12 subunits) facilitates transcription factor binding, and both SWI/SNF and RSC (15 subunits) disrupt the repeating 10-nucleotide cleavage pattern given by DNase I on mononucleosomes, showing disruption of the rotational setting of the DNA on the octamer surface. In yeast, the SWI/SNF complex is not abundant and not essential for viability, whereas the RSC complex is abundant and essential. SWI/SNF appears to be necessary for the transcription of only a small subset of genes, and in an *in vitro* system the dependence of transactivation on SWI/SNF activity is much reduced if there are multiple binding sites for the activator on the same nucleosome (55). It is possible that *in vivo* the SWI/SNF complex is needed only for remodeling of weak promoters. Altered forms of mononucleosomes generated by both SWI/SNF (56, 57) and RSC (58) complexes have recently been reported. They retain a full complement of histones and have altered physical properties that would be consistent with either a heavily modified mononucleosome or a dinucleosome. The SWI/SNF products have a higher affinity for transcription factors than unmodified nucleosomes. Much remains to be done to (a) elucidate the mechanisms by which the various chromatin remodeling machines act on chromatin, (b) define the roles of the various subunits, and (c) establish which mechanisms, *in vivo*, play a role in promoter disruption for transcription initiation, and whether others are primarily involved in reversing such disruption or in nucleosome assembly, and so on. The relationship between these complexes and the large acetylase, and deacetylase, complexes (see Histone Acetylation) also remains to be clarified, although the indications are that they cooperate in the remodeling of certain promoters.

The foregoing account has dealt solely with complexes that disrupt chromatin at promoters, allowing transcription initiation complexes to form. The transcriptional machinery also confronts nucleosomes during RNA chain elongation. Experiments on a reconstituted array of nucleosome cores show that the passage of eukaryotic RNA polymerase II is blocked by a nucleosome core and that a heterodimeric protein isolated from human cells will facilitate RNA chain elongation in a chromatin context. The protein has been designated FACT (*fa*cilitates *c*hromatin *t*ranscription) (59) and appears to be a DNA-binding protein, one subunit being an HMG-box protein. Little is yet known about it how it might work, but its action is not ATP-dependent. The *in vitro* assays show a rather modest extension of the transcript (50 to 150 nucleotides) before FACT stalls, and it is not yet clear whether FACT is designed to work only on the promoter-proximal nucleosome or needs cofactors for its normal action, or whether the modest extension is merely due to a technical limitation of the experiment. The chromatin template contains closely packed nucleosome cores (no linker DNA, no H1), and if octamer transfer via a loop of DNA is required, as demonstrated in model systems (48) (see text above), this may not be possible here.

6. Chromatin and Repression

There are hierarchies of repression, through chromatin structure, as there are of transcriptional activation. The most basic level, promoter occlusion by a nucleosome, was discussed above. Superimposed on this is repression through folding of the nucleosome filament into a 30-nm filament (whether this occurs in yeast is unclear). The higher-order structure is stabilized by a hypoacetylated state of the *N*-terminal tails of the core histones (see Histone Acetylation). In organisms other than yeast and *Drosophila*, DNA **methylation** is known to contribute to gene repression through chromatin structure, and a **5-methylcytosine**-binding protein (MeCP2) has recently been reported to recruit deacetylases (60, 61). This could favor a more stable 30-nm filament, which might be further stabilized by the tighter binding of H1 to methylated DNA (62). The 30-nm filament is not a template for transcription, and in some cases, 30-nm filament stabilization (eg, by specialized linker histone variants) and packing in the nucleus may be at least major players in general repression. This may be the situation in mature nucleated erythrocytes (eg, of birds, fish, and amphibia), where H1 is largely replaced by histone H5 and where there is a global and terminal shutdown of transcription; and in sea-urchin sperm, where highlycondensed chromatin is linked to the presence of sperm-specific H1. Other more complex mechanisms of repression also exist, however, resulting in heterochromatin. The essence of these mechanisms—although they differ in many respects in, for example, yeast and *Drosophila,* where they have been extensively studied—is the assembly, over particular chromosomal regions, of repressive multiprotein complexes that interact with chromatin. In the case of *Drosophila* at least, the chromatin is probably in the form of the 30-nm filament, and the mechanisms add an additional layer of repression for genes whose permanent inactivation is crucial and where inappropriate expression cannot be tolerated.

Yeast chromosomes are too small to allow heterochromatin to be seen cytologically, but nonetheless some chromosomal regions show many of the features of heterochromatin in more complex eukaryotes (replication late in S phase, localization at the nuclear envelope, and position effects on gene expression that are inherited **epigenetically**). In *Saccharomyces cerevisiae*, such regions occur at the silent mating type loci, *HML* and *HMR*, and at telomeres (the ends of the chromosomes; genes placed here are repressed) and have been extensively studied by genetic analysis (63). In each case, a multiprotein complex of Sir2, Sir3, and Sir4 proteins (Sir = *s*ilent*i*nformation*r*egulator information regulator) interacts with the *N*-terminal regions of histones H3 and H4. At the telomeres, which contain the sequence $[C_{1-3}A]_n$, the **silencers** consist of multiple binding sites for RAP1 (*r*epressor *a*ctivator *p*rotein 1), whereas silencers at *HML* and *HMR* consist of binding sites for ABF1 (*A*RS-*b*inding *f*actor 1), the *o*rigin *r*ecognition *c*omplex (ORC) and RAP1. Residues 16 to 29 of H4 are required for interaction with Sir3 and Sir4 and for silencing, presumably by providing interactions necessary for stabilization of the multiprotein complex. In addition, although the core histones at the silenced loci in yeast are hypoacetylated, there is a specific requirement for Lys12 in acetylated form, possibly for interaction with Sir3 (63). In the current model for telomeric repression, RAP1 binds to the telomeric repeats, initiating polymerization of Sir3/Sir4 over the adjacent chromatin domain, the binding of the Sir proteins being mediated by interaction with the H3 and H4 *N*-termini, possibly stabilized by acetylation of H4 at Lys12. Other repressive mechanisms in yeast also involve the *N*-terminal tails of H3 and H4 (64).

Extensive genetic studies of heterochromatin have also been carried out in *Drosophila*. Genes brought into juxtaposition with heterochromatin (eg, at centromeres) may be silenced in a subset of cells that normally express the gene—an effect known as position effect variegation (PEV) (2). Chromatin structure is altered in variegating genes, as shown by the properties of the *hsp*26 transgene inserted at various chromosomal locations; the heterochromatic *hsp*26 gene has a noninducible promoter and is packaged in an unusually regular nucleosomal array (65). Modifiers of PEV, identified genetically, are either (a) structural proteins that are components of multimeric protein complexes that interact with chromatin or (b) proteins that could play indirect roles in regulating the formation of chromatin—for example, by modifying histones or DNA. One such protein is the histone deacetylase RPD3 (see Histone Acetylation). However, mutations in this protein that increase acetylation *increase* PEV, rather than decreasing it, as might be expected; this is probably because of the requirement for acetylation at Lys12, as in yeast heterochromatin, against a background of general histone hypoacetylation. The multiprotein complexes that affect PEV, and presumably stabilize chromatin higher-order structure, contain (a) HP1 (heterochromatin protein 1), which binds to chromatin but not to DNA, and (b) the protein termed Su(var)3–7, which interacts with HP1 and chromatin (65). The principles underlying PEV in *Drosophila* seem also to apply to the stable inactivation of **euchromatic** genes needed for maintaining differential expression of developmental regulators (eg, the homeotic genes that control the segmental identity of the insect body). Locally silenced heritable chromatin structures are generated by the assembly of multiprotein complexes that contain members of the Polycomb group (Pc-G) of proteins, which are homologues of HP1 and contain a “chromodomain” (66). The Pc-G genes are responsible for maintaining long-range repression of homeotic genes over multiple enhancers in the later stages of *Drosophila* development. Like HP1, Pc-G proteins appear not to bind DNA. However, specific DNA sequences that recruit Polycomb group proteins and associated silencing factors [Polycomb response elements; (PREs)] have been identified and appear to be essential for stabilizing determined expression states, which are usually (but not invariably) repressive (see Ref. 66). Various models have been proposed for the mechanism of repression, including propagation of a repressive array of interacting proteins over chromosomal domains (the "spreading model" by analogy with the "spreading" effect of heterochromatin into euchromatin in PEV), an alternative model has been proposed in which clusters of Pc-G proteins interact cooperatively with each other to create tethered loop domains of chromatin which ensure repression (67). Mammalian homologues of HP1-like proteins have been found, as have interacting partners, and it seems likely that the same mechanism of silencing, by assembly into repressive heterochromatin, may be used to regulate some developmentally pivotal mammalian genes whose leaky expression would be disastrous for the cell.

Mammalian X-Chromosome Inactivation is an extreme case of heterochromatin formation over a whole chromosome. The precise molecular basis is not known, but there are some notable features of the chromatin composition: hypoacetylation of histone H4; the presence of an unusual H2A variant, macroH2A (see Histones); heavy methylation of the DNA; and the presence of an unusual large untranslated RNA, termed Xist, which is expressed from the inactive X-chromosome, and which is of prime importance in an early event in X-inactivation (68). It would not be too surprising if X-inactivation turned out to have at least some features in common with telomeric and position effect variegation in yeast and *Drosophila*.

7. Replication-Linked Chromatin Assembly

During S-phase of the cell cycle in eukaryotes, it is not just the DNA that undergoes replication, but the chromatin as a whole. Chromatin assembly is tightly coupled to DNA replication and the passage of the replication fork. It involves assembly of nucleosomes on daughter strands, followed by conversion of an initially irregularly spaced array of nucleosomes to a regular array—a process known as maturation. There has been recent progress in understanding the participants in both of these processes. Assembly involves, in equal amounts, both old (parental) histones in preexisting nucleosomes, which are recycled, and newly synthesized histones, which are apparently randomly segregated on to the two nascent duplexes. The temporal order of deposition of newly synthesized histones on to DNA reflects the structural organization of the nucleosome; it begins with the deposition of H3 and H4 to form the central organizing tetrameric core, followed by H2A and H2B as two dimers, and finally addition of H1.

The newly synthesized H4 deposited at the replication fork is diacetylated, at lysines 5 and 12, in all species so far examined (see Histone Acetylation). Newly synthesized H3 is apparently also modified (acetylated or phosphorylated?), although perhaps not in all cell types. The role, if any, played by acetylation *per se* in the assembly process is not well understood. Acetylation is transient and is erased by deacetylases shortly after deposition of histones on to the DNA; one possibility might be that any tendency for premature formation of internucleosome contacts is avoided by the acetylation (see Nucleosome). The deposition of acetylated H3 and H4 involves the participation of chromatin assembly factor 1 (CAF-1), (69), which acts as a core histone **molecular chaperone**. It forms a stable complex with newly synthesized acetylated H3 and H4 and somehow targets them specifically to the replication fork (70); the histone chaperone NAP1 appears to handle H2A and H2B in *Drosophila* (71). Other proteins may also be involved in the assembly process. CAF-1 purified from human cells contains three subunits, indicated by their mass in kDa: p48, p60, and p150; homologues exist in yeast and *Drosophila*. The small subunit (p48) of human CAF-1 is homologous to the regulatory subunit (p46) of the human B-type histone acetyltransferase (responsible for deposition-related acetylation); both subunits bind to histone H4 and, significantly, at a site that is accessible only in the free histone and not in chromatin (as shown by the structure of the nucleosome core particle; see Nucleosome). Strikingly, similar subunits also occur in chromatin remodeling machines (eg, the p55 subunit of *Drosophila* NURF) as noted, as well as in histone deacetylases (see Histone Acetylation), leading to the suggestion that these subunits target the various complexes to their histone substrates in a manner that is regulated by nucleosomal DNA (72). They are members of the highly conserved family of proteins that contain "WD repeats," multiple distinctive sequence motifs that appear to be involved in protein–protein interactions. Because the site of interaction of CAF-1 with H4 is accessible only in the free histone, CAF-1 would have to be displaced before nucleosome assembly could occur; the interactions appear to be disrupted by ACF (*A*TP-requiring *c*hromatin assembly and remodeling *f*actor; see text above). ACF was initially identified as a factor capable of regularly spacing an irregularly spaced nucleosome array (51) and would be well-suited to this role during the maturation step of chromatin assembly. It is also potentially able to participate in the remodeling of nucleosomes that accompanies transcriptional activation (see text above: chromatin remodeling machines).

8. Chromatin Reconstitution

Reconstitution *in vitro* of chromatin from its component parts, like any complex biochemical structure, would allow questions to be asked about structure–function relationships. Reconstitution of the nucleosome core is straightforward. It is achieved by gradual dialysis of a 1:1 molar ratio of histone octamer and 146 bp DNA from 2M NaCl to low salt (eg, 10 mM NaCl). Nucleosome core particles (see Nucleosome) for X-ray crystallography were made in this way. The histones can be presented either as the intact octamer or as a 1:1 molar ratio of H2A–H2B dimers and $(H3)_2(H4)_2$ tetramers.

Long "chromatin" reconstituted *in vitro* by mixing histones at high ionic strength (eg, 2M NaCl), and then dialyzing to low ionic strength, shows close packing of octamers, irrespective of the presence of H1, which has no effect because it is the last histone to bind in this procedure. In attempts to determine what cellular factors determine nucleosome spacing (nucleosome repeat length), several cell-free extracts, from *Xenopus* eggs and oocytes and from *Drosophila* embryos, have been developed that will assemble plasmid DNA, irrespective of sequence, into "physiologically" spaced chromatin in an ATP-dependent fashion, independent of replication. Nucleosome spacing (and hence linker length) is increased by H1. The earliest extracts were from *Xenopus* eggs, which contain a large maternal histone pool, and led to the discovery of two acidic histone chaperone proteins, nucleoplasmin and N1/N2, which facilitated chromatin assembly in this system. Work on the *Xenopus* system is summarized in Ref. 2 (Section 3.4.2). The true role of these proteins may be storage of the large histone pool in the egg. Whether similar proteins exist in somatic cells is unclear, although nucleoplasmin-like proteins have been reported. The *Drosophila* embryo extracts are the same ones that led to the discovery of CHRAC (53) and ACF (51) (see text above: Chromatin remodeling) which themselves have nucleosome spacing activity. Spacing may also have an electrostatic component, involving neutralization of charges on linker DNA (73), and a connection between nucleosome spacing and formation of higher-order structure, which is also ionic strength dependent, has been suggested.

A well-defined *in vitro* system starting with pure components, which has recently been further explored (74), will also assemble "properly spaced" chromatin, in an H1-dependent, ATP-independent manner. Irregularly spaced octamers are first deposited on the DNA by dialysis from high to low NaCl concentration, and then a more regularly spaced array is generated by incubation at "physiological ionic strength" (150 mM NaCl) with H1(H5) in the presence of polyglutamate (which probably binds histones reversibly and allows equilibrium to be reached in the histone positions on the DNA). Interestingly, the system is sensitive to the DNA sequence, and regular nucleosome arrays were generated on only about half of the ~2-kbp cloned chicken genomic sequences tested; the sequences tested (by **Southern blotting**) behaved in essentially the same way in chicken liver nuclei. It is argued (74) that genomic chromatin is a mosaic of less well-ordered regions and regular regions that are about 10 nucleosomes long and contain a nucleosome positioning sequence (or sequences), which effectively acts as a boundary (18) against which linker-histone-dependent nucleosome alignment can occur. It is possible that egg, oocyte, and embryo extracts, which appear to be indifferent to DNA sequence as well as ATP-dependent, are designed to assemble chromatin through rapid cycles of cell division, and not to be responsive, for example, to genomic signals that may be necessary to specify arrays of nucleosomes compatible with gene expression and regulation in somatic cells.

Chromatofocusing

Biological macromolecules differ in their compositions of **buffering** groups, such as amino acids and **purine** or **pyrimidine** bases, thus giving each biomolecule its own unique charge properties. Generally, at low or acidic pH values, most biomolecules have a net positive charge, whereas at a higher or basic pH they carry a net negative charge. Of course, at a certain pH, the isoelectric pH or isoelectric point (p*I*), these biomolecules do not possess a net electric charge. This unique isoelectric pH provides the basis for the selectivity of chromatofocusing in **chromatographically** separating biomolecules.

Chromatofocusing is a special kind of technique classified within the ion-exchange chromatography of biomolecules. A weak ion-exchange matrix and a pH gradient are used in chromatofocusing, instead of a strong ion exchanger and a salt gradient as in normal ion-exchange chromatography. This technique was first described theoretically and experimentally demonstrated by Sluyterman and co-workers (1, 2). They proposed that a pH gradient could be produced in an ion-exchange column packed with an appropriate ion-exchange resin with good buffering capacity. Although a pH gradient in a column can be produced in a manner similar to that of a salt gradient by using two different pH buffers in a mixing chamber of a gradient maker, a pH gradient can be created internally in the column by taking advantage of the buffering capacity of the weak ion-exchange resin. In practice, a certain pH buffer is used to equilibrate a column packed with a weak ion exchanger. Then another buffer with a different pH is passed through the column, which generates a pH gradient in the column. If such a pH gradient is used to elute biomolecules bound to the ion-exchange resin, the biomolecules elute in order of their isoelectric pH.

The mechanism of chromatofocusing is based on the buffering action of the charged groups on the ion-exchange resin and on the fact that a biomolecule has a net negative charge at a pH above its isoelectric point. In a descending pH gradient, a single molecular species exists in three charged states—negative, neutral, and positive. When a positively charged column (ie, packed with an anion exchange resin) is equilibrated with a starting buffer of high pH, biomolecules that become negatively charged are initially retained on the column. When an elution buffer of lower pH is passed through the column, a pH gradient develops and the individual molecules continuously change their charged states. The molecules at the rear of the sample zone are the first to be titrated by the low-pH buffer. These molecules become positively charged when the pH is less than their p*I*, so that they are repelled from the column matrix and are carried rapidly to the front of the sample zone, because of the high velocity of the moving buffer. In traveling to the front of the sample zone, the molecules encounter an increase in pH and are titrated from their positive form to neutrality and back to their negative form. Once the molecules become negatively charged again, they readsorb on the matrix and again fall back to the rear of the sample zone. The cycle between the front and rear of the sample zone results in "focusing" (ie, a continuous narrowing of this zone) until the molecules elute from the column. At this point, the pH of the column effluent is approximately the same as p*I* of the components eluting.

Chromatofocusing is an analytical or preparative technique for separating biomolecules according to their p*I*. The details of this technique relating to column packing, sample preparation, and sample application used in this technique are similar to those for affinity chromatography. A detailed operational protocol is beyond the scope of this article, so the interested reader is directed to other reviews (3, 4).

There are a number of advantages in using chromatofocusing. In this technique, a biomolecule is not subjected to a pH greater than its p*I*, and the resulting focusing effects concentrate the sample into a sharp, highly resolved band. One of the great benefits of chromatofocusing is its ease of operation. No gradient-forming devices or mixers are required. The pH gradient is formed with a single isocratic eluent. Chromatofocusing is used widely in research as the method of choice for resolving **isozymes** and molecular species with very similar charge characteristics, such as transferrin, ferritin, and hemoglobins [see refs. in 3-5].

Chromatography

Chromatography constitutes a family of closely related methods for separating and analyzing a wide variety of chemicals. Today, despite developments in analytical chemistry that link scientists to many modern and extremely sophisticated devices, the classic methodology of chromatography still plays a very important role among analytical techniques. It is almost impossible to imagine a laboratory without chromatographic equipment. Quality control, product purification, and basic research are some of the fields in which chromatography is used.

1. Definition

The term chromatography, first used by Tsvet (1872–1919), a Russian botanist, derived from the two Greek words *Khromatos* (color) and *graphos* (written). He used the term chromatography to describe his studies on pigment separation using a chalk column (1, 2), thus defining chromatography as a method by which the components of a mixture were separated on an adsorbent column in a flowing system (1, 2). The International Union of Pure and Applied Chemistry (IUPAC) has further defined chromatography as

A method, used primarily for separation of the components of a sample, in which the components are distributed between two phases, one of which is stationary while the other moves. The stationary phase may be a solid, or a liquid supported on a solid, or a gel. The stationary phase may be packed in a column, spread as a layer , or distributed as a film, etc.; in these definitions chromatographic bed is used as a general term to denote any of the different forms in which the stationary phase may be used. The mobile phase may be gaseous or liquid (3).

2. Historical Perspective

Although some phenomena that form the basis of chromatographic methods have been known for a long time, Tsvet is generally referred to as the father of chromatography. In 1906, he described the separation of plant pigments by column liquid chromatography using over 100 adsorption media (1, 4, 5). During the next forty years after Tsvet's work, there were some important developments in the field. For example, Kuhn et al. published two papers in 1931 on separating carotenoids on a calcium carbonate column (6, 7). Kuhn, Karrer, and Ruzicka applied the chromatographic technique to their own fields of interest and were awarded the Nobel prize (1937, 1938, and 1939, respectively) for their contributions to chromatography. Tiselius (8) and Claesson (9) developed the now classical procedures involving the continuous observation of optical properties of solutions flowing out of chromatographic columns. Tiselius was awarded the Nobel prize in 1948 for his research on "Electrophoresis and Adsorption Analysis". The introduction of gradient elution in 1952 (10) was an important contribution to all column chromatographic methods.

Chromatograpic developments greatly accelerated after the famous paper by Martin and Synge appeared in 1941 (11). They presented the invention of liquid-liquid (or partition) chromatography in columns and in planar form (paper chromatography). They also provided a theoretical framework for the basic chromatographic process. Martin and Synge were awarded the Nobel prize in 1952 for this work. When thin layers of supported silica gel were introduced as an alternative for paper in the late 1950s (12, 13), the field of **thin-layer chromatography** (TLC) was born and became so popular that it has largely replaced the older technique. Another main development in the progress of chromatography was the introduction of gas-liquid chromatography (GLC) by James and Martin (14), which had an unprecedented impact on the analytical chemistry of organic compounds. Porath and Flodin introduced **size-exclusion chromatography** in 1959 (15), allowing easy separation of macromolecules. Modern liquid chromatography (**HPLC**) was introduced in the early 1970s, permitting the efficient separation of a wide range of components.

The theory of chromatography was first studied by Wilson (16), who discussed the quantitative aspects in terms of diffusion, adsorption rate, and isothermal nonlinearity. The plate theory was first presented by Martin and Synge (11) and was further explored by Craig (17) and Gluechauf (18). In this theory, chromatography is described in terms closely analogous in its mode of operation to distillation and extraction fractionating columns. Lapidus and Admunson (19), followed by van Deemter and co-workers (20), developed the rate theory, an alternative to the plate theory. In this theory, column efficiency was described as a function of the mobile-phase's flow rate and diffusion properties and the stationary-phase particle size. In 1959, Giddings published another paper on this topic (21), and the rate theory has since become the backbone of chromatographic theory. In 1963, Giddings (22) pointed out that, if the efficiencies of gas chromatography were to be achieved in liquid chromatography, particle sizes of 2 to 20 μm were required. This prediction was found to be correct with the development of HPLC systems. Numerous detailed descriptions of chromatographic theory exist in the literature. Notable examples include a monograph edited by Jönsson (23) and the excellent reviews of Snyder (24) and Horváth and Melander (25).

This is only a small glimpse of the historical development of chromatography. The book *75 Years of Chromatography—A Historical Dialogue* (26), which describes many of the individuals who deserve credit for developing this technique, can be consulted for more complete accounts.

3. Retention Mechanism Classification

There are three common ways to classify chromatographic methods. The first and most popular classification is based on the mechanisms of retention, the manner in which the analyte interacts with the stationary phase. In this classification, chromatography may be divided into the five following basic types:

3.1. Adsorption Chromatography
This technique is based on competition for neutral analytes between the mobile phase (gas or liquid) and a neutral solid adsorbent. Therefore, analytes with **polar groups** are retained longer by a polar adsorbent, and nonpolar analytes interact better with a nonpolar stationary phase. In this type of chromatography, the analytes are simultaneously in contact with both the stationary phase and the mobile phase.

3.2. Partition Chromatography
This technique is based on competition for neutral analytes between the mobile phase (gas or liquid) and a neutral liquid or liquid-like stationary phase (the latter is usually called a “bonded-phase” when long alkyl chains or their derivatives are bonded to a matrix and behave like a liquid). In partition chromatography, the analyte is transferred from the bulk of one phase into the bulk of the other, so that the analyte molecules are surrounded only by molecules of one phase. Separation in partition chromatography is achieved by differences in the partition coefficients of the analytes between the mobile and stationary phases.

3.3. Ion-Exchange Chromatography
This technique is based on the electrostatic interaction between a charged solute and an oppositely charged solid stationary phase. Separation in ion-exchange chromatography is achieved by the differing affinities of ions in solution for oppositely charged ionic groups in the stationary phase. Ion-exchange chromatography is applicable to any solute that acquires a charge in solution. Thus, even carbohydrates, which are largely uncharged below pH 12, are separated by this type of chromatography at sufficiently high pH.

3.4. Size-Exclusion Chromatography
This technique is based on the sieving principle and is variously known as gel chromatography, **gel filtration** and gel-permeation chromatography (see Size Exclusion Chromatography). In this technique, the stationary-phase particles have a wide range of pore sizes, causing the stationary phase to behave like a molecular sieve. Small molecules permeate the pores, and large bulky molecules are excluded. Thus, the solutes are separated on the basis of molecular weight and size, and the larger ones elute first.

3.5. Affinity Chromatography
This technique is based on the unique biological specificity of **ligand-binding** interactions (ie, the lock-and-key mechanism) (see Affinity Chromatography). The ligand is covalently bonded to the matrix that forms packing material for the column. Separation is achieved after the applied macromolecule becomes specifically, but not irreversibly, bound to the ligand. The macromolecule is eluted by altering the composition or pH of the eluent so as to weaken its interaction with the ligand, thus promoting dissociation and facilitating elution of the retained compounds.

Many other types of chromatography, such as **hydrophobic-interaction**, **chiral**, ion-pair, and **salting-out** chromatography, are also frequently used. Furthermore, in practical chromatography intermediate or mixed types are often used. So, although one dominant mechanism is presented, the chromatographic modes are not mutually exclusive. To know more about the relationships of different chromatographic modes, see a schematic diagram by Saunders (27).

4. Development Procedure Classification

The second classification is based on the development procedure, the mechanism by which the sample is removed from the column, and therefore depends on the nature of the mobile phase. This classification was introduced by Tiselius (8) in 1940. There are three chromatographic modes in the classification: (1) elution development, (2) displacement development, and (3) frontal analysis. The principles of each mode are illustrated by Braithwaite and Smith (28). In practice, only elution development and to a lesser extent displacement development are commonly used.

5. Fractionation Phase Classification

The third classification is based on the phases between which the fractionation process takes place. In chromatography, one phase is held immobile or stationary, and the other one (the mobile phase) is passed over it. Therefore chromatography is mainly divided into two large groups named according to the state of aggregation of the mobile phase, liquid chromatography and gas chromatography. Further groupings can be made by naming both the mobile and stationary phases, thus liquid-liquid, liquid-solid , gas-liquid, and gas-solid chromatography have been named. More recently, supercritical fluids have been used as mobile phases, and these techniques have been named supercritical fluid chromatography, irrespective of the state of the stationary phase.

Chromocenter

The salivary gland nuclei of *Drosophila melanogaster* contain polytene chromosomes. These specialized chromosomes essentially contain duplicated repeats of the **DNA** in the entire chromosome. Polytene chromosomes are fused at their centromeres to form the chromocenter . This specialized chromosomal domain in *Drosophila* consists of constitutive heterochromatin. The DNA sequences within the chromocenter consist of two types of repeats. One type that is assembled into a-heterochromatin is composed of highly repeated simple DNA sequences, whereas the second, b-type is more complex. Structural components of heterochromatin at the chromocenter have been identified (1). The best-characterized protein that accumulates selectively at the chromocenter is known as heterochromatin protein 1 (HP1). Antibodies to HP1 colocalize with the type of DNA repeat found in b-heterochromatin called the Dr.D element (2). This is at the edges of the chromocenter in what is termed pericentric heterochromatin.

HP1 contains a protein motif that is found in other chromatin binding proteins and is known as the chromodomain (for chromatin organization modifier). Recent studies have established that the chromodomain family of proteins comprises more than 40 members (3) that can be subdivided into two major groups. Proteins, such as HP1, contain both an amino-terminal chromodomain and a carboxy-terminal “shadow” chromodomain (4). The amino-terminal chromodomain directly binds to heterochromatin, whereas the carboxy-terminal “shadow” chromodomain determines nuclear localization and assists in binding to chromatin (5). The second group of proteins relies on interactions with other proteins to target association with particular chromatin domains (6). The structure of the chromodomain was recently determined using NMR (7). The chromodomain has strong homology to two archaebacterial DNA-binding proteins. However, the eukaryotic chromodomain does not interact with DNA and is involved in protein-protein interactions. Each chromodomain consists of an amino-terminal, three-stranded, antiparallel beta sheet that folds against a carboxy-terminal alpha-helix. The presence of both a chromodomain and a shadow chromodomain are thought to allow proteins, such as HP1, to function as adapters in assembling large multicomponent proteins.

The chromocenter is a useful chromosomal domain for identifying the structural components of heterochromatin and potentially for actually understanding how heterochromatin is organized at a molecular level. The formation of the chromocenter indicates how similar nucleoprotein complexes that share common structural components can self-associate. It provides a nice example of a specialized nuclear compartment that is assembled so that depends on protein–nucleic acid interactions.

Chromogenic Substrate

A chromophore is any light-absorbing group (see Absorption Spectroscopy), and a *chromogenic* substrate is one that is acted on by an enzyme so as to increase or decrease the absorption of light at a particular wavelength as substrate is converted to product. An example of a naturally occurring chromogenic substrate is **NADH**, which absorbs light strongly at 340 nm. The absorbance decreases as NADH is oxidized by a pyridine nucleotide-dependent dehydrogenase, because NAD does not absorb substantially at 340 nm. Artificial chromogenic substrates have been used extensively for kinetic studies on a range of enzymes. *p*-Nitrophenylphosphate is hydrolyzed by **phosphatases** to release *p*-nitrophenol, which has a yellow color in alkaline solution. The increase in absorbance with hydrolysis is measured at 400 nm. *p*-Nitrophenylesters are used in a similar manner to measure the activity of *esterases*. Phenazine methosulfate is used as a convenient means of determining the activity of flavoprotein enzymes, as the oxidized form of the electron acceptor is yellow and the reduced form is colorless. An extensive list of artificial, chromogenic substrates has been recorded (1).

Chromomere

Chromomeres represent discrete structures in chromosomes that are visible under the light microscope in mitotic or meiotic **prophase** (see Chromatid). Electron microscopy and staining indicate that chromomeres represent regions of move complex, higher order structure than the 30-nm chromatin fiber (1). It has been suggested that they represent sites of the preferential chromatin compaction that occurs early in the prophase, coincident with the separation of sister chromatids (2). However, electron microscopic images of native chromatin in the **interphase** nuclei at physiological ionic strengths reveal that chromomeres may be identical to globular clusters of nucleosomes [(superbeads)] that probably represent local coiling of the 30-nm fiber. It is also possible to detect bead-like discontinuities in the chromatin fiber in sectioned nuclei. Under certain conditions, these superbeads are remarkably uniform and contain between 8 and 48 nucleosomes. This suggests that chromomeres represent discrete structural units (3). The failure to find a ubiquitous organization of chromatin into chromomeres or superbeads, however, indicates that all chromatin does not adopt this form of higher order structure in interphase nuclei *in vivo*. This irregularity may in fact represent the true state of affairs within the nucleus, because, clearly, eukaryotic DNA is not packaged into structures of a crystalline order and stability.

Chromomeres are useful for discriminating between different chromosomes. They are arranged in a specific and consistent pattern along each chromosome. In lampbrush chromosomes, chromomeres occur where there are long regions of inactive chromatin that are consequently compacted into higher order structures.

Chromosomes

Chromosomes are the nucleoprotein complexes that provide the structural framework for the expression of **genes** and mediate the transfer of genetic information from generation to generation. The nuclei, mitochondria, and chloroplasts of all cells, both **eukaryotes** and **prokaryotes**, plus **viruses**, all contain chromosomes. These various chromosomes can vary greatly in size, from very large (see Polytene Chromosome, Lampbrush Chromosomes) to very small (see Double Minute Chromosome; Minichromosome). All chromosomes contain **DNA**, which can be packaged by different proteins to assemble a nucleoprotein complex. The DNA in the chromosomes of a eukaryotic cell nucleus is packed with small basic proteins known as histones. The most striking property of every chromosome within the eukaryotic cell nucleus is the length of each molecule of DNA incorporated and folded into it. The human genome of 3×10^9 bp would extend over a meter if unraveled and straightened, yet it is compacted into a nucleus only 10^{-5} m in diameter. It is an astonishing feat of engineering to organize such a long linear DNA molecule within ordered structures that can reversibly fold and unfold within the chromosome.

The basic architectural matrix of the chromosomes found within eukaryotic cell nuclei is chromatin. All of the DNA in the nucleus of a somatic cell is packaged into chromatin by the histone proteins, together with other DNA-binding proteins. In specialized **germ cells**, such as sperm, protamines can replace the histones as the primary means of packaging DNA. There is considerable specialization in the type of chromatin assembled in different regions of a chromosome, depending on its functional requirements. Chromatin containing genes that are being expressed in a cell is called euchromatin. A large chromosomal region that contains inactive genes is assembled into facultative heterochromatin. Specialized chromosomal structures that contain very few genes but have other essential architectural roles in the chromosome are assembled into constitutive heterochromatin. The centromere is an essential structure containing constitutive heterochromatin that mediates segregation of the chromosomes. The molecular motors that drive this process are found within the kinetochore that is attached to the centromeric heterochromatin. Other heterochromatic domains are at the ends of chromosomes in specialized structures known as telomeres. Within the telomere are many reiterated terminal repeat sequences resulting from the activity of the enzyme telomerase. The telomere protects the end of the chromosome from degradation, fusion, and progressive loss of DNA during chromosomal **duplication**.

The position of the centromere relative to the rest of the chromosome provides an important reference point for describing different types of chromosomes. Chromosomes can be **metacentric**, with a centromere near the middle of the chromosome, or **acrocentric**, when it is near the end of the chromosome, or even potentially **telocentric**, when it is at the very tip. Most eukaryotic chromosomes are **monocentric**, having a single centromere, but some are **holocentric** and have multiple centromeric domains. Holocentric chromosomes have specialized mechanisms for segregating chromosomes during **cell division** that differ from those found in most plant and animal cells.

In animal cells, the presence of multiple centromeres in a single chromosome is often the product of chromosomal rearrangements. Such events usually occur as a result of chromosomal damage and can involve **duplications**, **inversions**, and translocations. A **dicentric** chromosome contains two centromeres following one of these rearrangements, whereas an **acentric** chromosome lacks a centromere entirely. Isochromosomes might also be formed, where a chromosome contains multiple identical chromosomal arms. All of these rearrangements lead to major problems for segregating chromosomes during the cell division of **meiosis** and **mitosis**. Chromosomal damage can be very useful in mapping the positions of genes relative to each other by methodologies that apply somatic cell genetics (see Radiation Hybrid).

Each **diploid** cell receives two sex chromosomes, either two X-chromosomes in females or one X- and one Y-Chromosome in males, plus two copies of each of the other chromosomes, known as autosomes. Each pair of autosomes consists of two homologous chromosomes, one from the father and one from the mother in humans. Immediately after mitotic division, each chromosome consists of a single DNA molecule. This single molecule of DNA is assembled into a chromatid, which duplicates during the **S-phase** of the cell cycle to form two sister chromatids. Then these sister chromatids are segregated to the two daughter cells at mitosis. In meiosis, haploid germ cells are created. This involves segregating of homologous chromosomes at the first meiotic division before the sister chromatids are segregated at the second meiotic division. Because homologous chromosomal regions are aligned during meiosis, chromosomal rearrangements can lead to major problems in segregating homologous chromosomal material. This can lead to multivalent chromosomes, whereas a normal meiosis would produce only bivalent chromosomes.

For organisms that undergo sexual reproduction, special sex chromosomes exist. In humans, these are known as the X- and Y-chromosomes. Female cells contain two X-chromosomes, whereas male cells contain a single X-chromosome and a Y-chromosome. Mary Lyon proposed that **gene expression** from the two X-chromosomes in a female cell should be the same as that from the single X-chromosome in a male cell (see Lyon Hypothesis). This is accomplished by silencing one of the two X-chromosomes in a female cell (see X-Chromosome Inactivation; Random X-Inactivation). The silenced X-chromosome is converted to a Barr body made up of facultative heterochromatin. X- and Y-chromosomes share some limited regions of homology that mediate their pairing and subsequent segregation during meiosis.

An important aspect of chromosomal biology involves mapping individual genes on chromosomes, which facilitates diagnosing particular diseases. A wealth of mapping procedures exist. These make up the field of cytogenetics, which is based on visualizing chromosomes. Mapping procedures involve using particular stains for the DNA and protein components of the chromosome (see C-Banding; G Banding). In recent times, these methodologies have been supplemented with high-resolution denaturation mapping techniques. Then all of the stained chromosomes of a particular cell that make up the karyotype can be displayed formally as an ideogram.

At a more refined level, structure at the level of chromosome and chromatin also determines the functions of particular genes. It has long been known from visualizating the large polytene chromosomes that individual chromosomal **domains** exist. Individual domains like the Balbiani rings contain chromatin that reversibly changes structure to reflect different functional states. Balbiani rings appear as **puffs** when they are being **transcribed**. Other regions of the polytene chromosome, known as interbands, contain the regulatory DNA sequences that control the appearance of puffs. Chromosomal rearrangements can lead to positioning genes next to large domains of constitutive heterochromatin. Placing a gene next to the chromocenter in *Drosophila*, where the centromeres fuse together, **represses** expression of the gene. This position effect indicates that structurally specialized domains of chromosomes exist and presents a major problem for biotechnology and gene therapy in expressing foreign DNA in target cells.

Nucleases like **DNase I** have been very useful in mapping regulatory DNA in the chromosome. The **locus control regions**, enhancers, and **promoters** that control gene expression exist as sites that are **hypersensitive** to digestion by DNase I. These elements often control the expression of clusters of contiguous genes that have related functions in the cell. Sites with extreme DNase I sensitivity are also found at the regulatory elements controlling the initiation of DNA replication at the **origin of replication**. The **terminally redundant** regulatory elements of retroviruses are also assembled into nucleoprotein complexes that retain accessibility to DNase I.

Chromosomes are fascinating structures around which much of modern medicine and biotechnology revolves. They also provide the foundation for considering basic molecular mechanisms that control gene expression and for considering the forces that facilitate evolution. Genes require a chromosomal environment to be maintained throughout the generations and within which to realize their full regulatory potential.

Chymotrypsin, Chymotrypsinogen

Chymotrypsin (E.C. 3.4.21.1) is a mammalian digestive serine proteinase, of the **trypsin** family, that is synthesized in the acinar cells of the pancreas in the form of an inactive precursor, *chymotrypsinogen*. This zymogen is stored, along with other digestive enzymes and enzyme precursors, in pancreatic granules, whose contents are released into the duodenum when the pancreas is stimulated by the hormones cholecystokinin and acetylcholine, which are secreted in response to eating a meal.

Chymotrypsinogen is a single polypeptide chain of 245 amino acid residues that becomes enzymatically active on **proteolytic** cleavage of the peptide bond that connects Arg15 and Ile16. This cleavage is catalyzed by another pancreatic enzyme, **trypsin**, which in turn is generated from its zymogen precursor, trypsinogen, by enterokinase, an intestinal serine proteinase. Cleavage of the Arg15—Ile16 bond results in a reorganization of the protein structure, alignment of the catalytic triad, and generation of a substrate binding site (1). Other proteolytic cleavages accompany activation of chymotrypsinogen, but only the one cited is crucial for generating enzymatic activity.

The biological function of chymotrypsin is to digest dietary proteins in the small intestine. It catalyzes the cleavage of peptide bonds in which the carbonyl group is supplied primarily by aromatic or bulky **hydrophobic** amino acids (tyrosine, tryptophan, phenylalanine, leucine, isoleucine, methionine). These residues become the C-termini of the product peptides and are subsequently removed by digestion with carboxypeptidase A. The catalytic mechanism of chymotrypsin and other serine proteinases is described elsewhere (see Serine Proteinase).

Numerous chymotrypsin-like enzymes generally referred to as *chymases* have been identified in various animal tissues, particularly in mast cells, neutrophils, and lymphocytes (2). The biological functions of these enzymes are not well understood, but a chymase isolated from human heart is a major angiotensin II -forming enzyme (3). The *prostate-specific antigen*, which is used in the diagnosis of prostate cancer, is a serine proteinase with limited chymotrypsin-like activity (4).

Being a serine proteinase, chymotrypsin is inhibited by diisopropylfluorophosphate (DIFP) and also by numerous, naturally occurring **serine proteinase inhibitors** and serpins (5), as well as many small synthetic peptide analogues or active site reagents (6).

Cilia and Eukaryotic Flagella

Cilia and eukaryotic flagella are long (10 µm to 40 µm), narrow, membrane-bounded structures that contain a highly ordered, stable microtubule array, consisting of nine fused outer doublet microtubules surrounding a central pair of singlet microtubules. These microtubules are firmly anchored at the base of the cilium or flagellum in basal bodies. The microtubules of cilia and flagella are extremely stable, and their movement is not complicated by dynamics. In addition to the tubulin backbone, these microtubules contain a large and diverse array of microtubule-associated proteins (MAPs), most of which have not been characterized, and several forms of dynein, a large multicomponent ATP-transducing mechanochemical motor protein. The various MAPs create and maintain the stable axoneme structure, and the dynein is responsible for creating the movement. The movements of cilia and flagella involve bending of these long organelles, which is caused by the sliding of stable double-microtubule pairs past each other. Sliding is effected by the dynein motors; the base of the motor is attached permanently to the A microtubule of one outer doublet pair, and the head, which contains the motor **domain**, transiently attaches and detaches to the B subfiber of an adjacent outer doublet pair. The dynein motor "walks" along the B subfiber toward the minus end, creating the movement. The dynein-mediated sliding of outer double-microtubules occurs in a fashion similar to filament sliding in muscle contraction, in which actin filaments and myosin filaments slide past each other through the action of the ATP-transducing myosin motor "heads."

Circadian Rhythms and Clocks in Fungi

Circadian clocks are ubiquitous and present in organisms as distantly related as **fungi** and mammals. Classically defined as rhythms that persist under constant environmental conditions, circadian clocks control daily rhythms that correlate with changes in the external environment. Most likely, circadian rhythms were selected early in evolution for conferring an evolutionary advantage on the organisms containing them.

To compare the properties of circadian rhythms among different organisms, the concept of circadian time (CT) was developed. The circadian day is divided into 24 equal parts, each one circadian hour. By convention, CT0 is subjective dawn, and CT12 represents subjective dusk. The normal circadian cycle in *Neurospora* can be reset in a time-dependent manner by external signals (a property called entrainment) such as light (1) or temperature (2).

Lower eukaryotes are ideal models for clock study because of their genetic and biochemical tractability. *Neurospora crassa* is such an example. Circadian rhythms in *Neurospora* are easily observed with the use of specialized growth tubes called ***race tubes***. When wild-type strains of *Neurospora* are inoculated on one side of a race tube, the organism initiates a rapid vegetative growth toward the opposite side. After growth for a day in constant light, the position of the growth front is marked, and the culture is transferred to constant dark. The light-to-dark transfer synchronizes the culture on CT12 (subjective dusk). Monitoring of the growth front every 24 h reveals a typical pattern of alternate conidial and aconidial bands, whose frequency permits the determination of both period length and phase of the rhythm. The *Neurospora* circadian rhythm has a period of 22 h at 24 °C. This period does not change significantly between 18°C and 30°C, as demanded by the circadian definition of a rhythm (a phenomenon called temperature compensation).

Three general questions drive research in fungal chronobiology: What is the biochemical and/or genetic basis for the clock? How does the clock gets its input from its extracellular and extraorganismal environment? How is time, as paced by the clock, transduced within the cell?

1. The Clock

The central oscillator of the *Neurospora* clock is the *frq* locus. Originally identified by chemical and ultraviolet mutagenesis, mutations at this locus alter the normal circadian clock of the cell but have no severe morphological defects in growth or development (3, 4). Cloning of the *frq* locus elucidated a complex pattern of gene transcription (3, 5). Two overlapping transcripts of 4 and 4.5 kb were identified, both containing long leader sequences, with several upstream open reading frames. These transcripts have been predicted to encode a putative 989-amino-acid-residue protein. Recent data, however, support the existence of two forms of FRQ (6). The long form ($FRQ^{1–989}$) starts at the first in-frame ATG start codon, whereas the short form ($FRQ^{100–989}$) starts at the third in-frame ATG of the longest reading frame in the region (6). Temperature regulates the ratio of FRQ forms by favoring the use of different initiation codons at different temperatures. For example, the long form of FRQ ($FRQ^{1–989}$) is favored at high temperatures, whereas at lower temperatures the short form of FRQ ($FRQ^{100–989}$) is predominant. These similar but functionally distinct forms of the clock protein FRQ represent a novel adaptive mechanism designed to keep the *Neurospora* clock running over a wide range of temperatures (6). Despite its fine regulation, the biochemical function of FRQ remains unknown (7). However, the presence of a nuclear localization signal [required for FRQ activity (8)], a weak **helix–turn–helix** DNA-binding domain (9), and a conserved acidic region strongly suggest the involvement of FRQ in transcription. As predicted for protein regions important for function, all of these FRQ transcription-factor-like signatures are conserved in FRQ homologues isolated from other distantly related fungal species (10).

The autoregulatory feedback cycle controlled by *frq* takes one day to complete. This loop involves the transcriptional activation and repression of the *frq* locus. Starting with low levels of *frq* transcript and protein (dawn), *frq* transcripts begin to rise, reaching a peak accumulation 4 to 5 h later [just before noon—(8)]. The maximal level of FRQ protein can only be observed 4 to 6 h later (relative to the peak in *frq* mRNA). This time lag is probably due to post-transcriptional regulation of *frq* mRNA or FRQ protein. Synthesized FRQ protein enters the nucleus (8) and acts rapidly, either directly or indirectly, to repress *frq* (11). The repressing activity of FRQ remains until the protein begins to be **phosphorylated**, linking the activity of unknown protein kinases to the clock. Phosphorylation of FRQ increases its turnover (12), until its scarcity allows positive factors like *white collar-1* (*wc-1*) and *white-collar-2* (*wc-2*) (1, 7) to restart the cycle (see text below).

2. Input

Light and temperature are among the most important environmental stimuli controlling circadian rhythmicity. The light-dependent signal transduction pathway is thought to involve an as yet uncharacterized flavin-dependent blue-light photoreceptor (13, 14). When wild-type strains of *Neurospora* grown in the dark receive a pulse of light, the levels of *frq* mRNA increase. Two global regulatory genes, *wc-1* and *wc-2*, have been established to be involved directly or indirectly in the induction and maintenance of *frq* mRNA levels following this light treatment. For example, the light response observed in wild-type strains (ie, the increase in *frq* mRNA levels) cannot be detected in strains mutant in *wc-1*, but it is normal in strains mutant in *wc-2*. Interestingly, the products of both loci (*wc-1* and *wc-2*) are required for the maintenance of high-level expression of *frq* mRNA in the light. Therefore, the pulse of light positively stimulates *frq* mRNA levels in an FRQ-independent, WC-dependent manner (1, 15). Moreover, the light dosage positively correlates with the amount of *frq* mRNA, and, depending when this pulse of light is perceived, it can reset the clock, thereby phase advancing or phase delaying the conidiation rhythms of the organism. Complete elucidation of the roles of WC-1 and WC-2 on *frq* gene expression will be essential for a complete understanding of the signal transduction pathway responsible for clock input.

3. Output

Genes whose rhythmic regulation equals the period of the strain under study are said to be part of the output component of the oscillator (ie, they execute the commands given by the master oscillator and establish the cellular rhythm). To be defined as such, loss-of-function mutations in these classes of genes must not affect the functioning of the clock. With this rationale in mind, a systematic search for clock-controlled genes (*ccg*) was carried out in *Neurospora* (16). Most, but not all, of the *ccg* genes identified were found to be induced during the asexual **sporulation** pathway. The ones that were not were postulated to be involved in other developmental pathways (eg, sexual sporulation) or other unknown output pathways (7). Although rhythmically regulated, the levels and amplitude of expression differ among different clock-controlled genes. In addition, their expression pattern in both frq^+, and *frq* changes from gene to gene [ie, some genes are repressed, while others are derepressed or unchanged (7)]. To date, a direct link between *frq* (the central master oscillator) and *ccg* (the foot soldiers) has not been established, despite being an area of active investigation. It is not surprising to find that the *ccg* identified have nothing or very little in common. For example, *ccg-1* codes for a small polypeptide of 71 amino acid residues with no known homologues in other organisms (17), despite its elevated level of expression (18), whereas *ccg-12*, encodes copper metallothionein (18). See Refs. 18 and 19 for a complete description of *ccg* genes. While the mechanisms of circadian rhythms are incompletely understood at this time, it remains undeniable that the molecular strategies employed by fungi are an excellent model system with which to study similar systems in higher eukaryotes.

Circular Chromosome

All **Hfr strains** (for high frequency of recombination) of *Escherichia coli* originate from F^+ strains (males, possess the *F* sex factor). When mated with F^- recipients (females), they generate about a thousand times more recombinants than the equivalent F^+ strain under identical conditions (1). The recombinants obtained inherit a particular segment of the donor chromosome exclusively (1). The way in which *Hfr* donors transfer their chromosome to recipients was elucidated by violent agitation of a mixture of mating Hfr and F^- in a high-speed mixer. The mating was interrupted at different time intervals and the mixture was plated for detection of recombinants. It was found that recombinants acquire different selected characters from the donor cell at different times. The order in which these characters appear is the order of their arrangement on the chromosome. The only reasonable interpretation of these results is that the effect of agitation is a rupturing of the chromosome during the transit from the donor to recipient bacteria. Only those genes that have already penetrated the recipient bacteria at the time of treatment can appear in recombinants. Thus, the strain Hfr used comprises a homogeneous population of donor bacteria, all of which transfer their chromosome in the same specifically oriented and linear way, so that a particular extremity, designated O (for origin), is always the first to penetrate the recipient bacteria (2, 3).

A number of Hfr stains of independent origin were analyzed with respect to the markers they transferred to recipients and to the orientation of the transfer. The outcome was remarkable and unforeseen. Although all of the bacteria of any one Hfr strain transfer a given set of markers in a particular sequence, different strains transfer different chromosomal segments, parts of which may overlap. Some strains transfer their genes in a direction reverse to others. The relationship of the various genes to one another however, is the same irrespective of the Hfr strain used to map them. This gives an unequivocal general linkage map for *E. coli*, consisting of a single linkage group. Each strain transfers its chromosome as a linear, oriented structure with a specific head and tail, for example,

Y CBAZO OBAZY

_______---------________, or ____ -------- ________

Another strain can always be found which transfers genes A and Z as closely linked markers, for example,

ZY CBAO

__________----- _______

Thus, in spite of this linear transfer, it is impossible to define any extremities on the chromosome. It is concluded that the chromosome of *F*+ donors is originally continuous or circular and that Hfr strains arise by opening up the circle at a point characteristic for each Hfr type to yield a linear, transferable structure (3).

The circular nature of the *E. coli* chromosome has been confirmed by gentle liberation and dispersion of its DNA and visualization by autoradiography or by electron microscopy. Therefore there is indisputable, direct evidence that this chromosome is indeed a continuous, circular thread of double-stranded DNA (4, 5).

Circular Dichroism

Circular dichroism (CD) is a form of spectroscopy that uses circularly polarized light and is highly sensitive to the conformations of molecules. Because of this conformational sensitivity, CD is one of the most widely used techniques for characterizing the conformations of proteins, **nucleic acids**, and carbohydrates, and for monitoring conformational transitions induced by temperature, solvent composition, **ligand binding**, etc.

The principal conformations of polypeptide chains—alpha-helix, beta-sheet, b-turns, and the so-called unordered conformation—all have distinctive CD spectra that permits these **secondary structures** to be readily recognized in their pure forms or in simple combinations. Even in globular proteins, which represent complex mixtures of these and other conformations, in most cases the CD spectrum can be analyzed to provide reasonably accurate estimates of the fraction of residues in the various secondary structures. CD signals due to aromatic side chains and nonprotein chromophores provide sensitive probes of protein tertiary structures and of protein–ligand interactions. In the field of nucleic acids, CD also provides valuable information about the nature of the secondary and higher order structures detecting the binding of small molecules and proteins. CD has more restricted application to carbohydrates and polysaccharides, but it has some important applications to studies of carbohydrate conformation.

In addition to its pronounced sensitivity to conformation, CD has other advantageous features. Only small amounts of material are required, comparable to those required for a UV-visible absorption spectrum, and it is relatively easy to survey a broad range of conditions of temperature, pH, ionic strength, and solvent composition. Moreover, the cost of the instrumentation is moderate, and it is easy to operate and maintain. The principal limitation of CD is that it provides lower resolution structural information than X-ray crystallography or NMR spectroscopy. A CD signal can rarely be assigned to a specific residue or group in a macromolecule. Whereas CD gives an estimate of the fraction of residues in a globular protein that are in a-helical segments, it cannot provide information on their location in the sequence. These limitations, however, are outweighed by the conformational sensitivity and other experimental advantages of CD.

1. Fundamentals of Circular Dichroism

1.1. Definition of Circular Dichroism

Circular dichroism is a type of spectroscopy in which the difference in absorption of right- and left-circularly polarized light is measured. In circularly polarized light (cpl), the vector **E** describing the electric field of the light, rotates about the direction of propagation once in each period or wavelength of the light. As seen by an observer looking toward the light source, the electric vector may rotate in either a clockwise sense, corresponding to right-circularly polarized light (rcpl), or in a counterclockwise sense, corresponding to left-circularly polarized light (lcpl). At a given instant, the tip of the electric vector of rcpl follows a right-handed helix in space, whereas the tip of the electric vector of lcpl follows a left-handed helix. Therefore, cpl is **chiral**, and rcpl and lcpl are related as mirror images, that is, they are **enantiomeric**. Because of their enantiomeric character, it is to be expected that rcpl and lcpl interact differently with a chiral molecule, giving rise to differences in optical properties for a chiral molecule measured with rcpl and lcpl.

CD is defined as the difference in absorbance of rcpl and lcpl:

$$\mathrm{CD} = \Delta A = A_1 - A_r = \epsilon_1 c \ell - \epsilon_r c \ell = (\epsilon_1 - \epsilon_r) c \ell = \Delta\epsilon_M c \ell \qquad (1)$$

Here A_l and A_r are, respectively, the absorbances for lcpl and rcpl; c is the molar concentration of the chiral species; ℓ is the pathlength of the sample cell (in cm); e$_1$ and e$_r$ are the molar extinction coefficients of the chiral species for lcpl and rcpl, respectively; and De $_M$ is the molar CD, commonly called simply the CD.

To facilitate comparisons of the CD of proteins or nucleic acids of very different molecular masses, it is nearly universal practice to normalize the CD by dividing the molar CD by the number of amino acid or nucleotide residues, yielding the mean residue CD,

$$\Delta\epsilon = \Delta\epsilon_M / n_r = \Delta A / c_r \ell \qquad (2)$$

where n_r is the number of residues and c_r is the molar concentration of residues. Near-UV CD spectra of proteins are reported as either molar CD or mean residue CD, and visible CD spectra are usually reported as molar CD of the protein or the molar CD per visible chromophore, for example, per heme in vertebrate hemoglobins. The reader must always carefully check the basis for reporting CD spectra in the literature.

Although nearly all CD instrumentation measures DA and hence yields De most directly, many instruments are calibrated in units of ellipticity, an angular unit based on an earlier method for measuring CD. The molar ellipticity is defined as

$$[\theta]_{\mathrm{M}} = 100\theta/c\ell \tag{3}$$

where q is the measured ellipticity in degrees and *c* and ℓ have the same meaning as before. Molar ellipticity is directly proportional to molar CD:

$$[\theta]_{\mathrm{M}} = 3298\Delta\epsilon_{\mathrm{M}} \approx 3300\Delta\epsilon_{\mathrm{M}} \tag{4}$$

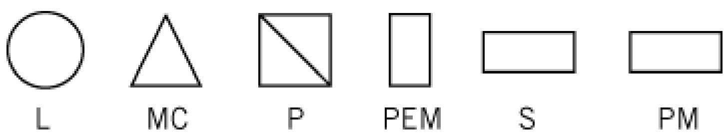
Mean residue ellipticity [q] is defined by analogy to mean residue CD and is commonly used for reporting protein CD data in the far UV and for CD of DNA and RNA.

1.2. Instrumentation (1)

Measurement of CD requires high sensitivity because the difference between e_l and e_r is small in comparison with their average value $e = (e_l + e_r)/2$, which corresponds to the molar absorbance coefficient measured with unpolarized light. Typically, De/e is of the order of 10^{-3} to 10^{-4}. To achieve adequate signal-to-noise ratios, CD spectrophotometers use a modulation technique. The light incident on a sample is switched between left- and right-circular polarization at a specific frequency. The difference in the sample response to the two forms of circularly polarized light is detected directly by selecting the part of the response that has a frequency component matching that of the modulation of the incident light.

Figure 1 shows a highly schematic representation of a CD spectrophotometer. Light from the source L is dispersed in the monochromator MC, and then a narrow band of wavelengths passes through the linear polarizer lP. The polarizer splits the unpolarized monochromatic beam into two linearly polarized beams, one polarized in the *x* direction, the other in the *y* direction (*z* is the direction of propagation). Then one of the two linearly polarized beams passes through the photoelastic modulator (PEM), which consists of a plate made of a transparent, optically isotropic material bonded to a piezoelectric quartz crystal. When an alternating electric field is applied, the light emerging from the PEM switches from lcpl to rcpl and back with the frequency of the applied electric field, typically about 50 kHz. If the sample S exhibits CD, the amount of light absorbed varies periodically with the polarization of the incident light, and so the intensity of light that reaches the photomultiplier PM exhibits sinusoidal intensity variations at the frequency of the field applied to the PEM. Thus, the photomultiplier output consists of a signal with a small alternating current (ac) component superimposed on a direct current (dc) component. The ac component is filtered out and amplified. The ratio of the ac to the dc component is directly proportional to the circular dichroism of the sample, and this quantity is recorded as a function of wavelength to provide a CD spectrum.

Figure 1. A block diagram of a CD spectrophotometer. L is the light source, MC the monochromator, P the polarizer, PEM the photoelasic modulator, S the sample, and PM the photomultiplier.



CD is most commonly measured in the visible and ultraviolet regions of the spectrum. Commercially available instruments are used in the 180 to 700-nm region. Some commercial instruments permit measurements to 170 nm, at the edge of the vacuum UV, or to 1000 nm, in the near infrared (IR). Xenon arc lamps, quartz optics, and photomultiplier tubes are used for the light source, the dispersing and polarizing elements, and the detectors, respectively.

CD is also observed in IR absorption bands, associated with vibrational transitions (see Vibrational Spectroscopy). This type of CD is called vibrational circular dichroism (VCD) (2). Some VCD instruments use the same type of layout as that shown in Fig. 1, although the light sources, dispersing and polarizing optics, and detectors are necessarily different. In addition, VCD instruments have been constructed that utilize the Fourier transform principle.

In recent years, CD has been widely used to measure the kinetics (3) of conformational changes in proteins and nucleic acids, especially in investigating protein folding in vitro and unfolding. Reactions on the timescale of a minute or longer are readily measured by using manual mixing and conventional CD instrumentation. A conventional CD instrument coupled to a stopped-flow mixing device permits measurements of reactions with halftimes down to a few milliseconds. Still faster reactions, triggered by temperature or pressure jumps, or by laser or electron pulses, require specialized CD instrumentation (4) that does not utilize the modulation technique. Such instruments have been constructed for nanosecond and picosecond timescales.

1.3. Theoretical Background (5)

The connection between theory and experiment in CD spectroscopy is provided by a quantity called the rotational strength, *R*. Experimentally, the rotational strength is proportional to the area under a CD band, that is, the integral

$$R \propto \int (\Delta\epsilon/\lambda) d\lambda \approx (\lambda_{\max})^{-1} \int \Delta\epsilon d\lambda \qquad (5)$$

The integral is taken over a CD band attributable to a single electronic or vibrational transition. CD bands are generally rather sharp, so it is a satisfactory approximation to replace the l^{-1} factor in the integrand of Eq. 5 by $\lambda_{\max}^{-1}$, where l_{max} is the wavelength at which the CD band has maximal intensity.

The rotational strength is related to molecular properties by the equation

$$R = \mathrm{Im}\{\mu_{0a} \cdot \mathbf{m}_{a0}\}, \qquad (6)$$

where Im indicates the imaginary part of a complex quantity. The first factor in the curly brackets is the electric dipole transition moment for the transition from the ground state 0 to the excited state a. The second factor is the magnetic dipole transition moment of the transition. Qualitatively, $\mathbf{m}_{0a}$ can be interpreted as the linear displacement of charge associated with the transition, and $\mathbf{m}_{a0}$ as the circular displacement of charge. Therefore a non zero rotational strength requires that the transition have both a linear and a circular displacement of charge and that the axis of the circulation not be perpendicular to the linear displacement. This corresponds to a helical motion of electronic charge, where the sense of the helix is determined by the relative orientation of $\mathbf{m}_{0a}$ and $\mathbf{m}_{a0}$ and this determines the sign of the CD band.

1.4. Related Phenomena

Phenomena that depend upon differences in the interaction of a sample with left- and right-circularly polarized light are called chiroptical phenomena. CD is the most widely used chiroptical phenomenon in molecular biology, but others are important for historical reasons or have specialized applications. The first chiroptical phenomenon discovered was optical rotation (OR), the rotation of the plane of polarization of plane-polarized light as it passes through a chiral medium. The angle through which the plane is rotated, commonly measured at 589 nm (the Na D line), is still widely used in organic chemistry to characterize chiral molecules. OR was also used in protein chemistry, but was supplanted in the 1950s by optical rotatory dispersion (6) (ORD), the wavelength dependence of OR, and in the 1960s by CD. The specific rotation a of a sample is defined as

$$[\alpha] = 10\alpha/c'\ell \tag{7}$$

where a is the angle through which the plane of polarization is rotated by the sample, ℓ is defined as in Eq. (1), and c' is the concentration of the chiral substance in g/mL. Molar rotation and mean residue rotation are defined by analogy to the corresponding CD parameters. It should be noted that refraction is a scattering phenomenon and occurs at all wavelengths, not just in absorbance bands. For this reason, OR and ORD can be measured at visible wavelengths for substances that absorb only in the ultraviolet.

2. Proteins

2.1. General Aspects

In the far UV, the peptide groups of the backbone generally dominate the CD spectrum. The peptide group has two electronic transitions in the normally accessible far UV. These are the np^* transition near 220 nm and the pp^* transition near 190 nm in secondary amides and 200 nm in tertiary amides (X-Pro peptide groups). The np^* transition is weak in absorbance, but it gives rise to strong CD bands. The pp^* transition is associated with strong absorbance and CD. Because of the strong electric dipole transition moment, pp^* transitions in neighboring peptide groups interact with each other, giving rise to two or more absorbance and CD bands. This phenomenon, called exciton splitting , is most clearly seen in the a-helix CD spectrum, described later.

The aromatic side chains of **Phe, Tyr,** and **Trp** residues have strong absorbance bands in the far UV that contribute to the CD spectrum (7). In most cases, their contribution is small compared to those of the much more numerous peptide groups. For some proteins, however, aromatic CD bands are clearly discernible.

In the near UV, the CD spectrum of proteins is dominated by the aromatic and disulfide transitions. The near-UV CD bands of the aromatic side chains are generally relatively sharp and have a characteristic fine structure due to vibrational effects. In proteins with a small number of aromatic side chains, the near-UV CD bands can frequently be assigned to one of the three types of aromatic side chains and in some cases, through site-directed mutagenesis, to specific residues in the sequence. The CD bands due to the disulfide bond are generally distinguishable from aromatic CD bands by their much greater width.

For proteins containing only the normal amino acids, there are no CD bands at wavelengths above 300 nm. Many **prosthetic groups**, **coenzymes**, transition-metal ions, and other ligands have absorbance bands in this wavelength region, and these are associated with CD bands in complexes with proteins.

2.2. Secondary Structure Analysis

The various types of secondary structure (see Secondary Structure, Protein) in proteins have characteristic CD spectra, as established by studies of model oligo- and polypeptides. Figure 2 shows CD spectra of a-helix, b-sheet, unordered polypeptides, and b-turns. The a-helix has the most distinctive and strongest CD spectrum with two negative bands of comparable magnitude at ca. 222 and 208 nm and a stronger positive band near 190 nm. The 222 nm band results from the np^* transition of the amide group, whereas the 208 and 190 nm bands both arise from the amide pp^* transition. The latter two bands are from exciton splitting of the pp^* transitions in the amide groups that are held in a well-defined helical geometry. Interactions between the transition dipole moments in a very long helical array give rise to three absorbance bands, one at 208 nm polarized parallel to the helix axis, and two bands at 190 nm, polarized in the two independent directions perpendicular to the helix axis. For a right-handed a-helix, the parallel band is associated with the negative CD band at 208 nm, and the perpendicular bands with the positive CD band at 190 nm. The CD of the a-helix is largely, but not completely, independent of the solvent and of the sequence of amino acids. Aromatic residues (Phe, Tyr, Trp) modify the a-helix CD spectrum, especially if they constitute a sizeable fraction of the residues. In homopolymers of aromatic amino acids, the a-helix CD spectrum is modified beyond recognition.

Figure 2. (**a**) CD spectra of model polypeptides in three conformations: a-helix (——), poly(Glu), pH 4.5 (33); b-sheet (– – – –), poly(Lys-Leu), 0.5 M NaF, pH 7.4 (34); and unordered (· · · · · ·), poly(Lys-Leu) in salt-free aqueous solution (34). (**b**) CD spectra of model peptides in two b-turn conformations: Type I b-turn (– – – –), cyclo(L-Ala-L-Ala-Aca), where Aca is e-aminocaproyl; Type II b-turn (——), cyclo(L-Ala-D-Ala-Aca). Spectra acquired in water at 22°C (35).

The CD of b-sheets is more variable than that of a-helices. A negative band near 217 nm and a positive band in the 195 to 200-nm region are characteristic of b-sheets (Fig. 2). Theory (8) predicts that the absolute value of the ratio of the ellipticity at the positive maximum near 197 nm to that at the negative maximum near 217 nm increases with increasing twisting of the sheet, and is larger for parallel than for antiparallel twisted sheets. The relative amplitude of the 217 nm and 197 nm bands varies considerably among model systems, ranging from ~1.7 for the antiparallel b-sheet formed in poly(Lys) by heating to 52°C at pH 11.1 to 8.3 for the parallel b-sheet of Boc(Val)$_7$OMe in trifluoroethanol.

Several types of b-turn can be distinguished, but only two fundamental types are common in proteins: the type I turn (and its variant, type III), which can accommodate any L-amino acid at either of the positions in the turn, and the type II turn, which usually has a Gly at the second residue of the turn. The CD characteristics of b-turns vary in accordance with the range of conformations. However, studies of cyclic peptides with well-defined b-turns indicate that type I turns have a-helix-like CD spectra, with negative maxima at ~220 and 210 nm and a positive band near 190 nm, whereas type II turns have a CD spectrum like that of a b-sheet, but with the maxima shifted 5 to 10 nm to longer wavelengths, that is, the negative band in the 220 to 225-nm region, and the positive band between 200 and 210 nm (Fig. 2).

All models for unordered random coil polypeptides have a strong negative band near 200 nm (Fig. 2), but some have a long-wavelength positive band and others a negative shoulder at longer wavelengths. The resemblance of the CD spectra of charged poly(Lys) and poly(Glu) to that of poly (Pro) II led to the proposal that these polypeptides are not truly unordered but contain short segments of the poly(Pro)II helix. The current view (9) of unordered polypeptides is that those peptides with a negative shoulder in the 210- to 220-nm region have amino acid residues predominantly in the a-helix and b-sheet regions of conformational space (see Ramachandran Plot) and those with a positive long-wavelength band have a substantial fraction of residues in the poly(Pro)II conformation. The latter systems undergo a noncooperative transition to the former as the temperature increases.

2.2.1. Protein Secondary Structure

Early applications of OR and ORD to the analysis of helix content in proteins have been reviewed (10). Initially, protein CD data were analyzed by fitting the CD spectra of the protein to a linear combination of data for model polypeptides, such as those shown in Fig. 2. However, such methods generally gave poor results because the CD spectra of globular proteins are too complex to be adequately represented by a simple linear combination of homopolymer spectra. Many methods for analyzing protein CD data to obtain secondary structure have been proposed (11, 12). Two features are essential for satisfactory results. First, a basis set of proteins of known secondary structure is needed to calibrate the method by providing information on the CD contributions of the various types of secondary structure existing in real protein structures. Second, it is necessary to allow flexibility in weighting the proteins in this basis set when analyzing each protein. Several methods incorporating these features provide useful estimates of the fraction of a-helix, b-sheet, b-turn, and unordered conformations (11-14). VCD and IR absorption spectra (See Vibrational Spectroscopy) in the amide I region also provide estimates of the secondary structure content of globular proteins by using analytical methods similar to those used for electronic CD (15). Combinations of electronic CD, VCD and IR absorption can also be used.

The methods used for analyzing the secondary structure of proteins should be applied with caution to peptides, because globular proteins are used to calibrate these methods. The CD measured at 220 or 222 nm has frequently been used to determine the helix content of peptides. The difference in CD between the 217 nm negative maximum and the positive maximum near 195 nm, characteristic of b-sheets, has been utilized to quantify the b-strand conformation of peptides (16).

2.2.2. Tertiary Structure of Proteins

Far-UV CD spectra of proteins have been used to assign proteins to the broad classes of all-a, all-b, a + b, and a/b by cluster analysis (17). Aromatic side-chain bands (7) in both the near and far UV have been used as markers to identify tertiary structures. The **T-state** (deoxy) conformation of hemoglobins has a strong negative CD band at 287 nm, whereas the **R-state** (liganded) conformation has weak negative or positive CD at this wavelength. The magnitude of the negative CD band at 250 to 255 nm correlates with the T → R transition in insulin. Tertiary structural changes in the **chymotrypsinogen** → chymotrypsin conversion are associated with a reorientation of the Trp 175 - Trp 215 pair, leading to a large change in the 225 nm Trp CD band.

2.2.3. Protein Folding

One of the major aims in equilibrium studies of protein folding (see Protein Folding In Vitro) is detecting intermediates. If equilibrium intermediates are not detectable, the folding/unfolding process is said to be two-state because only the fully folded and fully unfolded forms are present at significant levels. If only these forms are present, the extent of unfolding is the same regardless of the physical property used to monitor it. CD is especially useful in this regard because the far-UV and near-UV CD measure primarily the secondary and tertiary structures, respectively. If the extent of unfolding measured by these two probes is identical within experimental error, the process is likely to be two-state. On the other hand, lack of coincidence of the unfolding curves measured in these two spectral regions is evidence that one or more intermediates exist.

A type of folding/unfolding intermediate observed in a number of proteins is called the molten globule. This intermediate is nearly as compact as the native protein and has a secondary structure content comparable to that of the native protein. However, the side chains are quite mobile and are not locked into a well-defined tertiary structure. CD is one of the most useful techniques for identifying the molten globule form of proteins. The CD spectrum of a molten globule is similar to that of the native protein in the far UV and reflects a substantial amount of a-helix and/or b-sheet but has only weak features in the near UV because the aromatic side chains do not have well-defined positions and conformations.

Another aspect of equilibrium protein folding studies in which CD has played a major role is investigating the effect of sequence on the stability of intact proteins and peptide segments. Here, the far UV is used to follow the **denaturation** profiles of the wild-type protein and of a series of mutant forms in which specific residues have been altered. From reversible thermal denaturation studies, changes in the free energy of unfolding, DDG_{unf}, can be obtained that measure the effect of the amino acid substitution upon the net stability of the protein and thus shed light on the effects of steric bulk, **hydrophobic** character, and charge effects. There have also been numerous CD studies of model peptides that adopt the helix conformation to examine systematically the effects of amino acid substitutions on a-helix stability (18). Similar studies have recently been reported for b-sheet-forming peptides and protein fragments (19).

Kinetic studies of protein folding by CD have been limited to stopped-flow methods and thus to the millisecond timescale. During the so-called dead time of the experiment, many proteins studied thus far (20) acquire a substantial fraction of a-helix and b-sheet, as evidenced by $[q]_{220}$ values that are generally closer to those of the native form than to the fully unfolded form. By contrast, the CD in the near-UV detected immediately after the dead time is essentially that of the unfolded form. These results generally have been interpreted as resulting from a so-called burst phase in which a molten globule-like intermediate is formed on the timescale of milliseconds or less. Then subsequent slower processes lead to additional formation or remodeling of the secondary structure and formation of the tertiary structure.

2.2.4. Membrane Proteins

The study of membrane proteins in their native environment poses problems for CD. Two kinds of potential artifacts must be avoided. Strongly scattering suspensions of membrane fragments exhibit preferential scattering of rcpl or lcpl, which manifests itself as an apparent CD signal that distorts the true CD of the membrane protein. The particulate character of membrane fragments also distort the CD signals because of the CD analog of Duysens' flattening (21), which occurs in samples with a highly inhomogeneous distribution of absorbing chromophores that is associated with clustering of the chromophores. Methods have been devised that correct for or avoid each of these difficulties, but in the flattening effect, they require that the membrane protein be transferred from the native membrane to small unilamellar vesicles that have, on average, no more than one protein molecule per vesicle. Alternatively, these artifacts are circumvented by solubilizing the membrane protein in a nonionic detergent. This poses some risk of inducing conformational changes in the protein, although nonionic detergents are usually relatively benign.

2.2.5. Protein–Ligand Interactions

CD is widely used to characterize ligand binding to proteins and yield binding constants, stoichiometry, and information about conformational changes in the ligand and/or protein, in favorable cases. If the ligand absorbs at wavelengths above 300 nm, it is convenient to monitor the corresponding CD bands. This is especially so if, as in many cases, the ligand is achiral or a rapidly interconverting racemate. In such cases, the free ligand contributes no background CD, and only the bound ligand contributes to the CD signal. This is effectively so even in chiral ligands, such as NADH, FMN, FAD, in which the chromophore is conformationally mobile in the free form and therefore has only a weak CD signal. Ligand binding is also studied at shorter wavelengths, where protein CD bands are normally studied, either as induced ligand CD bands or as a perturbation of the aromatic and peptide CD bands. These perturbations arise either through direct interactions with the ligand or through changes in the tertiary or secondary structure induced upon ligand binding.

The use of CD to determine **dissociation constants** (K_d) is straightforward, but there are limitations to the range of dissociation constants that can be determined accurately. To provide an accurate analysis, the concentration of the species being monitored must be comparable to the K_d. Given the typical magnitudes of CD, this requires $K_d >$ ca. 1 µM for successful measurements by conventional CD. Fluorescence-detected CD (22) may extend this range to ca. 10 nM.

If $K_d <$ ca. 1µnM, CD cannot be used to measure reversible dissociation, but the protein–ligand complex dissociates negligibly at µM concentrations and above. Studies of such complexes are very fruitful because the ligand serves as a tightly but noncovalently bound spectroscopic probe, capable of reporting conformational changes in the protein. Heme proteins (23) and flavoproteins are important examples. The CD signals from such proteins are highly sensitive to oxidation state, spin state (in heme proteins), and to substrate, inhibitor, and allosteric effector binding.

3. CD of Nucleic Acids

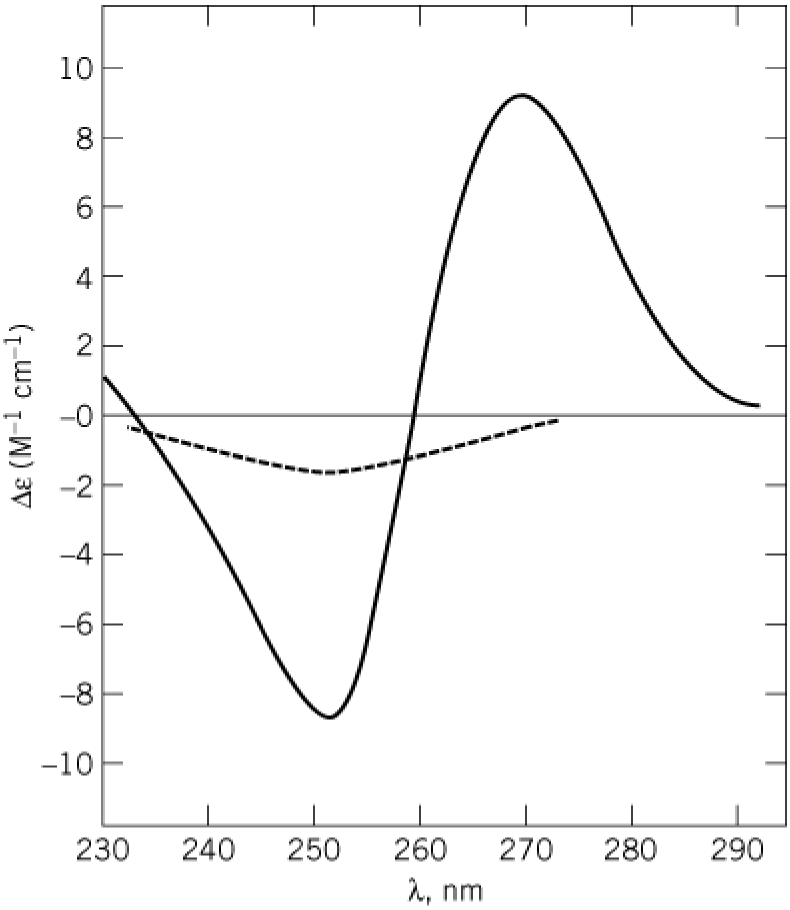
3.1. General Aspects (24)

The **purine** and **pyrimidine** bases of **DNA** and **RNA** are largely responsible for the CD spectra of nucleic acids in the wavelength range normally studied (180 to 300 nm). The sugar and phosphate groups do not absorb significantly above 200 and 180 nm, respectively. From the standpoint of CD, their main function is maintaining the relative geometries of the bases. Each base has a characteristic set of pp* transitions in the 180- to 300-nm region. The corresponding absorbance and CD bands are relatively broad. All five natural bases have one or two moderately intense pp* bands near 260 nm and several more intense bands in the 180- to 200-nm region. In addition, each base is expected to have several np* transitions in the 180- to 300-nm region, but these bands absorb weakly. Though potentially strong in CD, few np* bands have been identified, and the CD spectra of nucleosides, nucleotides, and polynucleotides are dominated by pp* contributions.

The CD spectra of nucleosides and nucleotides are relatively weak compared to those of polynucleotides. In the monomer, only base–sugar and base–phosphate interactions contribute, and the CD is averaged over a broad range of conformations. By contrast, oligo- and polynucleotide CD spectra are dominated by base–base interactions, and the range of conformations is usually narrower.

The CD spectra of oligonucleotides differ markedly from the sum of the constituent monomer spectra. This is illustrated by the spectra of ApA and pA (Fig. 3). The large difference is attributed to coupling of the pp* transitions in the two bases, another example of exciton coupling. This led to a model in which the adenine rings are stacked in a right-handed helix, like two successive bases in A-RNA or A-DNA. In fact, the CD of ApA closely resembles that of poly(A), except that it is only about half as large. This model is supported by theoretical calculations of the CD and more recently by NMR. Interestingly, although the CD spectra of dA, dAp, and dpA are similar to one another and to those of the riboA monomers, the CD spectrum of d(ApA) is quite different from that of ApA and reflect a difference in the geometry of base stacking.

Figure 3. Near-UV CD spectra of the dinucleoside monophosphate ApA (——)and the mononucleotide pA (– – – –). Spectra obtained in 0.1 M Tris, 0.1 M NaCl, pH 7.4 at 5.5°C for ApA and at 20°C for pA (36).



The CD of nucleotide trimers can be described in most cases by the equation

$$[\theta]_{\mathrm{ApBpc}} = (2[\theta]_{\mathrm{ApB}} + 2[\theta]_{\mathrm{BpC}} - [\theta]_{\mathrm{Bp}})/3 \tag{8}$$

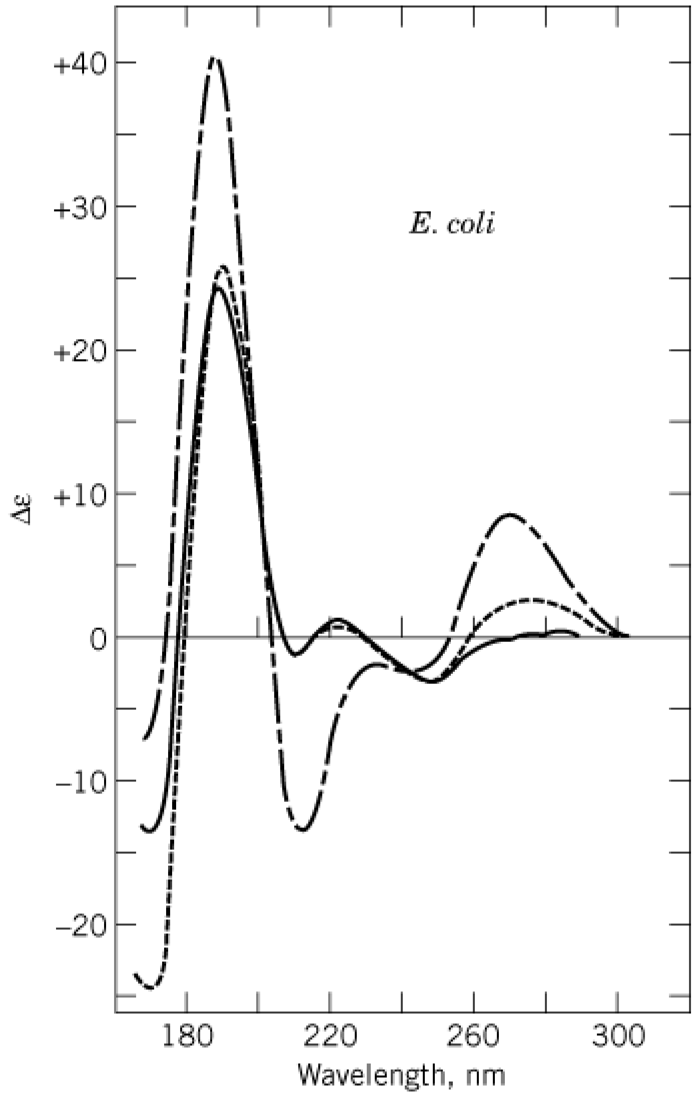
This model assumes that (1) nearest neighbor bases stack similarly in dimers and in higher oligomers and (2) only nearest neighbor interactions are significant for CD. The model works reasonably well for higher oligomers and for trimers and has been extended to double-stranded oligonucleotides of DNA and RNA. The same model has been used to derive nearest neighbor frequencies for DNA and

RNA from base-composition and CD data.

3.1.1. Secondary Structure

The CD of a DNA is highly diagnostic of its secondary structure. The B-DNA conformation normally found in aqueous solution has a positive CD band near 275 nm and a negative band of similar magnitude near 245 nm, as shown in Fig. 4. A pair of closely spaced bands of opposite sign is called a couplet, and it is characterized by the sign of its long-wavelength component as a positive or negative couplet. A couplet in which the two lobes are of very similar amplitude is called a conservative couplet. In the far UV, the B-DNA spectrum has a positive couplet with peaks near 190 and 175 nm that is nearly an order of magnitude more intense than the near-UV bands.

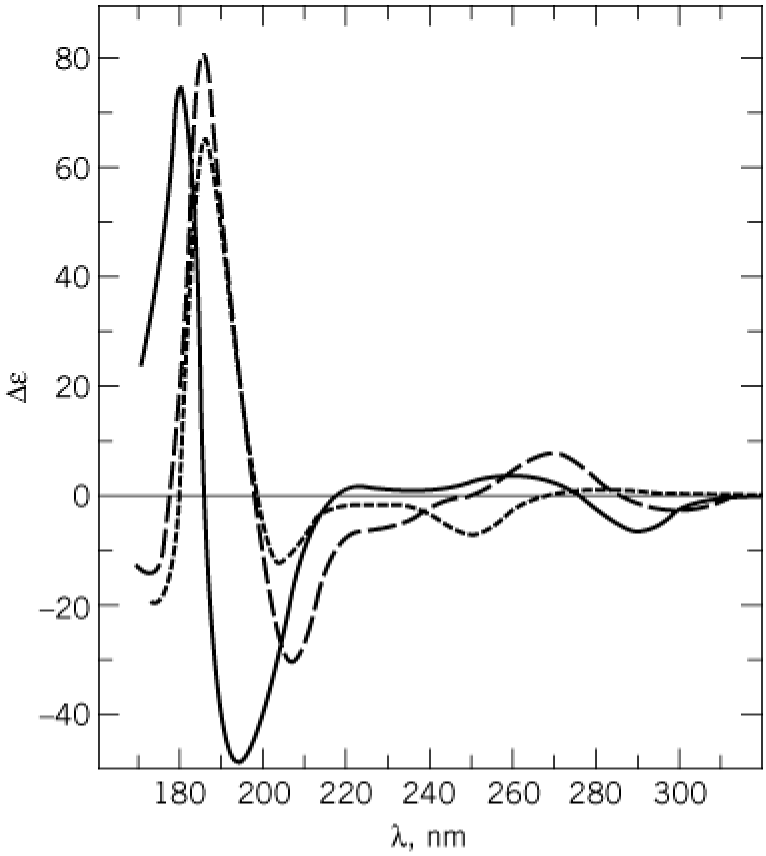
Figure 4. The CD spectra of *E. coli* DNA in the B form at low ionic strength (10 mM sodium phosphate buffer, – – – ––), the A form (0.67 mM sodium phosphate buffer, 80% trifluoroethanol, – · –), and the B form at high ionic strengths (6 M NH_4F, ——) (37). (Reprinted with permission from Ref. 37, © 1985, Wiley-Liss.)



The A-form of DNA (see A-DNA) is favored by low water activity and is induced by adding alcohols. In the near UV, the B → A transition is marked by a large increase in the positive band and a decrease in the magnitude of the 245 nm band. Therefore, the A-DNA CD spectrum is distinctly nonconservative. A strong negative band near 210 nm is also a characteristic feature of the A-DNA spectrum in contrast to the weak negative band in the B-DNA spectrum. Below 200 nm, a positive couplet is observed as in B-DNA, but the couplet is asymmetrical.

The B- and A-forms of DNA are both right-handed double helices. As expected, the left-handed Z form of DNA (see Z-DNA) has a very different CD spectrum, as shown for Z-form poly[d(G-C)] in Fig. 5. The near-UV bands for the Z-form are opposite in sign to those for the B-form and are shifted to longer wavelengths. The strong bands in the far UV are also reversed in sign and are red-shifted relative to those for the B-form. (Note that the CD spectrum of poly[d(G-C)] in the B-form differs from that of natural or "random-sequence" DNA. This is generally true for DNAs with simple di- and trinucleotide repeating sequences, in which specific features of geometry and electronic interactions are not averaged.) The reversed signs of the near-UV CD in the Z-form of poly[d(G-C)] were the first indications of a dramatically different conformation for this copolymer at high salt concentrations, but subsequent studies have shown that the signs of the near-UV CD bands do not reliably indicate helix sense for the double helix. However, the signs of the far-UV CD bands correlate with the helix sense in all known cases: a positive band between 180 and 192 nm for right-handed A-and B-forms and a negative band between 185 and 200 nm for the left-handed Z-form (25). Near-UV CD is widely used to monitor B → Z transitions in DNA.

Figure 5. CD spectra of poly[d(GC)] in three conformations. B form (10 mM sodium phosphate buffer, ...); A form (0.67 M sodium phosphate buffer, 80% trifluoroethanol, — — ——); Z form (10 mM sodium phosphate buffer, 2 M $NaClO_4$, ——) (38). (Reprinted with permission from Ref. 38, © 1985, IRL Press.)



tive to ionic strength. At ionic strengths comparable to physiological, the conservative CD pattern shown in Fig. 4 is observed. As ionic strength increases, the 275 nm band is selectively diminished, and at 6 M NH_4F, it nearly vanishes (Fig. 4). By contrast, the 245 nm band undergoes little change. Studies with closed circular DNA show that changes in ionic strength from ca. 0.1 M to 6 M change the number of base pairs per turn from ca. 10.4 to 10.2. The DNA in chromatin has a CD spectrum similar to that in 6 M NH_4F, indicating that it is a somewhat underwound form of B-DNA.

Double-stranded RNA is nearly always found in the A-form, and never in the B-form. Z-form RNA has been observed for poly[r(G-C)], but the conditions required to drive it into this form are more stringent than for the deoxy copolymer. A-form RNA has a CD spectrum similar to that of A-DNA, except that a weak negative band is commonly observed near 290 nm on the long-wavelength side of the 260 nm band. As with DNAs, the far-UV CD is diagnostic of the helix sense in double-stranded RNA, and the correlation between the sign of the far-UV couplet and the helix sense is the same.

In both RNA and DNA, the single-stranded forms have CD spectra that qualitatively resemble the double-stranded forms because base stacking has a much greater influence on the CD than does base pairing. Stand separation eliminates the latter but does not affect stacking significantly. Thermal denaturation of DNA leads to relatively small CD changes in the near UV but substantially larger far-UV CD changes. CD is also useful in characterizing **triplex** (26) forms of DNA and RNA.

3.1.2. Tertiary Structure

Supercoiling of DNA leads to readily detectable changes in the CD spectrum (27). The positive 275-nm band of B-DNA becomes more positive for negative superhelical supercoiling and conversely for decreased negative superhelical densities. For superhelical densities in the normal range, the CD changes are directly proportional to the superhelical density.

Although there is no evidence that the CD of RNA is directly sensitive to tertiary structure, it is sensitive to sequence and base pairing. Thus, CD has been used to test alternative models of RNA tertiary structure that differ in secondary structure distribution (28).

3.1.3. Ligand Binding to Nucleic Acids

Complexes of DNA and RNA with dyes, antibiotics, and other small ligands (See Intercalation) give rise to induced CD in the ligand absorption bands and to changes in the nucleic acid CD bands (29). These changes permit the determination of dissociation constants and stoichiometries for complexes of such small ligands with DNA and RNA. In some cases, additional structural information about the ligand or nucleic acid conformation is obtained.

CD is widely used to study DNA-protein and RNA-protein interactions (30). A very useful feature of CD in such studies is that the nucleic acid generally dominates the CD spectrum in the 260-nm region, whereas the protein dominates in the 200- to 240-nm region. Because each of these regions responds to the conformation of the dominant component, CD is of great value in monitoring conformational changes upon complex formation. Nonspecific protein–nucleic acid complexes often have dissociation constants in the micromolar range where CD is well suited for measuring K_d values. Specific protein–nucleic acid complexes usually have K_d s that are smaller by several orders of magnitude at physiological ionic strengths. In some cases, the K_d is shifted into the measurable range by increasing the ionic strength. Even if the binding is too tight to permit measuring the K_d by CD, conformational changes in the protein and/or nucleic acid are detected and characterized by CD. CD is also well suited for measuring the kinetics of protein–nucleic acid complex formation.

4. Carbohydrates

Circular dichroism has important applications in studying carbohydrates (31), although these are more limited than for proteins and nucleic acids. Of the chromophores common in carbohydrates, only the amide (N-acetyl sugars) and carboxyl groups (uronic acids) have CD bands above

200 nm. The hydroxyl, ether, acetal, and ketal chromophores that are most typical have their first longest wavelength CD bands near the short-wavelength limit of conventional CD instruments, near 180 nm. Higher energy transitions are studied only with vacuum UV instruments, but they are usually obscured by solvent absorption, so studies are limited to thin solid films. For these reasons, optical rotation and ORD measurements in the near UV and visible regions continue to play an important role in studying carbohydrates.

Monomeric sugars have been investigated extensively, and sector rules relating the signs of CD bands near 170 nm to the conformation of the sugar have been derived. A useful model relating the optical rotation at the Na D line to the conformation of a sugar has been developed. This model is useful in testing features of the conformational energy surface in disaccharides. In the study of polysaccharides, CD and optical rotation have been used to characterize order-disorder, single- to multistranded, and sol to gel transitions (32).

Cis Configuration

The prefix *cis* has been used in chemistry to indicate "on the same side" (1). The original use came from describing stereoisomers of molecules with a ring or containing carbon–carbon double bonds. When similar substituents are on the same side of the ring or double bond, the configuration is referred to as *cis*, and when they are on opposite sides, they are referred to as ***trans***. The C2 and C3 hydroxyl groups of the furanose form of **ribose** are *cis*. The conformation about a single bond may also be noted as *cis* or *trans*, particularly when all the substituents lie in a plane. The *cis* conformation of a peptide bond has both a-carbons on the same side of the *N*—*C* amide bond (see Cis/Trans Isomerization). The notation **s-*cis*** (2) is used to emphasize that the conformation about a single bond is being described, as in *s*-1-*cis* retinal. These different uses of the chemical prefix *cis* are shown in Figure 1.

Figure 1. The various uses of the prefix *cis* are shown. The common feature is that the prefix denotes "on the same side."

***Cis*-Acting**

This term is used in the context of regulation of gene transcription to denote DNA sequences that have to be physically joined to the **genes** in question to influence their activity. Trans-acting sequences, on the other hand, exert their regulatory effects regardless of whether or not they are present on the same chromosome as the regulated gene. *Trans*-acting genes generally encode proteins that bind to *cis*-acting DNA sequences.

Cis-acting sequences were classically identified as a result of their mutation, either silencing or activating the controlled gene, depending on whether the *cis*-acting sequence provided a binding site for **RNA polymerase** or other necessary **transcriptional factor** or for a repressor protein. These two kinds of *cis*-acting sequences, respectively positive and negative in their effect, were first identified in the *Escherichia coli* Lac operon, where they were called the **promoter** and **operator** sequences. With the development of recombinant DNA technology, it became possible to detect protein-binding sites in DNA without mutation (e.g., by footprinting or gel retardation assays), and then to determine their effects on transcription by "engineered" deletions.

Cis-acting sequences that act otherwise than by providing binding sites for regulatory proteins are comparatively uncommon, but two quite different examples should be mentioned. In bacterial operons, a mutation that causes premature translational termination of an upstream gene can cause a drastic reduction in the expression of genes in the same operon further downstream. This is a strictly *cis*-acting effect, acting within a single unit of transcription. The mechanism is explained under Lac Operon.

The second example is from female mammals where one of the two X-chromosomes in each cell lineage is largely inactivated with the notable exception of one gene, active only in the otherwise "silent" X, that is transcribed into a long RNA molecule called Xist. This transcript, which does not encode a protein, plays an essential role in silencing the rest of the chromosome. It acts only in *cis* and remains associated with the chromosome from which it is transcribed without effect on the other, active, X-chromosome (see X-Chromosome Inactivation).

X-chromosome inactivation involves propagating a certain type of condensed and transcriptionally inactivating chromatin structure, generally called heterochromatin, which, in most chromosomes, is restricted to certain segments. In *Drosophila melanogaster*, heterochromatin exerts a *cis*-effect in suppressing gene activity when, as a result of segmental chromosomal rearrangement, it is brought close to genes not normally associated with it. The multiprotein heterochromatin complex spreads along the chromosome, inactivating the genes in its path with a probability that decreases with distance (see Position Effect). Genes that are normally close to heterochromatin are apparently insulated in some way against this effect.

Cis-Dominance

Dominance, in the genetic sense, is a property of one form (**allele**) of a **gene** relative to another allele of the same gene, said to be recessive. Where dominant and **recessive alleles** are present together, the dominant, not the recessive, registers its effect on the organism. Most mutant alleles have lost part or all of their activity and then are usually recessive. When mutant alleles are dominant it is usually because they are hyperactive or have been freed from some normal constraint. The term *cis*-dominant means that the mutation is in an element that has to be physically joined to the gene to exert its effect (ie, in *cis*), not separated from it on another chromosome.

Insofar as a gene is, by definition, an integrated (*cis*-acting) unit of genetic function, any part of a dominant allele, including its coding sequence, could be said to be *cis*-dominant. But, in practice, the term (if it is used at all) is usually reserved for DNA sequences that govern gene activity in *cis* from outside the transcribed or translated sequence.

The concept of *cis*-dominance arose from the classical work of Francois Jacob and Jacques Monod at the Pasteur Institute in Paris on the utilization of the sugar lactose by the bacterium *E. coli* (see Lac Operon). Lactose utilization by the bacterium depends on two proteins, the enzyme b-**galactosidase**, which cleaves lactose to glucose and galactose, and a membrane protein, b-galactoside permease, needed for uptake of lactose into the cell. These proteins are normally synthesized by *E. coli* only in the presence of lactose in the growth medium, or a lactose analogue, that acts as an **inducer**.

Two classes of mutations result in failure to grow on lactose as a carbon source: *lacZ* mutants lack b-galactosidase and *lacY* mutants lack the permease. *LacZ* and *lacY* are two genes that are closely linked (together with a third, seemingly inessential gene *LacA*) in what was later shown to be a single unit of transcription, or operon, transcribed in the sequence Z - Y - A.

Two other kinds of mutants differ from wild type in producing b-galactosidase and permease **constitutively**, that is, whether inducer is present or not. They were mapped respectively in a separate gene, *LacI*, closely linked to *LacZ*, and in a so-called **operator** segment (*o*) at the end of *LacZ* that overlaps the LacZ transcription start point. The *LacI* constitutive mutants (*LacI*–) are recessive to wild type (*LacI*+), which is interpreted as meaning that *LacI*+ encodes a transcriptional repressor and that the repressor function is nullified by inducer. The wild-type operator segment (*o*+) was given the hypothetical role of binding to the *LacI* repressor, blocking *lac* operon transcription. The operator-constitutive mutants (o^c) are interpreted as changes in the DNA sequence of the operator so that it no longer bound the repressor. The inducer was thought to act by binding to the repressor protein and changing its conformation, so that it is no longer bound to the operator (see Fig. 1). All of these elements of the model have since been confirmed by molecular analysis.

Figure 1. The regulation of the *Escherichia coli lac* operon and two kinds of mutations that have dominant effects: $LacI^s$ (noninducible), dominant both in *cis* and in *trans*; and o^c (constitutive), dominant only in *cis*. The partial diploids for testing dominance (items 5–8) were made by introducing F′ plasmids that carry a second copy of the *lac* segment of the bacterial genome. o^c is resistant to the wild type ($LacI^+$) repressor and also to the $LacI^s$ superrepressor. $LacI^-$ mutants, not shown here, are constitutive and recessive. Information from Refs. 1 and 2.

		Lac Z (β-galactosidase) activity	
		No inducer	With inducer
1	[$I^+ O^+ Z^+$]	–	+
2	[$I^+ O^c Z^+$]	+	+
3	[$I^s O^+ Z^+$]	–	–
4	[$I^+ O^+ Z^-$]	–	–
5	[$I^+ O^+ Z^-$ / F′ $I^+ O^c Z^+$]	+	+
6	[$I^+ O^+ Z^+$ / F′ $I^+ O^c Z^-$]	–	+
7	[$I^s O^+ Z^+$ / F′ $I^+ O^+ Z^-$]	–	–
8	[$I^s O^+ Z^-$ / F′ $I^+ O^c Z^+$]	+	+

The tests for dominance were made in partial diploids (merodiploids) that have a second copy of the *Lac* operon brought into the cell as part of an plasmid. Some of the key results are shown in the table of Fig. 1. The formal demonstration of *cis*-dominance comes from the comparison of items 5 and 6. The *trans* merodiploid, $o^{+}LacZ^{-}/o^{c}\ LacZ^{+}$, is constitutive, but the *cis* merodiploid, $o^{+}LacZ^{+}/o^{c}$ $LacZ^{-}$, in inducible.

The *cis*-dominance of o^{c} is readily understandable. There is no way in which the binding of a protein to one piece of DNA could affect the transcription of an unconnected piece. The operator segment is an integral part of the *lac* operon and cannot function when separated from it. On the other hand, *LacI* is a separate and functionally autonomous gene that acts on *LacZ* in *trans* just as well as in *cis*.

Mutations of the rather uncommon $LacI^{s}$ type change the repressor into a superrepressor that is insensitive to inducer and confers noninducibility. Its dominance over $LacI^{+}$ (both in *cis* and in *trans* - see item 7 in Fig. 1) is due to the *LacI* repressor functioning as a **dimer**. In mixed $LacI^{+}/LacI^{s}$ protein dimers, the noninducibility of the $LacI^{s}$ component is imposed on the whole.

The concept of *cis*-dominance was important at a time when the idea that gene sequences had regulatory as well as structurally determining functions was just emerging. Monod and Jacob found that *LacI* acts in *trans* on *LacZ* (and *LacY*) activity and the *o* segment acts only in *cis*. Today it is recognized that the activities of most genes are regulated by multiple *trans*-acting proteins, encoded by other genes, that bind to DNA sequences (**promoters**, enhancers, **silencers**) that act in *cis*. But it is questionable whether *cis*-dominance is an appropriate term in reference to all these *cis*-acting transcriptionally controlling sites. Dominance implies that there are recessive alleles over which the dominance can be demonstrated, which is seldom the case, and the *cis-trans* comparison, which could provide the evidence that the effect applies only in *cis*, is hardly ever available.

One dominant mutation, in ***Drosophila***, for which the *cis-trans* comparison has been made in Contrabithorax (*Cbx*), which maps close to the ***Ultrabithorax*** (*Ubx*) gene and extends its activity in the embryo in an anterior direction. Here the effect of *Cbx* is strong in flies of constitution *Cbx* + / + *Ubx* (*Ubx* being a virtually null allele) but weak, though still significant, in *Cbx Ubx*/ ++. In the latter genotype, the *Cbx* regulator is separated from the gene that it regulates. *Cbx* can be called *cis*-dominant, but the observation that it also has a small effect in *trans* is interesting. E. B. Lewis (3) showed that this and other *trans* effects to do with *Ubx* depend on the close pairing of homologous chromosomes that is a special feature of several *Drosophila* tissues.

The concept of *cis*-dominance is an important part of molecular biological history, even though the current usefulness of the term is rather limited. The principle of *cis*-acting controls of gene activity, to which the concept led, is now a commonplace and essential part of molecular biology.

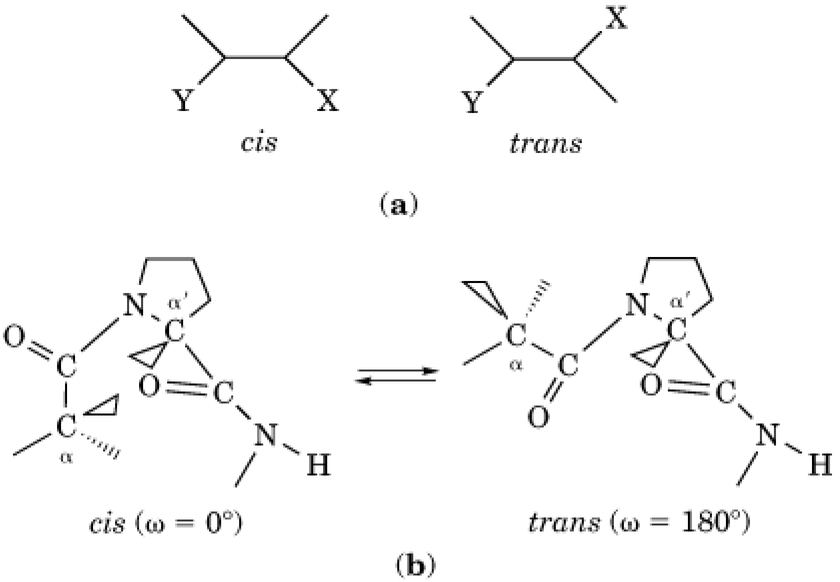
Cis/Trans Isomerization

The distinction between the *cis* and *trans* isomers of a molecule originates from a geometry-based classification of molecular structures. When the two substituents X and Y are on the same side of the structural unit [Fig. 1(**a**)] the isomer is *cis*. It is designated *trans* in the opposite arrangement. Ambiguities in the designation of the isomers are avoided by using the more sophisticated *E*/*Z* nomenclature, which often has *E* for the *cis* form and *Z* for the *trans* form. The interconversion between the isomers, the *cis*/*trans* isomerization, occurs by rotation about the central linkage [Fig. 1 (**a**)]. There is a barrier to rotation quantified by the **free energy** of activation DG‡ that is proportional to a first-order rate constant k_{obs}, where k_{obs} = ($k_{cis\text{ to }trans}$ + $k_{trans\text{ to }cis}$ for the reversible isomerization. The bond order of the central linkage correlates with the magnitude of the energy barrier DG‡. It ranges from high values of DG‡ > 100 kJ/mol for double bonds, via an intermediate range for linkages having a partial double bond character, down to low values in the range of $k_B T$ (where k_B is the Boltzmann constant and T the absolute temperature) for C–C single bonds. Under ambient conditions, a rotational barrier >90 kJ/mol indicates that the individual isomers are not readily interconverted, and they may exhibit quite distinct chemical properties. A corresponding DG‡ value has been used to discriminate semantically between different conformations (barrier to rotation <90 kJ/mole) and configurations of a molecule.

Figure 1. (**a**) General representation of *cis/trans* isomerism (**b**) *Cis/trans* isomerism of a prolyl peptide bond.



In a polypeptide chain, both the amide -CONH- and the **imide** ━CON < peptide groups are intrinsically competent to undergo *cis*/*trans* isomerization by rotation about the torsion angle w of the peptide bond (see Ramachandran Plot). Among the gene-encoded amino acids, the imide peptide bond is exclusively formed by proline residues. Because the lone electron pair of the nitrogen atom is delocalized over the peptide bond, the C–N linkage has a partial double-bond character. Typically, this destabilizes twisted conformations but stabilizes planar arrangements (*trans*, w = 180° *cis*, w = 0°) of the two a-C atoms adjacent to the peptide bond [Fig. 1(**b**)]. The *cis*/*trans* isomerization of the -CONH- moiety is relatively fast (half-time <1 at room temperature) and leads to a very small percentage of *cis* isomer, ≫1%, at equilibrium. In contrast, the peptidyl-proline moiety (in the following referred to as a prolyl bond) often has *cis/trans* isomers in comparable amounts. Steric constraints, which favor a *trans* arrangement in the case of -CONH-, are similar in both isomers for prolyl bonds, and the *cis* isomer generally occurs in about 20% of the prolyl peptide bonds. There is a relatively high rotational barrier $DG^{‡}$ of about 80 kJ/mol for the prolyl bond. The combination of a substantial population of both isomers and their slow interconversion implies that *cis* prolyl bonds have considerable influence on biochemical reactions of the polypeptide backbone.

In the absence of a folded conformation, polypeptide chains can theoretically form 2^n *cis*/*trans* isomers, where *n* is the number of prolyl bonds in the molecule. In simple cases, as with a four-proline octapeptide derived from the prolactin **receptor**, all of the possible isomers have been detected and quantified in solution (1). Structural formation in the peptide chain, however, reduces the number of isomers substantially. A particular prolyl bond in native proteins is usually either *cis* or *trans* in all the molecules, although *cis*/*trans* isomerization in the native structure has been observed for a few proteins by **NMR** methods in solution. In the latter case, structural alterations propagate through the backbone around the isomeric proline residue, which can be accompanied by distinct biological activities of the isomeric proteins (2, 3). Depending on the polypeptide structure, the **half-time** for prolyl bond isomerization ranges from seconds to hours.

From stereochemical considerations, the peptidyl transferase center on the ribosome is thought to be constructed for synthesizing all peptide bonds in the *trans* conformation. However, in native, globular proteins of known three-dimensional structure, about 5 to 6% of prolyl peptide bonds are *cis* (4, 5). When proline-containing proteins are unfolded in the presence of high concentrations of **denaturants**, such as urea or **guanidinium chloride** (GdmCl), the random coil polypeptides generally equilibrate slowly to a mixture of numerous *cis*/*trans* isomers. For the fraction of unfolded molecules that have one or more nonnative isomers of a prolyl bond, subsequent **refolding** of the protein has to start from different conformational states. If the *cis*/*trans* isomerization is slower than refolding, slow kinetic phases of folding may be apparent when the time course of refolding is monitored. For that reason, *cis/trans* isomerization is the rate-limiting step in folding for some proteins. It is generally most easily detectable when there is a *cis* prolyl bond in the native state, because then a large fraction of unfolded molecules has the incorrect isomer (6, 7).

Chemical catalysis of prolyl bond isomerization is rare. Most organic solvents and micelles or phospholipid **vesicles**, cause a moderate decrease in the rotational barrier. The rate constants are independent of the pH value in the physiological range, unless dissociable groups are located adjacent to proline. An increased rotational barrier results from the O-protonation of the peptide bond in acidic solution, characterized by a $pK_a = –1$. In strong acids, N-protonated species become populated ($pK_a = –7$) that accelerate *cis/trans* isomerization (8). Many relationships between the peptide structure and prolyl bond isomerization have been elucidated. For example, when measured in oligopeptides, the increased barrier to rotation caused by aromatic amino acids that precede the proline residue is accompanied by an increase in the *cis* population of up to 40%, whereas small aliphatic side chains in the same position lead to lower $DG^{‡}$ values in conjunction and lower *cis* contents of 5 to 10% (9).

The conformational constraints on the polypeptide backbone induced by the prolyl *cis/trans* isomerization restrict bimolecular recognition processes. Conformational selectivity was demonstrated by the hydrogen bond directed preferential binding of proline peptides in the *cis* conformation to b-cyclodextrins (10) and to a synthetic, multidentate terephthaloyl amide (11). For the recognition of opioid peptides of the dermorphin type by m- and ∂-receptors, specificity for the *cis* conformers was suggested (12). In a biological context, it may be important that endoproteinases, such as **chymotrypsin**, **trypsin**, thrombin and clostripain cannot readily cleave a peptide bond adjacent to a *cis* prolyl moiety, even if the isomeric bond occupies a position remote from the scissile bond (13, 14). Due to this conformational specificity, the rate of the *cis* to *trans* isomerization of the prolyl bond limits the rate of proteolysis for good substrates in the presence of high protease concentrations, and this is a useful assay for isomerization. Even *in vivo*, the time course of bradykinin (Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg) degradation by pulmonary endothelial peptidases is controlled by the conformational specificity of the proteinases (15).

Clamp Loaders, Processivity Complex

Chromosomal **replicases**, the **DNA polymerases** that replicate chromosomes, are multiprotein complexes characterized by the high processivity of their DNA synthesis. These replicating machines polymerize thousands of nucleotides without dissociating from the template. The replicases of the three well-characterized systems (***Escherichia*** *coli*, **eukaryotes**, and **bacteriophage** T4), which span the evolutionary spectrum, are similar in function, structure, and overall organization. Their remarkable processivity is achieved by a ring-shaped processivity factor (or "**sliding clamp**") that binds the polymerase catalytic unit and tethers it to the DNA. Another complex of accessory proteins is required to load the clamp onto the DNA. The sliding clamp does not have any affinity for DNA and, therefore, other proteins are needed to assemble the clamp around the DNA. The accessory protein complex ("clamp loader"; also called a "molecular matchmaker") binds to the primer terminus and **couples** ATP hydrolysis to the assembly of the ring around the DNA primer. Therefore, the replicase can be thought of as having three components: (1) a polymerase, (2) a clamp loader complex that assembles the clamp around DNA and (3) a DNA sliding clamp (Table 1).

Table 1. Three-Component Structures of Chromosomal Replicases

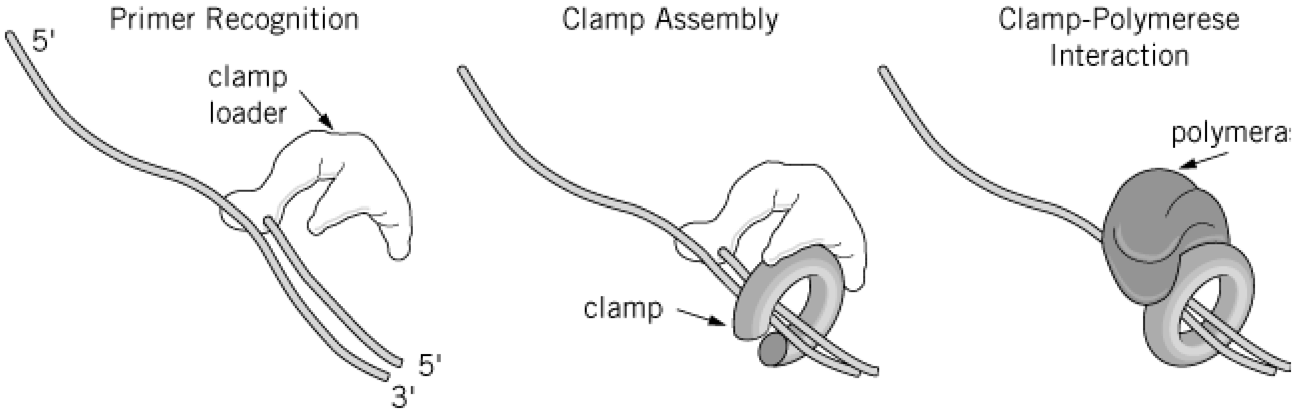
	DNA Polymerase	Clamp loader	Sliding Clamp
Eukaryotes	pold (3 subunits)	RF-C complex (5 subunits)	PCNA
E. coli	Core polymerase (3 subunits)	g-complex (5 subunits)	b-subunit
Phage-T4	gp43	gp44/62	gp45

1. The Clamp Loaders

The three best-studied replicases are the *E. coli* DNA polymerase III holoenzyme (polIII), the eukaryotic polymerase d (pold), and the replicase of phage T4. These three multisubunit complexes share structural and functional similarities (reviewed in Refs. 1-3). The clamp loaders for these systems are the g-complex of prokaryotes, the replication factor-C (RF-C) complex (also called Activator-1) of eukaryotes, and a complex of the products of gene 44 and gene 62 (gp44/62) of phage T4. The g-complex is composed of five subunits called g, d, d′, c and y. RF-C is also a five-subunit complex, composed of one large and four small subunits (p140, p40, p38, p37, and p36). gp44/62 contains only two polypeptides gp44 and gp62. In the complex, a tetramer of gp44 is tightly associated with one gp62. Interestingly, the three clamp loaders share amino acid similarities among the subunits (4, 5).

A detailed mechanism by which these clamp loaders operate in assembling the sliding clamp around DNA is not yet known. The basic steps of the loading process, however, have been elucidated (Fig. 1). In general, the clamp loader recognizes the 3′ end of the junction between the single strand and duplex DNA (primer/template) and uses ATP hydrolysis to assemble the clamp around the primer. The status of the clamp loader after assembling the clamp around DNA is not yet clear. It has not yet been determined whether the clamp loader leaves the clamp on the DNA, where it interacts with the polymerase to initiate processive DNA synthesis, or if the clamp loader is also needed to assist binding the polymerase to the clamp (the different features of each clamp loader are discussed later).

Figure 1. A model for clamp loader activity. The clamp loader recognizes the 3′ terminus of a primer and assembles the sliding clamp around the DNA. Following assembly, the clamp interacts with the polymerase and tethers it to the DNA f processive DNA synthesis.



In prokaryotes and eukaryotes, the clamp loader also functions as a clamp unloader (6). Upon completion of an Okazaki fragment, the polymerase rapidly dissociates from the clamp (7-9), leaving the clamp on the DNA (10). The clamps of polIII (the b subunit) and pold [proliferating cell nuclear antigen (PCNA)] are relatively stable on DNA (6, and references therein). Therefore, it was postulated that the sliding clamp remains assembled around the DNA when the synthesis of an Okazaki fragment is complete. During lagging strand synthesis, a new sliding clamp is needed for the synthesis of each Okazaki fragment. In *E. coli* about 10 times more Okazaki fragments are formed during replication than there are b-subunits within the cell. In human cells, the number of Okazaki fragments formed during one round of chromosomal replication has been estimated to be 100 times greater than the amount of PCNA. Therefore, recycling of the clamp (b and PCNA) is needed to fulfill the requirement for a constant supply of clamps for further DNA synthesis. In phage T4, the clamp readily dissociates from DNA upon completion of an Okazaki fragment. Thus, the clamp loader has a dual function during DNA replication: (1) loading of the sliding clamp onto DNA to initiate processive DNA synthesis and (2) recycling the clamps on the lagging strand.

1.1. g-Complex

The g-complex is composed of five subunits (g, d, d′, c, y) (reviewed in Ref. 11). The genes encoding them have been identified, and the purified proteins have been used to study the function of the individual subunits and subassemblies of the g-complex (discussed later). Four of the subunits (d, d′, c and y) are encoded by unique genes. The g-subunit is formed from the same gene (*dnaX*) that encodes t (another subunit of polIII) by an efficient translational **frameshift** mechanism that produces g in an amount equal to t (reviewed in Ref. 12). As a result, the g-subunit consists of the N-terminal 430 residues of t followed by a unique C-terminal Glu residue. In addition, the g-and d′-subunits show amino acid sequence similarity.

No one subunit alone can assemble the b sliding clamp around DNA (11 and references therein). At low ionic strength, a combination of g and d assemble b onto DNA, but the reaction is feeble. The d′-, c- and y-subunits are needed for an efficient loading reaction under physiological conditions (13).

The g-complex has only weak affinity for single-stranded and duplex DNA, and it exhibits weak DNA-dependent ATPase activity, but the ATPase activity is stimulated by the sliding clamp (b-subunit) (14). The best DNA effector for the ATPase activity is a singly primed template, indicating an interaction between the g-complex and the primer/template junction. The g-subunit is the only subunit of the g-complex with an ATP-binding motif, and it binds ATP (15). Furthermore, mutation of the ATP-binding site of g within the g-complex destroys the ATPase activity and the ability to assemble the b-ring onto DNA. The g-subunit, however, lacks significant ATP hydrolysis activity even in the presence of DNA (14, 15), and the d- and d′-subunits are required for ATPase activity, implying that the gdd′ complex recognizes DNA. The g-complex binds b in the presence of ATP. The d subunit interacts with b, with a strength similar to that of the entire g-complex (16), indicating that b binds the g-complex mainly through the d-subunit. Interestingly, however, the interaction between the b-subunit and d does not depend on ATP (whereas the g-complex requires ATP to bind the clamp). These apparently contradictory observations can be explained if the d subunit is buried within the g-complex and ATP induces conformational changes that lead to the interaction of d with b (16). The g-complex also interacts with single-stranded DNA binding protein (SSB) via the c subunit (11). These interactions are important for efficient clamp assembly at physiological ionic strength.

The results obtained with the individual subunits and their subassemblies demonstrate the basic features of the g-complex action during loading of the clamp onto DNA (Fig. 1). Upon binding of ATP, the g-complex undergoes conformational changes leading to interaction of the d-subunit with b. The g-complex recognizes a primed template, aided by the interaction between c and SSB. Assembly of the ring around the DNA primer stimulates the ATPase activity of the g-complex. ATP hydrolysis results in conformational changes such that d is again buried within the g-complex leaving the clamp around the DNA primer. Now the clamp interacts with the polymerase to initiate processive DNA synthesis (Fig. 1).

1.2. Replication Factor-C (RF-C)

RF-C was first isolated from human 293 cells as an essential replication factor for the *in vitro* replication of simian virus-40 (SV-40) (17). The factor was purified later from different sources, including yeast and human cell lines (18 and references therein), based on its ability to stimulate processive DNA synthesis by pold in the presence of PCNA and ATP.

Purified RF-C is a five-subunit complex (p140, p40, p38, p37, and p36). The genes that encode all RF-C subunits from yeast and humans have been identified (4, 5 and references therein), and all are essential in yeast. Although encoded by different genes, they show extensive amino acid sequence similarities in the central region of the protein (reviewed in Ref. 5).

Early biochemical studies determined the role of RF-C as a clamp loader of PCNA and suggested a mode of action during the assembly reaction (Fig. 1). RF-C binds preferentially to single-strand/duplex DNA (template/primer) junction in the presence of ATP (19, 20). PCNA interacts with the RF-C/DNA complex. The DNA-dependent ATPase activity of RF-C is stimulated by the binding of PCNA. The hydrolysis of ATP leads to conformational changes within the RF-C, which locks the PCNA sliding clamp around the DNA. Then the clamp interacts with the polymerase to initiate processive DNA synthesis (Fig. 1).

Biochemical analysis of RF-C individual subunits and the protein–protein interactions within the RF-C complex is underway (eg, 21, 22). Purified proteins, subcomplexes and mutational analysis have shed light on the function of the individual subunits and subassemblies of the RF-C complex. Although each subunit contains an ATP-binding motif, only p40 binds ATP (20). Yeast p36 (23) and a subcomplex of human RF-C (p36-p37-p40) exhibit DNA-dependent ATPase activity. The DNA-binding activity resides within the large subunit (p140) (20), although the p37 subunit also binds DNA weakly. All of the subunits, except p37, bind PCNA (24-26). The intact complex, however, is needed for the assembly of PCNA around the DNA and, to date, no subunit combination analyzed performs this task. Unloading is probably a simpler mechanism, as the p40 subunit is sufficient to unload PCNA from DNA and also interacts with pold (26). The role of this interaction in DNA synthesis, however, is not yet clear. RF-C also interacts with SSB. The interaction between RF-C and SSB might be needed for the assembly of the clamp, as demonstrated for the *E. coli* g-complex.

1.3. gp44/62

Similar to the g-complex and RF-C, the clamp loader of phage T4, the gp44/62 complex, is also composed of five subunits (Table 1). In this case, however, only two polypeptides form the pentamer, where a tetramer of gp44 binds a single subunit of gp62 (27). Like the clamp loader of eukaryotes and prokaryotes, the gp44/62 complex exhibits ATPase activity that is stimulated by the sliding clamp (gp45) and by DNA (28, reviewed in Ref. 29). A DNA structure that resembles a template/primer junction is the best effector for stimulating ATPase activity (27). Cross-linking and protein-DNA footprinting assays demonstrate that the clamp loader interacts with DNA in the absence of gp45, but these interactions are relatively weak, and the clamp is needed for binding to DNA (reviewed in Refs. 29, 30). Studies with individual subunits of the gp44/62 complex revealed that the gp44 exhibits the ATPase activity, whereas gp62 interacts with the clamp (31).

The exact mechanism of action of the gp44/62 complex is not yet fully understood. The overall features of its activity, however, have been determined and are similar to those of the g-complex and RF-C (Fig. 1). The gp44/62 complex interacts with gp45 in an ATP-dependent manner. The complex recognizes the primer terminus, which stimulates the ATPase activity of the clamp loader, bringing about conformational changes that lock the clamp around the primer and allow it to interact with the polymerase to initiate processive DNA synthesis.

2. Concluding Remarks

The polymerases responsible for replicating chromosomal DNA during cell division are multiprotein complexes. The processivity of these enzymes relies on a ring-shaped protein that encircles DNA and tethers the catalytic unit to DNA for processive DNA synthesis. The mechanisms by which the clamp loaders assemble the ring around DNA and disassemble them from DNA are only beginning to be understood. The complexity of this mechanism is inferred from the observation that it requires the coordinate activity of several polypeptides in eukaryotes, prokaryotes, and phage T4. Future studies are needed to elucidate the mechanisms by which the clamp loaders operate in the loading and unloading reactions. Purification of the clamp loader complexes and the individual subunits will enable further analysis of these mechanisms.

Class Switching

Upon stimulation with an immunogen, the circulating antibodies belong first to the IgM isotype, before being replaced by immunoglobulins of another class (most frequently an IgG in the bloodstream). This phenomenon is known as isotype switching (or switch) and is the consequence of a gene rearrangement that takes place in the centrocytes, located in the light zone of the germinal center. As a result, the V–D–J rearranged section of the mature B cell, which was initially associated with a Cm constant region to make a complete m chain, will now become associated with the constant region of another isotype. This gene rearrangement involves recognition sequences termed "switch regions" that are located at 5′ of each constant CH gene (with the exception of the d chain gene). These regions are very similar in sequence and are presumably recognized by an enzyme system, which has not been identified to date, but does not involve recombinase. As a result of this recombination event, the portion of DNA localized between the two switch regions concerned is deleted. The light-chain genes are not affected by the isotype switching, so the antibody combining site is unaffected. In other words, isotype switching has changed the Ig isotype without modifying the specificity of the cell. It has simply conferred on the antibody a distinct biological function, which will amplify the physiological action of the immune system in a number of ways, such as to fight more appropriately against pathogens, ensure fetal protection through transplacental transfer, be expressed in secretions, and so on, depending upon the selected isotype. Isotype switching is another example of a mechanism that necessitates interaction between T cells and B cells and makes use of two sets of molecules. One involves CD40 ligand (CD40-L) and CD40, expressed at the cell surfaces of T_H and B lymphocytes, respectively, and ensuring direct contact between the cells. The second signal is provided by the T_H cell and is a **cytokine** that is released as a soluble factor in the immediate proximity of the B cell. Depending upon the nature of the cytokine, and therefore on the type of interacting T cell, the switch mechanism will generate a discrete isotype. For example, secretion of **interleukin**-4 (IL-4) will favor a switch toward the IgE class, whereas transforming growth factor b1 will induce switching to IgA.

Clathrin

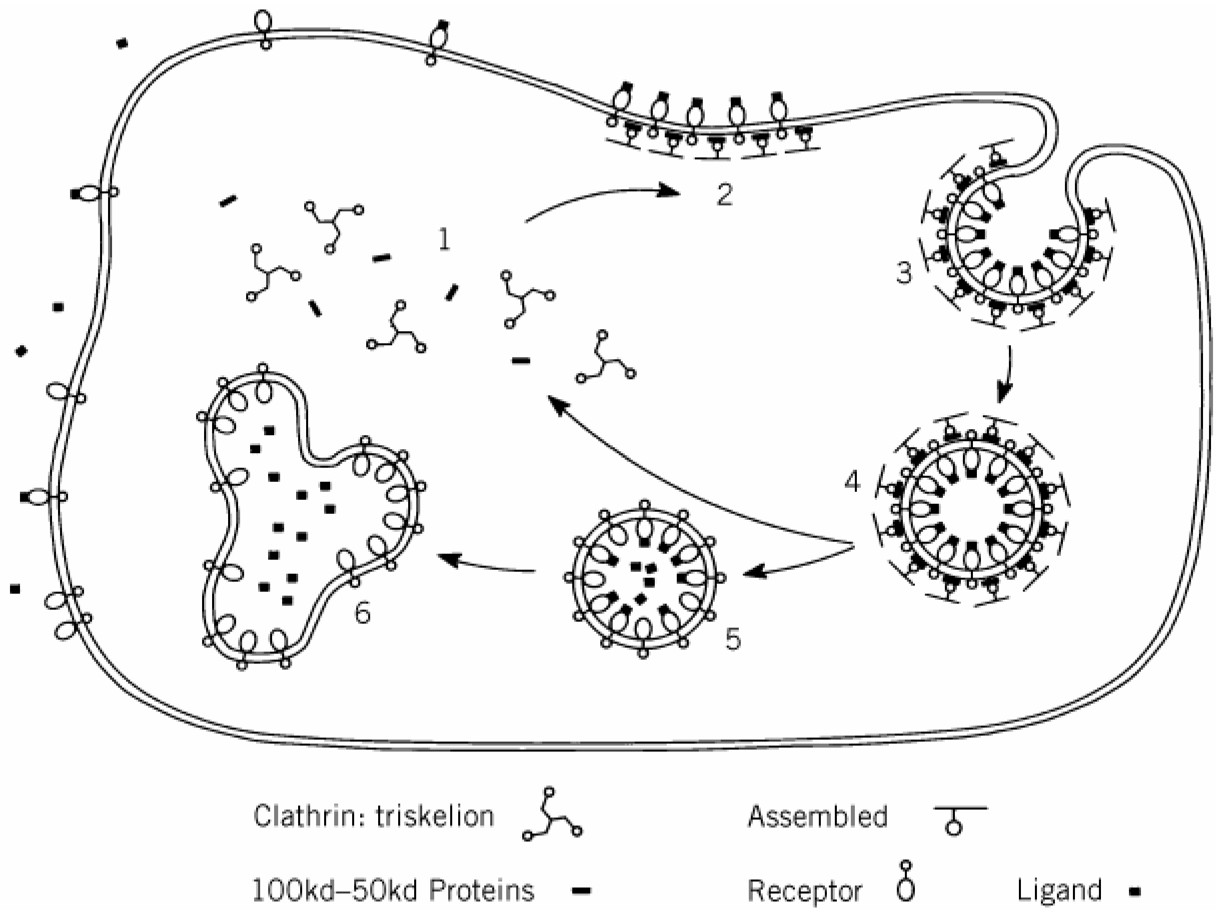
Clathrin is the major component of purified **coated vesicles** (1), intracellular structures that derive from coated membrane involved in endocytosis and **receptor** recycling.

Clathrin-mediated endocytosis (2, 3) is the major route for the uptake of specific macromolecules into cells for example, **low density lipoprotein** carrying cholesterol and transferrin bearing iron. Such macromolecules are concentrated from the surrounding cellular fluid by binding to the receptors exposed on the surface of cells. The receptors, in turn, have features in their cytoplasmic tails that enable them to cluster into clathrin-coated pits and thus be endocytosed efficiently in small vesicles. (Fig. 1). The vesicles, in addition, carry other molecules that target them to an internal compartment, the endosome, and allow them to fuse with the endosomal membrane, thus delivering the cargo of nutrients into the lumen for use by the cell. Meanwhile, the coat proteins and receptors are recycled through the endosomal compartment and back to the plasma membrane. The coat proteins diffuse through the cytoplasm to reform coated pits there for a further round of endocytosis.

Figure 1. Endocytosis promoted by a round of clathrin assembly and recycling. [Taken from B.M.F. Pearse and R.A.

Crowther (1987) *Ann. Rev. Biophys. Biophys. Chem.* **16**, 49–68.] (1) Cytoplasmic clathrin triskelions and adaptors (containing specific 100 kDa adaptins and associated subunits) are triggered to assemble on the membrane in a reaction involving GTP-binding proteins with a selection of receptors to form a coated pit(2). The coated pit invaginates as further receptors and coat proteins assemble(3). Pinching-off the completed coated vesicle(4) requires dynamin to promote fusion in the neck region. Uncoating follows, releasing the vesicle (5), which carries molecules primed for fusion with the endosome(6), and the soluble coat components, which recycle(1).

A similar coated vesicle cycle takes place in many nerve terminals. In this case, the cycle replenishes the synaptic vesicle population, whose efficient fusion with the presynaptic membrane, on stimulation, depends on, among other molecules, synaptobrevin, syntaxin, and munc18 (29-32).



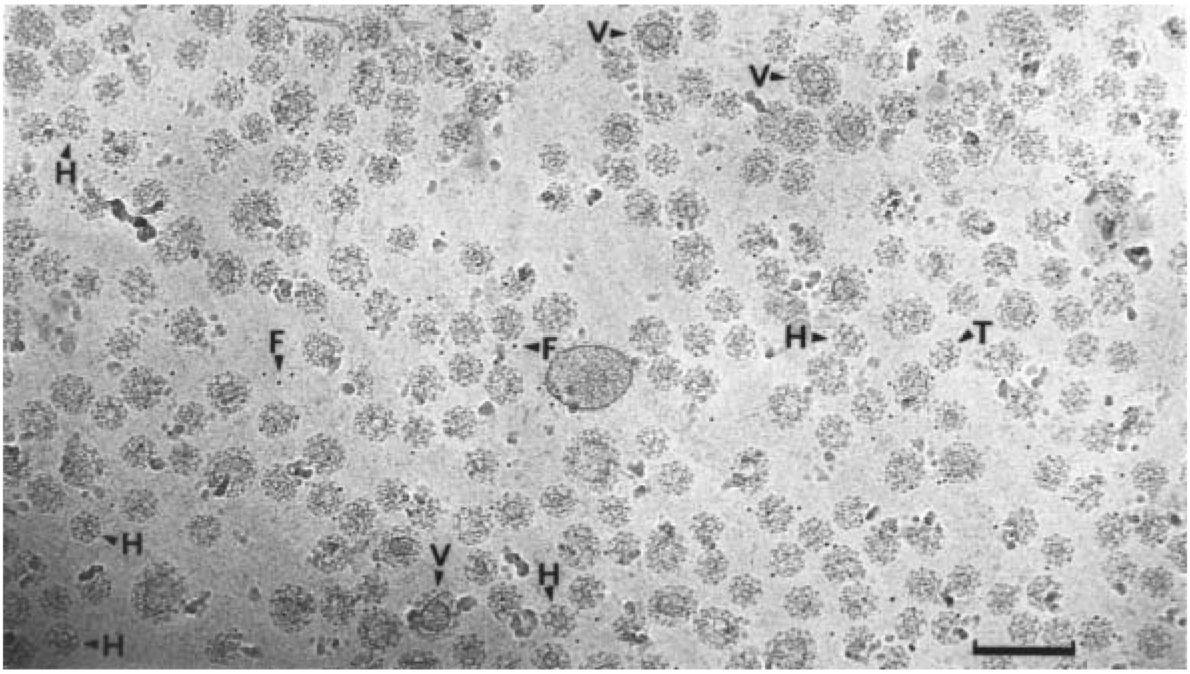
This system of budding coated vesicles is used again and again throughout cellular biology. Thus clathrin-coated vesicles are involved in **antigen presentation** in immunology (4) in delivering receptors and signaling molecules at the right place and time during development (5) and in recycling synaptic vesicle components in nerve synapses (6). In essence, clathrin and its associated proteins provide a mechanism for efficient recycling of specific receptors that are controlled in various ways. Other non-clathrin coated vesicle systems that contain a spectrum of related molecules and certain quite distinct coat components mediate sorting and recycling steps throughout the secretory pathway (7, 8). Clathrin-coated vesicles are more particularly associated with sorting specific molecules from the trans **Golgi** network into the pre-lysosomal/endosome network in addition to their endocytic function.

Unfortunately, **viruses** [eg, influenza virus (9)] exploit the endocytic system to infect cells, and various other pathogens and foreign substances do damage to cells by this route. Defects in the system are also the root cause of certain medical conditions, for example, familial hypercholesterolaemia (2), and I-cell disease (10).

1. Clathrin

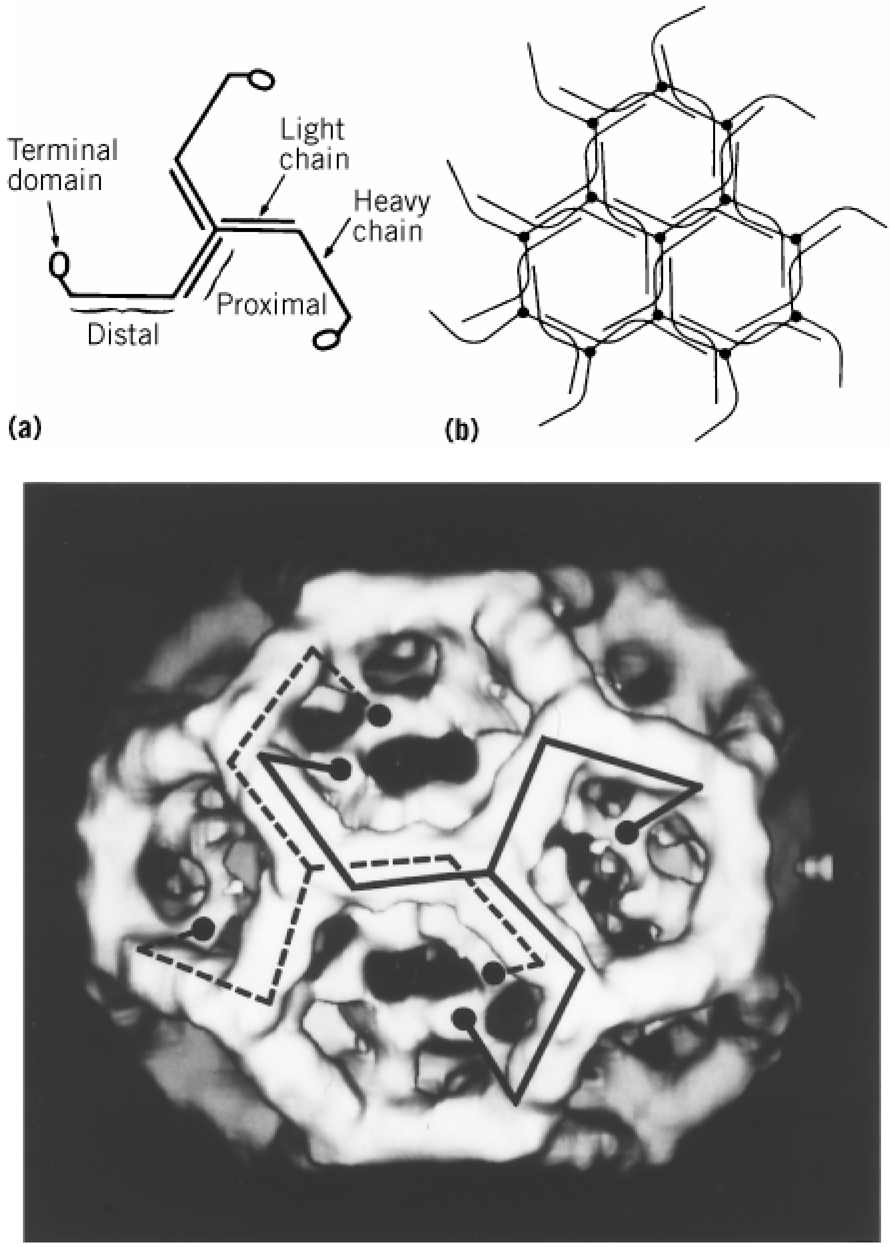
The function of clathrin is to form the strong outer, or cytoplasmic, surface of the coat, a remarkable honeycomb of hexagons and pentagons (Fig. 2). This flexible, structural network accommodates extensive areas of flattish membrane or encloses a range of vesicles, the smallest of which (250 Å diameter) is contained within a truncated icosahedron composed of 20 hexagons and 12 pentagons (for review, see Ref. 11).

Figure 2. Field of unstained placental coated vesicles in ice. Hexagonal barrels (H), tennis ball structures (T), larger coats containing vesicle (V), and ferritin (F) are indicated. Scale bar 200 nm. [Taken from G.P.A. Vigers, R.A. Crowther, and B.M.F. Pearse (1986) *EMBO Journal* **5**, 529–534.]



The modular design of the clathrin molecule is extraordinary and unexpected [Fig. 3(**a**)]. The overall shape is that of a triskelion (12, 13). Three heavy chains (180 kDa) and three light chains (one LCa and 2 LCb) form the three-legged structure. The C-termini of the heavy chains come together to form the hub of the structure, and the N-termini are in the terminal domains of the extended legs. The light chains are located along the proximal leg regions, possibly contributing in some way to the geometry at the vertex. Beyond the light chains, the heavy chains exhibit a kink, and the distal ends bend yet again to form a more globular terminal domain.

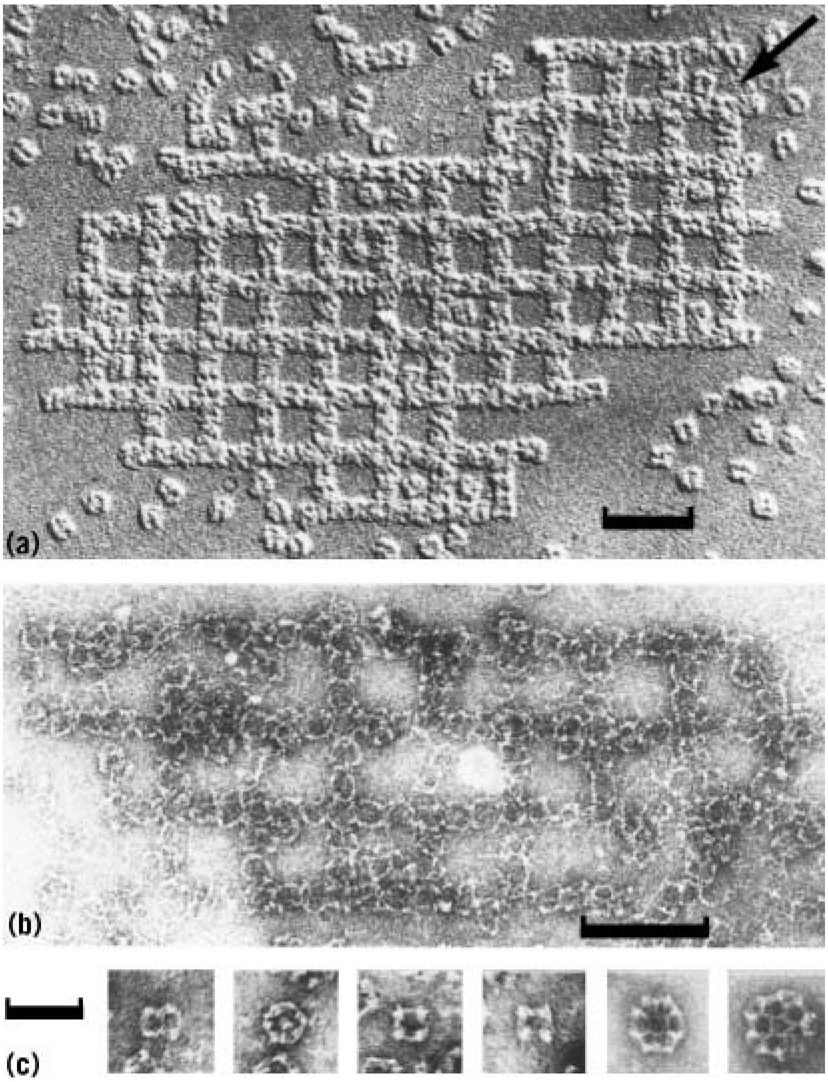
Figure 3. (**a**) Schematic drawing showing the modular structure of the triskelion. (**b**) Packing diagram showing how triskelions (lacking terminal domains for simplicity) form a hexagonal lattice. (**c**) Three-dimensional map of a clathrin cage containing 12 pentagons and 8 hexagons, computed from electron micrographs of unstained specimens embedded in vitreous ice. Each triskelion leg runs from one vertex along two neighboring polygonal edges and then turns inward. Its terminal domain forms the inner shell of density. [Taken from B.M.F. Pearse and R.A. Crowther (1987) *Ann. Rev. Biophys. Biophys. Chem.* **16**, 49–68.]



The packing arrangement of the triskelions (lacking terminal domains for simplicity) to form a hexagonal lattice is shown in Fig. 3(**b**). The profiles of two complete triskelions are shown at adjacent vertices of a clathrin cage in the form of a hexagonal barrel in Fig. 3(**c**).

In vitro in artificial conditions, clathrin exhibits its versatility as a construction molecule (Fig. 4). Among other small particles, clathrin makes cubes [Fig. 4(**c**)] a variant of the normal cage (14). In turn the cubes pack together to form remarkable arrays that resemble the foundations of buildings [Fig. 4(**a**) and (**b**)].

Figure 4. The most astonishing type of clathrin aggregate produced *in vitro* is an open square packing of cubes in a pattern reminiscent of the foundations of an ancient building visualized by (**a**) unidirectional shadowing; (**b**) negative staining in uranyl acetate (bar 0.2 μm); (**c**) comparison of cubes with cages, showing from left to right, two-fold, three-fold, and two four-fold views of the cube plus cages of the hexagonal barrel and truncated icosahedron type (football). The edge of the cube is more than twice as long as the vertex to vertex distance in the cages. Bar, 0.1 μm. [Taken from P.K. Sorger, R.A. Crowther, J.T. Finch, and B.M.F. Pearse (1986) *J. Biol.* **103**, 1213–1219.]



cDNAs coding for clathrin heavy chains and light chains have been **cloned** and sequenced (15, 16). The sequences suggest that part of the light chains form a coiled-coil structure with a corresponding part of the heavy chain to form the proximal legs. Extensive studies of the interaction between light chains and heavy chains, using antibodies and **mutational** analysis, have provided further evidence for the positioning of the light chains along the proximal leg, studies also indicate that the C-termini of the light chains occur at the vertex, where they might influence the structural angles involved in cage assembly (see, eg, Ref. 17). Now the prospects are good for obtaining crystals suitable for determining the high-resolution structure by X-ray crystallography from material produced by expressing parts of the triskelion (e.g., the hub region) in E. coli (17).

An interesting problem is how spurious clathrin cage formation is prevented in the cytoplasm or indeed how clathrin triskelions are disassembled from the coat structure after vesicle budding but are not prevented from forming coated pits. Recently, other attendant "**chaperone**" proteins, hsp70c and cofactor auxilin, have been found, which modulate cage assembly in the cytoplasm (18).

Cloning of clathrin genes has also led to further exploration of the role of clathrin by gene knockout and mutation. Deletion of the clathrin gene in yeast makes various strains very sick, slow growing, or dead. In those that survive, membrane organization is affected. In particular, the processing of pre-pro-a-factor by the kex2 endoproteinase is disrupted, leading to secretion of the immature a-factor and failure in sexual reproduction, and endocytosis of specific molecules, for example, kex2, is reduced, and the cells fill with abnormal vacuoles (19). In a temperature-sensitive mutant of clathrin, transient defects have been observed in sorting to the vacuole. The picture emerging (20) is not dissimilar to that observed in mammalian cells, that is, clathrin is involved in specific sorting steps both in the trans Golgi region and during endocytosis at the plasma membrane. These are the sites where the characteristic coated structures, now confirmed as clathrin-coated pits, were seen in abundance in early **electron microscope** pictures of fixed cell sections (21, 22). In a more complex creature, the slime mold, *Dictyostelium discoideum* (23), failure of clathrin heavy chain expression in cells impairs endocytosis and causes a lack of endosomes and contractile vacuoles, leading to defects in osmoregulation. Such cells also cannot follow the developmental program.

In *Drosophila melanogaster*, the clathrin heavy chain gene is essential (24). However, in flies, a dramatic effect is caused by the shibire mutation. This is a temperature-sensitive mutation in the molecule, now known to be **dynamin**, that is required for budding off a clathrin-coated vesicle (25, 26). At the nonpermissive temperature, the flies drop down as if dead. They cannot recycle their synaptic vesicle components in synapses and therefore cease to fly. However, when cooled down again, they start to fly as usual. These results confirm and extend the original electron microscope observations of abundant clathrin-coated vesicles in nerve synapses (27) and particularly the neuromuscular junction (28). Recent studies have identified many more components in the synaptic vesicle cycle (6) and explored their role by genetic manipulation in *Drosophila* and *Caenorhabditis elegans* [see Fig. 1; (29-32)].

In the worm, *C. elegans*, clathrin-mediated sorting has been implicated in the development of the vulval region (5). This study suggests that even apparently quite subtle perturbations in sorting by the coated vesicle system have profound effects in the development of a complex organism.

Recently, a second clathrin heavy-chain gene (CLTD) has been identified in humans, which has its maximal level of expression in skeletal muscle (33). This gene was found in the region commonly deleted in velo-cardio-facial syndrome (VCFS). Based on the location and expression pattern of CLTD, the suggestion is that **hemizygosity** at this locus plays a role in the etiology of one of the VCFS-associated **phenotypes**.

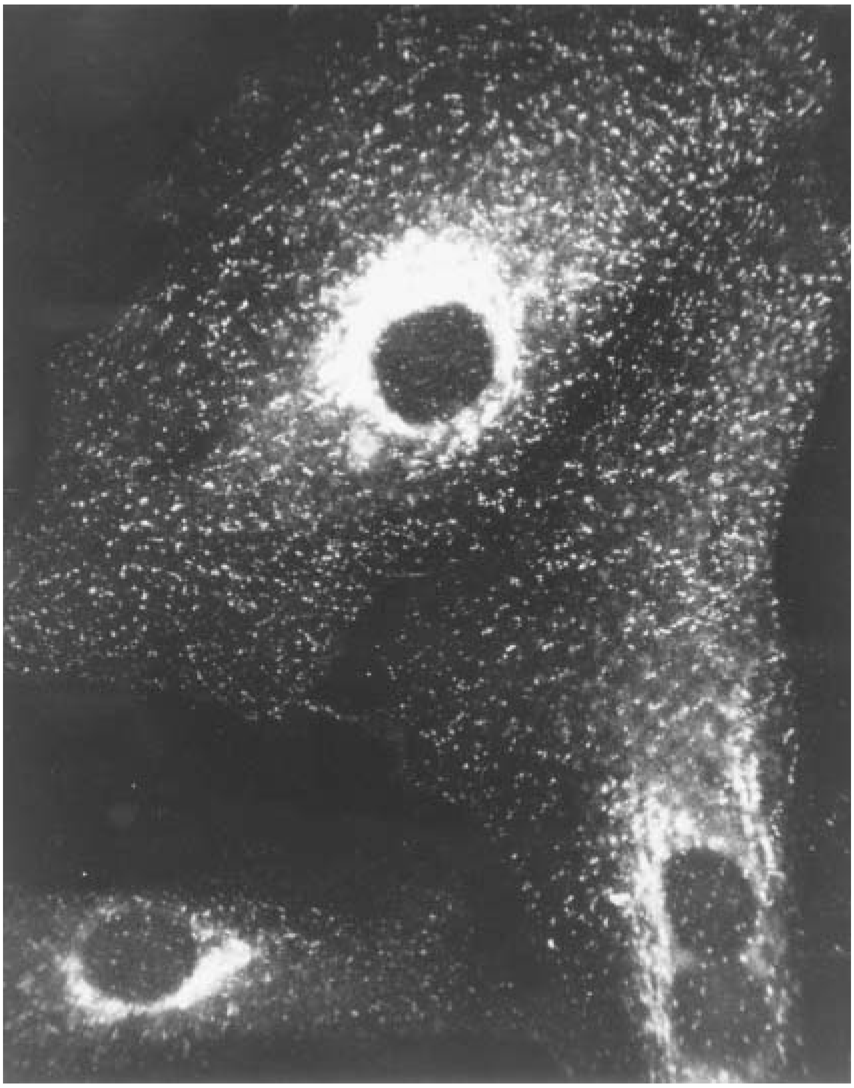
In summary, the clathrin molecule is an extraordinary building unit that has an intricate packing arrangement and forms coated structures of striking beauty. It carries out an important function.

The assembly properties of clathrin with the coated structures and vesicles it encloses have allowed purifying and identifying many of the other functional components involved. Chief among these are the clathrin adaptors, heterotetrameric complexes that coassemble with clathrin to form the vesicle coat.

1.1. Clathrin Adaptors

Two distinct types of clathrin adaptor complexes have been identified (3, 34). One of these (the PM-adaptor) consists of an a-adaptin (~100 kDa) combined with b-adaptin (~100 kDa) and two smaller subunits, AP50 and AP17. This adaptor is found by **immunofluorescence** with a monoclonal antibody against a-adaptin mainly in plasma-membrane-coated pits. In contrast, the second, the Golgi adaptor, consists of g-adaptin (~95 kDa) combined with b′-adaptin and two other subunits, AP47 and AP20, and is found by immunofluorescence using a monoclonal antibody against g-adaptin in coated pits in the trans Golgi network (Fig. 5).

Figure 5. Immunofluorescence localization of clathrin in fibroblasts showing coated pits on the plasma membrane and in
Robinson and B.M.F. Pearse (1986) *J. Cell Biol.* **102**, 48–54.]



Then the problem immediately arises of how these different adaptor coat complexes assemble on the others. In fact, the problem increases as new related adaptors (35), coats and coatomer complexes (7, the intracellular membrane system. The problem is still incompletely understood, although numerous identified in the cytoplasm and on membranes by a combination of **yeast** genetics and biochemistry. ways in the assembly of particular coated vesicles, their budding, and the control of membrane traffi earlier control proteins identified in post-Golgi membrane transport is Sec4, a small **GTP-binding** p range of GTP-binding proteins have been implicated throughout the recycling system, including Rab sense, **Rho** (38) and heterotrimeric G-proteins (39). For instance, distinct Rab proteins take up a cha particular membrane compartments in the cell and are found in coated pits on those membranes (40) the kinetics of fusion of vesicles from one compartment with another (41), although precisely how th is unclear. ARF, on the other hand, has been implicated in coat binding to membranes notably in the dynamins are concerned with actual budding of coated vesicles, as previously mentioned (see Fig. 1)

When clathrin-coated vesicles assemble on a membrane, they concentrate certain specific receptors i other membrane proteins behind. These specific receptors are recognized by features in their cytopla find its own characteristic **steady-state** distribution throughout the sorting system because each rece sequence. There is no single, defined, clear-cut sequence indicating that a receptor will assemble effi Nevertheless, at least in endocytosis, mutational analysis has pinpointed certain small groups of resid receptors that constitute primary sequence 'features' which allow the normal accumulation of their r Typically, such a 'feature' contains four residues, the first and probably most important of which is t residues (one or both of which is often charged) followed by a bulky aliphatic residue. Such tetrapep with the AP50 subunit of the plasma membrane adaptor (44). However, as more examples are studie possible signals exist and that other factors, such as phosphorylation of receptor tails, play a role in p

(46).

One of the most investigated examples of a receptor that is routed via clathrin-coated vesicles contai network (TGN) is the cation- independent mannose 6-phosphate/IGF-II receptor (MPR). The MPR r lumenal sorting signals, **mannose 6-phosphate**-containing sugar chains on **lysosomal** enzymes, and as cargo inside coated vesicles on their way to lysosomes (47, 48). The MPR has a 163-residue cyto features involved in directing the receptor along its complex, intracellular, recycling pathway, includ Tyr-Lys-Tyr-Ser-Lys-Val (49, 50). The tail region containing these residues, apparently, also acts as lysosomal enzymes, separately or in combination with the C-terminal region (51).

Both types of coated vesicle adaptors bind to the MPR tail. Recognition by the plasma membrane ad the tyrosine residues important for the endocytosis signal, but these same mutations do not abolish s adaptor (52). There is also evidence that the Golgi adaptor preferentially binds to the MPR tail when addition to these cytoplasmic features that determine the routing of the MPR, the extracellular doma play some role in the precise steady-state distribution of the receptor, at least in CV1 and COS cells (

1.2. Clathrin Coats

A low (~50 Å) resolution three-dimensional map of a clathrin coat has been generated from electron in vitreous ice (Fig. 6) (see Electron Imaging). The major components of the coat, clathrin, and adap from purified coated vesicles and separated. Three types of particles were reassembled from these pr clathrin cage itself. The second was derived from the first by partial trypsin digestion to remove the t triskelions, and the third was the complete coat containing both clathrin and adaptors. Maps of each computer imaging tilted specimens of several examples of individual particles of the three different t the incomplete structures from those of the complete coat, three different layers of the overall coat w coded in the image presented (Fig. 6). Thus the outer polyhedral clathrin lattice is highlighted in red, **domains** extends into the structure (green), and the adaptors form an inner shell (blue). These particl the absence of a vesicle, and in fact are actually too small to accommodate a vesicle. Probably the sn contain a vesicle is a truncated icosahedron, which can also be reconstituted as a coat. If purified coa projection they exhibit the same coat thickness composed of three shells of density, whereas the vesi of high density contained within the coat. Now a higher (~20 Å) resolution version of the coat struct types of hexagonal barrel preparations and the equivalent icosahedral specimens by using improved highly developed imaging techniques currently available. This will allow further identification of sm especially if combined with specific antibodies to decorate those domains. It is also possible to gene vesicles from their cytoplasmic constituents and membranes enriched in relevant proteins in physiol exciting prospect as it may lead to a greater understanding of the specificity underlying the assembly locate some of the controlling elements in the structure.

Figure 6. See color insert section. Clathrin encapsulates coated vesicles, the organelles responsible for uptake of essent especially across the placenta in mammals and into oocytes in chickens). (**a**) A three-dimensional map of a clathrin coa specimens reassembled from their constituent protein complexes. Colors highlight the outer polyhedral clathrin lattice (domains (green) revealed in (**b**) and an inner shell of adaptors (blue) exposed in (**c**). These three maps led to the descrip LEGO model. Cleveland Map

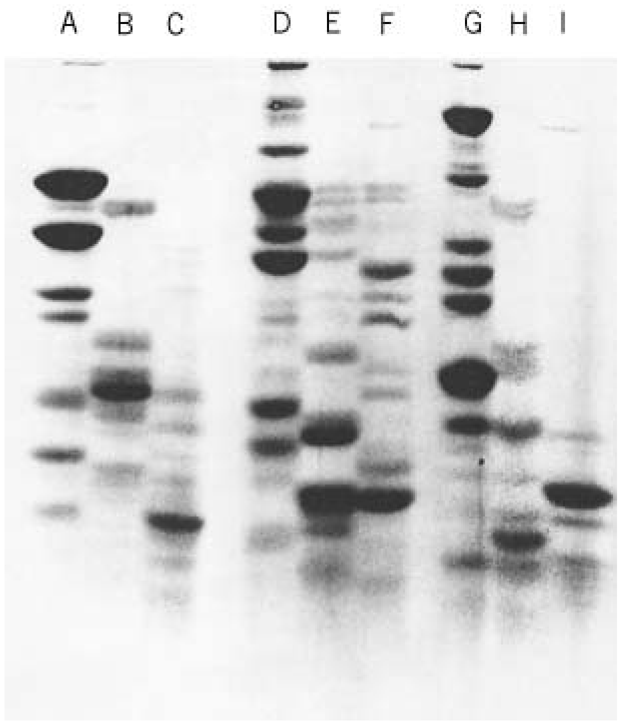
This method of peptide mapping involves generating of protein fragments via limited **proteolysis**, usually in the presence of **SDS**, followed by electrophoretic separation in SDS-PAGE. The resulting one-dimensional peptide patterns are characteristic of the protein substrate and are used to evaluate structural relationships between proteins and to aid identification of individual polypeptide chains. The technique is named after the first author of a 1977 publication describing the procedure (1), and many variants of this method have subsequently been presented (2).

After initial separation and excision from a primary gel, the protein substrate is digested in solution or, typically, in the stacking zone of the SDS-PAGE "mapping gel." The solution approach relies on purifying the protein by conventional chromatographic procedures or preparative SDS-PAGE followed by excision and electroelution from the gel (3). Protein preparation in SDS-containing gels is feasible because the subsequent digestion is performed in the presence of SDS. Frequently, SDS-PAGE isolation of the protein is possible at an early stage of purification, which is important when only a small amount of the protein is available. For Cleveland mapping, the efficient approach is to place the gel slice that contains the protein band of interest directly into a well of a second SDS/polyacrylamide gel and to add a suitable proteolytic enzyme. After electrophoresis just long enough for the protein substrate to migrate out of the gel piece and enter the stacking zone with the proteinase, the power is temporarily switched off and the gel left for digestion to take place. When the power is turned on again, the fragments of the protein substrate are separated from the proteinase and are mapped in the resolving gel. This procedure is preferred when handling small amounts of protein because of the direct transfer between primary and secondary gels.

The original Cleveland protocol (1) involved brief staining of the primary gel with Coomassie Brilliant Blue, followed by rapid destaining and excision of the band corresponding to the protein substrate. Because fixation of the protein is undesirable due to the electrotransfer, negative staining with 1 M KCl may be an alternative and has been used for subsequent electroblotting and sequence analysis (4). The excised gel piece is equilibrated in buffer containing 0.1% (w/v) SDS to unfold the protein substrate and to obtain a suitable pH of 6.8 for stacking gel electrophoresis and digestion (1). Often, 5 to 10 µg of protein substrate is required for application onto the primary gel to generate a proteolytic pattern detectable by Coomassie Blue staining, but the minimum amount can be substantially lowered if **silver staining fluorescence** techniques or **radiolabeling** are used to visualize the peptide map.

After equilibration, the gel piece that contains the protein is placed in a well of the "mapping gel," and, in the original protocol, overlaid with a solution of the appropriate proteinase in the same buffer. In later protocols, loading of the proteinase below the gel piece is suggested to avoid a variable depth of enzyme solution around the gel piece (2). Once a narrow stack has formed after the initial period of current, usually when the tracking dye (e.g., bromphenol blue) is approaching the bottom of the stacking gel, the power is turned off for 30 to 60 min. This is normally sufficient for the proteinase to cleave susceptible peptide bonds, which typically generates 10 to 20 fragments of 50- to 70-kDa proteins (1). It is crucial that the proteolytic enzyme is active in 0.1% SDS (up to 0.5% for in-solution digestions). Suitable enzymes are **trypsin**, a-**chymotrypsin**, and papain, in addition to the popular V8 proteinase from *Staphylococcus aureus*. All are added in proportions corresponding to an enzyme to substrate ratio in the range of 1:10 to 1:50 (w:w). After digestion, electrophoresis is resumed, and the resulting fragments are resolved, typically in a 15 or 20% acrylamide gel of the discontinuous type (Fig. 1). A unique proteolytic pattern is obtained for each protein substrate and for each individual proteinase. This discriminating feature makes Cleveland mapping useful as a tool for visually judging the similarity between proteins.

Figure 1. One-dimensional Cleveland maps of albumin (A,D,G), tubulin (B,E,H), and alkaline phosphatase (C,F,I), generated by cleavage with papain (A–C), *Staphylococcus aureus* V8 proteinase (D–F), and chymotrypsin (G–I), followed by SDS-PAGE in a 20% (w/v) acrylamide gel. Each combination of protein substrate and proteinase gives a unique pattern. From Ref. 1 with permission.



In addition to enzymes, specific chemical cleavage is employed where the protein substrate within a gel is treated in a test tube. Suitable reagents are **cyanogen bromide** for cleavage after methionine residues, *N*-chlorosuccinimide for cleavage at tryptophan, **hydroxylamine** for cleavage at Asn-Gly peptide bonds, and formic acid for cleavage at Asp-Pro bonds. As for the size of the protein substrates, the method is generally applicable to polypeptide chains in the range 10 to 100 kDa.

Peptide fragments smaller than 10 kDa are difficult to resolve into informative peptide maps, although separating such small peptides is possible by using different SDS-PAGE systems. An alternative is to recover small fragments separately by size exclusion chromatography for subsequent peptide mapping by reverse-phase **HPLC**. This can be useful also for proteins large than 10 kDa in order not to waste small fragments (5).

Clonal Selection Theory

At the beginning of the twentieth century, Ehrlich was the first to propose that antibodies did exist prior to the introduction of antigen or immunogen and that antigenic stimulation only promoted amplification of molecules of the appropriate specificity. This proposal was quite pertinent, because it contained several key ideas, proven correct some 70 years later. One is the selective process of a preexisting repertoire, the other is that immunoglobulins (Igs) may exist as surface or secreted molecules. The only aspect that was not verified is that Ehrlich imagined a cell to express many different antibodies. After a long period during which hapten analysis indicated the exquisite precision of antibody–antigen interactions, it seemed impossible that antibody structures might preexist to recognize laboratory artifacts, like the haptens being studied. This resulted in the template theory of antibody formation, which required the presence of antigen prior to the synthesis of the corresponding antibodies. Revival of the selection theory was proposed in 1955 by Jerne, but it took another 4 years before the final form of the “clonal selection theory” was put forward by Burnet. The essence of the theory was that antibody specificities were preformed, but in a clonally distributed manner, so that one cell makes only one antibody of one given specificity. This was crucial to provide a mechanism accounting for acquisition of discrimination between self and nonself, after the observation on induction of immunological **tolerance** by the group of Medawar in 1953,when it was demonstrated that tolerance was an acquired phenomenon, resulting from a contact between the immature immune system and the self antigens during gestation or the perinatal period. Burnet most simply explained tolerance by a deletion of those clones that could interact with self components, leading to the concept of “forbidden clones.” Once the basic anti-nonself repertoire established, an antigen was seen as merely selecting and amplifying the cell population of clones expressing the corresponding specific antibodies.

Many investigators worked to define models that would prove the clonal theory, and the literature is amply documented on this point, with many very elegant approaches, such as those based on limiting dilutions, either *in vitro* or *in vivo* after transfer in irradiated mice. The ultimate proof came from molecular analysis, first at the protein level on myeloma proteins and then when the mechanism of gene rearrangement of Ig **genes** was elucidated, under the control of allelic exclusion. Some exceptions to the clonal expression of Ig molecules have been periodically reported. Some were not exceptions, as in the case of lymphocytes coexpressing multiple isotypes that, in fact, share identical V_H and V_L regions, and therefore having the same specificity. Upon reactivation of the recombinase genes upon immunization, for example, a transient coexpression of different V genes may occur, leading to secondary gene rearrangements. But this rarely results in long-term production of antibodies of different specificities. The clonal theory is widely accepted and considered proven, and the fantastic use of monoclonal antibodies is (for most biologists) daily living proof of its pertinence.

Cloning

The word "cloning" has several different meanings. For example, it is possible to clone cells, that is, to cause cells to reproduce themselves so as to make a population of identical cells. In molecular biology, any piece of **DNA** can be cloned—inserted into a **vector** that replicates in a host to produce many copies of the same recombinant vector. It is also possible to clone **genes**. Gene cloning is the process of identifying and isolating a specific gene of interest. Cloning genes is a major focus of molecular biology, and the ability to clone genes has revolutionized biology. Once a gene is identified and cloned into an appropriate vector, it can be manipulated in many different ways. Cloning dramatically amplifies the DNA so that it can be **sequenced**. A cloned gene inserted into an expression system creates an organism that produces up to 25% of its total protein or more as the gene product, allowing large-scale production of the protein (1). A cloned gene can be mutated, and the mutated form inserted back into an organism that lacks a functional copy of the gene (2). This allows structure-function analysis of the gene product. A cloned gene or set of genes can be introduced into a new host to create a new metabolic pathway or to modify an existing pathway (3).

In many cases, gene cloning is carried out by fragmenting the **genomic** DNA from the organism containing the gene of interest and inserting the fragments into self-replicating DNA molecules (vectors) using recombinant DNA techniques; **transforming** the resultant population of recombinant molecules, which comprise a DNA library, into a host organism, screening or selecting the transformants to identify cells that contain the desired DNA, and isolating the vector DNA.

1. Preparation of DNA for Cloning

Genomic DNA must be fragmented before cloning into a suitable vector. It is important to have fragments that contain the gene intact. One way to ensure this is to use a restriction enzyme that makes frequent cuts in the DNA under conditions of partial digestion (so that only some of the sites are cleaved) so as to obtain fragments of the desired size. The restriction enzyme *Sau*3A is often used because it has a four-base recognition sequence and therefore cuts DNA at many sites in the genome. Additionally, it produces cohesive, sticky ends that ligate with BamHI, a site often present in polylinkers. Mechanical shearing also fragments the DNA, but sheared DNA cannot be cloned directly. First, the ragged ends must be filled in and polylinkers added.

Because small fragments of DNA **ligate** to a vector more readily than large fragments, the DNA to be cloned is often fractionated by sucrose density gradient centrifugation (see Sedimentation Velocity Centrifugation) to obtain DNA of the desired size (pp. 2.85–2.86 of Ref. 4). It is important to set up the conditions for ligation so that most of the recombinant molecules produced contain only a single DNA fragment. This means that nearly equal numbers of vector molecules and fragment molecules should be present and that the total DNA concentration should not be too high (~40 µg of vector DNA per mL).

It is necessary to produce a large enough number of transformants or recombinant **bacteriophage** to have a high probability that a fragment carrying the intact gene is present in the population. The exact number depends on the size of the genome from which the gene is being cloned (the larger the genome, the more transformants need to be screened) and the size of the inserts (the larger the insert size, the fewer transformants need to be screened). A major problem in cloning is restriction enzymes in the host, which can degrade foreign DNA. Mutant strains of *Escherichia coli* are available that lack restriction enzymes, and these are best for constructing large libraries for screening or selection. Once a gene is cloned, restriction enzymes in a host are not usually a problem because large amounts of DNA overcome the restriction barrier (5).

Prokaryotic genes are usually cloned from genomic DNA, whereas **eukaryotic** genes are often cloned from complementary DNA (cDNA), which is prepared by copying messenger RNA with **reverse transcriptase.** Most eukaryotic genes contain **introns**, which prevent them from being expressed in prokaryotes, but the introns are not in the cDNA. The cDNA clone is often used as a probe to isolate the gene from a genomic library. The genomic clone can be sequenced to identify the nature and location of the introns and the upstream and downstream sequences of the gene.

2. Cloning Vectors

There are four general types of vectors that are used in *E. coli*: **plasmids**, phage, **cosmids** or bacterial artificial chromosomes (BACs):

1. Plasmids have the advantage that they are smaller than the other vectors and usually give larger amounts of vector DNA from a given volume of culture because of their high **copy number**.
2. Phage vectors allow larger sized inserts of foreign DNA, so that a smaller number of **plaques** are needed to give a high probability that the entire genome of the organism is present in the library that is being screened. Furthermore, phage systems give more plaques per weight of DNA than plasmids give colonies, and plaques are easier to screen than colonies because they are smaller and more uniform. Phage T4 vectors allow cloning inserts as large as 120 kbp (6), whereas phage P1 vectors allow 80-kbp inserts (7), and lambda phage vectors allow up to 40-kbp inserts (pp. 2.2 to 2.125 of Ref. 4). Once a positive plaque is identified, the insert DNA is subcloned into a plasmid vector to take advantage of the greater amplification and ease of DNA preparation associated with plasmid vectors.
3. Cosmid vectors combine features of the preceding two classes because they can be packaged into phage but also replicate as plasmids. They also allow inserts up to 40 kbp (8).
4. Bacterial artificial chromosomes are based on the single-copy **F factor** plasmid and accept >300-kbp DNA fragments (9). Another important system for cloning very large DNA pieces is **yeast artificial chromosomes** (YAC). YACs accept fragments over 200 kbp and are used in genome sequencing and positional cloning of genes (10). Although **yeast** is not as easy to work with as *E. coli*, it is useful for studying eukaryotic genes that cannot be expressed in *E. coli.*

3. Identifying the Gene of Interest

Screening is usually the most difficult step, and there are many different approaches available. The simplest method is to complement a mutant gene in a host organism (see Complementation), which allows direct selection of the desired clone (11). A powerful example of direct selection is cloning a **transposon-tagged** gene where selection is for antibiotic resistance encoded in the transposon.

Another approach is to screen transformant colonies for the gene product, either with specific antibodies (pp. 12.11–12.29 of Ref. 4) or by an enzymatic assay (12). This requires a sensitive, specific assay because foreign genes are often expressed at a low level, and enzymes from the host organism must not interfere with the assay. In addition, the gene to be cloned needs to be expressed in the host organism.

The most general screening approach is to transfer the colonies to a filter, lyse the cells, **denature** the DNA on the filter and **hybridize** a labeled nucleic acid probe to the filter (see Southern Blots (DNA Blots)). The probe pairs with complementary sequences in the DNA on the filter, and the colony to which the probe hybridizes is visualized by the label. There are various methods to design or obtain an oligonucleotide probe that specifically hybridizes to the desired gene.

If one wants to clone the gene coding for a known protein, it is possible to sequence the protein, usually at its N-terminus (see Edman Degradation), and to use reverse translation to determine the probe sequence. However, sequences from internal peptides produced by specific cleavage of the polypeptide chain (eg, by an **arginine**-specific proteinase or by **cyanogen bromide** cleavage at **methionine residues**) are also used if the N-terminus is blocked or if the N-terminal sequence is unsuitable for reverse translation (pp. 11.44–11.57 of Ref. 4).

Another method is using a segment of the DNA from the gene of a closely related organism as the hybridization probe (13). A modification of this approach is looking at **homologous** sequences from a set of organisms to identify highly conserved regions that are used to design an oligonucleotide probe specific for the desired gene. It is important to choose organisms with DNA base compositions close to that of the organism from which the gene is to be cloned.

With the large amount of genomic and cDNA sequence information (see Expressed Sequence Tag) becoming available in computer databases, genes of interest are frequently identified during database searches. Hybridization probes are designed from the sequence information and used to screen a library or to amplify the gene directly.

An ingenious way of selecting for a full-length clone in a phage vector, when a partial clone is available, is inserting the sequence next to the *sup*F gene in a plasmid, infect *rec*A$^+$ cells carrying the plasmid with the phage library, and plate the resulting phage on an *E. coli* strain, where only phage containing *sup*F grows (14). Recombination between the complementary sequences introduces the *sup*F only into the desired phage.

4. Positional Cloning of a Gene Identified by its Mutant Phenotype

Often genes are identified because they have an interesting **phenotype** when mutated. The mutation is mapped by using DNA-based markers. The most closely linked marker is used as a hybridization probe to screen a YAC, BAC, or cosmid library, thus initiating a **chromosome walk** to the gene (15). Once a library clone is identified that is deemed to contain the gene of interest, it is subcloned into a vector used to transform the mutant. The subclone containing the gene is identified by its ability to complement the mutant phenotype.

4.1. Potential Problems with Library-Based Cloning

One problem with direct selection is potential contamination of the library with host DNA, which leads to cloning a host gene, rather than the gene from the original organism. Therefore it is necessary to show that genes isolated by complementation are from the desired organism, which can be done by a Southern blot. Other potential cloning problems are that some DNA fragments cannot be cloned because they contain a poison sequence. DNA fragments containing **repeated DNA** sequences are often unstable, because they recombine easily. So *rec*A mutant strains of *E. coli* are often used as a host for cloning to minimize recombination (16).

A major problem in cloning a DNA fragment that has identical ends (cohesive or blunt) is recircularization of vector molecules that do not contain an insert because the two ends of the cut vector are also identical. This gives a high background of transformants or plaques lacking an insert. One method of minimizing this problem is treating the cut vector with calf alkaline phosphatase to remove its 5′ phosphate groups (pp. 1.60–1.62 of Ref. 4). Dephosphorylated vector molecules cannot circularize, but they ligate to the 5′-phosphate groups on the DNA fragments to be cloned. The resulting recombinant molecule circularizes, producing a circular molecule with a single-stranded nick in each strand. These molecules give transformants. It is necessary to completely inactivate the alkaline phosphatase before the DNA to be cloned is added to the vector. The dephosphorylation reaction must be run under conditions that remove most 5′-phosphate groups but do not inactivate the plasmid, so the reaction has to be monitored carefully.

Another method of dealing with the problem of vector molecules lacking inserts is blue-white screening. Many *E. coli* vectors contain an N-terminal portion of the **beta-galactosidase** gene that codes for the a-fragment that complements the inactive b-fragment. A polylinker is introduced into the b-galactosidase gene so that the a-fragment is inactivated when a DNA molecule is ligated into the polylinker. The ligation mixture is transformed into an *E. coli* host that produces the b-fragment, and the transformants are plated on selective plates. The colonies that contain an insert are white, whereas colonies without an insert are blue (pp. 1.85–1.86 of Ref. 4).

When a probe that hybridizes to the gene to be cloned is available, the cloning process is simplified by using the probe to identify an appropriately sized restriction fragment that contains the gene by using Southern blots run on digests of a number of restriction enzymes. The appropriately sized fragments are eluted from a preparative agarose gel electrophoresis run on genomic DNA digested with the chosen restriction enzyme. The fragments are ligated into a vector cut with a compatible restriction enzyme, and the resulting transformants are screened with the probe. This process significantly reduces the number of colonies or plaques that need to be screened (1 of 40 positive vs. 1 of 1,000 for a *Thermomonospora fusca* gene) (17).

5. PCR to Clone Genes

Whenever sequence information is available for a gene, it is possible to design **PCR** primers that amplify all or part of a gene directly from DNA isolated from the desired organism. The PCR product is used as a probe to screen for the clone, or the PCR product is cloned.

6. Insertional Mutagenesis

Transposons (see Transposon Tagging) and retroviruses are used as insertional mutagens to “tag” genes. If a previously identified transposon or retrovirus inserts into a gene, the sequence of the transposon or retrovirus is used as a tag to identify the host DNA flanking the insertion. Techniques, such as IPCR, plasmid rescue, and library screening (using the element as a probe) are all successful in identifying flanking DNA from a “tagged” individual.

7. Cloning Tissue- or Treatment-Specific Genes

In some cases, researchers do not want to identify a specific gene, but instead they are interested in a certain class of gene, for example, liver-specific genes or genes induced by a hormone. There are numerous methods for identifying such specific types of gene, including subtractive hybridization, differential display, database analysis, and analysis of microarrays (see Expressed Sequence Tag).

8. Immunochemical Methods

Another method for cloning a gene, where the protein has been identified previously, is using an antibody that recognizes the protein to immunoprecipitate **polysomes** making the protein and then to isolate its mRNA. The mRNA produces a cDNA copy that is cloned. The cDNA clone is also used as a probe to isolate a genomic clone.

9. Conclusion

There are a large number of ways to clone a gene or set of genes of interest. The method used depends on what materials are available, such as protein sequence, antibodies to the protein coded for by the gene, gene sequence information, useful libraries for screening, or a “tagged” or “untagged” mutation in the gene of interest. The purpose of cloning a gene is to generate large amounts of DNA for further analysis, such as sequencing or mutational analysis. A cloned gene is also useful for producing the protein or for **antisense** studies, and in some cases it is used to disrupt the endogenous gene by homologous recombination. A cloned gene is also useful as a probe in **gene expression** studies. Cloning a gene is one of the first steps to understanding its function.

ClpAP and ClpXP Proteinases

These large ATP-dependent proteinases are involved in **protein degradation** in prokaryotes. Each enzyme is composed of two subcomplexes, both of which are essential for ATP-dependent **proteolysis**. (A similar enzyme system is also found in chloroplasts of plant.)

1. ClpP

The ClpP proteolytic component is a serine proteinase composed of 14 identical subunits, organized in two seven-membered rings. The rings enclose a central chamber where the active sites are localized. To be degraded, proteins must enter this chamber through openings in the rings. By itself, ClpP can hydrolyze small peptides but not polypeptides. To degrade proteins, this proteolytic component must associate with either of two homologous ATPase complexes (ClpA or ClpX), which determine the substrate specificity.

2. ClpA and ClpX

ClpA and ClpX complexes are hexameric rings that associate with each end of the ClpP to form a four-ring active enzyme. These ATPases bind different types of polypeptides, probably unfold them, and facilitate their entry into ClpP for degradation.

Coding Strand

This is an ambiguous term, and perhaps best avoided. Because **DNA** is double-stranded and only one strand of the DNA of a **gene** is usually **transcribed** to make **RNA**, there is a distinction between the transcribed and the nontranscribed strand at any point in the genome. Using the useful terminology "upstream"/"downstream" to refer to the direction in which the gene is transcribed and translated, the nontranscribed DNA strand runs upstream to downstream in the chemical direction 5′ to 3′, whereas the complementary transcribed strand has the opposite 3′ to 5′ polarity. The transcript RNA runs 5′ to 3′, like the nontranscribed DNA strand. Thus, the nontranscribed DNA strand matches the mRNA in its base sequence (with thymine replacing uracil), not the transcribed strand which has the back-to-front complements of the codons, as explained in Figure 1. Consequently, in predicting encoded amino acid sequence of the encoded protein from a gene DNA sequence, one uses the sequence of the nontranscribed DNA strand because this is the strand from which the codons can be read directly. For this reason, the nontranscribed strand is sometimes called the coding strand.

Some workers, however, adopt the opposite convention because, after all, the transcribed strand provides the information for the codon sequence of the mRNA. Therefore, it is best to eschew the coding versus noncoding terminology and to distinguish the two DNA strands as transcribed versus nontranscribed.

It should be remembered that both strands of a particular segment of DNA can be transcribed, though probably never in the same cell type and at the same time. This may be the case, for example, when genes are "nested" within the introns of other genes (see Gene Structure).

Codon Usage and Bias

The genetic code is degenerate, in the sense that (except for methionine and tryptophan) a given amino acid can be specified by either two, three, four, or six alternative **codons**. When the same amino acid is specified by three, four, or six codons, they cannot all be recognized by the same transfer RNA anticodon, and so in these cases at least two or three distinct transfer RNAs must carry the same amino acid (isoaccepting) but with different anticodons (see Transfer RNA and Aminoacyl tRNA Synthetases).

Not all codons for a particular amino acid are used equally frequently. Generally, strong biases favor some codons and are against others, and different codons are favored in different organisms (Table 1). Some genes within an organism show much greater codon usage bias than others, and there is a strong correlation between the degree of bias shown by a gene and its level of expression in terms of the amount of encoded protein produced. For example, in all organisms where the matter has been examined, the genes that encode ribosomal proteins, which are always relatively abundant, are among the most highly biased. The excellent correlation in *Escherichia coli* between codon bias and level of protein product is shown in Fig. 1. This suggests that the preferred codons are more efficiently translated than the relatively rarely used codons.

Figure 1. Frequency of using favored ("optimal") codons in *E. coli* genes plotted against the quantity of the gene protein products. From Ref. 1 by permission.

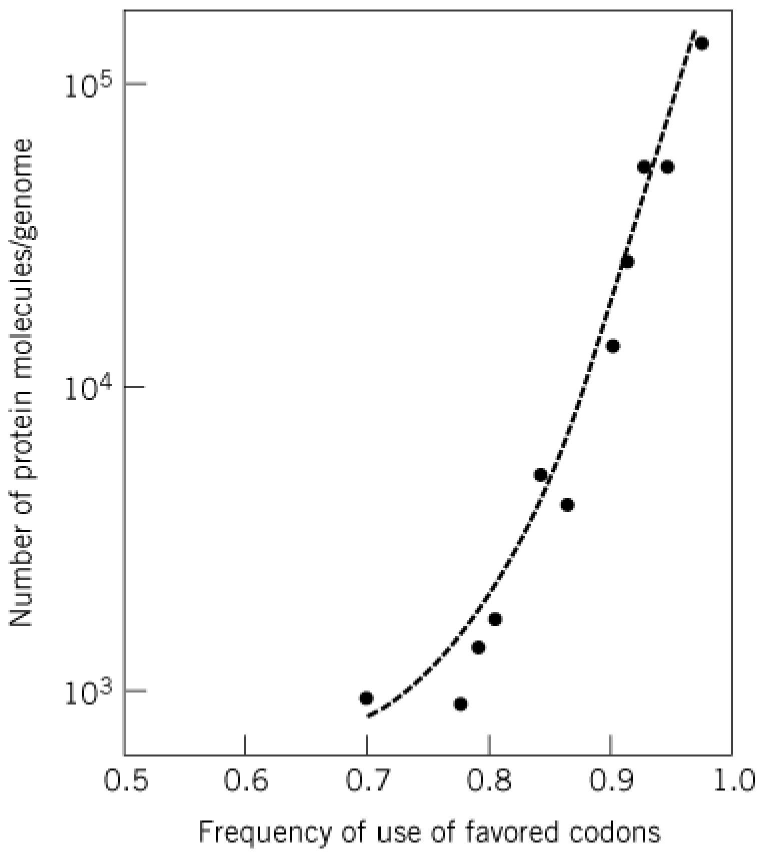

Table 1. Codon Bias in Different Organisms[a]

Amino Acid	Possible Codons	Favored [and Disfavored] Codons: *Drosophila*	*Saccharomyces*	*Escherichia coli*
Leucine	CUU CUC CUA CUG UUA UUG	CUG	UUG	**CUG**
Arginine	CGU CGC CGA CGG AGA AGG	CGU CGC	AGA	CGU CGC
Proline	CCU CCC CCA CCG	CCC	CCA	CCG
Glutamine	CAA CAG	**CAG**	**CAA**	CAG
Lysine	AAA AAG	**AAG**		
Alanine	GCU GCC GCA GCG	GCC	GCU,GCC	
Valine	GUU GUC GUA GUG	*[GUA]*	GUU GUC	*[GUC]*
Glycine	GGU GGC GGA GGG	*[GGG]*	**GGU**	GGU GGC
Serine	UCU UCC UCA UCG AGU AGC	*[AGU]*	UCU UCC	UCU UCC AGC
Threonine	ACU ACC ACA ACG	ACC	ACU ACC	ACC,ACU
Isoleucine	AUU AUC AUA	AUC	AUU AUC	AUC
Asparagine	AAU AAC	**AAC**	AAC	**AAC**
Phenylalanine	UUU UUC	**UUC**	UUC	UUC
Tyrosine	UAU UAC	UAC	UAC	UAC
Glutamic acid	GAA GAG	**GAG**	GAA	GAA
Cysteine	UGU UGC	**UGC**	UGU	
Histidine	CAU CAC	CAC		CAC
Aspartic acid	GAU GAC			

[a] *Drosophila* data from a pool of 15 high-expression genes (3); *E. coli* and *Saccharomyces* from pools of highly expressed genes (1, 2). The codons indicated show strong majority usage (heavy type indicates 90%) except those italicized in brackets where the bias is strongly against. Blanks indicate no strong bias or insufficient data.

Different translation efficiencies of different codons is largely accounted for by a number of factors, pointed out by Ikemura ("Ikemura's rules"), the first of which is that when different isoaccepting tRNAs are present at very different concentrations, the favored codons will be those that are serviced by the most abundant tRNAs. There is evidence for this generalization from *E. coli, Saccharomyces* (1, 2) and *Drosophila* (3). Where a particular amino acid has both codon bias and unequal concentrations of isoaccepting tRNAs, the rule holds virtually without exception. For example, the favored arginine codons in *E. coli* are CGU and CGC, whereas AGA is strongly favored in *Saccharomyces*. In the former organism, the tRNA that has anticodon GCI (I for inosine) recognizing CUC/U is present at several-fold higher concentration than that recognizing AGA, with anticodon UCU* (U* is a modified uridine), whereas in yeast the tRNA inequality is very much the opposite.

The different relative abundances of tRNAs do not, however, explain codon usage bias when it operates between codons served by the same isoaccepting tRNA. Here the bias can be explained in terms of Ikemura's other rules, which account for the fact that an anticodon may pair more comfortably with one codon than with another, even though it recognizes both. Thus an anticodon that has a thiolated uridine or 5-carboxymethyl uridine in the 5′ position (the "wobble" pairing position, see Anticodon) prefers a 3′ A in the codon over 3′ G (rule 2); 5′ inosine (I) prefers U or C to A, even though it pairs with all three (rule 3); and codon-anticodon interactions dependent on the relatively weak A–U or T–A pairings in both of the first two positions work best with a stronger G–C or C–G pairing in the third (rule 4). Examples from *E. coli* consistent with these rules are the biases in favor of GAA over GAG (rule 2), CGU or CGC over CGA (rule 3) and AUC over AUU (rule 4) (1).

1. Effects of Altering Codons

If the more rarely used codons really are translated relatively slowly, one would expect that their introduction into normally highly expressed genes would decrease protein yields. This prediction has been tested experimentally, and substantial effects have indeed been found, especially when multiple and contiguous rare codons have been introduced into the upstream ends of open reading frames. Hoekema et al. (4) carried out a total replacement of the normal codons by synonymous infrequently used codons in the upstream third of the normally highly expressed *Saccharomyces PGK1* (phosphoglycerate kinase) gene and found a tenfold reduction in enzyme yield. There was also a threefold reduction in the level of **messenger mRNA**. In the gene encoding glutamate dehydrogenase, in *Neurospora crassa*, a double frameshift mutant that generated three successive rare codons, numbers 54 to 56 of a 453-codon sequence, brought about a threefold reduction in enzyme without appreciable effect on mRNA level (5). And in *E. coli*, the insertion of an additional mRNA segment containing five contiguous rare AGG arginine codons 24 bases downstream of the initiation codon of *lacZ* (**b-galactosidase**) reduced the enzyme yield by 90% in the early exponential phase and virtually to zero thereafter. Another insertion, identical except that AGG was replaced by the favoured CGU codon (6), had little effect. However, when the distance between the inserted AGG-containing sequence and the initiation codon was increased by additional insertions, the yield of b-galactosidase increased almost linearly with distance, as if the rare codons have maximum effect when translation is just starting and progressively less effect as it proceeds. The mechanism of such distance-dependence is unclear. Chen and Inouye (6), reviewing the positions of rare codons in *E. coli* genes, noted that they fall within the first 25 codons after the initiating AUG and suggested that their function is to modulate the rate of translation. This would only be a regulating mechanism if there were some means of increasing or decreasing the effect, for instance, by adjusting the levels of the least abundant tRNAs. But there is as yet no evidence for this.

If rare codons have strong negative effects on the protein yields of genes, they may be an obstacle to the expression of **transgenes** in alien host cells. A codon that is abundant in the donor organism may be rare in the recipient. Therefore, to obtain a good yield of a foreign protein, it may be necessary to adjust the coding sequence of the introduced gene by *in vitro* DNA manipulation. Perhaps the best example of successful application of this idea is provided by the work of Cormack *et al.* (7), who wished to confer on the fungus *Candida albicans* the ability to produce the green fluorescent protein (GFP) native to the jellyfish *Aequoria victoria*. Introduction of the natural GFP gene into *Candida* on a replicating plasmid **vector** resulted in the formation of some GFP mRNA in the fungus, but no detectable GFP. Replacing the single CUG codon with CUU, in case the *Candida* coding idiosyncracy of translating CUG as serine rather than leucine (8) was responsible for the failure, brought no improvement. But when all the *Aequoria* codons that are comparatively rare in *Candida* were replaced by codons that are common in the fungus, introduction of the transgene produced an abundance of GF protein. The level of GFP mRNA was also considerably increased, which suggests, as does the yeast *PGK1* example mentioned before (4), that blocked translation, and hence failure to cover the mRNA with ribosomes, may expose the mRNA to enzymic degradation.

Coenzyme, Cofactor

The term cofactor has been used as a general term to indicate that a compound was required, in addition to the enzyme, for a reaction to proceed and that the compound remained unchanged at the end of the reaction. Cofactors were considered to be either activators, such as metal ions, or *coenzymes* , organic molecules that participated in enzymic reactions. **NAD** and NADP were named originally as Coenzyme I (CoI) and Coenzyme II (CoII), respectively, because in studies on metabolic reactions they appeared to function as electron carriers. They certainly perform that role in coupled reactions, such as those catalyzed by glyceraldehyde-3-phosphate dehydrogenase and lactate dehydrogenase:

$$\begin{aligned}&\text{Glyceraldehyde-3-phosphate} + \text{NAD} + P_i\\&\rightleftharpoons \text{1,3-bis glycerophosphate} + \text{NADH} + \text{H}^+\end{aligned} \tag{1}$$

$$\text{Pyruvate} + \text{NADH} + \text{H}^+ \rightleftharpoons \text{lactate} + \text{NAD} \tag{2}$$

with the sum of reactions (1) and (2) being

$$\begin{aligned}&\text{Glyceraldehyde-3-phosphate} + P_i + \text{pyruvate}\\&\rightleftharpoons 1,3\text{-bis glycerophosphate} + \text{lactate}\end{aligned} \tag{3}$$

However, this is not the role of NAD/NADH when functioning as substrates for a dehydrogenase reaction. Similar comments can be made about Coenzyme A (CoA), which functions as an acyl carrier, and Coenzyme Q (CoQ, ubiquinone), which acts as an electron carrier. In this connection, it is of interest that nucleoside phosphates, such as ATP, are not usually classified as carriers of phosphoryl groups.

Other compounds that have been considered as coenzymes are biotin, flavin adenine di- and mono-nucleotide (**FAD**, **FMN**), lipoic acid, pyridoxal phosphate, and thiamin pyrophosphate. Biotin, lipoic acid, and pyridoxal phosphate are bound covalently to carboxylases, acyl transferases, and aminotransferases, respectively. FAD may, or may not, be bound covalently to oxidases. The interaction of thiamin pyrophosphate with decarboxylases is noncovalent, although the binding is tight.

It would seem preferable to consider a compound as a coenzyme only under conditions where it is functioning as a carrier and not when it is simply a substrate for a single enzyme. Compounds that are covalently or tightly bound to an enzyme might better be regarded as **prosthetic groups**. The features that these compounds have in common are the helping groups that they provide to enzymes. These groups possess chemical attributes that the enzymes do not have and that are essential for catalysis.

Cohesive, Sticky Ends

Cohesive ends are short single-stranded sequences of **DNA**, usually 1 to 3 bases long, that are produced at the end of a double-stranded DNA molecule by the action of a type II restriction enzyme that makes staggered cuts in a symmetrical, **palindromic** sequence (1). For example, *Pst*1 cuts the sequence 5′ ..CTGCAG.. to give the ends ..C and TGCAG.. . The two ends 3′ ..GACGTC.. ..GACGT.. C.. produced in this way are complementary, so they bind together by base pairing and allow DNA Ligase to repair the break. Furthermore, any fragment cut by an enzyme of this type binds to any other DNA fragment cut by the same enzyme or to one that creates the same cohesive ends. When the cohesive ends ligated together are cut by enzymes that have different recognition sequences, the new sequence is not cut by either enzyme. In the case of *Bam*HI, 5′ ..GGATCC.. and *Sau*3a, ..GATC.., which produce the same sticky ends ..CCTAGG.. ..CTAG..but have different length recognition sites, the sequence created can always be cut by *Sau*3a but can be cut only by *Bam*HI if the sequence cut by *Sau*3a is a *Bam*HI site. Some restriction enzymes recognize degenerate sequences, so that only when both DNA fragments cut with this type of enzyme have the same sequence do they pair and allow ligation. Depending on the position of the cuts in the two strands, either a 5′-strand or the 3′-strand, creating a 5′-overhang or a 3′-overhang is possible, but each enzyme produces only one type.

Cohesive ends are also present on some **bacteriophages**. For example, on lambda phage they are 12 bases long and are produced by staggered cutting of a symmetrical sequence site (cos site) by a phage enzyme during DNA packaging (2).

Coiled-Coils

A coiled-coil is a generic name for any helical structure that has an axis that is itself helical. A general feature of all such coiled-coil conformations is that the handedness of coiling alternates at successive levels of structure, in line with the well-established practice employed by ropemakers over the centuries. This maximizes the interactions between strands and minimizes relative slippage. There are two particularly well-known classes of coiled-coil structures in biological structures: (i) the a-fibrous proteins and (ii) the collagens. The structure of each will be described.

a-Fibrous proteins display a characteristic **heptad** quasi-**repeat** of the form $(a–b–c–d–e–f–g)_n$, where about 75% of the *a* and *d* are positions are occupied by nonpolar residues such as leucine, isoleucine, and valine (1, 2). These sequences adopt a right-handed a-**helical** conformation with about 3.6 residues per turn. Because the apolar residues in the heptad repeat are 3.5 residues apart, on average, it follows that they will form an apolar stripe on the surface of the a-helix, and this will wind around the helix in a left-handed manner (3). In an aqueous environment, apolar residues tend to pack as closely together as possible to shield each other from the water and, in doing so, provide the **hydrophobic** driving force for assembly. This can be facilitated in this case by two or more a-helices coming together, optimizing the packing of the apolar residues along their interface (so-called knobs-into-holes packing) and winding around one another to generate a left-handed coiled-coil structure (Fig. 1). Favorable electrostatic interactions can also be made between the chains, which help to specify both the relative chain direction and the axial displacement between the chains (1). The interchain ionic interactions occur predominantly between oppositely charged residues in positions *e* and *g* of different chains. Calculations and experimental observations on two-stranded a-helical coiled-coils have shown that the strands are parallel (rather than antiparallel) and in axial alignment. The types of apolar residues in positions *a* and *d* are important in specifying the number of chains in the coiled-coil molecule (see Leucine Zippers). Two-stranded coiled-coils occur in muscle **myosin**, intermediate filaments, plectin, streptococcal M proteins, centrophilin, kinesin, b-giardin, and a host of other proteins. Three-stranded structures are found in the laminins, fibrinogen, the spectrin superfamily of proteins, bacteriophage leg proteins such as gp17, cartilage matrix protein, mannose-binding protein, macrophage scavenger receptor protein, and many others. Four-stranded ropes are found in the silks of the bees, wasps, and ants (*Hymenoptera aculeata*), as well as in globular proteins (such as the **four-helix motif**). Five-stranded coiled-coils have recently been described in HIV capsid protein and in collagen oligomeric matrix protein (COMP) (Fig. 2). As Cohen and Parry (3) have pointed out, it is not the bending of the axis of the a-helix in the supercoiled conformation that is crucial but rather the way in which it permits systematic apolar side-chain interactions to be made. It must also be pointed out that many sequences show discontinuities in their heptad substructures. A recent study by Brown et al. (4) has shown that all such (short) discontinuities can be classified as either “stutters” or “stammers”; these correspond to deletions of three and four residues, respectively, from an otherwise continuous repeat. Physically, a stutter results in a region in which the coiled-coil undergoes a degree of local underwinding to generate a longer supercoil pitch length, whereas the stammer causes a degree of local overwinding, thus giving rise to a shorter supercoil pitch length. The latter is likely to be stereochemically more difficult to achieve. The former has been observed experimentally. A coiled-coil is not confined to fibrous proteins with long rod-like domains as seen in myosin, intermediate filaments, and desmoplakin (for example), but occurs commonly in globular proteins in the form of a-helical bundles. These are generally short in length (say 3 to 10 heptads) and contain anything from two or three a-helices to sizable bundles containing six or even more. The same underlying heptad repeat is present, but it becomes less easy to recognize as the helix length decreases.

Figure 1. The structures of two-stranded coiled-coils. (Left) The backbone model of the two-stranded coiled-coil from a portion of the *N*-terminal end of **tropomyosin**. Two right-handed a-helices coil around each other in a left-handed manner. (Center) A space-filling model of the same structure with the strands shown separated. The apolar residues are shown in black. (Right) The two strands brought together. The apolar residues are interlocked in a systematic way along the axis of the coiled-coil and are shielded from water as a result. (From Ref. 9 with permission.)

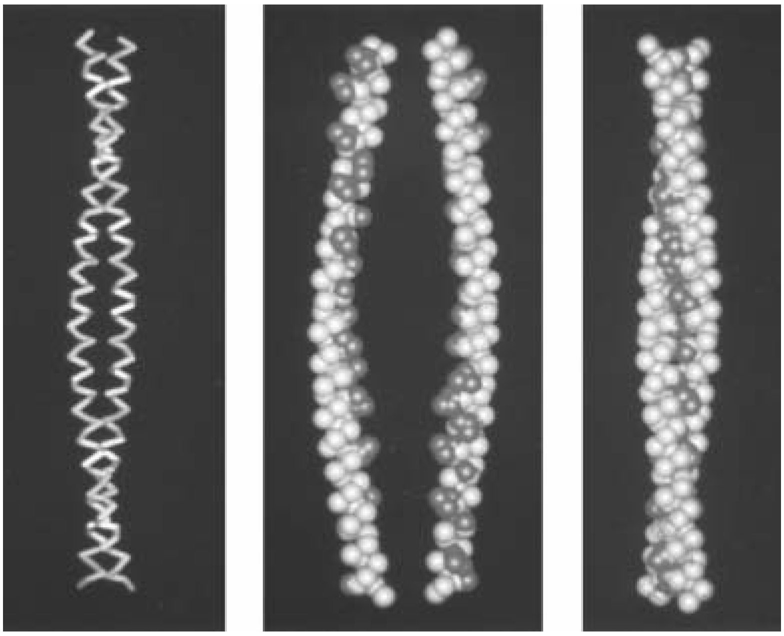

Figure 2. The five-stranded coiled-coil oligomerization domain of cartilage oligomeric matrix protein (COMP). Each of the a-helices forms about one-third of a complete turn over the length of the structure. The N-terminal end is at the bottom of the page. (Courtesy of R. A. Kammerer.) See color insert.

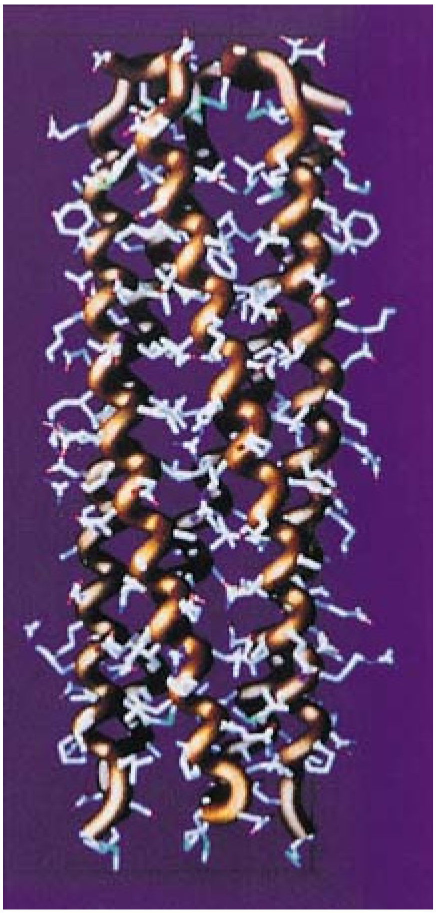

The a-chains in collagen contain a triplet repeat of the form (Gly—X—Y)$_n$, where X and Y can be almost any amino acid residue but are commonly proline and hydroxyproline, respectively. The chain folds up into a left-handed helical structure that is very similar to that seen in polyglycine II and polyproline II. Three a-chains then aggregate in parallel with a one-residue relative axial displacement between chains to generate a right-handed, triple-helical structure in which the glycine residues lie along the axis of the molecule (see Collagen). This class of conformation was originally formulated by Ramachandran and Kartha (5) and Rich and Crick (6) and has subsequently been refined by Fraser et al. (7, 8). The structure has 10 repeating units in three turns, a unit rise of 0.2894 nm, and a pitch length of 0.9647 nm. The individual a-chains have a pitch length of 8.68 nm. The conformation is stabilized by a single hydrogen bond per triplet between the peptide NH group of a glycyl residue and the peptide carbonyl group of an X residue in another chain. Furthermore, water molecules bridge the glycyl NH to the C=Oof a prolyl residue in another chain and the OH group of a hydroxyprolyl residue in the same chain. The diameter of a collagen molecule is about 1.4 nm. Its length varies from one type of collagen to another, but for a Type I collagen molecule its length is close to 300 nm. The molecule thus has a high axial ratio in excess of 200.

Cointegrative Vectors

Cointegrative vectors were the first type of **vector** developed for transferring foreign **DNA** from the bacterium Agrobacterium to **plant** cells, for use in plant genetic engineering (1). Although cointegrative vectors may be relatively difficult to work with in practice, compared with the alternative binary vectors, they offer **plasmid** stability in the **bacterial** cell.

The general concept of using cointegrative vectors relies on homologous recombination within *Agrobacterium* to introduce into a modified T-DNA the DNA to be transferred to the plant cell. First, the DNA to be transferred is introduced into an intermediate cloning vector based on an *Escherichia coli* plasmid. The intermediate vector that contains the foreign DNA is introduced by conjugation into *Agrobacterium* that contains the cointegrative vector. The cointegrative vector is a Ti plasmid from which the T-DNA genes that encode oncogenic function have been removed and/or replaced with a sequence that is also contained in the intermediate vector. The intermediate vector is not stable in *Agrobacterium*. Homologous recombination between the intermediate vector and the cointegrative vector results in transferring the foreign DNA to the cointegrative vector. These vectors are designed so that once the foreign DNA, is integrated into the cointegrative vector, it is located between its border sequences. The most generally used cointegrative vector system is the “split-end vector system” (2)

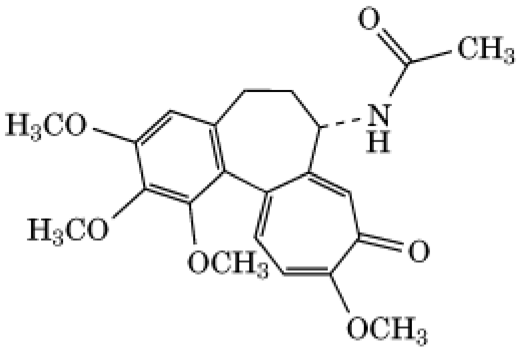
Colchicine

Colchicine (Fig. 1), a compound obtained from the autumn crocus, *Colchicum autumnale*, is an ancient drug that has been used for centuries for the treatment of gout (1). Its use in molecular biology began in the mid-1930s when its potent ability to inhibit eukaryotic cell proliferation at mitosis was discovered. Since then, colchicine has had a remarkable history as an experimental tool for characterizing the biochemical properties of tubulin, the protein subunit of microtubules, for characterizing the diverse processes in eukaryotic cells that are dependent upon drug-sensitive microtubules, and for studying the polymerization and dynamics properties of microtubules. For example, colchicine has been used to determine the role of microtubules in mitosis, protein **secretion**, axonal transport, and the development and maintenance of asymmetric cell shape. It has also been used extensively as a cytogenetic tool to determine chromosome numbers in karyotypes. Also, radiolabeled colchicine was used as an affinity marker to effect the first purification of tubulin from brain (2).

Figure 1. Structure of colchicine.



1. Colchicine Binding to Tubulin

The binding of colchicine to tubulin is not a simple process (3-6). The binding reaction is slow and highly temperature-dependent. Binding is extremely slow at 0°C, and 2 to 3 h is required to reach equilibrium at 37°C. The activation energy for the forward reaction is high, ~20 kcal/mol. The kinetics of binding are biphasic. The initial step is the formation of a reversible preequilibrium complex that is followed by a slow step in which conformational changes in tubulin lead to the formation of a final-state tubulin-colchicine (TC) complex. Although the binding of colchicine to tubulin is noncovalent, the final state TC complex is very poorly reversible.

Colchicine binds to tubulin at a single site with a dissociation constant in the range of 0.02 µM to 5 µM. Colchicine has very different affinities for tubulin isolated from different sources. For example, colchicine binds strongly to vertebrate brain tubulin, but it binds very weakly to plant, fungal, and yeast tubulins. Also, there are different tubulin isotypes, and colchicine binds differently to the isotypes purified from same tubulin source (7). Despite intensive investigation, the precise location in tubulin of the colchicine-binding site is not clear. The binding site is thought to reside in the b-tubulin subunit, near residues Cys 354 and Cys 241, close to the intradimer interface.

The binding of colchicine to tubulin induces conformational changes in tubulin, as well as in colchicine (6, 8, 9). For example, the binding of colchicine to tubulin quenches the intrinsic tryptophan **fluorescence** of tubulin, indicating that it induces a small change in the tertiary structure of the protein. It also perturbs the far-ultraviolet circular dichroism spectrum of tubulin, indicating that it changes the **secondary structure** of the protein. In addition, colchicine binding to tubulin strongly increases the intrinsic GTPase activity of tubulin, increases the affinity of the ab dimer association by threefold, changes the exposure of thiol groups in tubulin, and, under certain conditions, induces tubulin to self-assemble into nonmicrotubule polymeric structures. Tubulin is also subject to a time- and temperature-dependent irreversible decay of its protein structure. Binding of colchicine to tubulin slows the rate of decay. The concept that colchicine undergoes conformational changes upon binding to tubulin is evident from the development of colchicine-tubulin fluorescence and the change of the colchicine circular dichroism spectrum upon binding to the protein.

2. Inhibition of Microtubule Polymerization by Colchicine

Colchicine inhibits microtubule polymerization at concentrations that are far below the total concentration of tubulin (10, 11), indicating that colchicine inhibits microtubule polymerization by acting at the microtubule ends. In order to produce its potent actions on microtubule polymerization, colchicine must first form a TC complex. Substoichiometric concentrations of TC-complex only partially depolymerize microtubules, and relatively low concentrations of TC-complex can stabilize microtubules against dilution-induced disassembly (12). These studies support the hypothesis that the TC-complex forms a stabilizing “cap” at the end of the microtubule. Also, the TC-complex can form copolymers with unliganded tubulin when microtubules are assembled in the presence of TC complex (13).

3. Kinetic Suppression of Microtubule Dynamics

Microtubules exhibit two kinds of nonequilibrium dynamics: treadmilling and dynamic instability (see Microtubules). Recent studies have revealed that colchicine and other compounds that depolymerize microtubules (see Vinblastine) strongly suppress these dynamics at relatively low concentrations in the absence of appreciable microtubule depolymerization. Colchicine was found some years ago to suppress treadmilling *in vitro* and the rate of microtubule disassembly upon dilution of the microtubules [now called "kinetic capping" (11, 12)]. However, its stabilizing effects on dynamics were only fully appreciated with the introduction of real-time differential-interference contrast video microscopy, which enabled one to visualize directly in real time the stabilizing action of the drug on the growing and shortening dynamics of individual microtubules (14). Small numbers of incorporated TC complexes strongly suppress the rates and extents of growing and shortening and greatly increase the percentage of time that the microtubules spend in an attenuated state. In addition, the TC complex strongly suppresses the catastrophe frequency and increases the rescue frequency. At low submicromolar concentrations, TC complex suppresses the dynamics without reducing the polymer mass. Significant reduction of polymer mass requires relatively high TC complex concentrations. However, the surviving microtubules are extremely stable. Colchicine appears to suppress microtubule dynamics by binding at the microtubule ends, most probably by inducing a conformational change and/or by steric hindrance at the ends.

Cold-Sensitive Mutants

Cold-sensitive mutants are a class of **conditional lethal mutants** that cannot grow at a temperature below the organism's normal optimum. The low temperature may be lethal because the mutant form of the protein loses its function or because it forms inappropriate or inhibitory interactions with other proteins. Finding and characterizing second-site revertant mutations that **suppress** the cold-sensitive phenotype identifies protein–protein interactions (see Temperature-Sensitive Mutation).

Colicins

Colicins produced by and active against coliform **bacteria** constitute a subset of the bacteriocins generated by many groups of bacteria. They have been a subject of interest since very early in this century. In 1925, Gratia demonstrated that *Escherichia coli* strain V (virulent in experimental infection) in liquid media produces a heat-stable substance that in high dilution inhibits the growth of *E. coli* (1). This protein was designated as colicin V. It has now been shown that it fits better with the description of the so-called "microcins" (see Bacteriocins) (2). Then a whole series of colicins produced by *E. coli* and closely related members of Enterobacteriacae were discovered. Mainly as a result of the influence and efforts of Fredericq (3), knowledge of the colicins advanced at a great rate, and more than 20 different types were identified on the basis of their action against a set of specific resistant (generally receptor-deficient) mutants (Table 1). In contrast to the bacteriocins from **Gram-positive** bacteria that kill species other than those that are likely to have the same ecological niche, colicins are active only against *E. coli* and closely related bacteria (there is a similar relationship between the cloacins and *Enterobacter cloacae*, the klebicins and *Klebsiella* species, and the pyocins and pseudomonacae). A characteristic feature of colicinogenic bacteria is to be specifically immune to the colicin they make but not to other colicins. A large number of colicins have now been identified, and each has been characterized by the corresponding specific immunity protein. Colicins are **plasmid**-encoded, and each plasmid also bears an immunity protein, thus ensuring that plasmid carriers are protected from the colicin they themselves produce. There is probably a selective advantage for Enterobacteriacae to produce a colicin because 30 to 40% of natural isolates of *E. coli* carry colicinogenic plasmids (4). The colicins exert their lethal effect through a single-hit mechanism (5). There was some controversy about the meaning of this terminology, but now there is a consensus that sensitive cells are killed by a single event, implying that a single molecule kills, although not every one does.

Table 1. Characteristics of Colicins

Colicin	Colicin Activity Group		Receptor	Translocation System
E2,E7,E8,E9	A	DNase	BtuB	TolA, B, Q, R

E3,E6,DF13	A	RNase	BtuB	TolA, B, Q, R
E1	A	Pore-forming	BtuB	TolC, TolA, TolQ
A	A	Pore-forming	BtuB	OmpF, TolA, B, Q, R
N	A	Pore-forming	OmpF	OmpF, TolA, Q
K	A	Pore-forming	Tsx	OmpF, OmpA, Tol A, B, Q, R
Col5	B	Pore-forming	Tsx	TolC, TonB, ExbB, D
Col10	B	Pore-forming	Tsx	TolC, TonB, ExbB, D
Ia,Ib	B	Pore-forming	Cir	TonB, ExbB, D
D	B	Inhibition of protein synthesis	FepA	TonB, ExbB, D
M	B	Inhibition of synthesis of murein and LPS	FhuA	TonB, ExbB, D

Colicins are soluble proteins of 29 to 70 kDa (for colicin V, see previous). Their amino acid sequence is known, and they share the property of being linearly organized in three **domains** that have specific functions. They are also highly asymmetrical molecules and have axial ratios of 8 to 10 (6, 7). Another common feature is that their production is induced by exposure of colicinogenic bacteria to agents like UV light and genotoxic chemicals, such as mitomycin C, that elicit the SOS response. After induction, they are produced in large amounts, so they provide useful model systems to study fundamental biological problems, such as protein–protein interactions, polypeptide translocation and insertion across and into membranes, functioning of voltage-gated pores, etc.

The classification of colicins reflects bacterial rather than colicin properties. According to its activity spectrum against a variety of mutants, a particular colicin is unambiguously assigned to one of two groups, A and B (8, 9). Group B colicins are inactive on strains that have a lesion in the *tonB* gene but are active against strains mutant in *tolA* and *tolB* genes. Group A colicins show the opposite specificity. Now we know that group A colicins (A, E1 to E9, K, L, N, and cloacin DF13) and filamentous **bacteriophage** (f1, fd, and M13) need the Tol proteins to penetrate into cells (9-11). Group B colicins (B, D, Ia, Ib, M, 5, and 10) and phages T1 and F80 need TonB and its associated proteins (8, 9). In all cases studied so far, the determinants for colicinogeny are located on plasmids (Table 1) of two different types: small multicopy plasmids or large low-copy-number plasmids that generally correspond to the A and B groups of colicins. In general, group A colicins are encoded by small plasmids and are actively released to the extracellular medium, whereas group B colicins are encoded by large plasmids and are very poorly secreted.

At least three hypotheses have been proposed to explain the evolution of colicin plasmids: (1) positive selection of diversity, (2) recombinational shuffling, and (3) transposition (12). The different colicins may have evolved by DNA recombination of fragments encoding different colicin domains (see later). This is best exemplified by the common uptake route for colicins B and D, which have a highly homologous N-terminal and central polypeptide sequence (defining the translocation and receptor domains respectively; see later) but very different C-terminal domains with different types of activities (13).

1. Genes for Colicins and Associated Proteins

Regardless of the plasmid type, the genes for the colicin, immunity, and lysis (when there is one) are always clustered (14). The difference between immunity to the enzymatic colicins and to the channel-forming colicins and colicin M (whose target is the cytoplasmic membrane) is reflected in the regulation of their synthesis and the arrangement of the various colicin operons. In enzymatic colicins, the immunity gene is transcribed in the same direction as the colicin and lysis genes (15-17), whereas for the channel-forming colicins and for colicin M, immunity is encoded on the opposite DNA strand and is thus transcribed in the direction opposite to the colicin and lysis genes (18-20). Enzymatic colicin and cognate immunity genes form an operon under the control of an SOS **promoter** (see later). Thus, induction of colicin synthesis results in increasing the amount of immunity protein synthesized, but the presence of a terminator causes partial transcription arrest upstream of the lysis gene. In contrast, inducing the synthesis of pore-forming colicins from their SOS promoter does not result in a concomitant increase in the immunity protein. The immunity is constitutively expressed from a weak promoter (19, 21-23). The situation is similar for the murein-synthesis-inhibiting colicin M and its immunity gene (24).

Colicin production is inducible and suicidal. Under normal conditions, very few cells produce colicin because the expression is repressed by the LexA repressor and is switched on only during the SOS response normally associated with repairing damaged DNA. This means that, in culture, colicin production is inducible in a growing population of cells by mutagens (UV light, mitomycin C). This induction is very efficient. In the absence of mutagens, LexA exhibits a very tight repression (25) and ensures that only a small proportion of cells go down the dead-end road of colicin expression and export. Once they have done so, it is important to the plasmid clone as a whole that the sacrificial cells produce as much colicin as possible. This maximizes selection against non-plasmid-bearing cells. Meanwhile, the silent preservation of many identical copies of the same plasmid in immune cells ensures no significant loss of the plasmids in the producer cell.

2. Extracellular Release of Colicins

Most of the colicins (group A, but not group B) are actively released into the growth medium. Their release mechanism differs from that of proteins secreted by Gram-negative bacteria (see Protein Secretion):

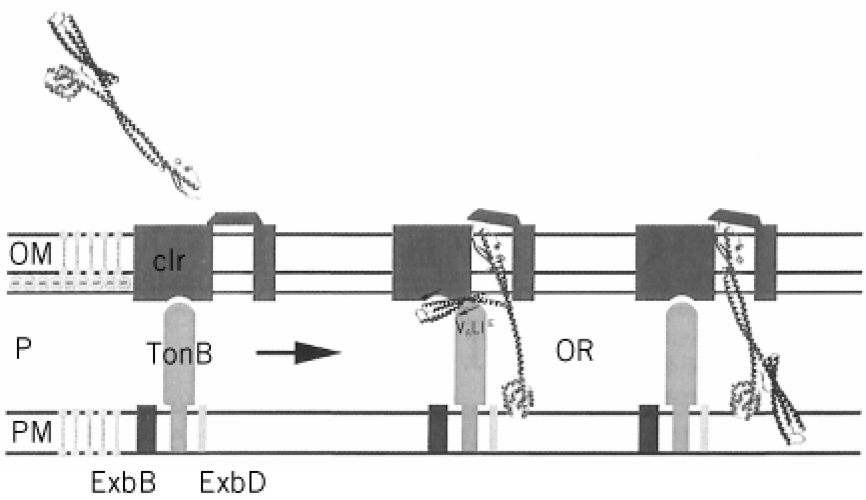
1. they do not contain an N-terminal or C-terminal signal sequence like **Sec**-dependent exported polypeptides or those depending on ABC transporters;
2. their release depends on the function of a lytic protein (variously called *kil*, *lys*, *brp*) whose gene is part of the colicin operon, downstream of the colicin gene;
3. they are released from the host cell some time after synthesis;
4. their extracellular release is not specific, and quasi-lysis proteins have various effect on cells in addition to causing the release of assorted proteins and small molecules (26).

The lysis genes encode short proteins produced in a precursor form with a **signal sequence** and a typical cysteine lipid-modification consensus box, implying that the precursor undergoes the following posttranslational modifications: (1) acylation of the cysteine residue, (2) cleavage of the signal sequence by signal peptidase II, and (3) fatty acylation of the amino group of the now N-terminal acylated cysteine. The maturation and processing of lysis proteins occurs slowly, so every intermediate form can be observed. Both the mature form and the signal sequence accumulate in *E. coli* after processing (27, 28). The addition of globomycin to *E. coli* cells stops processing of lysis protein precursors and inhibits colicin release (29). Acylation is essential for quasi-lysis (29, 30). The mature lysis proteins activate the normally dormant phospholipase A in the outer membrane of colicin-producing cells, thus causing production of lysophospholipids, quasi-lysis, and colicin release (31). However, lysis proteins must also affect the permeability of the inner membrane (32). The lysis protein must reach a critical concentration within the cells before quasi-lysis and colicin release, which also indicates that the lysis protein directly affects the inner membrane. Local modifications in the structure of the bilayer are induced by interactions with lipopeptide micelles, as previously suggested in the case of Iturin A and bacillomycin L (33).

3. Mechanism of Entry and Domain Organization of Colicins

Colicins bind to specific receptors in the bacterial outer membrane, from where they are translocated to, and eventually through, the inner membrane to reach their targets. Consistent with these three steps, their polypeptide chains are linearly organized into three domains: the *N*-terminal domain is involved in the translocation step, the central domain is responsible for receptor binding, and the C-terminal domain carries the lethal activity (Fig. 1). The boundaries of these domains were defined first by limited **proteolytic** digestion (34-36), then by genetic engineering (37, 38), and from sequence homologies between colicins with the same type of lethal activity and using the same receptors (E-type, for example) or the same translocation pathways. Even colicin M, which has a molecular mass of 29 kDa, has three functional domains (24).

Figure 1. The mechanism of colicin Ia attachment and translocation. The outer membrane (OM) receptor for colicin Ia consists of Cir, TonB, and accessory plasma membrane (PM) proteins ExbB and ExbD. The translocation domain (blue), receptor binding domain (green), and channel-forming domain (red) separated by a pair of helices (gray), each 16 nm long, are indicated in colicin Ia. The TonB box of colicin Ia may compete with the TonB box of Cir for linkage to TonB. The channel-forming C domain reaches the plasma membrane, where it forms an ion-conducting channel by subsequent insertion and rearrangement of helices within the membrane (not shown). The translocation T domain may remain near the periplasmic surface of the outer membrane during channel activity. However, the presence of the 16 nm-long T3 helix indicates an alternative possibility in which the T domain crosses the periplasmic space (P) to participate in channel formation *in vivo*. The location of the TonB box on the upper surface of the T domain of sequence Glu(E)-Ile(I)-Met(M) Ala(A)-Val(V) is indicated, reading right to left, as EIMAV. The arrows indicate the locations of the TonB box in the receptor and colicin Ia. Reproduced from (68) with permission.



To enter the cells, colicins have borrowed multiprotein systems used by sensitive cells for important biological functions. These proteins include porins, **vitamin B_{12}**, siderophore, nucleoside receptors, and multiprotein systems that cooperate with these proteins. The group A and group B colicins correspond to two different pathways of entry beyond receptor binding: the TonB and the Tol pathway. The receptors for the various colicins are given in Table 1. The protein most frequently used is BtuB, the vitamin B_{12} receptor, which defines the so-called E-type colicins (E2 to E9) (12). High-affinity receptors or iron siderophores are also used by many colicins. The nucleoside Tsx porin and the major porin OmpF are also receptors (Table 1). Depending on the colicin class, the colicin receptors function cooperatively with either the Ton B system or the Tol system.

The *tol* locus was originally defined as comprising four loci, *tol A*, *B*, *Q*, *R*, on the basis of group A colicin tolerance (39). These genes are organized in two operons that comprise three additional genes called *orf*1, *orf*2 and *pal* (40), whose gene products are not directly involved in colicin uptake. However, one of them, the Pal protein (peptidoglycan associated protein), a **lipoprotein** of the outer membrane, interacts with TolB (41). Both *tol* and *pal* mutants have an altered outer membrane (39). The only soluble Tol protein is TolB, which is principally located in the **periplasm** (42) but is linked to the outer membrane through interaction with Pal. The other Tol proteins are associated with the cytoplasmic membrane. TolQ contains three membrane-spanning segments, and TolA and TolR are anchored to this membrane by their *N*-terminal regions. All three proteins interact through membrane-spanning a-helices (43, 44). There is yet no direct evidence that TolB interacts with membrane-associated Tol proteins, but each of the Tol proteins cofractionates with a membrane fraction accounting for the presumed contact sites between the inner and outer membranes of *E. coli*. In colicin A-treated cells, the toxin was also found in this fraction, and the relative amount of Tol proteins was doubled, suggesting that the colicin itself may recruit more Tol proteins at the contact sites (45, 46).

Although both TolB and TolR are required to take up most group A colicins, neither is required for colicin E1, which in contrast requires the so-called TolC protein, a minor outer membrane protein that forms pores *in vitro* (47) and is also involved in secreting hemolysin (48) and colicin V (49). OmpF, another porin, is required for translocating many group A colicins (A, E-type, N) (50, 51). The N-terminal domain of group A colicins contains all the information needed for the translocation step (52) beyond receptor binding, including binding to OmpF (or TolC for colicin E1) and to Tol proteins like TolA (53) and TolB (54). There are about 1000 translocation sites for colicin A per bacterium (55). In addition, it has been shown that: (1) unfolding occurs upon receptor binding (55), (2) the N-terminal domain interacts with Tol proteins, (3) the polypeptide chain spans the entire cell envelope after inserting the pore-forming domain (56), and (4) a reduced constriction of the lumen of the OmpF pore prevents translocation of colicin A and N (57). A hypothetical model of colicin translocation based on these results has been presented (11, 58).

Group B colicins are imported into sensitive cells through high-affinity siderophore receptors and the Ton B pathway. The Ton B system consists of a complex of proteins TonB-ExbB-ExbD, which facilitates the flow of energy from the cytoplasmic to the outer membrane for the energy-dependent transport of ferric siderophores and of vitamin B_{12}. ExbB and ExbD are physically and functionally homologous to TolQ and TolB (59). Ton B, like Tol A, has its N-terminal anchor in the cytoplasmic membrane and spans the periplasm (60). It has been proposed that an energized conformation of TonB, like FepA or FhuA, opens channels in the outer membrane, which act as receptors for the ferric siderophores. Until recently, each of the group B colicins studied uses a Ton B-dependent receptor, but it has now been reported that a new colicin (colicin 10) uses the Ton B system and binds to a Ton B-independent receptor Tsx. Colicin 10 also requires TolC for its uptake (61). Thus the interaction between the colicin receptor and Ton B is not obligatory if TolC is involved. This situation may be comparable to that of the group A colicin E1, which does not need TolB or TolR but does need TolC.

The high-affinity receptors for siderophores and vitamin B_{12} contain a pentapeptide motif close to the N-terminus, called the “Ton B box” (62). Mutations in the Ton B box reduce receptor activity dramatically. They are also **suppressed** by mutations in TonB (63), indicating physical and functional interactions between TonB and the receptors. Group B colicins, such as colicins B and D, which bind to the FepA receptor, and colicin M, which binds to the FhuA receptor, also contain a TonB box sequence close to the N-terminus. This indicates that these colicins interact directly with TonB during translocation. Mutations in the TonB box of colicin B affect its uptake and are suppressed by secondary substitutions clustered in TonB (63). A similar situation is observed with TonB, FhuA, and colicin M. These results suggest that group B colicins need to interact with TonB to be translocated, just as group A colicins need to interact with Tol proteins. Both the N- and C-terminal domains of the protein also interact with the inner membrane and therefore are protected from proteolytic degradation (64). This suggests that the Y-shaped structure (65) allows colicin Ia to span the entire cell envelope, as previously reported with colicin A (66). The receptor-binding domain would be the only part remaining exposed outside the cells.

A molecular model of colicin M uptake has been proposed (24). After first binding to FhuA in the outer membrane, colicin M is taken up in an energy-coupled process through the action of the TonB protein, which is anchored to the inner membrane and spans the periplasmic space. TonB binds to FhuA, inducing the release conformation of FhuA, which, in turn, results in the vectorial translocation of colicin M across the outer membrane. TonB itself has two conformations, energized and unenergized. Energization of TonB takes place in the cytoplasmic membrane. Induction of the receptor release conformation consumes energy, so TonB dissociates from the FhuA receptor and has to be reenergized to induce the next round of colicin M uptake. Because both FhuA and colicin M contain a TonB box, the TonB protein most likely interacts with both of them sequentially. The role of ExbB and D is still unclear. They are involved either in energy transduction (cycling of the TonB conformational change) from the cytoplasmic membrane to TonB or in stabilizing TonB, which is physically and functionally unstable (24, 67, 68).

The 626-residue colicin Ia is about 21 nm long and consists of three functional domains separated by a pair of a-helices 16 nm long. A central domain at the bend of the hairpinlike structure mediates binding to the outer membrane receptor. A second domain mediates translocation across the outer membrane via the TonB pathway. The TonB box recognition motif of colicin Ia is on one side of three 8 nm-long helices arranged as a helical sheet. The third domain, made up of 10 a-helices, is the pore-forming domain (see below). The two exceptionally long 16 nm a-helices enable colicin Ia to span the periplasmic space between the outer and inner membranes (Fig. 1) (68). This type of structure, which will very likely be found in each colicin, strongly suggests how these toxins exploit the machinery of the target cell to get across the periplasmic space (Fig. 1).

4. Mode of Action of Colicins

The biochemical effects of colicins on sensitive bacteria fall into four classes: (1) the RNase colicins typified by colicin E3, (2) DNase colicins typified by colicins E2 and E9, (3) pore-forming colicins like colicin E1, and the still unique colicin M, which inhibits cell wall biosynthesis (24).

4.1. RNase Colicins
The two most extensively studied members of this class are colicin E3 and cloacin DF13 (derived from a strain of *Enterobacter cloacae* closely related to *E. coli*). The 11 kDa and 12 kDa C-terminal segments of these bacteriocins cleave the 16S ribosomal RNA, either in isolation or in intact 30S ribosomal subunits, which explains their inhibitory effect on protein synthesis (69). Colicins E5 and E6 have the same type of activity (70). Although they are highly homologous in their RNase regions (71), colicins E3, E5, E6, and cloacin DF13, each have a specific immunity protein. No structures are yet available for any of these RNase domains.

4.2. DNase Colicins
In 1970, it was shown that colicin E2 causes both single- and double-strand breaks in the DNA of sensitive cells (72), and three new types of DNase colicins were subsequently described (colicin E7, E8, and E9). The sequential identity between the various DNase domains is greater than 80% (71), yet each is inhibited by a specific immunity protein. This is similar to the situation in the RNase-type colicins. Structural and biophysical analysis of the DNase immunity protein complexes has been aided by the *E. coli* overexpression systems developed by Wallis et al. (73-75).

4.3. Pore-Forming Colicins
Pore-forming colicins constitute the largest group. Colicin V must be set apart in this class because it fits the definition of microcins better than that of colicins (2). Pore-forming colicins dissipate the membrane potential (76-80), which causes a series of metabolic effects, such as inhibition of **active transport** and of protein and nucleic acid synthesis, decrease of the internal ATP concentration (see

Adenylate Charge), and leakage of potassium ions (81-85). Cell death results from the depletion of the ATP pool following efflux of phosphate through the channel and ATP hydrolysis (86). Ten pore-forming colicins have been identified thus far. Sequential homologies indicate that they should be separated into two groups: (1) E1, 5, Ia, Ib and (2) A, B, and N (87), differing mainly in a segment containing the loop between helices 8 and 9, as defined in the X-ray crystal structure of the C-domain of colicin A (88). The structures of soluble forms of the channel domains of colicins A, Ia and E1, are known to varying extents (89-92). The pore-forming domain is composed of a bundle of 10 a-helices arranged in three layers in a novel protein fold (93). The N-terminal layer (helices 1 and 2) is connected to another layer consisting of two pairs of amphipathic helices (helices 3 + 4 and 6 + 7), and a single helix (helix 5) connects the two helix pairs. The middle layer is composed of helices 8 and 9, which form a **hydrophobic** hairpin buried in the core of the molecule (Fig. 1). The external sides of the peripheral helices are hydrophilic, which explains the paradox of how the same protein domain exists either in a water-soluble form or in a membrane-inserted state (see later). Because the C-terminal domain of colicins is easily purified by proteolytic digestion of the whole colicins or by genetic engineering, many biophysical studies have been carried out to improve our understanding of this step in the action of pore-forming colicins (for a review, see Suggestions for further reading).

Schein et al. (78) were the first to demonstrate that colicin A forms well-defined channels in planar lipid bilayers that permit ions to cross the membrane (94, 95). Pore-forming colicins form channels of 10 to 30 picosiemens (pS), which correspond to 10^7 ions/sec/channel. These channels are characterized by their sensitivity to the electrical potential across the membrane. The gating voltage (corresponding to the activation or to the inactivation of 50% of the channels) varies for a given colicin. Values are +21, +50, and +70 mV for colicins N, A, and E1, respectively. There are multiple membranes states at the single-channel level. With colicin E1, channels of 10 pS are initially observed. With increased activation in 1 M KCl, channels of 20, 40, and 60 pS with substates appear, and flickering is observed. Similar observations with other colicins suggested the existence of many closed, open, and inactivated states. Thus, the concept of a single-membrane-inserted conformation appears to be incorrect, although a simplified model with a single or a few membrane-inserted forms has been very helpful.

The channel properties of the C-domain and of whole colicin are qualitatively similar for colicin E1, but not for colicins A (96) and Ia (97). Differences are ascribed to the influence of the other domains on the pore-forming domain in the intact molecule. The pores are permeable to cations and anions, but the rates at which they are transported are low (98). There is a relative preference for cations versus anions that is modulated by the pH and the lipid composition (99, 100). Using the relative permeabilities of large organic cations and anions and taking into account their asymmetrical shapes, the size of the channel diameter was estimated at only 0.4–0.5 nm. This implies strong interactions between permeable ions and the side chains of residues exposed in the channel lumen (100).

The transition of pore-forming colicins from a water-soluble to a membrane-inserted state involves large structural changes, which is of interest in the context of **protein folding**, protein translocation, and protein insertion into membranes. From studies with model membrane systems, a likely sequence of events for membrane insertion and pore formation has been proposed for colicins A and E1 (see Suggestions for Further Reading). Briefly, the C-domain first binds to the outer face of the cytoplasmic membrane. The negative charge density plays a part in the binding and the kinetics of insertion (101, 102). After binding, but before insertion, the pore-forming domain must have lost the tertiary structure of the water-soluble form and adopted primarily a **molten globular** conformation, which is still compact and has kept its native secondary structure (87, 103, 104). As mentioned later, the interaction of the N-terminal and central domains with the translocation machinery might trigger the appearance of a molten globular conformation of the channel domain *in vivo* (105). The topology of the membrane-inserted state has been extensively studied, mainly with the pore-forming domains of colicins E1, A, and Ia. The membrane-bound state involves insertion of the hydrophobic helical hairpin formed by H8 and H9 into the bilayer. In contrast to colicin A, which is more dependent on electrostatic interactions, the protein would lie flat on the membrane surface. The hydrophobic hairpin could not insert because the density of charged residues on the membrane surface is too high (103).

The polypeptide translocation involved in voltage-dependent gating has been studied through three main experimental approaches: (1) By using lipophilic radiolabeled probes, Merill and Cramer (106) demonstrated that a 42-residue region of colicin E1 corresponding to helices 5 and 6 was labeled in the presence, but not in the absence, of a membrane potential in a vesicle system with **valinomycin**-induced diffusion potential. Another segment corresponding to the hydrophobic hairpin was strongly labeled in the presence or absence of membrane potential. (2) The existence of a drastic change triggered by a transnegative membrane potential *in vivo* was also demonstrated by disulfide-bond engineering (107). The same technique further showed that a-helices 1, 2, 3, and 10 remain at the membrane surface after application of a membrane potential. (3) Colicin Ia with biotin, conjugated to specific cysteine residues introduced by site-directed mutagenesis, were inserted into a lipid bilayer, and the channels were opened or closed by varying the membrane potential. Then streptavidin was added on the *cis*- or *trans*-side of the membrane. The results demonstrated (108) that a region of the pore-forming domain of colicin Ia reversibly flips across the membrane, implying a large conformational change when potential is applied. A region of at least 68 residues is able to flip back and forth with channel opening and closing. Several open, channel structures probably exist (109).

4.4. Inhibition of Murein Biosynthesis

Colicin M is unique among the colicins in that it inhibits murein biosynthesis (110) by interfering with the dephosphorylation of C_{55}-polyisoprenyl pyrophosphate, which leads to cell lysis (111). It also has a much shorter polypeptide chain than other colicins (29 kDa as compared to 40 to 70 kDa). Yet, it has the same basic design of three functional domains (see previous). The largest part of the C-terminal domain of colicin M resides in the cytoplasmic membrane because the carrier lipid and pyrophosphatase activity were found in the membrane fraction (112). Colicin M does not penetrate deeply into the cytoplasmic membrane but acts mostly at the periplasmic side of this membrane (24). Furthermore, cytoplasmic colicin M does not kill the cells, and only external colicin M, after its import through the energy-dependent TonB system (see previous), has access to the target in the cytoplasmic membrane. A chimeric protein of colicin M linked to a signal peptide directing the C-domain to the periplasm (the outer face of inner membrane) causes cell lysis. The amount of colicin M at the target was so high that immunity broke down (24).

5. The Systems Immune to Colicins

The immunity of colicinogenic cells to the action of the colicin they produce was first noted by Fredericq in 1957 (113). The cell relies for its survival on the immunity protein. The individual cell is safe from its own colicin when that gene is carried on the same plasmid as the *imm* gene. Much progress with regard to the specificity determinants has been made during recent years on the basis of the immune activity, especially for nuclease-type and pore-forming colicins.

5.1. Immunity Against RNases

The determinants for specificity of colicin-immunity interactions with colicins E3, E6 and cloacin DF13 are likely to reside in a limited number of amino acid residues, eight in the nuclease domains and up to nine in the corresponding immunity proteins (114, 115). These determinants are located in the N-terminal regions of both the RNase domain and the immunity protein. A single residue either in Im3 or in Im6 is critical for defining the specificity (116). Other residues are also likely to be involved in the interaction but have more peripheral roles in defining specificity. The 84-residue Im3 (117) is folded into a four-stranded antiparallel b-sheet connected by loops and a single short a-helix, in marked contrast to the structure of a DNase-specific immunity protein Im9 (118), which contains four a-helices. The specificity-determining residues of Im3 at the two main positions are exposed and line one face of the b-sheet (117). No structures are yet available for any RNase domains.

5.2. Immunity Against DNases

The sequences of the DNase domains of colicins E2, E7, E8, and E9 are more than 80% identical, yet they have specific immunity proteins. Site-directed mutagenetic studies identified six Col E9 residues in the C-terminal DNase domain as possible specificity determinants (119). The sequences of Im2, Im7, Im8, and Im9 are 58% identical but are not homologous to the RNase-type immunity proteins. Two amino acid residues were identified as specificity determinants of Im8 and Im9 by using homologous recombination (74) and site-directed mutagenesis (118, 120).

Further structural and biophysical studies of DNase-immunity protein complexes have shown that the DNase E9-Im9 complex is extremely stable (like the Col E9-Im9 complex) with a $\boldsymbol{K_d}$ of 9.3×10^{-17} M, one of the highest affinities ever measured for a protein interaction (121). The association of the nuclease with the Im9 protein is essentially **diffusion-controlled**, involves electrostatic steering, and follows a two-step mechanism in which the proteins form an initial encounter complex before undergoing a conformational change to yield the final stable complex (121). Although there is no cross-reactivity between DNase-type colicins (E2, E7, E8, and E9) and noncognate immunity proteins under normal levels of expression, biophysical studies indicated that the latter bind to the DNase domain of colicin E9 and inhibit its activity (122). The K_d values range from 10^{-17} M (IM9) to 10^{-4} M. Consistent with this result, overexpressing each of the noncognate *Im* genes in bacteria results in significant levels of cross-reactivity toward the ColE9 toxin, and the order of *in vivo* cross-reactivity (Im9 > Im2 > Im8 > Im7) mirrors exactly the measured *in vivo* affinities (122). The specificity for the DNase-Im complexes is controlled through the dissociation constant, which is more than 10^6-fold faster for the noncognate Im proteins. The Im9 fold consists of a distorted antiparallel four-helix bundle in which the second helix (from the N-terminus) is the main specificity determinant (118, 120). The surface regions of Im9 that interact with the DNase include the two central helices of the molecule, and the binding surface is heavily negatively charged, consistent with a positively charged partner DNase domain (118).

5.3. Immunity to Pore-Forming Colicins

The immunity proteins directed against nuclease-type colicins described previously are expressed at a level similar to that of their cognate colicins. In contrast, the proteins immune to pore-forming colicins are expressed constitutively at very low levels (10^2 to 10^3 molecules per cell). Another major difference is that these proteins protect the cells against external colicin because the membrane potential has the wrong orientation for colicin activity from the inside. Thus the immunity is directed against colicins produced by other cells.

Membrane vesicles from cells immune to colicin Ia are depolarized by colicin E1, but not Ia (123), which first indicated a cytoplasmic membrane localization for these types of immunity proteins. In addition, the construction of hybrids between colicins Ia and Ib, A and E1, or A and B, demonstrated that, independent of the translocation pathway, immunity is directed specifically against the C-terminal, pore-forming domain (19, 52, 124). ImmA has four transmembrane a-helices, and both the N- and C-termini are located in the cytoplasm (125). The shorter ImE1 has three transmembrane a-helices. The N- and C-termini are on the cytoplasmic and periplasmic sides of the membrane, respectively (127). These orientations are in agreement with the inside-positive prediction rule (128).

As with Im proteins directed against nucleases, there is no cross-reactivity between homologous immunity proteins directed against homologous A, B, or N colicins. Similarly, overproduction of the immunity protein leads to partial cross-reactivity (124). The main determinant for specific immunity recognition is located in the hydrophobic hairpin of the channel domain of the colicin (124, 129). Either the whole bacteriocin or the C-terminal domain of pore-forming colicins produced in the cytoplasm of *E. coli* are devoid of cytotoxicity. However, when the C-terminal domain is fused to a signal sequence, the channel is inserted and functional, and cell death follows. This could be inhibited by coproduction of the cognate immunity protein (130, 131). The cytotoxocity of the hybrid protein is independent of the uptake machinery normally used, demonstrating that the C-domain alone forms the channel *in vivo*, as in *in vitro*. The interaction of ImA with colicin A requires the immunity protein to assemble functionally but does not require the channel to be in the open state (131). In other words, the immunity protein interacts with the hydrophobic helical hairpin, as first suggested by the studies mentioned previously (124). This interaction was demonstrated directly using an epitope-tagged immunity protein (131). Site-directed mutagenetic studies of ImA indicate that a role for polar regions of ImA cannot be excluded, in addition to the intramembrane helix–helix interactions. Two roles are proposed for the hydrophilic loops in this protein: (1) they may stabilize its interactions with the channel on both sides of the membrane; (2) they may be required for the functional assembly of the transmembrane helices of ImA (132). The colicin E1 immunity protein tolerates a higher degree of substitution than ImA (127).

5.4. Immunity to Colicin M

Like the protein it inhibits, the immunity to colicin M is unique when compared with other Im proteins. It prevents colicin M from inhibiting murein synthesis. This 14 kDa protein has been localized in the cytoplasmic membrane, and a substantial portion is exposed to the periplasmic space. There is indirect evidence that the colicin M-immunity interaction occurs at the periplasmic side of the cytoplasmic membrane (133).

Collagen

Proteins of the *collagen* family are the major components of the extracellular matrix and facilitate the formation and maintenance of a multicellular system. Collagens serve as solid-state regulators for cellular function and as scaffolding of the tissue architecture, particularly in large vertebrates. They contain many proline and glycine residues and a distinct **secondary structure**: the polyproline II-like helix, which is distinct from the a-helix, b-sheet and turn secondary structures in other protein structures. This regular secondary structure arises because the sequences the collagen polypeptide chain consist largely of the repeated sequence Gly━X━Y, with abundant proline residues at the X positions and rich in *hydroxyproline* (Hyp) residues at the Y positions. Three polyproline II-like helices constitute the supersecondary structure of the collagenous triple helix, which is stabilized through hydrogen bonds nearly perpendicular to triple helical axis (see Triple-Helical Proteins). The collagen protein family includes all the structural proteins of the extracellular matrix with triple-helical collagenous **domains** in their molecular architecture.

The collagen superfamily is classified into groups (Table 1) according to their molecular and/or supramolecular structures. The molecular structures of the collagenous proteins can be depicted with ball-and-stick models (Fig. 1). The balls represent noncollagenous or globular domains, without abundant glycine and proline residues, while the sticks show the collagenous triple helices. Some of the triple-helical domains, including that of the type IV collagen, have interruptions in the Gly━X

—Y triplets, in that glycine residues do not always occupy every third position.

Figure 1. Molecular architecture of collagen superfamily depicted with ball and stick models (stick = collagenous, triple-helical domain; ball = noncollagenous domain).

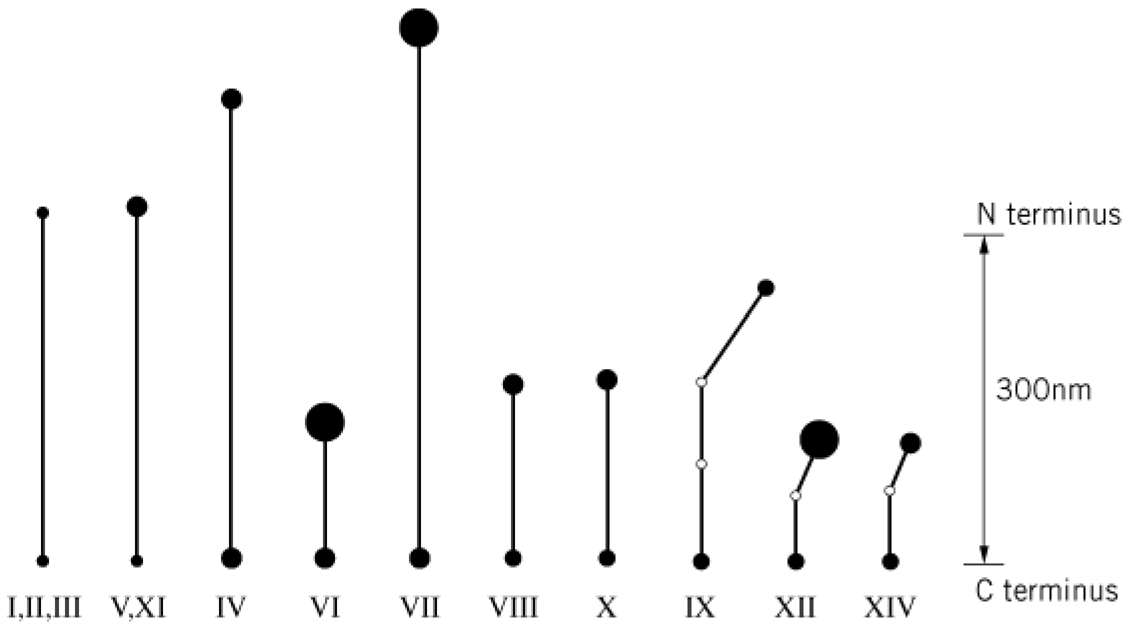

Table 1. Collagen Classification

Family	Types of Molecuels or Chains
Fibrillar collagen	Type I, type II, type III, type V, type XI
Meshwork-forming collagen	a1, a2, a3, a4, a5, and a6 chains of type IV
Fibril associated collagen with type interruptedtriple helices (FACIT)	Type IX, type XII, type XIV, type XVI
Collagen with long triple helix	Type VII
Collagen with short triple helix	Type VIII, type X, type VI
Membrane associated collagen	Type XVII
Others	Type XIII, type XV, type XVIII, type XIX

The structure, assembly, and supramolecular aggregation of type I collagen is the prototype from which has developed our understanding of collagenous structure, particularly the fibrillar collagens. Type I collagen is one of the major components of the fibrous collagens that occur in the greatest amounts. The structure and characteristic properties of triple-helical domains have been deduced from the study of type I collagen, together with comparative studies of other types of collagen. Unless otherwise mentioned, the description of collagen triple helices given below is based primarily on the information obtained through the studies type I collagen. These properties are generally shared with the triple-helical domains in other collagen types, especially regarding the characteristic features distinct from a-helix or b structure in noncollagenous proteins. However, most recent studies suggest that the triple-helical regions have structures and properties specific for each type, particularly in their intermolecular interactions. The characteristic features of the various collagen types are due to differences in the distribution of charged residues along the triple helix, content of glycosylated hydroxylysine and bulky **hydrophobic** residues, as well as imperfection of the Gly—X—Y repeat, which is a prerequisite for the triple-helical conformation.

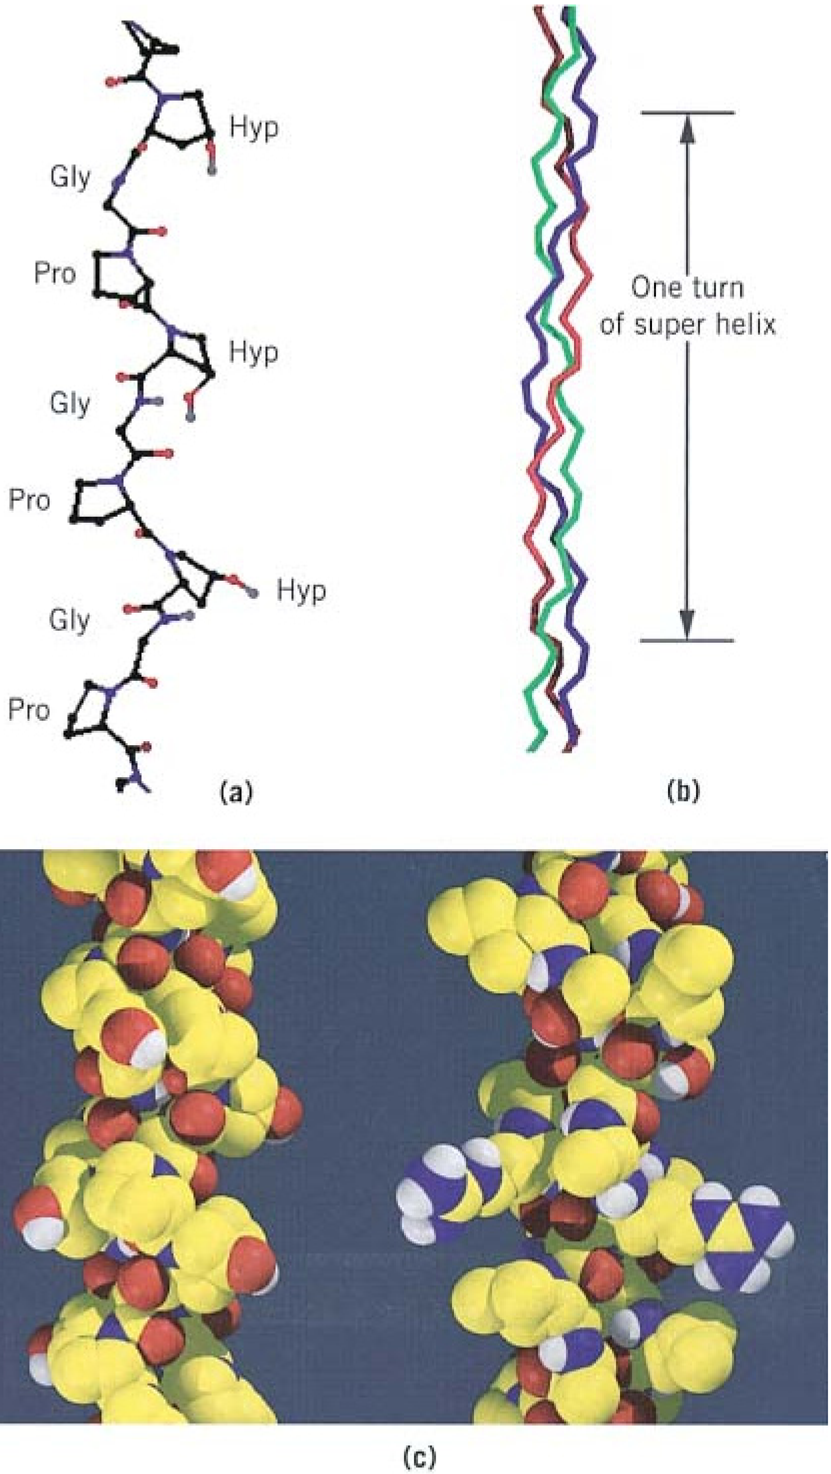
1. Collagenous Triple Helix; Common and Specific Features among Different Types of Collagen

1.1. Shape and Structure of the Triple-Helical Domains

A variety of physicochemical studies, including direct visualization of individual molecules by rotary shadowing techniques in the **electron microscope**, have demonstrated the rod-like nature of the collagen triple-helical domain. The molecules of type I collagen have a length of about 300 nm (Fig. 1) and a diameter of about 1.4 nm. The rod is neither rigid nor randomly flexible, but appears to possess an intermediate level of semiflexibility.

Details of the three-dimensional structure of the collagen triple helix were established by model building to fit X-ray fiber diffraction data. Frequent occurrence of proline and hydroxyproline residues (which together account for approximately two-ninths (~22%) of the amino acid residues) favor a polyproline II-like conformation. The axial distance between one amino acid and the next in the polyproline II-like helical structure is 0.286 nm, close to twice that in the a-helix (0.15 nm). The triple-helical structure of the synthetic peptide (Pro—Pro—Gly)$_{10}$ was also determined by X-ray crystallography. The overall helical symmetry is left-handed, with 10 residues per three turns (108°/residue) or 7 residues per two turns (103°/residue), with a pitch of 2.9 nm. The three polyproline II-like helical chains are further coiled about a central axis, to form a right-handed helix (Fig. 2). The occurrence of glycine as every third residue gives rise to a polymer of repeating tripeptide units with the formula of (—Gly—X—Y—).

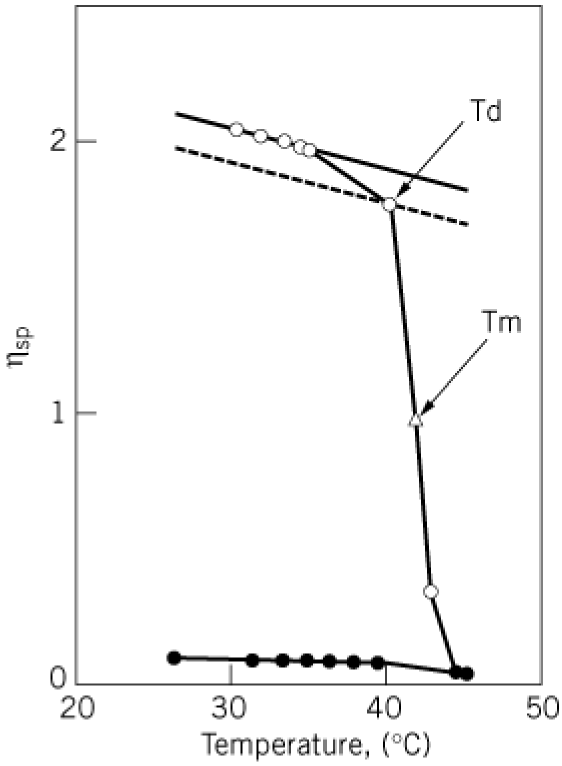
Figure 2. Collagenous triple helix. (**a**) Gly—Pro—Hyp repeated sequence of a chain in a model of part of one a chain in the collagenous triple helix. Both NH and CO groups project perpendicular to the fibrillar axis (C, black; N, blue; O, red; H, gray). (**b**) Backbone of the collagenous triple helix. (**c**) Gly—Pro—Hyp trimer (*left*). Note that there is a groove on the surface of the helix. A part of human type III collagen molecule, [a1(III)]$_3$ in the sequence of GITGARGLAGP (*right*). Note that all the residues except Gly project to the outer surface of the molecule (C, yellow; N, blue; O, red; H, white). See color insert.



1.2. Thermal Stability of the Triple-Helical Conformation

Flexibility of the collagenous triple helix may vary along the chain. Collagen triple helices of different types have varying flexibility, depending on what residues occupy the X and Y positions. Yet the thermal stability in terms of the helix-to-coil transition temperature (see Helix–Coil Theory) is similar, regardless of the type of collagen, in the same animal or animal tissues. The collagenous domains are heat-stable up to the upper limit of animal body temperature. Heat denaturation of collagenous domains starts around 37°C in mammalian collagens (Fig. 3). The most recent study on the denaturation temperature of the bovine type IV collagen triple-helical domain indicated that the domain also has denaturation temperature above 37°C. This suggests that interruptions in the triplet repeats do not greatly decrease the thermal stability.

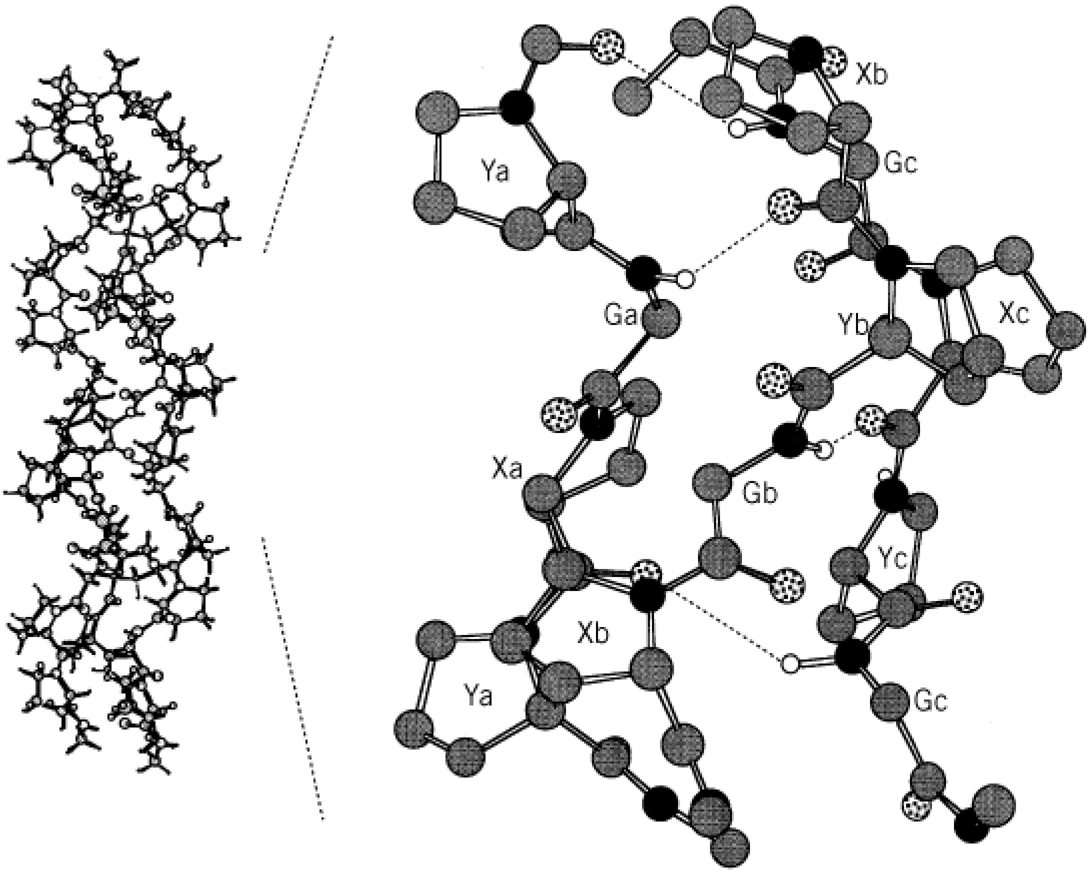
Figure 3. Denaturation temperature of collagen triple helix. The temperature was raised stepwise by 1.5°C at intervals of 20 min, and the specific viscosity (h_{sp}) was measured. Pepsin-treated acid-soluble collagen from calf skin (0.8 mg/mL) was dissolved in 0.15 *M* potassium phosphate buffer, pH 6.8, and 1 *M* glucose. Open circles indicate the specific viscosity of the native collagen solution with increasing temperature; filled circles correspond to the values of the denatured collagen solution when the temperature was lowered the same way as it was raised. The broken line is drawn through the values 5% less in the specific viscosity compared with that expected for the native collagen solution. The triangle (T_m) corresponds to the denaturation temperature obtained by the conventional method of taking the midpoint of the curve.



1.3. Primary Sequence Required for the Triple-Helical Conformation

The characteristic primary structure of polypeptides adopting collagenous triple-helical structures consists of repeats of the sequence Gly━X━Y, where Gly represents glycine and X or Y represents any other amino acid residue. Glycine is the only amino acid that can pack tightly at the center of the triple-stranded collagen monomer, where it provides HN groups for hydrogen bonding to O=C━ groups in the peptide bonds of the other chains (Fig. 4). The stability of the triple-helical conformation is due in part to these hydrogen bonds, which are aligned nearly perpendicular to the helical axis. Interruptions of the Gly━X━Y repeats decrease the stability of the conformation. Substitution of a glycine residue occurring within the sequence Gly━X━Y of triple-helical domains destabilizes and disrupts the helical conformation. In the triple helix, the side chains of all the X and Y residues are exposed on the surface of the triple helix.

Figure 4. A schematic drawing illustrating direct interchain hydrogen bonding between (Gly)NH··CO(Pro in X position) the collagenous triple-helix. The three charms (a, b, and c) with repeated Gly-Pro(x)-Pro(y) sequence, eg, -Ga-Xa-Ya, -C Yb-.



1.4. Proline Residues at Position X and Hydroxyproline Residues at Position Y
The helical conformation of individual a chains arises largely as a result of steric repulsion between
proline residues in the X position (approximately 120 residues per a1(I)) and 4-hydroxyproline resid
the Y position (approximately 100 residues per a1(I) chain) and because the five-membered rings of
imino acids are rigid and limit rotation about the peptide N—C bond. The proline and hydroxyprolin
residues also stabilize the triple helix. The contribution to helix stability from the pyrrolidine rings o
and hydroxyproline is thought to be entropic, in that these residues may not acquire as much freedon
denaturation as other residues. Another interpretation for contribution of the pyrrolidine rings to the
stability of triple-helical conformation is related to the fact that these side chains are located on the s
of the triple helix. Pyrrolidine rings are surprisingly favorable in contact with water. Furthermore,
hydroxylation of the proline residues before Gly or Y positions increases the thermal stability greatly
although hydroxyproline residues at X positions or after Gly decrease the stability. Whether the hydr
group is at the 3 or 4 position of proline residues also influences greatly the thermal stability of the tr
helical conformation.

The amino acid sequence responsible for the formation and stability of the collagenous triple helix is
susceptible to **proteolysis** by collagenases. The sequence specifically recognized by bacterial collage
usually in sequences such as ━GlyXYGlyProYGlyXHypGlyXY━. Cleavage occurs at the amino si
Gly residues.

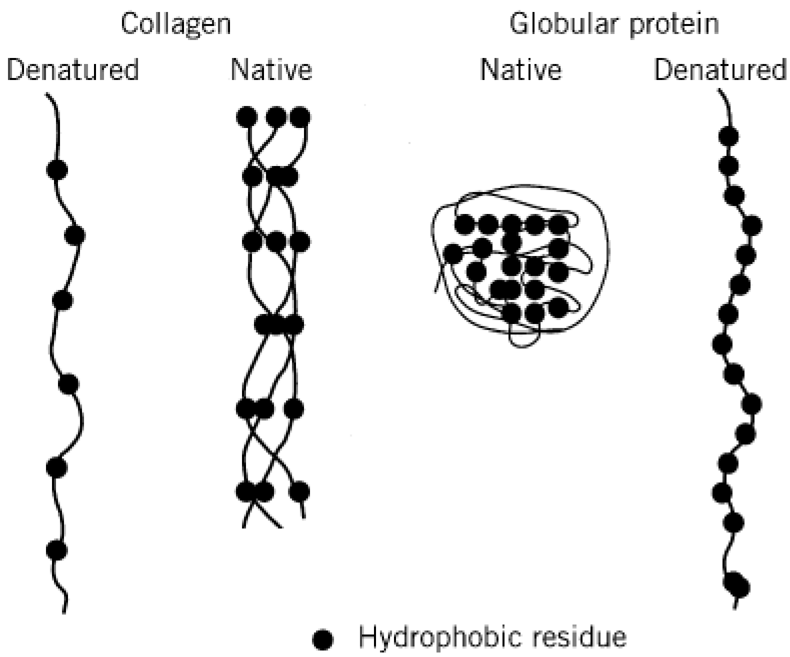
1.5. Resistance of the Triple-Helical Domains to Pepsin or Other Proteinases
The intact triple-helical domain is generally resistant to most proteinases. However, when heated abo
physiological temperatures, it undergoes a helix-to-coil transition and, once melted, becomes suscep
degradative enzymes. Protein consisting primarily of collagenous domains stays in solution at acidic
the collagenous domains have generally been isolated by **pepsin** treatment of otherwise insoluble tis
a number of triple helices of recently discovered collagen family members, the occurrence of glycine
every third residue is occasionally interrupted. The interrupted sites are speculated to lower the stabi
the triple helix and might form kinks in the rod-like triple helix. Thus, collagen helix that is otherwis
unsusceptible to many proteinases might become susceptible at the interrupted sites of Gly━X━Y r

Thus, type IV collagen may be degraded gradually at the interrupted sites of glycine—X—Y triplets being liberated from the aggregates with pepsin treatment.

1.6. Other Amino Acid Residues at Positions X and Y

All sides chains at positions X and Y protrude out along the surface of the triple helix. Consequently contribute to the hydrophilicity, ionization, hydrophobicity (see Fig. 5), and steric roughness of the p **molecular surface**, including the size of the groove of the triple helix (Fig. 2). Charged groups, toge with their neighboring sequences, may also affect the stability of the triple helix, presumably due to differential contributions from water of hydration on the surface.

Figure 5. Hydrophobic residues in collagen polypeptide chains. The content of hydrophobic residues in collagenous do (indicated as filled circles) is relatively low compared to the globular proteins. However, they projected to the surface o triple helix, while the globular protein keeps most of the hydrophobic residues inside.



The amino acid residues other than proline or hydroxyproline residues at positions X and Y can prov another classification of the collagen protein family. In general, the collagenous triple-helical domai contain a higher content of basic (arginine + lysine) than of acidic (aspartate + glutamate) residues, r in a basic isoelectric point. Two groups of collagens can be classified on the basis of their relative co of arginine and lysine: the high arginine group (Arg/Lys > 1) and the low arginine group (Arg/Lys < greater content of Lys residues may result in a greater content of hydroxylysine residues, which furth provides a possibility for additional **glycosylation**. A high content of glycosylated hydroxylysine sho contribute greatly to the surface roughness of the triple-helical domains. Another general feature abo amino acid composition of collagens is the low content of hydrophobic amino acid residues. The inte the triple helix is not stabilized by hydrophobic interactions, but they are strong between triple helice because all the hydrophobic residues are exposed on the surface of the triple helix. The content of la hydrophobic residues in the collagenous triple helices also classifies the collagenous proteins into tw groups. One group contains a high ratio of Ala/hydrophobic amino acids (Val, Leu, Ile, Phe, and Me the other group contains a low ratio.

2. Classification of Collagens Based on the Primary Sequence

In the fibrillar collagens, the triple-helical conformation occurs throughout 95% of the length of the ı monomer (Fig. 3). Thus, of the 1057 residues in the a1(I) chain of human collagen, 1014 occur in re Gly—X—Y triplets. The *N*-terminal 17 residues and the *C*-terminal 26 residues (referred to as *telop* do not have glycine as every third residue. The type I collagen helical molecule is a heterotrimer con two identical a1(I) chains and one a2(I) chain. The a1(I) and a2(I) chains are very similar, but their p structures are coded by separate genes and are sufficiently different for the chains to be separated by exchange chromatography and by SDS-PAGE. The a-chains each contain over 1000 amino acid resi have molecular weights of approximately 95,000.

The existence of a family of collagenous proteins in the connective tissues of vertebrates was first id when cartilage collagen (type II) was found to be genetically distinct from the type I collagen of skir and tendon. A third collagen (designated type III) was detected in skin. More than 30 different colla polypeptides have been found in the extracellular matrix in the form of at least 19 different collagen (designated from I to XIX; see Table 2).

Table 2. Polypeptide Chain Composition of Genetically Distinct Collagen Types

The collagen numbering system (with Roman numerals for each collagen type and Arabic numerals individual a-chains) to some extent reflects the relative abundance of the various collagens, in that g the more abundant collagens were identified earliest. In addition to these collagens, there exists a nu secreted proteins that contain collagenous amino acid sequences and short triple-helical conformatio as the **complement** component Clq, acetylcholine esterase, lung surfactant protein, conglutinin, seru mannose-binding protein, scavenger receptors (AR-I and AR-II), and MARCO. The collagenous seq in these proteins contribute to their distinctive structures and functions. Since they have no known st role in the extracellular matrix, however, they are not classified as collagens.

From the data derived from amino acid and gene sequencing, collagen molecules can be grouped int groups shown in Figure 1 and Table 1. Fibrillar collagen molecules are characterized by an uninterru helical domain of approximately 300 nm. They are synthesized as procollagens comprised of three p chains that undergo processing to a chains and subsequently assemble into collagen fibrils and fibers Fibrillar collagen molecules (ie, types I, II, III, V, and XI) exhibit several common structural feature reflect the highly conserved exon–intron structure of the genes.

Polygonal meshwork-forming collagens (type IV collagen polypeptides) have large triple- helical do (>160 kDa) with a length of >350 nm. Their primary structures are characterized by imperfections in ━Gly━X━Y━ triplet sequence. These interruptions are a particular feature of type IV collagen, in the helical domain contains more than 20 short stretches of non-helix-forming amino acids.

Short triple-helical collagen molecules and (types VI, VIII, X) contain interruptions in the helical do (as in types IX, XII, and XIV). Collagen types VIII and X show remarkable homology and might ha similar roles in tissues. Type XII and type XIV collagens have similarities to type IX collagen in the domain structures. A portion of these triple-helical domains have the potential to interact with fibrill collagen. Thus, these three types of collagen, plus type XVI, comprises a group of fibril-associated c with interrupted triple helices (FACIT collagens).

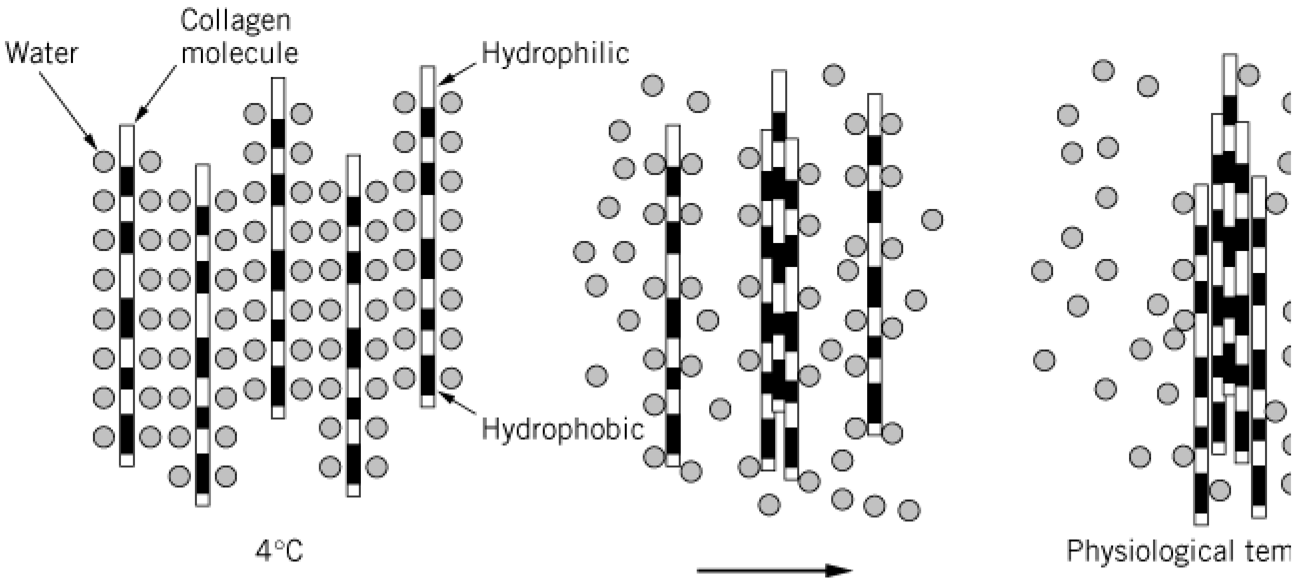
An alternative approach for classifying the collagens depends on supramolecular structures that migh related to their physiological function. Individual collagen types may themselves represent a family of related collagenous structures in the extracellular matrix. Type IV collagen is a family of six hom a chains (a1, a2, a3, a4, a5, and a6), and type V/XI is a family of 6 a chains: a1(V), a2(V), a3(V), a1((XI) and a3(XI).

3. Self-assembly into Supramolecular Structure (Fibrillar Aggregates or Polygonal Meshworks)

3.1. Lateral Interactions Between Triple-Helical Domains

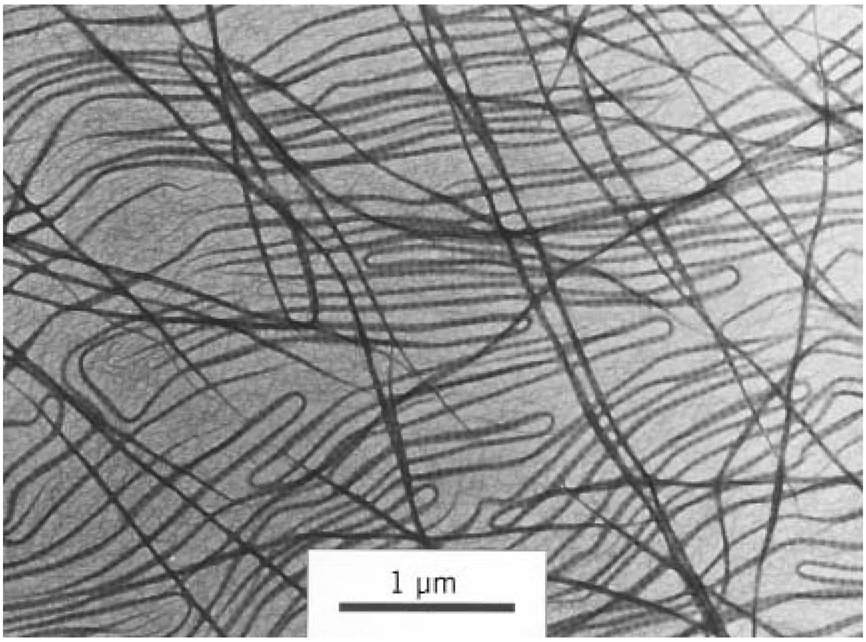
The collagen triple helix is essentially a one-dimensional molecule, with its near-constant axial sepa between amino acid residues throughout the triple-helical domain. This has permitted a direct correl structural data obtained by electron microscopy with chemical sequence data. Lateral association of collagenous triple-helical domains, to form fibrils, is a common feature of the collagen family. Fibri self-assemble spontaneously from solutions of extracted type I collagen when the pH, temperature, a strength are adjusted to physiological values. This lateral association appears to be promoted by elev temperature, suggesting that **hydrophobic interactions** are the principal driving force (Fig. 6). Fibri formation is controlled to a large extent by the amino acid sequence of the collagen and, in particula distribution of polar and hydrophobic residues that are exposed on the surface of the triple-helical do Hydroxylysine and glycosylated hydroxylysine residues might be a most potent candidate involved i limiting the lateral growth of the collagenous domains. The residues on the surface of collagen triple may well be bulky enough to cause steric hindrance in the lateral association of the triple-helical do (Fig. 15, see later). The situation would be particularly pronounced in the triple-helical domains of t and type IV collagens, which respectively contain more than 20 and 50 glycosylated hydroxylysine r in a single polypeptide.

Figure 6. Lateral association of triple-helical domains. Triple-helical domain is highly hydrated at 4°C. At physiological temperature such as 37°C, water molecules on the hydrophobic domains will be dehydrated. Collagen molecules accomp lateral association of the triple-helical domains through the exposed hydrophobic regions.



There is stringent control over lateral growth of the collagen fibrils *in vivo*, in that the distributions o fibrillar diameter are sharp in a wide range of extracellular matrices of various tissues. That type I cc can be organized in fibrils with different diameters may indicate the involvement of other regulatory elements. Heterotypic fibrils containing molecules of type III and type V, in addition to type I, collag molecules may predominate *in vivo*. The presence of the **propeptide** of type III procollagen, for exa the surface of collagen fibrils has led to the suggestion that this peptide may have a role in limiting tl diameter. Type V collagen was shown to form banding fibrils with finite diameter (Fig. 7). It has bee postulated that the type V collagen can form hybrid fibrils with the type I collagen. The responsible in the type V collagen appears to be the triple-helical domain, since pepsin-treated type V collagen f only fine fibrils. This finding suggests that type V collagen functions as one of the regulatory elemer fibril diameter, since the triple-helical domain of type V collagen forms D-period banded fibrils, witl potent ability to limit the lateral growth.

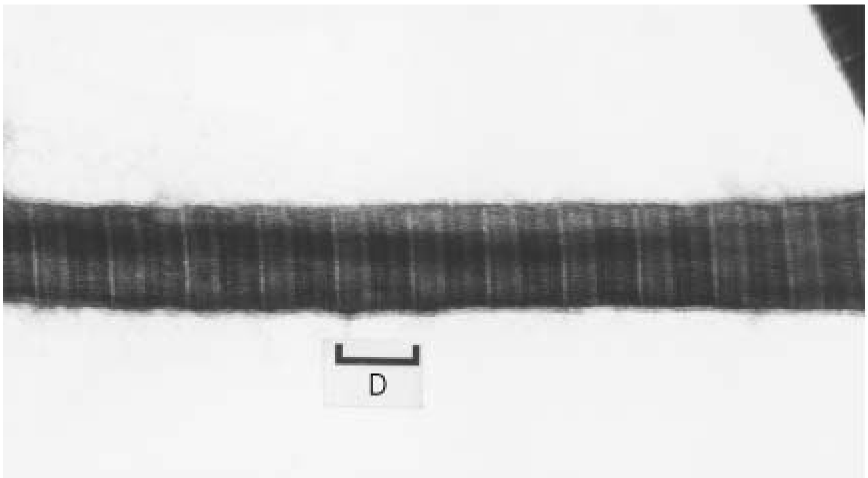
Figure 7. Reconstituted type V collagen fibrils. Purified pepsin-treated type V collagen from human placenta with the cl composition of $[a1(V)]_2a2(V)$ forms the banded fibrils with finite thickness. The periodicity of the banding pattern is approximately 65 nm. Fibril thickness is 35 nm in average.



3.2. D-Staggered Lateral Association

The fibrillar structures with banded patterns are accounted for by the specific parallel and mutually staggered alignment of the triple-helical domains of the fibrillar collagens (Fig. 8). The sequence of hydrophobic and charged residues distributed along the triple helix provide maximum electrostatic and hydrophobic interactions between the neighboring molecules. The reconstituted fibrils exhibit a cross-striated banding pattern in the electron microscope, demonstrating conclusively that the aggregation of collagen molecules into axially ordered fibrillar structures is basically a self-assembly process, where the information for association is contained within the assembling molecules themselves.

Figure 8. D-staggered array of type I collagen in banded fibrils.



It has been recognized for over 30 years that the cross-striated periodic structure of the native collagen fibril is a consequence of the assembly of molecules in a parallel array, but mutually staggered (ie, axially displaced with respect to one another) by approximately one-quarter of their length—often, which is referred to as the *quarter-staggered array*. The periodicity of the cross-striations in the fibril is explained by the fact that each collagen monomer has eight highly charged regions 67 nm apart that appear under appropriate conditions as stained bands.

The banded period (the D period) is confirmed by low-angle X-ray scattering of rat-tail tendon fibrils, and the overall length of a fibrillar collagen monomer is 4.4 D units (when D = 234 amino acids, the length of one cross-striation period is 67 nm). Within a collagen fibril, the molecules are staggered by integral multiples of the distance D (Fig. 8).

3.3. Collagen Supramolecular Aggregates in Tissues

The organization and arrangement of the collagen fibrils and polygonal meshwork in tissues are subject to considerable variation. Fibrillar collagen, type I collagen in particular, provides the major mechanical strength of skin, tendon, bone, dentine, cornea, sclera, and so on. The fibrillar collagen types form long, unbranched, banded fibrils with a characteristic periodicity of 60–70 nm. The fibrillar aggregate of collagen is classified as a quasi-crystal, because of its highly symmetrical insoluble structure built up of essentially identical subunits. Especially in tendon, type I collagen accounts for approximately 90–95% of the dry weight of the tissue and is present as large, highly orientated fibers. All the fibrillar units are arranged in large parallel bundles, with the average diameter of the fibrils varying between 50 and 500 nm. In dermis, where type I collagen accounts for 80–90% of the collagenous proteins, the fibrils form a coarse network partially oriented in the plane of the skin, with the average diameter of the fibrils between 40 and 100 nm. The orthogonally arranged and precisely packed fibrils in corneal stroma are of particular interest, since the arrangement may well be related to tissue transparency. In the cornea, which has a high content of type V and type I collagens, the collagen fibrils have a uniform diameter of approximately 25 nm. Concentric circles of collagen fibrils in cortical bone provides another type of organization and arrangement.

The skeletal structure of the basal lamina has a special three-dimensional meshwork with an average pore size of about 18 nm. Isolated type IV collagen can reconstitute into polygonal meshwork (Fig. 9) with an average pore size also of about 18 nm (Fig. 10). This suggests that the self-assembled supramolecular structure of the type IV collagen is formed primarily through the lateral interactions of the triple-helical domain, which has kinks or bending points due to interruptions of the Gly—X—Y repeat.

Figure 9. Polygonal meshwork structure of type IV collagen aggregates. Bar in lower right corner is equal to 100 nm. Arrowheads indicate globules presumably formed through NCl domains.

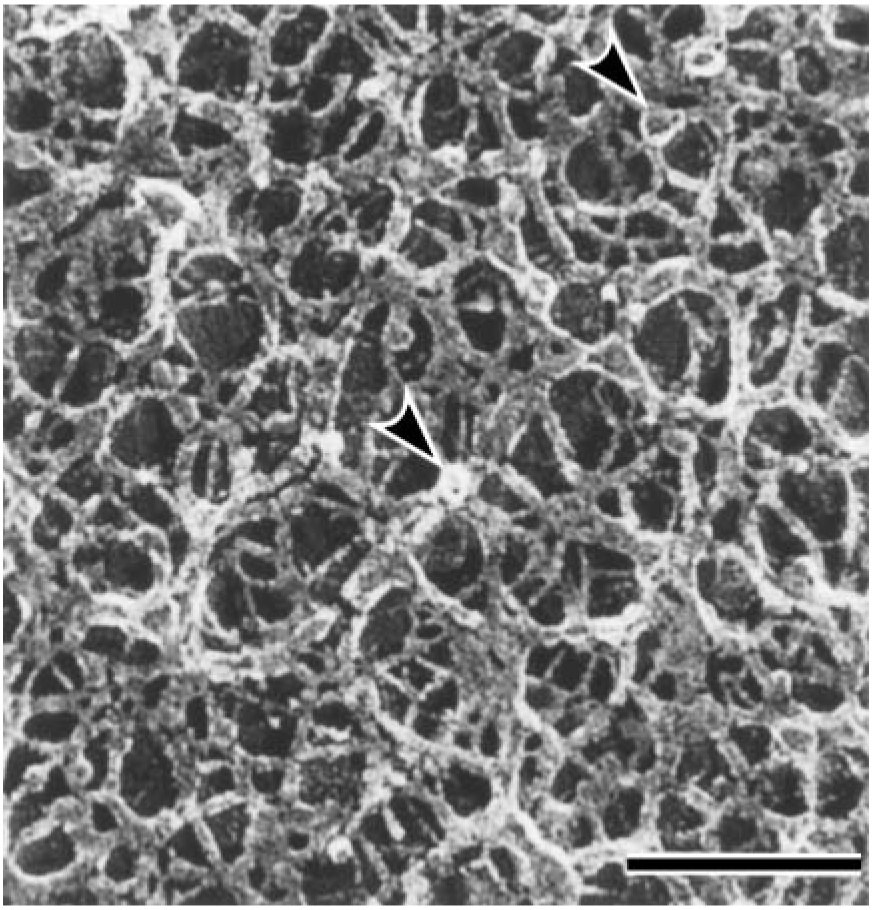


Figure 10. Histograms of the distances between two branching points of polygonal meshwork of type IV collagen aggregates.

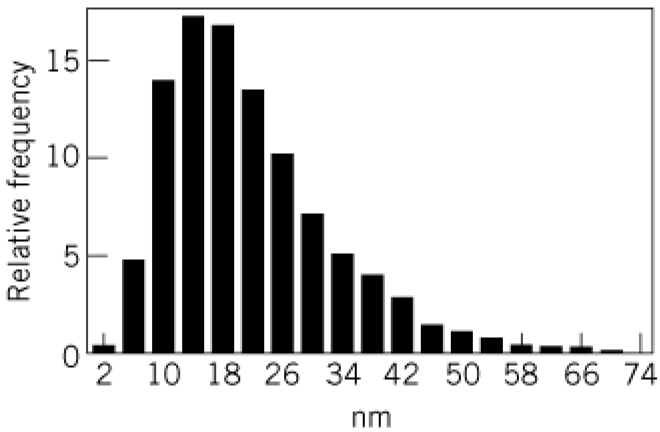
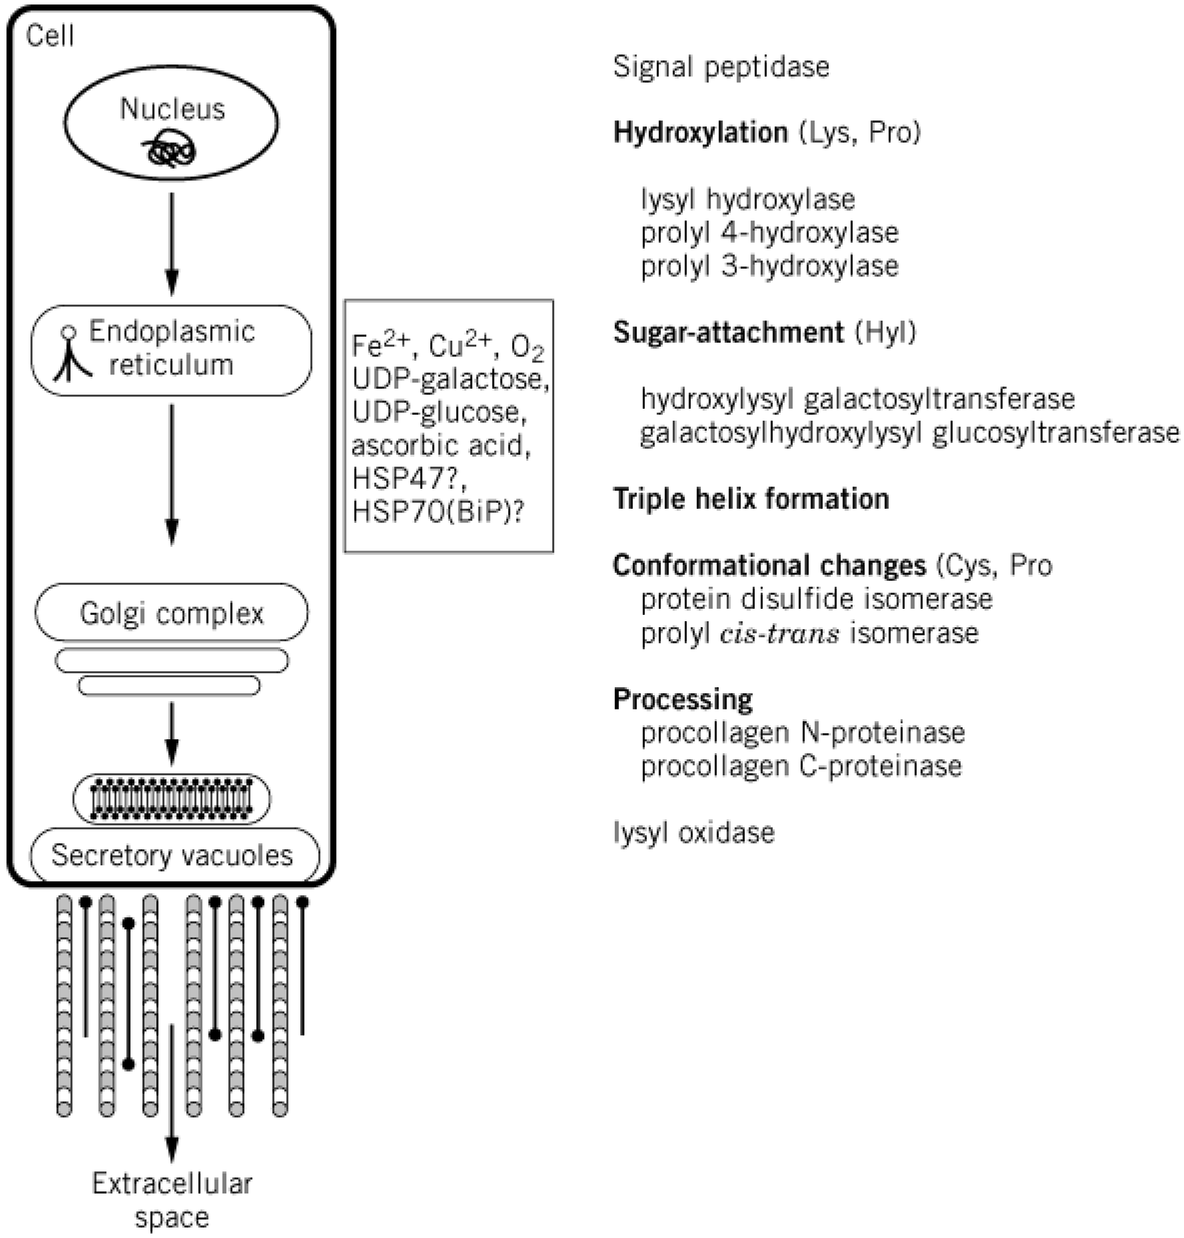


4. Biosynthesis and Chain Assembly of Collagen

Biosynthesis of the collagen molecule is a complex process that begins with transcription of the individual collagen **genes** and culminates in the chains assembled into collagen molecules (Fig. 11). This biosynthetic process involves a number of co- and posttranslational modifications unique to collagenous sequences. Intracellular modifications of the newly synthesized polypeptide chains result in the formation of triple-helical molecules. At least 10 different enzymes have been implicated in the posttranslational processing of the collagen molecule. The biosynthesis of type I collagen can be regarded as a useful model exemplifying many of the common features of collagen biosynthesis. The nonfibrillar collagens may, however, deviate from the general scheme.

Figure 11. Schematic drawing of the complex process of biosynthesis of collagen. Collagen translation products are directed into the endoplasmic reticulum by the *N*-terminal signal peptide that is the cleaved from the polypeptide chain by signal peptidase. Individual procollagen chains undergo complex enzyme-catalyzed post-translational modifications prior to the completion of chain assembly and the folding of the triple helix. Hydroxylation of Lys and Pro and attachment of sugars to hydroxylysine (Hyl) are characteristic post-translational modifications of collagenous polypeptides.



4.1. Pre-procollagen mRNA Translation

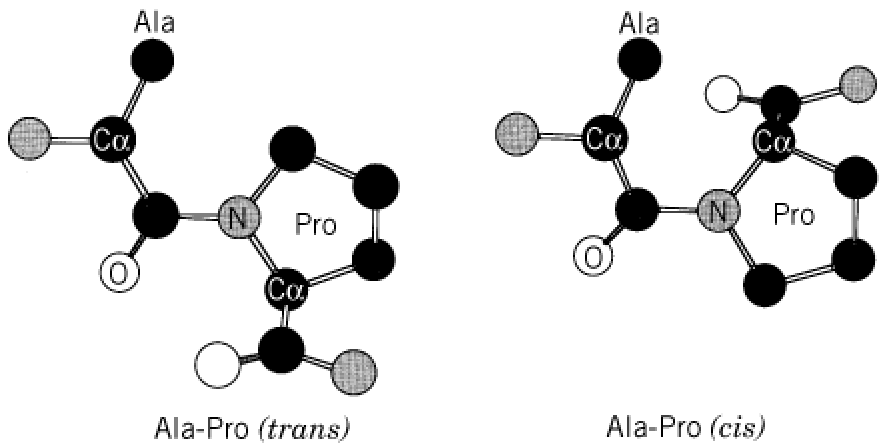
The pre-proa collagen chains that are the primary translation product contain hydrophobic *N*-terminal **signal sequences** of 22–26 amino acid residues, similar to those in most other secreted proteins and are essential for targeting of nascent polypeptides to the endoplasmic reticulum (see Protein Secretion). During or shortly after translocation, the signal sequence is removed by the signal peptidase on the luminal side of the endoplasmic reticulum membrane.

Hydroxylation of proline and lysine residues of the newly synthesized collagen polypeptide chains results in the formation of procollagen molecules containing an array of hydroxyproline and hydroxylysine residues. This hydroxylation is produced by collagen-specific enzymes within the cell (see Hydroxylation (Lysine, Proline)).

4.2. Helix Formation and Secretion

The assembly of three polypeptides into a triple-helical collagen molecule is a complex process initiated by association of the three *C*-terminal **propeptides** (in the case of type I collagen), which involves chain alignment, nucleation, and propagation into the triple-helical conformation. Requiring the *C* terminus of the polypeptide chain, chain association and alignment (in the case of type I collagen) takes place only as the chains near full elongation, and folding may proceed in the *C*- to *N*-terminal direction. Association of the *C* termini is stabilized by disulfide bond formation catalyzed by the enzyme protein disulfide isomerase (PDI). Assembly of the triple helical molecule might be limited by cis–trans isomerization (Fig. 12) of the peptide bonds preceding proline residues, which is catalyzed by a cytosolic enzyme, peptidylprolyl cis–trans isomerase (PPI). Formation of the triple-helical conformation appears to preclude further enzymatic post-translational modifications. The procollagen in a triple-helical conformation is ready to be secreted into the extracellular space.

Figure 12. *Cis–trans* isomerization of Ala-Pro peptide bonds. H atoms are not shown.

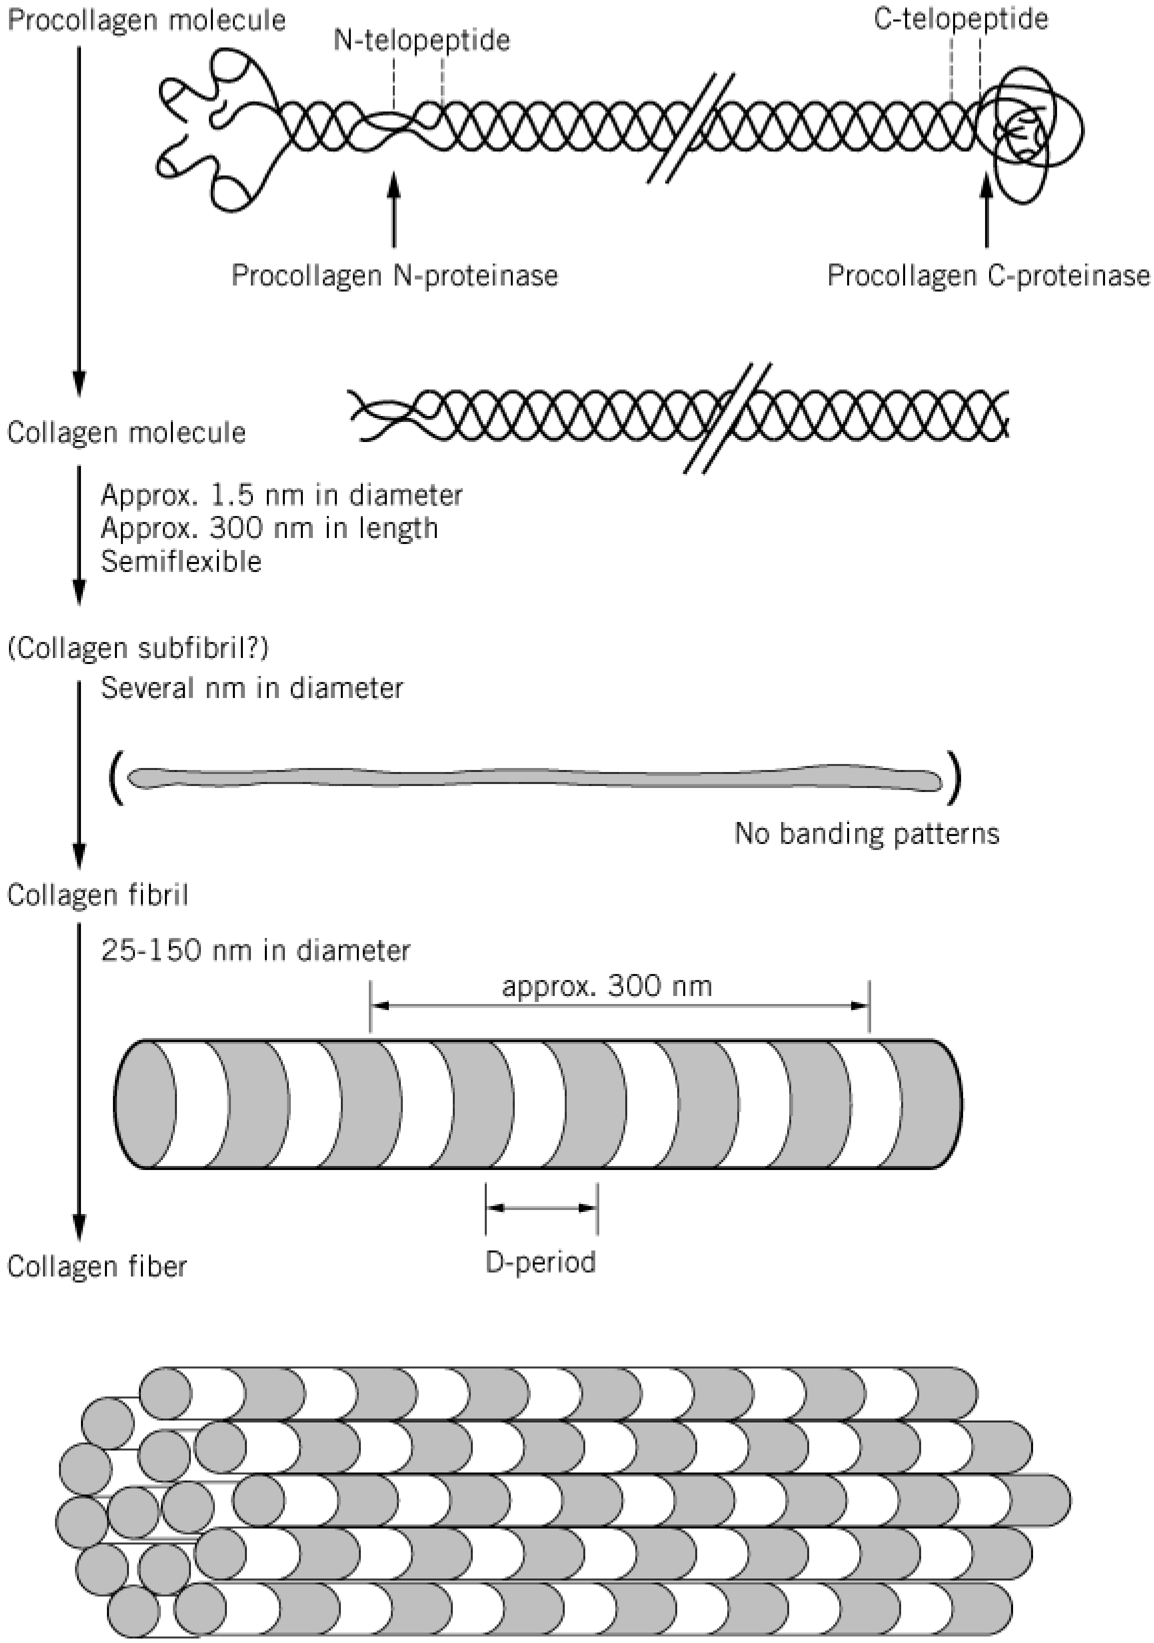


Stable triple helix formation requires 4-hydroxyproline in the Y position of a high proportion of —Gly—X—Y— triplets (at least 100 of the 1000 amino acids of the helical domain of type I collagen) (see Hydroxylation (Lysine, Proline)). The normal rate of procollagen secretion is apparently dependent on triple-helical conformation. If triple helix formation is prevented by inhibiting prolyl hydroxylase (by the use of a,a′-dipyridyl or by limiting the availability of the cofactors Fe^{2+} or O_2), the nonhelical proa(I) chains first accumulate within endoplasmic reticulum.

4.3. Extracellular Polymerization

Fibril formation involves the specific enzymatic cleavage of the procollagen *N*- and *C*-terminal propeptides in the extracellular space (Fig. 13), and these enzymes must therefore play a key role in regulating the aggregation. Such processing is characteristic of the fibrillar collagens and may not be a universal prerequisite for the assembly of all collagen types. The cleavage of the *N*- and *C*-terminal propeptides from the procollagen I molecule at specific peptide bond cleavage sites is achieved by two specific neutral metalloproteinases—procollagen *N*-proteinase and procollagen *C*-proteinase—both of which require Ca^{2+} for activity and are inhibited by metal chelators. These enzymes act essentially only on molecules in the triple-helical conformation. Type I procollagen *N*-proteinase cleaves the *N*-terminal propeptides of types I and II procollagens between a proline and a glutamine residue. A separate enzyme is involved in the processing of the *N*-propeptide of type III procollagen. The type I procollagen *C*-terminal proteinase cleaves the *C*-terminal propeptides of both the proa1(I) and proa2(I) procollagen chains at an Ala—Asp bond. Most recently, procollagen *C*-proteinase was found to be BMP-1(bone morphogenetic protein-1), and recombinant BMP-1 was shown to act as procollagen *C*-proteinase. The enzyme is also able to cleave the *C*-terminal propeptides of type I procollagen homotrimer, type II procollagen, type III procollagen, and other proteins, including laminin-5 and prolysyl oxidase.

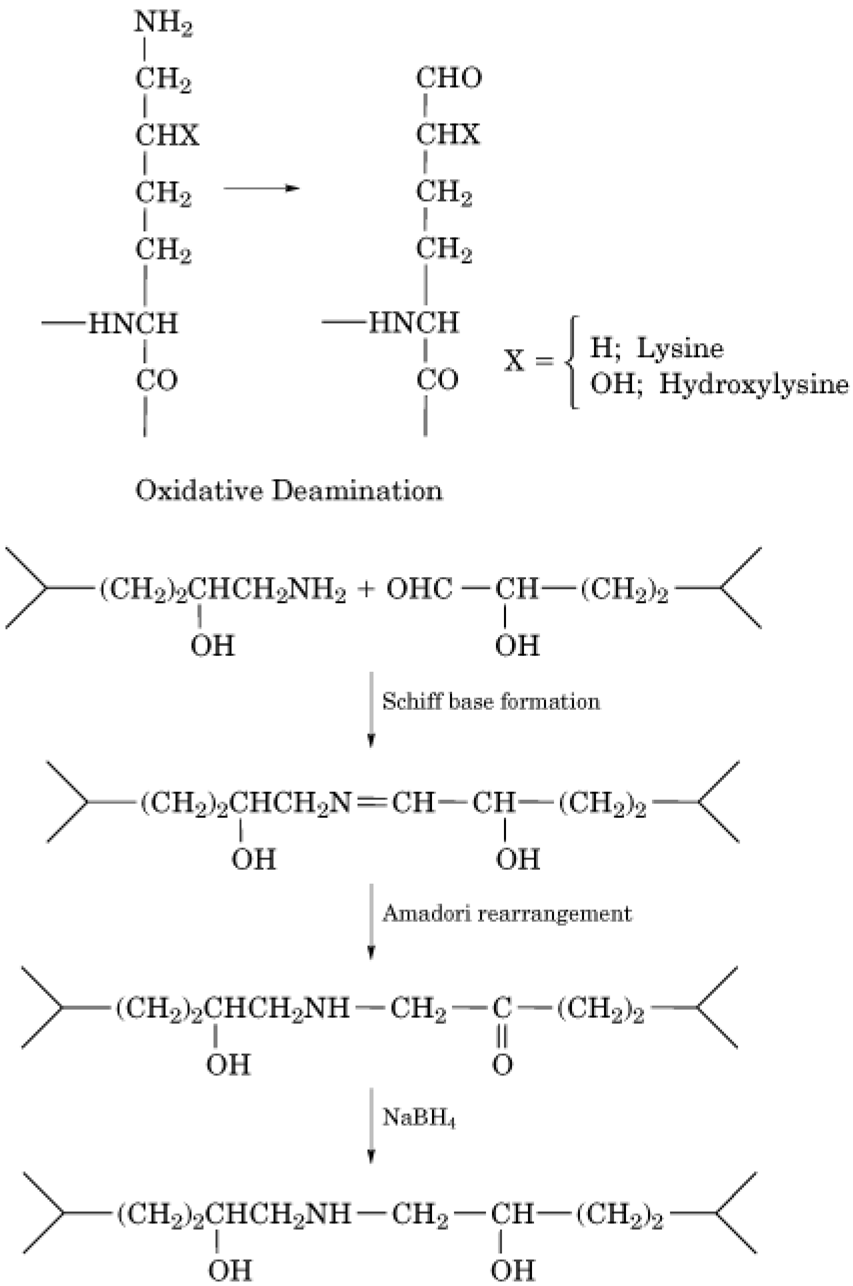
Figure 13. Processing of type I procollagen to fibril formation.



4.4. Crosslinking of Type I Collagen in the Fibrils

Covalent crosslinking of type I collagen in the fibrils involves oxidative deamination of specific lysine or hydroxylysine residues in the nonhelical (telopeptide) regions at the ends of the triple helix. Thus, lysyl and hydroxylysyl aldehydes are generated by lysyl oxidase (protein lysine 6-oxidase) (Fig. 14). The catalytic activity of lysyl oxidase is dependent on strict steric requirements (in the case of type I collagen, the quarter-stagger arrangement of molecules in the fibril) and on the sequence of amino acids surrounding the "target" lysyl/hydroxylysyl residues. The recombinant enzyme was produced as a proenzyme, which could be processed for activation by BMP-1 or procollagen *C*-proteinase.

Figure 14. Oxidative deamination and crosslinking of lysine or hydroxylysine residues. The oxidative deamination, Schiff base formation, and Amadori rearrangements take place *in vivo*. The last step, treatment with sodium borohydride, is carried out in the laboratory to stabilize the crosslinks for chemical analysis.



The majority of covalent crosslinks stabilizing the fibrillar collagens involve the telopeptides and, consequently, pepsin treatment of insoluble, crosslinked fibrils tends to release the triple-helical domain, which can be recovered in its native conformation.

5. Posttranslational Modifications of Proline and Lysine Residues

Hydroxylation of proline and lysine residues is a post-translational modification that is specific to collagen (see Hydroxylation (Lysine, Proline)). The reason for hydroxylation of proline residues at the 3 position is not known, but the presence of an appropriate number of 4-hydroxyproline residues in the —Y— position of —Gly—X—Y— is a crucial determinant of the stability of the triple helix under physiological conditions. The hydroxyl group forms hydrogen bonds that contribute to the thermal stability. The transition temperature (thermal denaturation temperature; melting temperature, T_m) of triple helices formed *in vitro* by nonhydroxylated collagen is about 25°C, which is 15°C lower than the fully hydroxylated collagen triple helix (Fig. 3). The importance of hydroxylysine may be inferred from the inherited connective tissue disorder, Ehlers–Danlos syndrome type VI, in which lysyl hydroxylase deficiency results in impaired crosslink formation and consequent susceptibility to mechanical disruption of tissues.

5.1. Glycosylation of Hydroxylysine Residues

Vertebrate collagen molecules contain the monosaccharide galactose and the disaccharide glucosyl–galactose. The glycosides are covalently linked through the hydroxyl group to hydroxylysine residues within the triple-helical domains (see Figs. 15 and 16).

Figure 15. Glycosylated hydroxylysine residues on the surface of the collagen triple helix. The molecular model of a portion (36 residues/chain) of human type V collagen, $[a1(V)]_2a2(V)$, was built up by the McMolw (Molecular Images Software, San Diego, CA, USA) and Chem3D (CambridgeSoft Corporation, Cambridge, MA, USA) programs, using the 2CLG file of the Protein Data Bank, which is the theoretical model of the $(Gly—Pro—Hyp)_4$ trimer. The two lysine residues of the two a1(V) chains are either left unchanged (*left*) or changed to glulcosylgalactosylhydroxylysine (*right*). The glycosylated hydroxylysine residues are evidently bulkier than other residues.

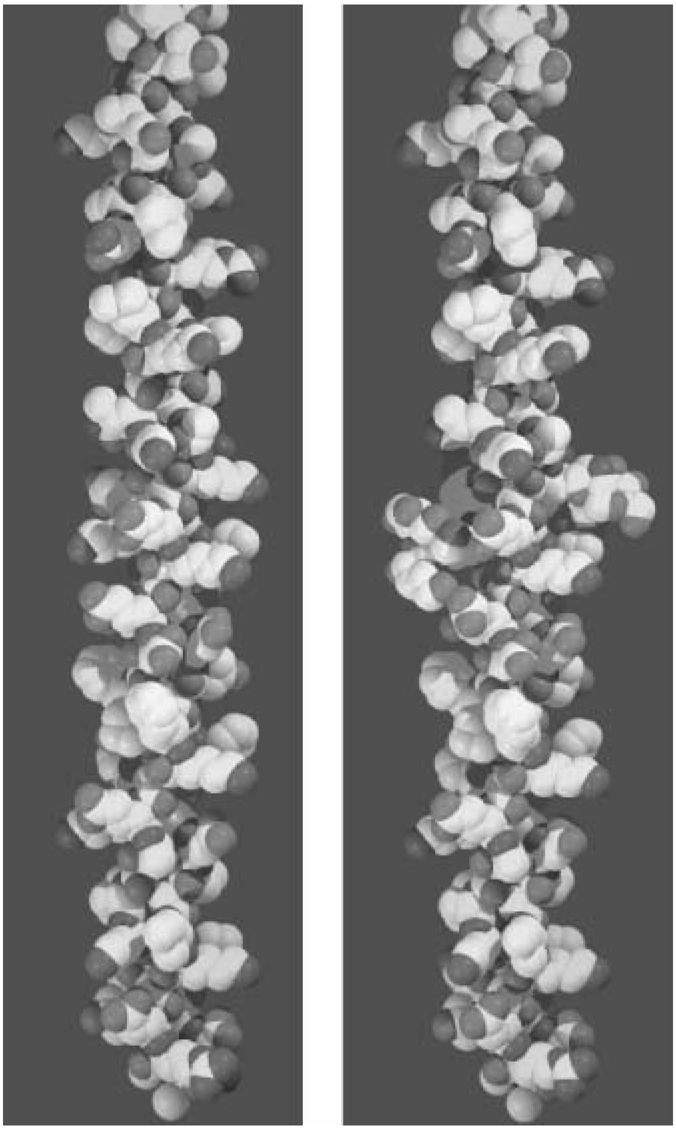


Figure 16. Attachment of galactose and glucose groups to hydroxylysine residues of collagen. (**a**) Enzymatic steps in coupling the two sugars; (**b**) stereo view (direct) of glucosylgalaclosylhydroxylysine. H atoms are not shown.

UDP
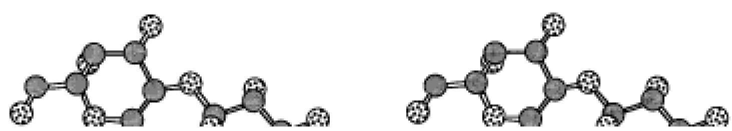
UDP glucose

(**a**)



This glycosylation is unique to collagen, and its extent is variable both between collagen types and within the same collagen in different tissues and at different ages. A potential biological role of the specific carbohydrate units would be the regulation of the lateral assembly of the triple-helical domains. An inverse relationship exists between carbohydrate content and collagen fibril diameter, suggesting that the steric hindrance to the formation of highly ordered fibrils might be caused by the bulky glycosylated hydroxylysine residues. The glycosylation of hydroxylysine residues within the triple helix proceeds through the action of two isolated enzymes: hydroxylysyl galactosyl transferase (UDP galactose: 5-hydroxylysine–collagen galactosyltransferase) and galactosyl hydroxylysyl glucosyl transferase (UDP glucose: 5-hydroxylysine-collagen glucosyltransferase). Galactose is transferred to hydroxylysine residues by the former enzyme, while glucose is transferred to galactosyl-hydroxylysine residues by the latter enzyme. The carbohydrates are provided in both reactions by the appropriate UDP-glycosides. Both enzymes require a divalent cation (preferably Mn^{2+}) for the activity. A free e-amino group in the substrate hydroxylysyl residue and a nonhelical polypeptide conformation are requirements for both transferases. The reactions are more favorable with longer peptides. Hydroxylysyl galactosyl transferase can bind at least two manganese ions per molecule of active enzyme.

Colony-Stimulating Factors

Colony-stimulating factors (CSFs) are **glycoproteins** that stimulate the proliferation, differentiation, and survival of hematopoietic (blood) cells and also activate mature myeloid cell functions. CSFs were first described in the 1960s as activities in various conditioned media that stimulated the growth of colonies of bone marrow cells in semisolid cultures. These colony-forming cells are the precursors of our red and white blood cells (see Hematopoiesis). Purification and characterization of these activities were difficult with the biochemical techniques available because they were present in conditioned media in very low concentrations and also because they were heterogeneous, largely due to variable glycosylation. Eventually, in the late 1970s and 1980s, four different murine CSFs were purified, followed by their human counterparts. These were called

1. Multi-CSF or interleukin-3 (IL-3)
2. Granulocyte-macrophage (GM)-CSF
3. Granulocyte (G)-CSF
4. Macrophage (M)-CSF, or CSF-1

Since then, the development of molecular biology has led to the cloning of CSF complementary DNAs and the production of purified recombinant proteins, facilitating *in vitro* and *in vivo* studies of their activities. All four CSFs have been tested in clinical trials, and both G-CSF and GM-CSF are used in clinical practice to elevate leukocyte levels in a variety of situations. In addition to these CSFs, many interleukins and growth factors have been described that stimulate or co-stimulate bone marrow cell colony growth. The most important of these are the early-acting stem cell factor (SCF) and FLT3/FLK-2 ligand (FL) (1), the erythroid lineage stimulator erythropoietin, and the megakaryocyte and platelet stimulator thrombopoietin (TPO). Recently, TPO has been found to have multilineage activities (2).

1. Biochemical Characteristics

The CSFs belong to a family of **cytokines** that have little sequence identity but were predicted to be similar in structure (3). The protein structures of all four have now been determined, although for IL-3 a mutant molecule with enhanced stability was used, rather than the native molecule (4). They are all **four-helix bundles** with up–up–down–down connectivity. IL-3, G-CSF, and GM-CSF are monomeric secreted proteins, but the soluble form of M-CSF is a **disulfide-bonded** homodimer produced by **proteolytic** cleavage of cell-membrane molecules. Other characteristics are given in Table 1.

Table 1. Biochemical Characteristics of the CSFs

	IL-3		GM-CSF		G-CSF		M-CSF

2. CSF Genes and Their Expression

The cloning of **genomic** DNA encoding the CSFs and analysis of the regions 5′ of the genes has resulted in a better understanding of the control of CSF expression (see Table 2). A single messenger RNA species is transcribed for IL-3 and GM-CSF, whereas a minor **alternatively spliced** mRNA is produced for human G-CSF that results in a three-amino-acid-residue insertion in the protein after residue Leu35 and a 20-fold reduction in activity. Transcription of M-CSF mRNA is more complex, with four species resulting from alternative splicing of the 10 exons (see Introns, Exons). The largest two differ only in the 3′ untranslated region and encode identical 522-residue **transmembrane** proteins. The smaller two result from splicing out of part of exon 6, which results in loss of the proteolytic cleavage site from the protein produced from the 1.6-kb **transcript** and expression of a stable transmembrane protein (5). The DNA regions upstream of the coding regions contain **promoter** and enhancer elements that have been partially characterized and shown to respond to CSF inducers such as tumor necrosis factor (TNF), IL-1, lipopolysaccharide (LPS), and antigens. The control of CSF gene expression is not understood completely, but it involves control of mRNA stability by elements in the 3′ untranslated region of the mRNAs, as well as control of transcription.

Table 2. Characteristics of the Genes Encoding the CSFs

	IL-3		GM-CSF		G-CSF		M-CSF	
Property	**Hu**	**Mu**	**Hu**	**Mu**	**Hu**	**Mu**	**Hu**	**Mu**

3. CSF Production

Many cell types have been shown to produce CSFs *in vitro* in response to various stimuli, such as bacterial products (LPS) and inflammatory cytokines (TNF, IL-1), but the role of CSFs in maintaining white blood cell levels in normal healthy individuals is not entirely clear (see later). Whether unstimulated cells produce CSFs is still debated (6). GM-CSF, G-CSF, and M-CSF are produced by macrophages, endothelial cells, fibroblasts, and stromal cells. In addition, T lymphocytes produce GM-CSF, M-CSF (in humans), and IL-3. Mast cells have been shown to produce IL-3 and GM-CSF. Other cell types have been reported to produce GM-CSF and IL-3, but these studies have yet to be confirmed.

4. CSF Receptors

The CSF receptors are transmembrane proteins belonging to the cytokine receptor class I family, except for the M-CSF receptor, which is a tyrosine kinase receptor. The class I receptors contain a structurally conserved module called the cytokine-binding **domain** (CBD), the hemopoietin domain, or the cytokine receptor homology domain. This module comprises two fibronectin type III domains with four conserved cysteine residues in the *N*-terminal domain and a conserved Trp━Ser━X━Trp━Ser sequence in the *C*-terminal domain. Ligand binding causes dimerization or oligomerization of the receptors, which initiates signal transduction. The IL-3 and GM-CSF receptors form heterodimers of a ligand-specific a-chain and a common b-chain that is also shared with the IL-5 receptor. In the mouse, there is an additional b-chain that is unique to the IL-3 receptor. The G-CSF and M-CSF receptors form homodimers. Receptor dimerization activates tyrosine kinases (intrinsic in the M-CSF receptor, cytoplasmic **JAK** kinases for the other receptors) that **phosphorylate** the receptors, providing binding sites for other signaling molecules that are in turn activated by phosphorylation of tyrosine residues and, in some cases, serine or threonine. Ultimately, these signaling cascades lead to alterations in gene transcription, but the components of the biochemical pathways are still being defined (reviewed in Refs. 7-9).

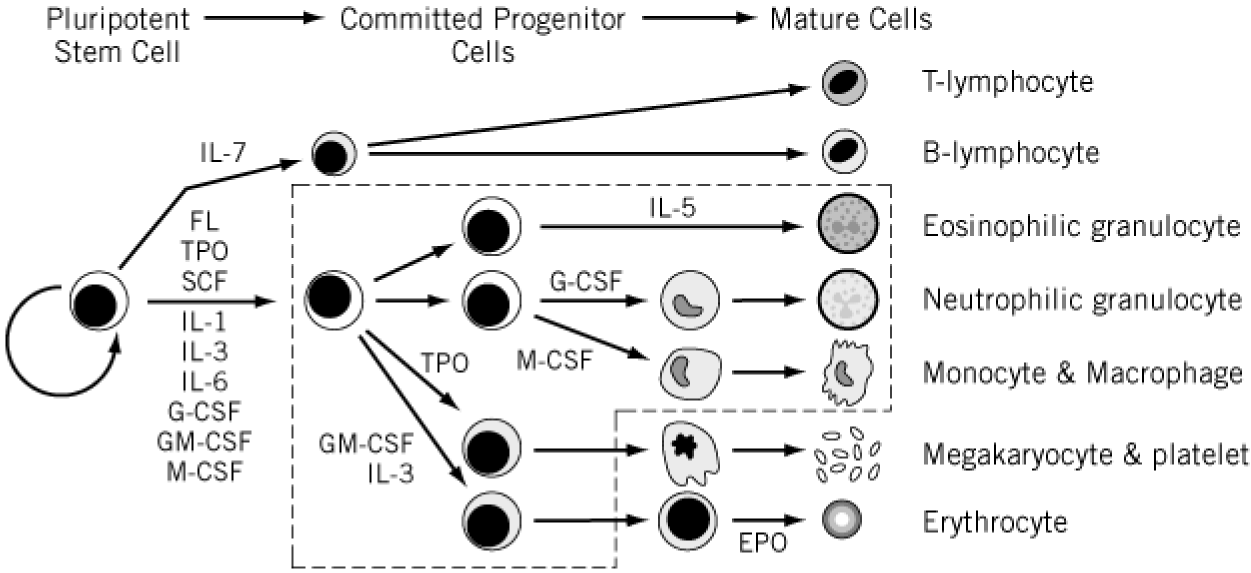
The CSF receptors are expressed at low levels on hematopoietic cells, usually a few hundred receptors per cell. IL-3 receptors are expressed on neutrophil, eosinophil, and macrophage lineages, on mast cells, and on undifferentiated blast cells. GM-CSF receptors are expressed on neutrophil, eosinophil, and macrophage lineages. G- and M-CSF receptor expression is more restricted; G-CSF receptors are present on neutrophils and at a low level on macrophages, and M-CSF receptors are found on macrophages, osteoclasts, and placental trophoblasts. Recent studies have detected expression of receptors on purified stem-cell populations. Human $CD34^+$ cells expressed SCF, FL, G-CSF, and, at a low level, GM-CSF receptors (10). Murine stem cell populations expressed IL-1a, IL-3, IL-6, and G-CSF receptors (11).

5. Biological Activity

5.1. *In Vitro*

All four of the CSFs stimulate the proliferation and differentiation of bone-marrow progenitors to form colonies in semisolid agar. The type of mature cells in the colonies varies with the stimulator (see Fig. 1). IL-3 was otherwise called multi-CSF because it stimulates the largest number of different cell lineages. Colonies of granulocytes, macrophages, eosinophils, megakaryocytes, undifferentiated blast cells, and mixed cell lineages are obtained. In liquid cultures, proliferation of mast cells is strongly stimulated by IL-3, and some types of B lymphocytes are reported to respond. GM-CSF stimulates growth of granulocytic, macrophage, and eosinophil colonies. Production of dendritic cells, which are important **antigen-presenting** cells in the immune response, is stimulated by GM-CSF. G-CSF and M-CSF are more lineage restricted, producing mainly granulocytic and macrophage colonies, respectively. The CSFs can give enhanced or synergistic responses when used in combination with each other and with other interleukins and growth factors. Some effects of CSFs on nonhematopoietic cells have been reported. G- and GM-CSF can stimulate proliferation of endothelial cells. Placenta-derived cells and oligodendrocytes proliferate in response to GM-CSF. M-CSF stimulates proliferation of trophoblast cells and may be important in pregnancy.

Figure 1. Schematic representation of hematopoiesis and the CSFs and other cytokines required for mature cell production. IL, interleukin; FL, FLT3/FLK-2 ligand; SCF, stem cell factor; TPO, thrombopoietin. GM-CSF and IL-3 stimulate cells inside the dotted line box.



5.2. *In Vivo*

The effects of CSFs *in vivo* have been determined both by injection in mice and humans and by analysis of CSF-deficient mice created by gene targeting and, in the case of M-CSF, a naturally occurring mutation. Injection of IL-3 or GM-CSF elevates circulating levels of neutrophils, monocytes, and eosinophils. G-CSF causes a greater elevation of neutrophils than does IL-3 or GM-CSF, but only a weak increase in monocytes and no effect on other lineages. M-CSF causes a selective elevation of monocytes. The magnitude of these increases depends on the dose of CSF administered. It is interesting that in response to infection, circulating IL-3 or GM-CSF are not usually detected, whereas G-CSF and, to a lesser extent, M-CSF are frequently elevated in serum. These observations suggest that IL-3 and GM-CSF may be important in local inflammatory responses in the tissues rather than in a systemic response to infection.

The importance of the CSFs in maintaining basal hematopoiesis has been assessed by analysis of CSF-deficient mice. For IL-3, GM-CSF, and G-CSF, gene “knockout” mice were created by introduction of a defective version of the gene of interest into embryonic stem cells by homologous recombination. The embryonic stem cells were injected into blastocysts to create chimeric mice that were then bred to create heterozygous and homozygous deficient mice. For M-CSF, mice with a naturally occurring point mutation (*op*/*op*) that resulted in a frameshift in the sequence and a loss of M-CSF production were discovered. The IL-3- and GM-CSF-deficient mice were able to produce normal levels of circulating blood cells and bone marrow progenitors. The GM-CSF-deficient mice developed pulmonary alveolar proteinosis and increased pulmonary infections, presumably as a consequence of defective pulmonary macrophage function. Recent studies in IL-3-deficient mice have shown that IL-3 is important for elevation of basophils and mast cells in response to a parasitic infection (12) and for some delayed-type hypersensitivity (T-lymphocyte-dependent) responses (13). G-CSF defective mice were neutropenic, with neutrophil numbers reduced to 20–35% of wild-type control mice. Bone marrow cellularity was normal, but some granulocytic and macrophage progenitors were reduced in number. These mice were more susceptible to a bacterial infection (*Listeria monocytogenes*) than wild-type mice. Young M-CSF-deficient mice have osteopetrosis, a severe macrophage and osteoclast deficiency resulting in failure of teeth eruption and overgrowth of bone that occludes the marrow cavity and reduces marrow cellularity. Unlike the other CSF-deficient mice, the *op/op* mice overcome their defects with age, which suggests that other cytokines may be able to compensate for the lack of M-CSF. Thus, the CSF-defective mice have shown that each CSF has a unique function *in vivo*. GM-CSF and IL-3 are not required for steady-state hematopoiesis. G- and M-CSF are required for normal neutrophil and macrophage production, respectively. All four CSFs contribute in different ways to control of infection. They may have other nonunique functions that are not revealed in the deficient mice because of compensatory activities of other cytokines. These may be detected in future studies of multiply deficient mice.

6. Myeloid Leukemia

Acute and chronic myeloid leukemias (AMLs and CMLs) are clonal diseases of bone marrow cells in which the predominant cell types are granulocytes and macrophages, although leukemic cells of other lineages are also found. There are potentially two ways in which CSFs could be involved in leukemia: They may be required for the proliferation of the leukemic cells, and they may cause differentiation and clonal extinction of the leukemia. In semisolid agar cultures, CML cells will produce colonies of normal appearance containing granulocytes, macrophages, and eosinophils. The colony growth is dependent on CSF stimulation, and all four CSFs are active. In contrast, AML cells produce small clones with little maturation, and growth is very variable from patient to patient. The cells are responsive to CSFs to a variable extent, and in a proportion of patients (<30%) there is colony growth in the absence of CSFs. The colonies do not contain clonogenic cells that are able to form further colonies in secondary cultures. The leukemic stem cells have not been identified, and their dependence on CSFs is unclear. Whether autocrine production of CSFs by leukemic cells is important is also unknown, with the exception of leukemic monocytes, which produce CSFs like their normal counterparts. Lopez and colleagues have produced a GM-CSF antagonist that induced remission in a murine model of juvenile myelomonocytic leukemia (14). Although there are some leukemic cell lines that differentiate and cease proliferation in response to CSFs *in vitro*, many cell lines are not suppressed by CSFs. There may be defects in the signal transduction pathways that prevent differentiation. In a small number of patients with congenital neutropenia who develop AML, a mutation in the G-CSF receptor expressed by the leukemic cells has been described that prevents differentiation in response to G-CSF (15). However, it is not known whether this mutation contributed to the development of AML.

7. Clinical Use of CSFs

The use of chemotherapy in cancer treatment is limited by its toxicity, primarily neutropenia. Both G-CSF and GM-CSF have been tested extensively in clinical trials and shown to reduce neutropenia, allowing the intensification of chemotherapy doses. Clinical trials have not yet shown, however, whether dose intensification improves survival. G-CSF has fewer side effects and is more effective at elevating neutrophil levels than GM-CSF and thus is usually the CSF of choice, but GM-CSF may be more effective in reducing infectious complications (16). In high-dose chemotherapy followed by autologous bone marrow transplantation, both CSFs reduced the time taken for recovery to ≥500 cells/mm^3 by about one week and, in some trials, reduced the duration of hospital stay. G-CSF (and GM-CSF) treatment increased the levels of circulating progenitor and stem cells so that G-CSF-mobilized peripheral blood progenitor cells are now used instead of bone marrow cells for reconstitution after high-dose chemotherapy. This treatment results in more rapid recovery than bone marrow transplantation.

Patients with congenital neutropenia or idiopathic chronic neutropenia respond to G-CSF treatment with elevation of neutrophil levels, resulting in fewer infections and less time in hospital. A few of these patients (3% in Ref. 17) develop myelodysplasia or leukemia, but at present there is no evidence whether G-CSF increases the frequency of these cases. Despite initial concerns that treatment of leukemia patients with CSFs might exacerbate the disease, there is no evidence that this occurs. Neutrophil recovery has occurred more rapidly in leukemia patients receiving G-CSF or GM-CSF after chemotherapy, but reduction in duration of hospital stay was not usually observed.

There have been fewer clinical trials with M-CSF and IL-3. M-CSF appears to improve recovery from fungal infections and is approved in Japan for use in allogeneic transplantation, induction therapy of AML, and dose-intensive therapy of ovarian cancer. IL-3 given after chemotherapy reduced the recovery time from leukopenia and elevated the levels of neutrophils, monocytes, and eosinophils. In the future, it is likely that combinations of cytokines will be tested.

Combinatorial Libraries

Few fields have emerged as rapidly as the technologies collectively referred to as combinatorial chemistry. The origins of combinatorial “thinking” as applied to biological problems can be traced to our understanding of the immune system. Humoral immunity is based on the generation of billions of different antibody molecules through unique **gene recombination** events. Upon exposure to a foreign immunogen, the subset of the antibody repertoire with specificity for the invader is clonally expanded. During expansion, the active antibody subpool undergoes additional recombination and mutation events, and the most active variants are further selected. This process is reiterated until mature antibody molecules are produced that are highly optimized against the foreign antigen. In essence, antibody repertoires are combinatorial libraries—collections of related but distinct molecules representing different combinations of genetic elements. The recognition of these facts preceded the creation of the first combinatorial library, which was based upon the synthesis and screening of large numbers of synthetic peptides in order to identify selected antigenic determinants of a viral pathogen (1). Given the parallels between the immune system and combinatorial libraries, it is not surprising that the original application of this emerging technology was in the derivation of immunogens capable of stimulating immune protection in animals not yet exposed to certain pathogens.

The hallmarks of a combinatorial approach are the generation and use of complex compound mixtures to identify molecules with desirable properties. Four basic operations underpin combinatorial approaches: (i) generation of libraries containing related but diverse compounds, (ii) selection of molecules with desirable properties from the library, (iii) characterization of the selected molecules, and (iv) amplification of the identified products. Depending upon the chemical composition of the library, the selected molecules may require amplification before structure determination. For example, DNA libraries can be amplified using the polymerase chain reaction (**PCR**) before the final products are identified by sequencing. Synthetic peptides and small molecules cannot be amplified per se and must be subjected to structural elucidation, and then resynthesized for subsequent use. Regardless of the library composition, the four operations enumerated above can be applied in an iterative fashion to progressively refine the selected compounds.

Several entries in this volume deal with the application of combinatorial approaches to complex biological problems. Issues central to the implementation of combinatorial technologies in biological systems will be described below, including cognitive aspects of library design, practical aspects of library construction, basic issues in affinity selection and library screening, and discussions of different library types and their applications. The breadth of the topic Combinatorial Libraries is so expansive that it is impossible to cover any topic in great detail. The entries entitled Libraries, Combinatorial Synthesis, and Affinity Selection are intended to provide a generic introduction to the principles underlying combinatorial operations. The remaining entries, DNA libraries, Genomic libraries, cDNA libraries, Expression libraries, Peptide libraries, and Phage display libraries, provide more specific details regarding the major types of combinatorial libraries in widespread use. Small molecule synthesis or drug discovery applications are not dealt with in detail, although many basic concepts from these fields are presented. The reader is referred to the suggested reading list for additional discussion of these related topics.

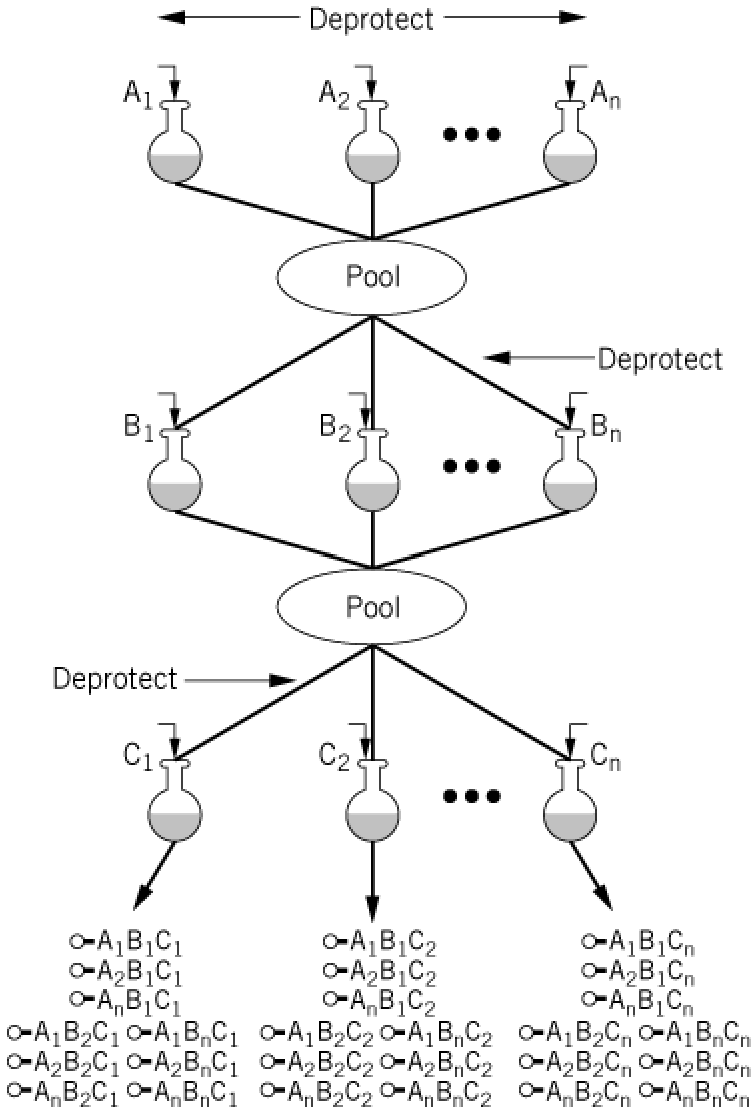
Combinatorial Synthesis

The diversity of a molecular library may be derived from natural sources, or it may be created through specialized techniques in synthetic chemistry. Traditionally, synthetic chemists focus on preparing individual compounds, paying careful attention to stereochemical control and to achieving the greatest possible yield and purity. This often requires the use of highly specialized reactions and can be a painstakingly slow process. In contrast, chemists engaged in combinatorial organic synthesis employ transformations that are more general in scope and can be applied to the simultaneous preparation of many chemically distinct compounds. In exchange for the ability to prepare many compounds in a short time frame, compromises are accepted that may result in sacrificing, within acceptable limits, yield and purity of individual reaction products. This entry deals with the basic issues faced in preparing and screening synthetic combinatorial libraries and some of the relevant technologies and methods. No attempt has been made to provide exhaustive coverage of the rapidly expanding range of chemistries now amenable to library synthesis, nor have we attempted to cover the application of combinatorial chemistry as it applies directly to the field of drug discovery. See Combinatorial Libraries.

Combinatorial chemistry seeks to create all possible combinations of a set of building blocks and then extract the identity of members that exhibit a desired property. Thus, if a traditional synthesis involves incorporating building block A, followed by B, and then C to give the desired compound A–B–C, then the analogous combinatorial synthesis would employ a set of monomers, A_1–A_n, followed by a second set of monomers, B_1–B_n, and then a third set of monomers, C_1–C_n, giving all possible combinations of $(A_{1\text{ to }n})$–$(B_{1\text{ to }n})$–$(C_{1\text{ to }n})$. Such processes can be described as n^k sets, where n is the number of building blocks used in each cycle of synthesis and k is the total number of synthetic cycles. The number of individual species generated by these approaches become vast very quickly. For example, a relatively short DNA library of 100 random nucleotide positions has a theoretical complexity of 4^{100}, or 1.6×10^{60} different sequences. This number exceeds the number of protons in the sun. Complexities of more realistic peptide libraries using the 20 amino acids incorporated into proteins are as follows: A library of all possible tripeptides will contain 8000 (20^3) distinct peptide sequences; a library of all possible tetrapeptides will contain 160,000 (20^4) distinct peptide sequences; and a library of all possible pentapeptides will contain 3,200,000 (20^5) distinct peptide sequences. Specialized methods are required to prepare, assay, and elucidate the identity of active compounds from collections of this size. In order to facilitate product purification, compounds are typically synthesized while covalently attached to inert solid supports, including polymeric pins or resin beads, although other materials have been used. Use of solid phase synthesis enables many reactions to be carried out simultaneously using parallel arrays of individual reaction chambers. If each reaction yields a single product, the result is a library of spatially discrete compounds. This approach has the advantage that the identity of compounds can be ascertained immediately, based on the position in the synthetic array and the associated synthetic history. The initial application of this approach was reported by Geysen et al. for synthesis of peptide libraries (1); however, many variations have been reported since then, involving a wide range of chemistries. Although convenient and straightforward to implement, the number of compounds that can be synthesized and screened using this approach is limited by the physical dimensions of the arrays to approximately 10,000 different species. Miniaturization and photolithographic masking techniques have enabled arrays containing more than 100,000 compounds to be synthesized on silica chips (2). Although this has been applied to a variety of chemistries, it is perhaps most widely recognized as the DNA chip technology of Affymetrix (3). Unfortunately, this approach requires highly specialized instrumentation for the photolithographic masking, as well as for assay of the resulting arrays.

The synthesis of larger libraries requires pooling methods that overcome the size limitations of spatial arrays (4). Pooling methods employ mixtures of reactants at each synthetic step (5). For example, in random DNA oligonucleotide synthesis, two or more deoxyribonucleotide phosphoramidites are introduced during each coupling cycle. One major problem with mixture synthesis is that variation in reactivity can result in some building blocks being under- or overrepresented in the final compound pool. At least in some cases, the initial concentration of reactants can be adjusted to correct for these variations in reactivity. A more attractive approach, first introduced by Furka, is the “split synthesis” strategy (6). Briefly, a portion of synthesis resin is “split” or divided into equal portions and placed into individual reaction vessels (Fig. 1). Each vessel receives a single building block in large excess, which drives the reaction to completion. The resin from all the vessels is then recombined, mixed thoroughly, and then redistributed. A second set of building blocks is then introduced. This process is repeated the desired number of cycles, to produce all possible combinations of the desired building blocks. Because each resin bead is exposed to a single building block at each step, there will be only one compound (but many copies) attached to each bead. This has led to the term one-bead, one-compound (OBOC) libraries (7, 8).

Figure 1. Schematic flow of a split synthesis. The resin is first divided into *n* equal portions. Following deprotection, each resin batch is reacted with a different monomer from set A. The resin is pooled, mixed, and divided into equal portions. After deprotection, individual monomers from set B are coupled. The process is repeated, and monomers from set C are added. Each final reaction batch is held separately for subsequent assay.



Compound identification is straightforward for spatially discrete libraries; however, identifying active species in the large and complex mixtures that result from pooling strategies presents a formidable problem. Typically, each member of a pool is present in a quantity that, although sufficient for determining biological activity, is insufficient for isolation and structure determination by standard analytical methods. As a result, strategies to identify the active members must be built into the synthetic schemes and closely coupled to the types of assays that will be performed with a particular library.

Compounds can be identified from soluble libraries using deconvolution strategies such as those introduced by Houghten (9, 10). This approach relies on cycles of synthesis and screening to focus progressively in on active species. An initial library is prepared in which one position of diversity is held constant. Each individual pool of compounds contains a different building block at the constant position but a mixture of building blocks at the remaining positions of diversity. Screening identifies the pool and therefore the optimal building block at the defined location. A second library is then synthesized in which all members have the optimal building block at this first position, but each pool contains a different building block at a second position of diversity. This process is repeated until the preferred building block for each position is determined. The chief disadvantage of this approach is that it is a laborious and time-consuming process. Moreover, this strategy does not guarantee that the most potent library member will be identified since selection of a “preferred” building block depends on the cumulative activity of a pool. Selection of a particular building block could, therefore, result from the presence in a pool of a relatively few number of potent compounds or a large number of relatively poor inhibitors.

Several strategies have been developed that allow the active members of a library to be determined without requiring cycles of synthesis and screening. The method of positional scanning (11) involves synthesizing a series of combinatorial libraries, each fixing a single position of diversity. Synthesis of each library is divided such that each component pool is prepared using a single building block at the defined position, while the remaining positions are synthesized using mixtures of building blocks. Although this method does not require resynthesis, it does require additional synthetic effort to prepare a complete set of scanning libraries, and the total number of syntheses is greater than for deconvolution approaches. Moreover, because each position is defined independently, there is an increased chance of missing the most active members in the library.

Orthogonal pooling strategies also avoid the resynthesis burden of deconvolution methods (12). In this approach, two separate libraries are synthesized such that any given pool of the first library has only one compound in common with any pool of the second library. Determining the common species between positive pools from the two libraries reveals the identity of active compounds. The chance for misidentifying the optimal building block at any given position is avoided by this approach, but there is a considerable synthetic burden, as well as compound tracking issues.

The second general assay format is designed to measure the interaction of a target (enzyme, receptor, cell, etc) with compounds while they remain attached to the solid support used for library synthesis. Geysen pioneered this approach for assaying libraries of peptides arrayed on pins (1); however, the full potential was realized only when it was coupled to screening of OBOC libraries (8). Because each resin bead in an OBOC library carries a single library compound and the beads are physically distinct, each bead behaves as an isolated assay system. Briefly, a target is incubated with a pool of beads. The excess target is removed by washing, leaving behind only target that associates specifically with a compound attached to a resin bead. The active compounds are identified following visualization of those beads to which the target specifically interacts.

Specialized techniques are required to identify the compounds attached to individual beads, because each bead can carry at most a few nanomoles of compound, which is insufficient for structure determination except in a few rare cases (eg, peptides). These methods seek to “tag” or “encode” the beads with the synthetic history in a manner that is easily deciphered (13, 14). The code is introduced either prior to library synthesis or following each cycle of building block addition. In the latter case, the chemistries for library synthesis and code synthesis must be mutually compatible, which is one of the major obstacles in the development and utilization of this approach. Examples of encoding methods include the use of peptides read by Edman Degradation (15), nucleic acids read by PCR amplification and sequencing (16), several small molecule chemical classes identified by various analytical methods (17, 18), nonradioactive isotopic tags read by mass spectrometry (19), and radioisotopes encapsulated within the solid-phase support (20, 21). The development of encoding methods is an active area of research because the split synthesis method is currently the only tractable approach to preparing large libraries in which all possible compounds are represented.

Competence

Competence is the condition of bacterial cells that enables them to take up naked **DNA**. When this DNA can integrate into the chromosome by recombination or, in the case of **plasmids**, establish itself in the cytoplasm, the cells are said to be transformed (see Transformation). Competence is manifested by several species of bacteria—representatives of 29 different genera according to a recent count (1)—but far from all. Even in transformable strains, competence generally depends on the establishment of a particular physiological state. Four species have served as the major experimental models for studies of competence, and we shall therefore confine discussion largely to these: *Bacillus subtilis, Streptococcus pneumoniae* ("pneumococcus"), *Haemophilus influenzae*, and *Neisseria gonorrhoeae*. In view of the universal utility of *Escherichia coli*, which does not acquire competence naturally, we shall also review briefly the artificial induction of competence in this species.

The basic mechanism of DNA uptake appears to be the same in all naturally transformable organisms. Duplex DNA binds to the cell surface, and is then processed so that just one of the two strands passes through a specialized transmembrane channel into the cytoplasm, where it undergoes recombination with the resident chromosome. In **gram-negative** bacteria, a means of first passing through the outer membrane is also needed. The systems that regulate the uptake process, however, as well as the environmental stimuli to which these systems respond, appear to be more idiosyncratic, presumably reflecting the very different natural habitats in which the capacity to take up DNA is induced. Furthermore, the regulatory pathways of competence intersect with those of other metabolic activities. It is with the regulation of competence that this entry is chiefly concerned, the uptake process itself being deferred largely to the entry Transformation. We begin with the bacterium for which most is known at both the mechanistic and regulatory levels.

1. *B. subtilis*

B. subtilis survives and grows in many environments, but its natural reservoir is the soil. It was early appreciated that competence in this bacterium is a phenomenon induced by decelerating growth (2), such as occurs at the transition from exponential to stationary phase or upon depleting the medium of amino acids. Dependence of competence on transition to the stationary phase appears to reflect inhibition of competence by added amino acids (3). Prototrophs in minimal medium can attain competence in exponential phase (4). We now know that it is just one of a number of late-growth responses, which also include excretion of degradative enzymes, antibiotic production, development of motility, and **sporulation** (5). Regardless of the many overlapping inputs from these other pathways, induction of competence is mediated by a single transcriptional activator, the ComK protein (6). This protein stimulates expression of the genes that encode the 12 components of the DNA-uptake machine identified to date (7-9). These genes are distributed among four polycistronic transcription units, *com G*, *C*, *E* and *F*, which specify the DNA-binding apparatus and its assembly, as well as the functions that translocate a single strand of DNA into the cytoplasm. The **nuclease** that degrades the other strand has not been identified. ComK also stimulates (a) the synthesis of **RecA**, which catalyzes the final step of transformation, (b) the recombination of the imported strand with the chromosome, and (c) the synthesis of AadAB, a nuclease/DNA helicase that assists the process.

Several intersecting metabolic currents determine the net level of active ComK at a given moment, and hence the degree of competence. Some of these are indicated in Figure 1. What is remarkable about this system is that positive input from all these factors is necessary for high levels of competence; the absence of any one of them diminishes activation of ComK or reduces transcription of its gene. Stochastic variability, leading to limits on one or more of these factors, may explain why in *B. subtilis* cultures, unlike those of other species, only about 10% of the cells become competent, even with optimum inducing treatments. The special condition of these cells is underscored by assorted observations of their relatively quiescent metabolic state and reduced buoyant density (4).

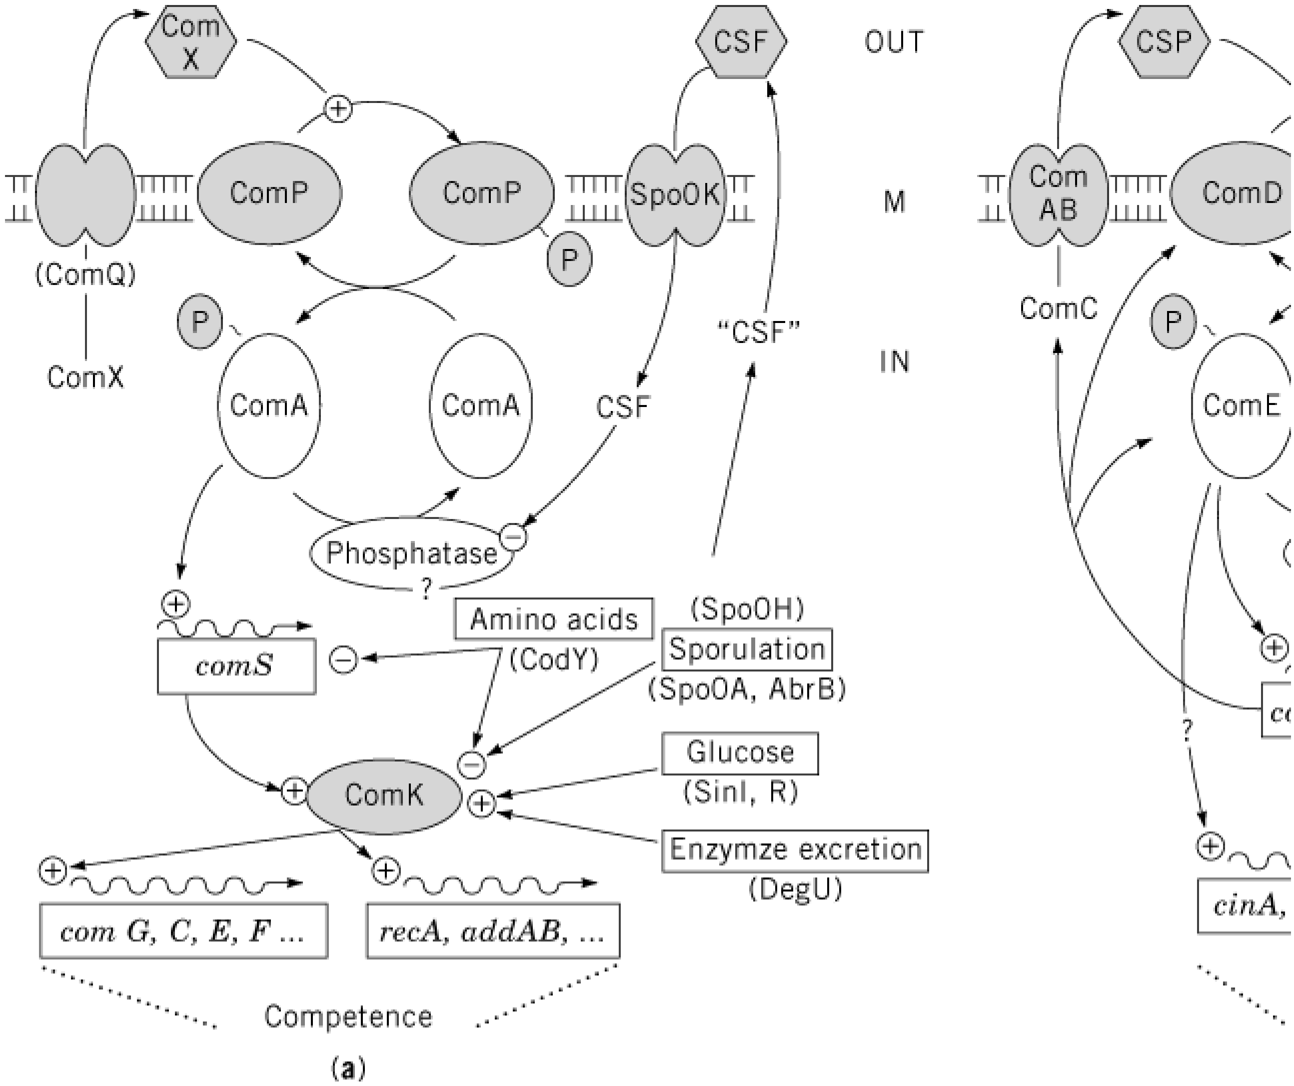
transmits the CSP signal to the known late competence genes, as well as, presumably, others not yet identified (*cin* genes
ComD homologue interacts directly with CSP (25). Because CSP ultimately stimulates transcription of its own gene, init
wholesale induction of the culture, effectively synchronizing competence development. The *comC, D*, and *E* genes const
coregulation. The importation of other peptides appears to modulate competence induction (27-29). Strains mutant for th
AliAB develop competence at much lower cell densities than the wild type, suggesting that importation of peptides serve
that the peptides repress *comCDE* transcription until exhausted at higher cell densities.



The finding that competence was attained earlier in cultures growing in medium already used for growth of cells to the competent state implied that extracellular signaling molecules promote development of competence (10), and this proved to be the case. Two such molecules are known, both generated by the cell and exported to the medium. The ComX pheromone interacts with the cell-surface protein ComP to initiate a cascade of interactions that culminate in competence (11, 12). Competence stimulating factor (CSF) is probably imported to stimulate this pathway. These interactions are shown in Figure 1 and described in the legend. It is possible that the apparent redundancy of competence-inducing function reflects only the co-opting of the CSF sporulation factor to protect the primary product of the competence-specific pathway, the phosphorylated form of ComA, ComA ~ P (13). Unlike ComX, which seems to be specific for competence, CSF production is intimately linked with the system that regulates sporulation; transcription of its gene requires the Spo0H sigma factor and is stimulated, indirectly, by the Spo0A ~ P transcription regulator. Grossman (14) has suggested that CSF is also a signaling molecule for sporulation.

The external actions of ComX pheromone and of CSF have led to the suggestion that these factors communicate cell-density information to the system that regulates competence (14). ComA thus serves as a depot for these signals, and in its phosphorylated form it sends them on by activating transcription of *comS* (12, 15-18).

This general induction pathway is also subject to nutritional signals: amino acids via CodY (3), and glucose via SinI and SinR (19). How these, as well as signals from the sporulation and enzyme secretion pathways (AbrB, DegU ¼), are integrated to allow the cell to decide whether to commit itself to competence remains an intriguing issue.

2. *S. pneumoniae*

This organism is an obligate parasite of the respiratory tract. In contrast to *B. subtilis, S. pneumoniae* readily attains competence during exponential growth in rich medium. Moreover, all the cells become competent, albeit briefly. Competence in *S. pneumoniae* does share with that of *B. subtilis*, however, an association with a distinct physiological state. This takes the form of altered surface properties, cessation of cell-wall synthesis, increased cell-wall fragility, and release of DNA into the medium. The onset of competence is very sensitive to culture conditions: temperature, the nature of the medium buffer, the concentrations of magnesium and calcium, and pH. In low-pH medium, there is only one peak of competence, at high cell density, whereas in high-pH medium there is a succession of peaks (20).

The competence induction pathway of *S. pneumoniae* shows notable similarities to that of *B. subtilis*, as depicted in Figure 1. Induction of competence is mediated by an extracellular signaling molecule, the competence stimulating peptide (CSP) (21-23), and this initiates the induction cascade via a sensor-regulator protein pair (24-26). Induction is also modulated by imported peptides (27, 28), though in this case the effect is negative (29).

Several proteins other than those shown in Figure 1 make their appearance at competence, some of them associated with the membrane (30); but the only one demonstrated to have a clear role in transformation, indeed in competence itself, is the RecA protein, which mediates homologous recombination (31).

S. pneumoniae cultures exhibit a particular aspect of competence that, though detected long ago (32), has received little attention. Filtrates of cultures that have passed their peak of competence prevent development of competence when added to another culture, suggesting that a specific inhibitor of competence is secreted into the medium. Such a factor might be induced at competence just in order to turn it off again, accounting for the brevity of the competence peak.

3. *H. influenzae*

H. influenzae lives in the mucus of the respiratory tract, where it may be exposed to large amounts of naked DNA (33). Only its own DNA, however, is taken up with high efficiency. This selectivity results from the presence throughout the genome of numerous copies of a short, specific base sequence, the uptake-signal sequence (USS), which is recognized by the uptake apparatus (34, 35). The outer membranes of competent cells extrude vesicles, termed *transformasomes* (or "blebs"), which encapsulate the DNA and then release it into the **periplasm** to allow transport into the cell (36-38). As in *B. subtilis*, growth-inhibiting conditions, such as transient anaerobiosis, nutritional downshift, and approach to stationary phase, induce competence. The level of competence attained varies and can be close to 100% of the population. Nevertheless, there appears to be no cell density sensing involved, each cell developing competence independently. *H. influenzae* cells implanted in the rat peritoneum rapidly develop the capacity to import DNA added with the inoculum and manifest other changes characteristic of the competent state (39).

Several factors important to the development of competence in *H. influenzae* have been identified, but the picture remains fragmented. Of crucial importance is the intracellular level of cyclic AMP (cAMP). Competence was abolished by mutations in the cyclic AMP receptor protein (CRP) and adenylate cyclase (Cya) genes, but could be restored to a *cya* mutant by addition of cAMP (40, 41). The cell senses sugar availability through a carbohydrate phosphotransferase system that increases cAMP synthesis in response to declining sugar availability: Mutations in two genes specifying components of this system, *ptsI* and *crr*, caused partial loss of competence, a deficiency that can be compensated for by added cAMP (42, 43). Competence in *H. influenzae* thus responds directly to nutritional state.

Some clues as to how cAMP might act in competence induction have recently emerged. Notably, cAMP stimulates transcription from a divergent **promoter** region of two genes essential for transformation, *tfoX* and *rec-1*. *TfoX* was originally identified by a mutation, *sxy*-1, that increased transformation 100-fold (44). Null mutations in the gene eliminated DNA binding and transformation, whereas overexpression of *tfoX* caused constitutive competence (45, 46), implying that TfoX is a positive regulator of competence. The finding that TfoX is needed for expression of other competence genes (*com101A*, *dprA*, and *rec-2*) (46, 47) supports this suggestion and hints at a central role in competence similar to that played by the ComK regulator of *B. subtilis*. Whereas *tfoX* transcription normally increases only as cells approach stationary phase, addition of cAMP to a log-phase culture causes an immediate stimulation (46).

On the other hand, transcription of *rec-1*, which encodes the general recombination enzyme that is analogous to RecA of *E. coli*, is only weakly stimulated by cAMP-CRP (48). It is, however, induced by single-stranded DNA, as befits its function of integrating transforming DNA. This common property of Rec proteins has been proposed to endow Rec-1 with another quite distinct function, that of triggering competence. Induction of competence in *H. influenzae* may be associated with the conversion of up to 5% of the chromosomal DNA to single-stranded form. Observing that overproduction of Rec-1 led to early development of competence, Stuy (49) suggested that formation of Rec-1/single-stranded DNA complexes might induce competence gene expression, as the equivalent complexes induce the SOS regulon in *E. coli*. The idea remains untested.

Several new proteins appear in the outer membrane at competence. Some of them, rather than being synthesized *de novo*, are redistributed from the inner membrane. One mutant that fails to do this also fails to bind DNA. It carries a lesion in the gene *por*, which encodes a periplasmic disulfide oxidoreductase, suggesting the need to assemble or fold **disulfide bond**-containing proteins (50) (see Protein Disulfide Isomerase). Two proteins probably involved in conducting DNA into the cytoplasm are induced at competence: Rec-2, which shares homology with the presumed transmembrane channel protein ComEC of *B. subtilis*, and DprA (47).

There is as yet no indication that *H. influenzae* competence responds to a specific extracellular signal. If it does, it now seems unlikely to do so via a sensor-regulator protein pair, such as ComP-ComA in *B. subtilis*: Mutation of the genes encoding four such systems, as deduced from the genome sequence, failed to affect competence (43). What is clear is that the identity and function of most of the components of the competence regulatory system are still unknown, and that the true place of the known ones in the system likewise remains to be shown.

4. *N. gonorrhoeae*

Unlike the bacteria already discussed, for which competence is a transitory response to growth conditions, transformable *Neisseria* strains are competent at all phases of growth (51). An early indication (52) that competence could be induced by a **proteinase**-sensitive factor present in conditioned medium has not been confirmed. The transformation mutants so far reported are defective in one or more of the individual functions known to be involved in transformation-pili and proteins for DNA binding, transport, and recombination (53-55), but none have suggested the existence of competence factors or regulators. The competent state may be so integrated into the general physiology of *Neisseria* that a specific regulatory system is not needed, or the regulatory elements are essential and therefore missed in mutant hunts. Transformation of cells in culture is influenced by pH and by the concentrations of mono- and divalent cations (53), but these factors probably affect DNA-cell envelope interactions directly, rather than by regulating competence gene output.

5. *E. coli*

In 1970, Mandel and Higa (56) discovered that *E. coli* could be induced to take up DNA by treatment of the cells with Ca^{2+} ions. Although this artificial competence has been a key technique in molecular genetics, its basis is not understood. Suspension of *E. coli* cells in cold $CaCl_2$ solution is known to induce the formation of transmembrane pores consisting of an outer shell of polyhydroxybutyrate, connected by Ca^{2+} to an inner sheath of polyphosphate (57). The role of these pores is unclear, because their internal diameter appears to be too small to allow the passage of double-stranded DNA. They do, however, have marked effects on temperature-induced membrane fluidity, and it is possible that, by anchoring an otherwise mobile membrane, they create tension that opens holes elsewhere in the membrane to admit the DNA (57, 58).

6. Summary

One of the most striking aspects of research on competence to emerge in recent years is the interrelationships between the proteins and regulatory factors involved and those of other phenomena previously considered distinct, perhaps the clearest example being *B. subtilis* sporulation (14). Indeed, acquisition of competence is usually accompanied by other major physiological changes. Because of this, and because our knowledge of competence is based largely on laboratory observation, it is fair to question whether DNA uptake itself is relevant in natural bacterial habitats. In fact there are good reasons for thinking that it is, and this issue is taken up in the entry Transformation.

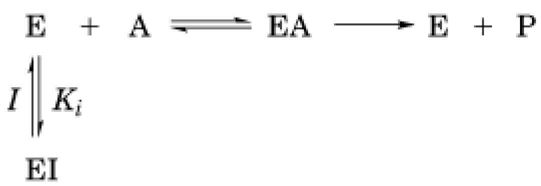
Competitive Inhibition

Analogues of the substrate of an enzyme can often bind at the same place within the enzyme's active site as the substrate but are not acted on by the enzyme. They are inhibitors of the enzyme, giving rise to dead-end inhibition, and they usually compete with the substrate, giving rise to competitive inhibition .

1. Linear

The simplest type of competitive inhibition occurs when an inhibitor combines reversibly at the active site of the same form of the enzyme as the substrate. The inhibitor may be a structural analogue of the substrate or a product of that substrate. In the following scheme, the inhibitor I combines reversibly with the free enzyme to form a dead-end EI complex that can only



dissociate back to the components from which it was formed. Therefore, the interaction of E and I is at thermodynamic equilibrium, and the inhibition constant K_i is a **dissociation constant**. The general equation that describes this type of inhibition is shown in Equation 1:

$$v = \frac{VA}{K_a(1 + I/K_{is}) + A} \tag{1}$$

where v is the observed velocity of the reaction, V the maximum velocity, K_a the Michaelis constant for the substrate present at concentration A, I the concentration of inhibitor, and K_{is} the apparent inhibition constant. For a single-substrate reaction, K_{is} would be equal to K_i. The double-reciprocal form, Lineweaver–Burk plot, of the equation for linear competitive inhibition (Eq. 2):

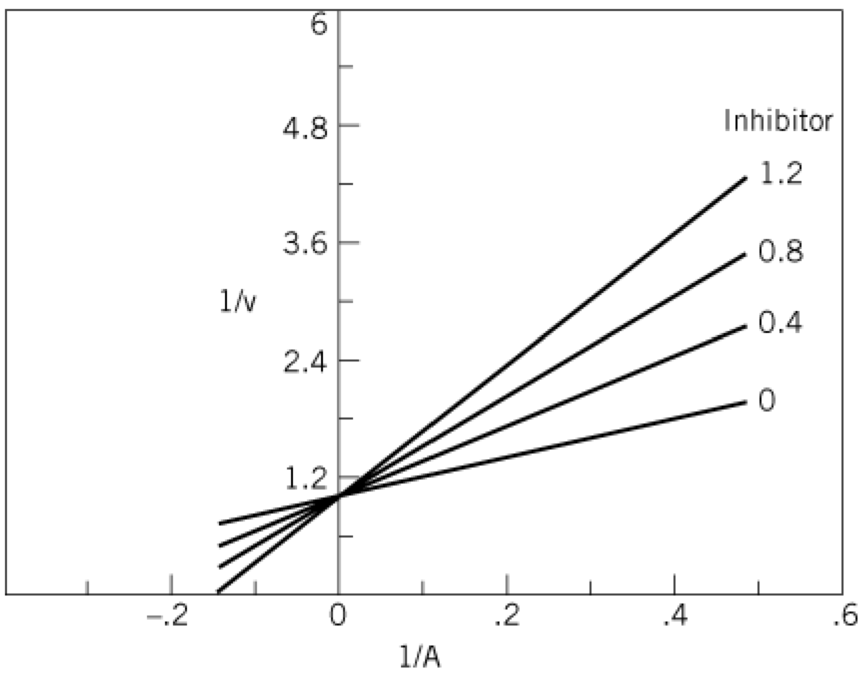
$$\frac{1}{v} = \frac{K_a}{V}\left(1 + \frac{I}{K_{is}}\right)\frac{1}{A} + \frac{1}{V} \tag{2}$$

indicates that a primary plot of $1/v$ against $1/A$ at different concentrations of I would yield a family of straight lines that intersect at the same point on the vertical ordinate (Fig. 1). This is the signature of competitive inhibition; sufficiently high concentrations of substrate can compete successfully with the inhibitor. The slope of each curve is given by Equation 3:

$$\text{Slope} = \frac{K_a}{VK_{is}}I + \frac{K_a}{V} \tag{3}$$

A plot of slope against inhibitor concentration would yield a straight line that intersects the abscissa at the point where $I = -K_{is}$. Since this secondary plot should be linear, the inhibition would be classified as linear competitive . Although values for K_{is} can be obtained by such graphical procedures, it is preferable to obtain its value by an overall fit of the primary data to the general equation by use of a least-squares fitting method (1).

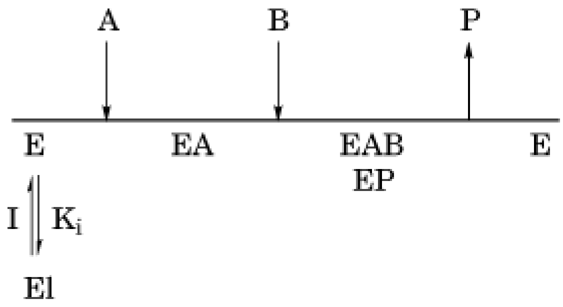
Figure 1. Primary double-reciprocal plot for linear competitive inhibition.



When two substrates are involved in a reaction, the value determined directly for K_{is} may be only an apparent constant, with its value dependent on the concentration of the nonvaried substrate (see Lineweaver–Burk Plot). In this case, it would also have to be stated that the inhibitor was linear competitive with respect to a particular substrate.

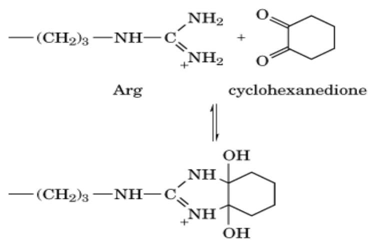
Linear competitive inhibition will also be observed with a two-substrate reaction when the inhibitor is an analogue of the first substrate to add in an equilibrium ordered mechanism, A, and the second substrate to add, B, is varied (Fig. 2). The inhibition by I with respect to A will be linear competitive because both A and I compete directly for the same form of enzyme (E). The inhibition by I with respect to B will also be linear competitive, even though I and B combine with different enzyme forms, because the reaction between E and A in an equilibrium-ordered mechanism is at thermodynamic equilibrium. Thus, increasing concentrations of B will ultimately reduce the concentrations of both EA and E to zero, so that no free enzyme remains to interact with I.

Figure 2. Equilibrium-ordered mechanism for which inhibition by *I* would be linear competitive with respect to both substrates.



2. Hyperbolic

This type of inhibition occurs when an inhibitor binds reversibly at a site on the enzyme, other than the active site, so as to make it more difficult for the substrate to combine at the active site. Thus, the inhibitor and substrate can be present on the enzyme at the same time. The reactions involved can be illustrated as follows:



where K_{is} and K_{id} denote dissociation constants for EI and EIA, respectively. It is a thermodynamic requirement that the affinity of the substrate A for the E and EI forms differs, so that

$$K_A = K_a \frac{K_{id}}{K_{is}}$$

For the inhibition to be competitive, the presence of the inhibitor on the enzyme must not affect the rate of product formation. The general equation that describes hyperbolic competitive inhibition is given in Equation 4:

$$v = \frac{VA[1 + \frac{I}{K_{id}}]}{K_a(1 + \frac{I}{K_{id}}) + A} \tag{4}$$

which can be arranged in double-reciprocal form as

$$\frac{1}{v} = \frac{K_a}{V}\left[\frac{1+\frac{I}{K_{is}}}{1+\frac{I}{K_{id}}}\right]\frac{1}{A} + \frac{1}{V} \qquad (5)$$

This is an equation of a straight line for a plot of $1/v$ against $1/A$, but it is apparent that the slopes of the lines will vary as a hyperbolic function of the concentration of I and the intercept of the curves with the vertical ordinate is independent of I. For a plot of slope as a function of I, the curve would be a concave-down, nonrectangular hyperbola, with limiting values of K_a/V and $K_aK_{id}/(VK_{is})$ at zero and infinite concentrations of I, respectively. Values for K_{id} and K_{is} may be obtained from a plot of 1/(slope$_o$ – slope$_i$ against $1/I$, where slope$_o$ and slope$_i$ are slopes of the primary plot in the absence and presence of inhibitor, respectively. Values for K_{is} and K_{id} are best obtained by an overall least-squares fit of the data to the equation that describes hyperbolic competitive inhibition (1).

It should be noted that the same kinetic mechanism would apply if I were an activator that enhances the combination of the substrate with the enzyme. In this case, the plot of slope against I would yield a concave-up, nonrectangular hyperbola (2).

Competitive Labeling

Competitive labeling is a method of chemical modification for determining the pK_a and the reactivity of functional groups in proteins. The extent of modification of a particular protein group at various pH values is compared to that of the same group in a standard compound. This gives the reactivity of the protein group relative to its intrinsic reactivity, and the pH-dependence gives the p K_a value. These data reflect the **accessibility** of the group in the folded protein, which provides information about the chemical reactivity of the group and its environment in the folded protein. This indirectly gives conformational information about the protein. Conformational transitions associated with function, association, and **ligand binding** can be monitored with this method.

Competitive labeling was originally employed in a study of the amino groups in elastase (1). A mixture of elastase and phenylalanine (the standard compound) was acetylated with a small amount of ^{3}H-labeled acetic anhydride (see Anhydrides). It is important that the amount of the labeling agent is less than that of the groups being modified. Under these conditions, the relative amounts of label in the standard and in the specific protein group will depend upon their relative ionization and reactivities. The fraction of the reactive, nonionized form of the amino group (a_i) and the ratio of reactivity ($r = k_i/k_{standard}$) of the ith group are derived from the known pK_a of the standard ($a_{standard}$) and the measured ratio of labeling:

$$\alpha_i r = \alpha_{\text{standard}}(\text{label on } i\text{th group/label on standard}) \qquad (1)$$

The label on the ith group could be determined by the radioactivity of the appropriate peptide separated by peptide mapping. The values on the right side of the equation are obtained experimentally at each pH and are plotted against pH. The values of the pK_a and of r of the protein group are obtained by theoretical curve fitting.

Besides using acetic anhydride to react with amino groups, 1-fluoro-2,4-dinitrobenzene has been used to react with amino groups and with histidine and tyrosine residues, and **iodoacetate** with thiol groups. A small agent is most suitable for this purpose of modification. Double labeling with ^{3}H-label, followed by ^{13}C-labeling after **denaturation** gives a much more sensitive analysis. In this case, the same group in the denatured protein is the standard.

Complement Fixation

Complement is a set of serum proteins that undergo a sequential series of cleavage and association reactions in response to antibody–antigen complexes. If these complexes occur on a cell surface, complement reactions can cause cell lysis (1). The lysis of erythrocytes is particularly easy to detect visually, due to the release of hemoglobin, and this lysis forms the principle for a type of immunoassay. Antibody–antigen complexes in solution cause complement reactions to occur without cell lysis. Since the complement reactions are stoichiometric and the products short-lived, these non-cell-associated complexes deplete a portion of the complement proteins, a process termed “complement fixation.” This depletion reduces the lysis observed when the complement is subsequently added to antibody-coated erythrocytes.

Key reagents for complement fixation assays, all available commercially, are complement, erythrocytes, and hemolytic antibody (2, 3). Guinea pig serum is usually used as a source of complement, since guinea pig complement reacts with antibodies of most experimentally significant mammalian species. Sheep erythrocytes, washed free of serum components, are used for lysis. Hemolytic antibody is obtained by immunizing rabbits with sheep erythrocyte membranes. The erythrocytes are sensitized in preparation for complement lysis by incubation with the hemolytic antibody. Once amounts of complement and sensitized erythrocytes appropriate for easy detection of lysis are determined, the reagents can be used to measure the interaction of an antibody–antigen pair (4). The antibody and antigen to be tested are incubated for a set time in the presence of complement. Standards containing known amounts of antibody and antigen are incubated simultaneously. Sensitized erythrocytes are next added, and lysis is measured after further incubation, by spectrophotometric determination of hemoglobin. Diminished lysis relative to a control indicates that the antibody–antigen pair in question has formed an aggregate and induced complement reactions to occur in solution, reducing the amount of complement available to lyse cells. Results observed with the standards are used to calibrate the correspondence between antibody–antigen complex formation and lysis. Because antibody–antigen aggregates are the most active species in fixing complement, bell-shaped response curves result when percent complement fixed is plotted against added antibody or antigen. Complement fixation is most efficient at roughly equivalent amounts of antibody and antigen, whereas either component in excess will favor formation of binary and ternary complexes that do not fix complement well. Consequently, several concentrations of antigen or antibody must be tested to establish whether the observed response lies on the increasing or decreasing slope of the standard curve.

As an analytical technique, complement fixation is sensitive to nanogram quantities of antigen, but is subject to reagent variation and interference by chemical components of the sample. A notable value, however, is in study of cross-reactivity between structurally similar antigens. Proteins that differ slightly in sequence give easily measured differences in complement fixation ability when they are probed with a single antiserum. This effect is so regular that complement fixation by homologous antigens can be used to establish the evolutionary relationship between closely related species (5, 6).

Complement System

1. Introduction

After the discovery of humoral immunity, Hans Buchner found that if fresh serum possessing an antibacterial antibody was added to bacteria, the bacteria were quickly lysed. However, if the serum was heated to 56°C, the lytic capacity of the serum was lost. He also demonstrated that the loss of lytic capacity could be restored by using unheated nonimmune serum in conjunction with heated immune serum. These studies were extended by others, including Jules Bordet, who concluded that serum contained two components necessary for cellular lysis. These two components are heat-stable antibodies and a heat-labile component that “complements” the lytic function of antibodies. He reasoned that antibodies had two binding sites, one for antigen and the other for heat-labile substance that was given the name ***complement***.

Complement is now known not to be a single component, but it consists of at least 20 chemically and immunologically distinct plasma proteins capable of interacting with one another in a highly regulated manner to provide at least four main biological functions. First, ***cytolysis*** is mediated by the association, or polymerization, of specifically activated complement components on the surface of targets cells. These components form pores that disrupt the integrity of the lipid membrane, and the cell is killed by osmotic lysis. Second, antibody and antigen combine to form ***immune complexes*** that, unless removed, can result in damage of body tissues. The binding of complement proteins prevent the damage from immune complexes by mediating their solubilization and clearance. Third, the ***opsinization*** of foreign particles is mediated by the binding of complement proteins (opsonins). Phagocytic leukocytes bear receptors for these complement proteins, so that opsinized particles are cleared from the body by phagocytosis. Finally, through the activation of complement, **proteolytic** fragments are released whose function are to ***mediate inflammation***. These fragments, or "anaphylatoxins," can act on several target cells such as neutrophils, smooth muscle, and vascular endothelium, as well as organ systems of the body.

The complement proteins are normally present in the circulation and are produced primarily by the liver and other extrahepatic sources, such as macrophages and fibroblasts. Some of the components are produced as functionally inactive proteinases that are activated only when proteolytically cleaved themselves by previously activated complement proteins. Complement activation occurs only at localized sites under specific conditions. The binding of specific antibody to antigen can initiate complement activation through what is called the ***classical pathway***. Additionally, in the absence of antibody, some complement components are directly activated by binding to the surfaces of infectious agents, such as bacteria, **fungi**, and **viruses**, through what is called the **alternative pathway**.

2. Overview of the Complement System

Individual proteins of the complement system are present in the serum as functionally inactive molecules. The individual precursor proteins are designated numerically, such as C1, C2, up to C9. Other proteins involved with the complement system have retained their common, or trivial, names such as properdin, factor B, and factor H. Individual components must be activated sequentially and specifically for the complement cascade to progress and mediate inflammation and lysis of foreign organisms. The activation of complement is a dynamic process that allows the proteins of the system to interact functionally and is not a static singular event.

An overview of the operation of the complement system is shown in Figure 1, and biochemical and physical information of the proteins involved in the complement system are listed in Table 1. A protein called C3 is the central component of the complement system. The alternative and classical pathways are two parallel, but entirely independent, mechanisms that lead to the formation of C3 ***convertases*** whose function is to cleave C3 into C3a and C3b. In the classical pathway, initial events involve binding of specific antibody to antigen. This antigen–antibody complex binds complement C1 and sequentially activates complement proteins C4 and C2, leading to the formation of the C4b2b complex that functions as the ***classical pathway C3 convertase***. In contrast, activation of complement via the alternative pathway occurs independent of antigen–antibody complexes. Instead, alternative pathway activation is dependent on activators that allow the formation and deposition of the C3bBb complex (**alternative pathway C3 convertase**) on their surfaces. Activators of the alternative pathway include many bacteria, fungi, and viruses. Both classical and alternative convertases can cleave additional C3, generating more C3b (see Fig. 1). The binding of additional C3b to these C3 convertases changes them conformationally to ***C5 convertases***, which specifically cleave C5. Once cleaved, both the alternative and classical pathways share the same terminal steps. These steps do not involve the proteolytic cleavage of additional components but instead involve the sequential binding of components C6, C7, C8, and C9. This terminal assembly leads to the formation of the ***membrane attack complex*** (**MAC**), resulting in the osmotic lysis or cytolysis of bacteria or other affected cells.

Figure 1. Schematic representation of the alternative and classical activation of the complement pathway leading to the assembly of the membrane attack complex.

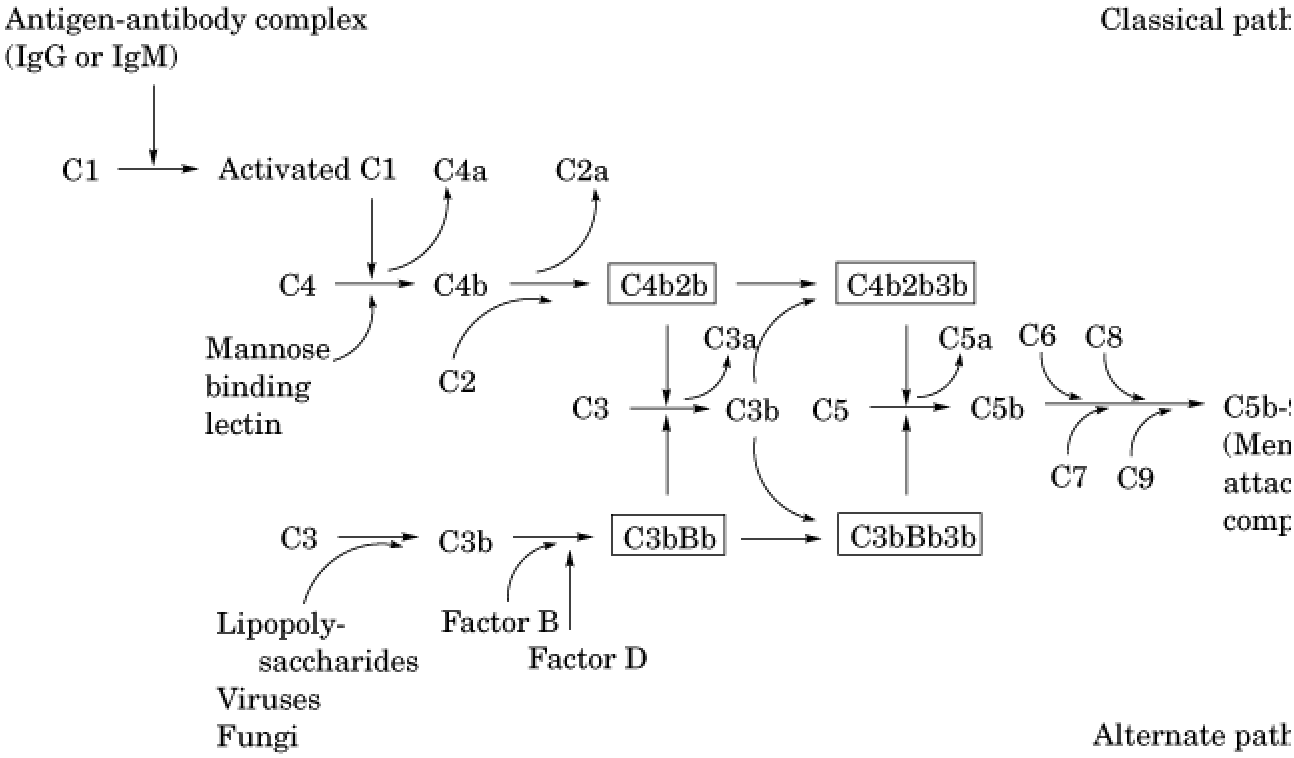

Table 1. Protein Components of the Classical and Alternative Pathways[a]

Component	Serum Concentration, µg/mL	Molecular Weight	Number of Polypeptide Chains	mRNA[b] Size, kb	Chromosome Location	Gene[b] Size, kb
			Classical Pathway			
C1q	75	410,000	6 of A at 24,000	0.52	1	2.5
			6 of B at 23,000	1	1	2.6

During activation, through either the classical or alternative pathway, various cleavage products mediate a variety of biological functions. As discussed, cytolysis is mediated through the membrane attack complex. Opsinization and subsequent phagocytosis by leukocytes is mediated primarily through C3b, a cleavage fragment of C3 that binds receptors for C3b. Cleavage products of C3, C4, and C5 (C3a, C4a, and C5a anaphylatoxins) mediate inflammatory events and the recruitment and activation of leukocytes.

3. Assembly and Activation of the Classical Pathway

The classical pathway is activated by antigen–antibody complexes or aggregated immunoglobulin acting on complement component C1 (Table 1). C1 consists of three distinct protein molecules, C1q, C1r, and C1s, which are held together by Ca^{2+}-dependent bonds. C1 is present in serum as a firm C1q-C1r-C1s complex, while individual C1 components are found only in pathologic conditions. C1 contains one molecule of C1q and two molecules of both C1r and C1s.

A molecule of C1q is comprised of 18 polypeptide chains of three distinct types (A, B, and C) which are twisted together comprising one subunit. Each C1q molecule is then made up of such six subunits connected together; once assembled, its structure is similar to that of collagen. The C1q molecule bears the sites that enable the entire C1 molecule to bind the Fc region of IgM and IgG immunoglobulin molecules. A single C1 molecule can bind about six IgG molecules. After binding to Ag-Ab complexes, C1q undergoes a conformational change that causes C1r to activate itself by a limited self-cleavage.

Activated C1r cleaves a single peptide bond in C1s, which then acquires enzymatic activity of its own. This newly generated enzyme is a serine esterase type and mediates the cleavage of component C4. With the activation of the C1s enzyme, the initial process is complete, and the earlier reactants, including antibody, antigen, C1q, and C1r, are no longer needed.

C4 is composed of three nonidentical polypeptide chains and is synthesized as a single-chain precursor in a beta–alpha–gamma orientation. C1 cleaves a single bond on the C4 alpha chain leading to the production of C4a and C4b. This cleavage leads to the formation of a labile binding site in the larger fragment of C4b, which enables it to bind to the activating surface (activator). The C4b alpha chain, like C3, contains an internal ***thioester*** bond formed between a glutamic acid and cysteine residue. Cleavage of the alpha chain of C4 is followed by stress-induced hydrolysis of the thioester bond. This permits the reactive acyl group of the glutamyl residue to form a covalent bond with a reactive hydroxyl or amino group on the surface of the activator.

C2 cleavage by C1s also generates a labile binding site of unknown chemical composition in the larger C2b fragment, which allows it to bind to C4b. Mg^{2+} ions are required for the formation of the C4b2b complex. Formation of the C4b2b complex is not very efficient, as the majority of C2 and C4 molecules entering into this reaction lose their labile binding sites before achieving union with membranes or with each other and diffuse away as inactive reaction products. The newly formed C4b2b is a proteolytic enzyme that assumes the role of continuing the complement reaction cascade, so earlier activating components are no longer required. The C4b2b complex is also called the **classical C3 convertase**, which acts to cleave C3.

The substrate for C4b2b is C3, which is synthesized as a single chain of beta–alpha orientation that is processed after translation. The larger, alpha chain, is cleaved at a single site located near the amino terminus. The smaller resulting fragment C3a (9000 M_r (relative molecular mass) is a biologically potent peptide that mediates inflammation and will be discussed later. A labile binding site is generated in the larger fragment C3b, which enables the molecule to attach to membranes at sites near, but distinct from, those utilized by antibody and C4b2b. Often described as the "lynchpin," C3 is the precursor of several biologically active fragments that function by association with the other proteins of the complement system leading to lysis of the target cell cell via either classical or alternative pathways. C3 has numerous distinct binding sites, one of which is the thioester domain that allows the molecule to bind covalently to target sites and particles, such as immune complexes and membrane surfaces.

The chemical site of the C3 thioester has the sequence Gly-Cys-Gly-Glu-Glu-Asn with the Cys and second Glu residues joined by a thioester bond, specifically a b-cysteinyl–g–glutaminyl thioester bond. This thioester bond is present in the C3d domain of the alpha chain. With the cleavage of C3 into C3a and C3b, the thioester undergoes a stress-mediated hyrdolysis, and the reactive acyl group of the glutamyl residue forms a covalent bond with a reactive hydroxyl or amino group on the activator surface. A major amount of reactive C3 fails to achieve binding with activators as most of these reactive thioesters have reacted with water.

The attachment of C3b to membranes in the vicinity of C4b2b molecules leads to the generation of the last enzyme of the classical pathway, C4b2b3b, **or the classical C5 convertase**. To this end, the classical pathway has finished the initial steps of activation. From here, the C5 convertase acts on C5 to initiate steps in the forming of the MAC.

4. Activation of the Classical Pathway

The activation of the classical pathway can occur by one of two ways: activation through the use of immunoglobulin or through nonimmunoglobulin activation by cleavage of C1. Immunoglobulin activation of the classical pathway involves the use of antibodies belonging to subclasses IgG_1, IgG_2, and IgG_3, as well as IgM, are capable of initiating the classical pathway. Immunoglobulins IgG_4, IgA, IgD, and IgE are inactive in this regard. Among the three listed above, IgG_3 is the most active in interacting with C1, then IgG_1 and IgG_2. Activation occurs when the first component C1 binds to a site in the Fc region of the IgG or IgM. Only one molecule of bound IgM is capable of initiating the activation of the classical pathway; however, it is estimated that six molecules of IgG are required.

Nonimmunologic activation of the classical pathway can be accomplished by diverse substances such as DNA, certain viruses, and **trypsin**-like enzymes, by direct proteolytic attack on the C1 molecule. Of particular interest are lectins that also act as a nonimmunological activator of the classical pathway. Mannose binding lectin (MBL) is a serum protein found in all mammals and is regulated as an acute-phase protein. MBL is capable of binding carbohydrate moities present on many microorganisms and subsequently capable of activating the classical pathway through C4 without the need for specific antibody or C1q.

5. Alternative Complement Pathway or Properdin Pathway

The alternative pathway may be activated immunologically by aggregates of human IgA and by certain complex polysaccharides, fungi, viruses, bacterial lipopolysaccharides, and trypsin-like enzymes. This system was originally described as the properdin system, a group of proteins involved in resistance to infection, but distinct from complement. The proteins of the alternative pathway, C3, factor B, factor D, and properdin (factor P) perform the functions of activation, recognition, and amplification of the pathway, resulting in the formation of the activator bound C3/C5 convertase. The alternate pathway system was found to be involved in the destruction of certain bacteria, neutralization of some viruses, and red blood cell of (RBC) lysis from patients with paroxysmal nocturnal hemoglobinuria.

6. Activation of the Alternate Pathway

Alternate pathway activation initially proceeds in a manner different from that for the classical pathway. The exact mechanism by which the first C3b molecule is produced is still controversial. However, it is clear that antibody is not required since mixtures of only highly purified alternative pathway proteins behave as well as serum. The ultimate aim of the proteins, C3, factor B, factor D, and properdin is the initiation, recognition, and amplification of the pathway that results in the formation of the activator bound **C3/C5 convertases**. The first requirement for activation is the presence of C3, which participates in the initiation and amplification of the pathway. It is generally accepted that activated C3 (but not-yet cleaved) [C3*] reacts with proenzyme B, and this complex is then cleaved by factor D, yielding two fragments, Ba and Bb. Bb then attaches to C3b forming the alternative pathway C3 convertase. The C3 convertase is able to cleave additional C3 into C3a and C3b. While most C3b remains in the fluid phase, some binds to various cell surfaces. Thus C3b is continuously generated and is deposited on the surface of the activator. The alternative C3 convertase is unstable and decays rapidly unless another alternative pathway member, **properdin**, binds to the C3 convertase and stabilizes it. Properdin binding of C3bBb extends its functional half-life eightfold. The function of the C3 convertase is to produce enough meta-stable C3 to deposit on the surface of surrounding particles. Surface-bound C3b then interacts with factor B and is activated by D to form more C3bBb. This enzyme is capable of cleaving large amounts of C3, and forms more C3bBb (C3bBb3b); thus, a positive feedback mechanism is formed that amplifies the initial stimulus. Many of the C3b molecules bind to the surface of the activator in close proximity to these enzymes, forming C3bBb3b or the alternative pathway C5 convertase. Like its counterpart in the classical pathway (C4b2b3b), the function of C3bBb3b is to proteolytically cleave C5 and initiate the assembly of the membrane attack complex.

7. The Membrane Attack Complex: C5–C9 Reaction

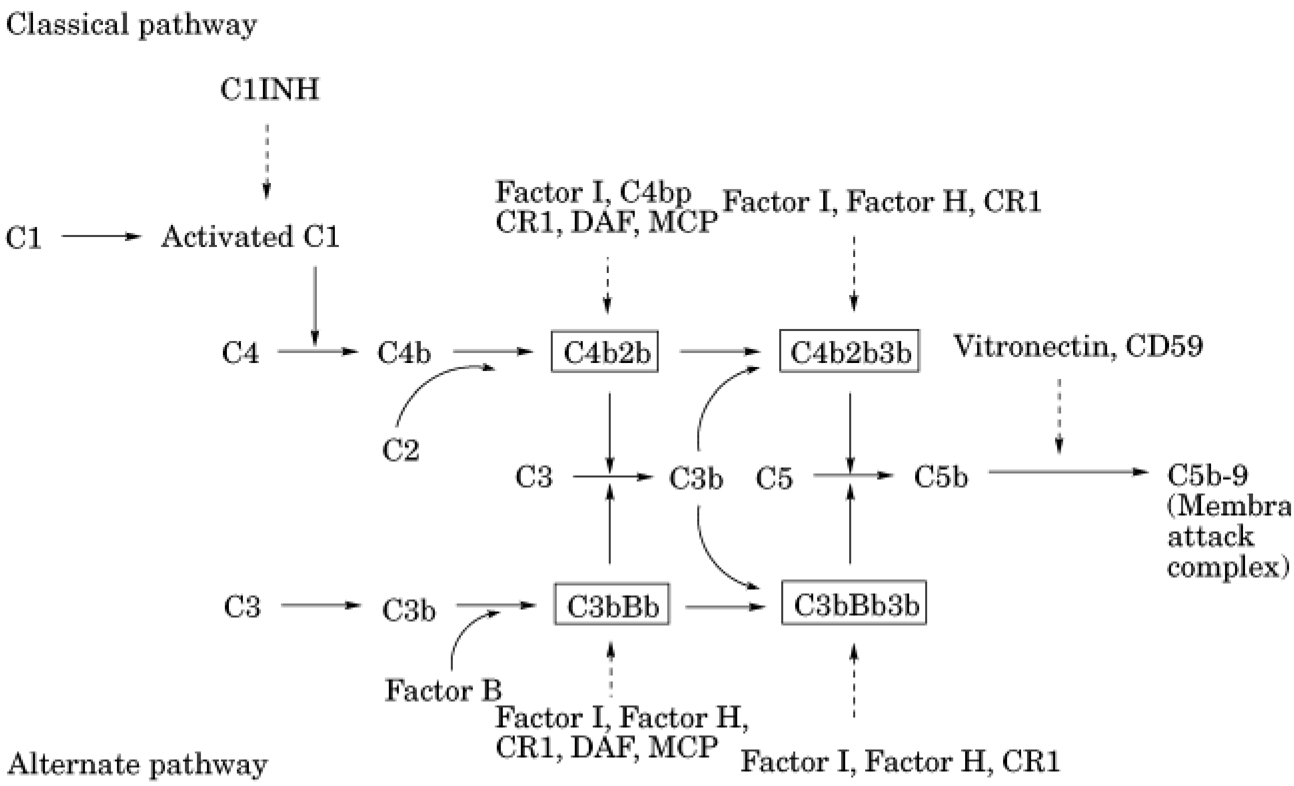
The terminal portion of the complement sequence is known as the MAC (complex). C5–C9 must become membrane bound for damage to occur. This complex may attach to a cell bearing the activation enzymes of the classic or alternate pathways, or it may attach to a bystander cell. The MAC is initiated by the cleavage of C5 by the alternative and classical C5 convertases.

Similar to C3, pro-C5 is secreted in a beta–alpha orientation prior to post translational modification. C5 shares sequence homology with C3 and C4, including the domain corresponding to the thioester region; however, C5 lacks the essential cysteine and glutamic acid residues necessary for thioester formation. Assembly of the MAC initiates with the cleavage of C5. Cleavage at residue 74 of the alpha chain, results in the generation of C5a anaphylatoxin and C5b (Table 1), where C5b can then bind C6. C6 is a single chain peptide that, when bound to C5b, remains loosely attached to the membrane until the addition of C7. Once a single C7 has bound the C5b6, the resulting complex is highly lipophilic and inserts into the lipid bilayer. When inserted, the C5b67 complex serves as a high affinity integral membrane receptor for a single C8 molecule. C8 is composed of three nonidentical polypeptide chains and has an interesting structure in that the alpha and gamma chains are covalently linked by one or more disulfide bonds and the beta chain is joined to the alpha–gamma chains by noncovalent forces. The C5b-8 becomes stably attached to the membrane by insertion of the C8 gamma chain into the lipid bilayer. With this early “MAC” formed, cellular leakage can occur at this stage. The cytolytic process is greatly accelerated by the attachment of C9, the final complement component. The C9 monomer polymerizes at the site of the C5b-8 complex. As few as 4 C9 molecules can result in lysis for many microorganisms. However, when the MAC contains as many 12 to 15 C9 molecules, the "poly-C9" forms a pore in the membrane and permits passive exchange of cytoplasmic contents with the extracellular media with subsequent osmotic lysis. The pores have an internal diameter of about 110 Å and appear similar in structure to those formed by lytic T cells when the related protein **perforin** is deposited on target cells.

8. Control Mechanisms of the Complement System

Given the lytic potential of the complement system, uncontrolled activation can lead to the formation of the MAC on normal tissues and significant generation of C3a, C4a, and C5a anaphylatoxins. Multiple fluid phase and membrane bound proteins tightly regulate both the alternative and classical pathways by acting at specific steps during activation. In addition, the uncontrolled activation of the complement cascade is also prevented by the necessity of specific activators, such as antibody–antigen complexes, as well as the lability of the activated complement components such as C3b. Deficiencies in regulatory proteins result in unregulated complement activation and are apparent in various disease conditions. An overview of the regulation complement pathway activation by both membrane-bound and soluble inhibitors are shown in Figure 2. The biochemical and physical information of these inhibitors are listed in Table 1.

Figure 2. Regulation of classical and alternative complement pathway activation by membrane and soluble inhibitors. Principal components and C3/C5 convertases are retained from Figure 1. Regulators of complement activation are showı italics.



9. Classical Pathway Inactivators

A protein celled ***C1 inhibitor*** (**C1INH**) acts to inhibit the initiation of the classical pathway. C1INH is a member of the serine protease inhibitor family and acts by blocking C1r and C1s of the C1 complex. As with other serpins, such as a_1-antitrypsin, C1INH uses a "bait" sequence that mimics the normal substrates of C1r and C1s. However, when C1INH is cleaved by C1r or C1s, it forms a covalent ester linkage that inhibits cleavage of C4 and C2, thus inhibiting the progression of the classical pathway. Most of the C1 in the serum is already bound to C1INH. On specific binding of C1 to antigen–antibody complexes, C1INH is released allowing classical pathway activation to proceed.

Other means to control the classical pathway involve interfering with the formation of the C3 convertase. Such inhibition can be mediated either through interfering with the assembly of the convertase or in promoting the dissociation of the convertase. Three proteins called ***C4-binding protein*** (***C4 bp***), ***complement receptor type I*** (***CR1***) (also known as CD35), and ***decay accelerating factor*** (***DAF***) (also known as CD55) function as inhibitors of the classical pathway by binding to C4b. In doing so, they compete with C2 for C4b and thus inhibit the formation of the classical C3 convertase. In binding C4b, they also promote the dissociation of the C3 convertase. All three proteins are structurally similar and are homologous members of a family of proteins called the regulators of complement activity (RCAs).

Another way that the C3 convertase can be inhibited is by the cleavage of C4b by a protein called **factor I**. Factor I is a serine esterase that cleaves C4b into two additional fragments: C4c and C4d. C4d remains bound to the original activating surface; however, it is unable to contribute to the formation of the classical C3 convertase. Cleavage of C4b by factor I can only occur in the presence of a "cofactor." The proteins that can serve a cofactor for factor I cleavage include CR1, C4b, and membrane cofactor protein (MCP), or CD46. MCP is also a member of the RCA family but does not possess decay accelerating activity.

10. Alternative Pathway Inactivators

Regulation of the alternative pathway is also accomplished by several circulating and membrane bound proteins, many of which also act on the classical pathway. In analogous fashion, the inhibition of convertase activity through either decay acceleration or by providing cofactor activity for factor I are the major ways in which this is accomplished.

Factor H is a soluble serum protein that possesses decay-accelerating activity that is specific for the Bb fragment of the alternative pathway. By competitively binding Bb, the formation of the alternative C3 covertase is impaired. Factor H is also a member of the RCA family and in binding Bb can also promote the dissassembly of the alternative C3 convertase.

In addition to its role in inhibiting the classical pathway activation, factor I can also cleave C3b using factor H, MCP, and CR1 as cofactors. The resulting fragment of C3b (iC3b) is unable to participate in the formation of the alternative C3 convertase.

11. Inactivators of the Membrane Attack Complex

With the alternative and classical pathways activated, the potential for normal or bystander host cells to be subjected to lysis is significant. Excessive cell lysis is normally prevented by a number of proteins that act to inhibit the formation of the membrane attack complex.

A membrane bound protein that is capable of inactivating the membrane attack complex is the ***membrane inhibitor of reactive lysis*** (***MIRL***), more commonly known as ***CD59***. CD59 is broadly expressed among different cell types and is probably the most important molecule in minimizing damage to bystander cells. It is thought that CD59 acts by binding C8 and C9 and thus inhibits the polymerization of C9 as well as the insertion of the MAC into the membrane.

As discussed above, when C7 binds C5b6, the resulting complex is lipophilic and it inserts into the membrane. This process of membrane insertion is inhibited by **S protein**, also known as **vitronectin**, a protein related to fibronectin and laminin. The S protein is thought to function by binding the C5b67 complex before it inserts into the membrane.

12. Complement Receptors and Biological Consequences of Complement Activation

Through the activation of the complement cascade, through either the classical or alternative pathways, numerous complement derived fragments are generated. Many of these fragments possess biological activities that are mediated through the use of specific receptors.

In addition to regulating the activation of complement, ***CR1 (CD35)*** serves as a high affinity receptor for C3b and C4b. CR1 functions as a receptor for C3b- and C4b-coated particles wherein macrophages ingest and remove these coated particles. Another receptor, ***CR2 (CD21)***, is expressed primarily on B cells, dendritic cells, and epithelial cells. CR2 is known to specifically bind iC3b and C3dg—both factor I–generated cleavage products. In addition, CR2 is also known as the Epstein–Barr virus receptor. ***Mac-1*** or ***CR3 (CD11b/CD18)*** is related to the integrin family and is a specific receptor for the factor I cleavage product of C3b, iC3b. CR3 is expressed on many different cells derived from the bone marrow including neutrophils, mononuclear phagocytes, mast cells and natural killer (NK) cells. The primary role of CR3 is the phagocytosis and clearance of iC3b-coated particles. **CR4 (CD11c/CD18)**, like CR3, is also a member of the integrin family and also binds iC3b as well as C3dg.

The cleavage of C3, C4, and C5 results in the production of **C3a**, **C4a**, and **C5a anaphylatoxins**. These hormone-like peptides mediate a variety of cellular and biochemical responses from leukocytes, including the generation of bacteriocidal superoxide radicals, proteolytic enzyme release from intracellular granules, cellular aggregation, smooth muscle contraction, and phagocytosis. In addition, C5a induces chemotaxis, or the migration, of leukocytes into areas of complement activation. The induction of chemotaxis was thought to be unique for C5a; however, recent findings suggest that C3a may be chemotactic for eosinophils, a cell whose function is mediating allergic reactions. These anaphylatoxins mediate their effects through specific receptors that are coupled to GTP-binding proteins and whose signal transduction can be abrogated by pertussis toxin. The C3a and C4a receptors have been found to be expressed on mast cells, basophils, lymphocytes, and smooth muscle cells. The C5a receptor has been found on mast cells, basophils, neutrophils, monocytes/macrophages, endothelial cells, smooth muscle, liver parenchyma, and epithelial lining of lung as well as astrocytes and microglia of the central nervous system. Of the three anaphylatoxins, the most potent is C5a in mediating biological effects. C3a is approximately 20-fold less potent, while C4a is about 2500-fold less potent than C5a. C5a has been shown to stimulate the release of tumor necrosis factor (TNF) from mast cells as well as stimulating P-selectin (CD62P) expression on vascular endothelium to promote neutrophil binding.

13. Complement Genes and Relationships

On the basis of sequence homologies, many of the complement proteins can be grouped together as members of families. Members of these families share structural and/or functional similarities by which relationships can be assessed.

One of the more defined families is that of the regulators of complement activity (RCAs) as previously discussed. Factor H, CR1, CR2, DAF, C4 bp, and MCP are all members of the RCA, and all share the ability to bind both C3b and C4b. At the peptide level, all members of this family possess multiple, tandemly arranged repeated structures called short consensus repeats (SCRs). Each SCR is 65–70 amino acids long with 11–14 conserved amino acid residues. The composition and number of SCRs each of these members contain vary, but structurally and functionally they form the foundation by which this family is based. The genes encoding H, CR1, CR2, DAF, C4 bp, and MCP are found within an 800-kb genomic segment on the long arm of chromosome 1.

Another group of complement genes that are linked together are C2, factor B, and C4 that all map within the major histocompatibility complex of both humans and mice. In the human, these complement genes, often called the Class III genes, map between the Class II HLA-DR and Class I B loci of chromosome 6. Similar to the Class I and Class II genes, the Class III genes are polymorphic as multiple alleles exist for each of these genes.

Complement components C3, C4, and C5 constitute a structurally homologous family of proteins that includes a_2-**macroglobulin** and pregnancy zonal protein. All except C5 are characterized by the presence of an interal thioester bond allowing these proteins to covalently bind with cell surfaces or other proteins. However, unlike the RCA family, C3, C4, and C5 reside on separate chromosomes (Table 1).

14. Pathologies Related to the Complement System

The complement cascade is a potent and powerful system whose function is the destruction of target cells and infectious agents. Unwanted deposition of complement as well as the production of significant quantities of inflammatory mediators can result in substantial damage to normal healthy tissues. The regulatory mechanism of the MAC and alternative and classical pathways establishes a fine balance between activation and inhibition so as to protect autologous cells but allow the destruction of foreign agents. Deficiencies in nearly any component of the complement system compromise the health of an individual by tipping the balance one way or another. In a general sense, complement deficiencies can be due to the absence of a component due to structural defect in the gene, or the production of a component that is incapable of functioning in its specific role in the cascade. Table 2 summarizes complement deficiencies, the resulting abnormalities, and associated pathologies.

Table 2. Complement Deficiencies and Associated Clinical Abnormalities

Component	Biological Defect	Associated Disease
	Classical Pathway	
C1q, C1r, C1s	Defective classical pathway	Systemic lupus erythematosis (SLE), bacterial infections
C4, C2	Defective classical pathway	SLE, bacterial infections, glomerulonephritis
C3	Defective classical and alternative pathways	Bacterial infections, glomerulonephritis
	Alternative Pathway	
Properdin, factor D	Defective alternative pathway	Bacterial infections
	Membrane Attack Complex	
C5, C6, C7, C8	Defective MAC assembly	Recurrent neisserial infections
	Inhibitors	
Factor I, factor H	Deregulation of complement activation Consumption of C3	Bacterial infections
CR3 (CD11b/CD18)	Impaired opsinization	Bacterial infections

C1 inhibitor	Deregulation of classical pathway	Hereditary angioneurotic edema (HANE)
DAF (CD55)	Deregulated C3 convertase	Paroxysmal nocturnal hemoglobinuria
MIRL (CD59)	Impaired MAC regulation	Paroxysmal nocturnal hemoglobinuria

Deficiencies in alternative and classical pathway components usually manifest clinically in recurrent bacterial infections. The most serious deficiencies are those in C3. Given its role in opsinization, phagocytosis, and lysis of bacteria, homozygous deficiencies in C3 often prove fatal. In contrast, C9 deficient individuals cannot effectively generate MAC formation, yet these patients have minimal or no associated pathology as the addition of C8 to the C5b-7 complex can result in osmotic lysis of target cells. Individuals deficient in the early classical pathway components (C1, C2, and C4) are impaired in their ability to solubilize and clear immune complexes, resulting in local inflammation associated with autoimmune diseases such as ***systemic lupus erythematosus (***SLE***)***.

Patients that are deficient in the terminal complement components (C5 through C9) have impaired ability to assemble the MAC. Of particular interest is that these patients seem to have a propensity for Neisseria bacterial infections suggesting that cytolysis may be the major defense mechanism against these bacteria.

Deficiencies in the soluble and membrane bound regulatory components of complement result in abnormal activation and deposition of complement. Defects in C1INH results in a condition called ***hereditary angioneurotic edema*** (***HANE***), in which the intermittent accumulation of edema (swelling) in the skin and mucosa occurs. The exact mechanism of how the edema occurs is not known; however, without C1INH to inhibit non-specific C1 activation, C2 and C4 are readily cleaved and their by products are implicated. Deficiencies in the expression of phosphytidylinositol-linked membrane proteins result in a condition called ***paroxysmal nocturnal hemoglobinuria*** (*PNH*), where patients suffer from recurrent bouts of intravascular hemolysis. As DAF and CD59 are PI-linked, they also serve to inhibit C3 convertase formation. However, erythrocytes are especially sensitive to lysis as they do not possess membrane bound form of CD59 as other cell types do.

15. Summary

The proteins of the complement system consists of at least 20 chemically and immunologically distinct plasma proteins that can dynamically interact with one another in a highly regulated manner. The complement system can be activated by using either of two converging initiation pathways: the classical pathway, which is activated by antibody–antigen complexes; and the alternative pathway, which is activated by the surface of invading organisms. This interaction of proteins results in (*1*) the lysis of target cells and bacteria, (*2*) the binding and clearance of immune complexes throughout the body, (*3*) the binding of complement based proteins to foreign particles and subsequently cleared by phagocytosis, and (*4*) the generation of inflammatory mediators to enhance the humoral and cellular immune response. The activation of complement is tightly regulated so as to protect host cells from nonspecific attack deposition while allowing the destruction of foreign agents. Deficiencies in complement components of either pathway or in regulatory components are associated with recurrent bacterial infections and autoimmune diseases.

Complementary DNA (cDNA)

The base-pair complementarity between a **gene** and its **transcript** leads to the formation of a DNA–RNA hybrid under experimental conditions that favor specific **hybridization**. Pioneering work by Gillespie and Spiegleman that made use of the complementarity between viral genomic DNA and RNA in infected cells (1) helped establish the beginnings of a new technology for the detection of specific RNA molecules hidden among an RNA background, in this case of viral RNA among host cell RNA. The potential advantages of *complementary DNA* (cDNA) as a probe for RNA detection were recognized before techniques existed to make specific cDNA conveniently for tagging genes. The great abundance in the genome of extra, nontranscribed DNA, which is a common feature of higher organisms, complicates the use of genomic DNA as a cDNA probe. Some time after the first references to cDNA, a **DNA polymerase** activity that depends on the presence of an RNA template was observed in RNA **viruses** (2, 3). This discovery, in addition to extending our knowledge of RNA virus replication intermediates, led to the identification and isolation of a previously unknown form of DNA polymerase called *reverse transcriptase* and to the identification of buffer conditions that allow some DNA-dependent DNA polymerases to use a DNA-primed RNA template to form a DNA product (4, 5). Largely due to the discovery of reverse transcription and the technical advantages it provides for *in vitro* cDNA synthesis, cDNA has become a fundamental research tool for use with higher organisms.

1. cDNA Copies of messenger RNA

Transcriptionally active genes represent only a relatively small fraction of the total host genomic DNA in higher organisms, only 3% in human cells, with the noncoding or nonexpressed DNA representing the majority of the genome. Reverse transcribed cDNA synthesized under carefully controlled conditions is a faithful and stable double-strand DNA copy of cellular RNA and is trimmed of excess genomic sequence. A full-length cDNA molecule made from messenger RNA (mRNA) contains only the protein-coding region of an expressed gene, together with the adjacent untranslated regulatory sequences; it lacks any unexpressed gene or genomic sequences not contained in the mature mRNA, such as **introns** (Fig. 1).

Figure 1. Schematic representation of cDNA synthesis from mRNA. Transcriptionally active genes are transcribed, resulting in pre-mRNA that is processed to the mature form. Nuclear processing includes the removal of intervening sequences (IVS, introns) and addition of a 5′ m_7G cap and 3′ poly dA tail. Different gene activities result in different mRNA abundance shown as A, B, or C. After mRNA isolation and reverse transcription, a population of DNA–mRNA hybrid molecules are formed where the DNA is anti-sense in relation to the mRNA. Second-strand synthesis produces a cDNA population in which the more active gene is represented more than the less active gene.

cDNA

For research that involves mRNA, the preparation of cDNA not only provides a DNA strand complementary to RNA, but it also serves to minimize the technical problems of working directly with RNA, which is chemically unstable at alkaline pH and susceptible to notoriously stable and ubiquitous cellular ribonucleases. A further advantage of cDNA is that in many applications it is integrated into a **prokaryotic** DNA **vector to** form recombinant DNA capable of autonomous replication when **transformed** into a host organism with a favorable genetic background. Engineered vectors with a variety of features are available for many different methods of cDNA analysis. As recombinant DNA, cDNA may be amplified through culturing of the host cells. Because each transformed host cell receives a single recombinant vector, clonal lines of host cells differing only in the recombinant vector received are established. As a copy of total cellular mRNA, however, cDNA is a complex mixture representing the complexity of the template mRNA used to direct its synthesis. Thus, cDNA integrated into a vector, transformed into a host, and cultured represents a complex mixture or **library** of transcripts, a cDNA library. The use of cDNA frequently requires the selection of a single **clone** or cDNA copy from a library, since the analysis of expression from a single gene is often the desired aim. The efficient selection of a previously uncharacterized cDNA clone from an entire cDNA library poses a major technical challenge. Selection of a new cDNA is complicated by the lack of any previous information to assist in the selection process. Often, the selection might start with little information other than observations about the encoded function of the desired cDNA clone or atypical cellular characteristics that could be associated with it.

As a stable copy of RNA, a single selected cDNA clone may be transcribed through vector signals to regenerate the RNA, which may in turn be used for synthesis of the encoded protein, either within a host cell or through the use of **protein biosynthesis *in vitro*** system. The purity of RNA or protein prepared from a single cDNA clone is absolute, thus justifying the effort to prepare a cDNA library and select a desired clone. This is an alternative to the task of biochemical purification of a protein from a tissue or cell extract. A purified cDNA in a regulated protein expression system may be used to provide a continuous renewable protein source for analysis of the structure, activity, or any characteristic of the encoded protein. Also, the effect that a cDNA's expression has on a relevant **eukaryotic** cell line may provide information about the biological role of the encoded function. Thus, cDNA-directed protein expression not only provides a source of pure protein for either *in vitro* or *in vivo* analyses, but it may also provide a method of cloning (selection) of a cDNA from a cDNA library. Many selections of new cDNAs start without protein or gene sequence information, but instead rely on the detection of the function or biological effect. This process is known as direct expression or functional cloning. Any direct expression cloning method mimics the classic genetic methods of rescue or complementation and so could be considered genetics in the absence of mating. To describe functional cloning in a general way, an altered host cell's **phenotype** or measured activity is restored to the wild-type when the genetic material encoding the host's deficiency is supplied. Although experimental approaches that rely on classic genetic methods have produced much information about cellular processes, they depend on good genetic systems to which the genetic material can be delivered. Systems that lend themselves to an imposed manipulation and selection, generally single-cell organisms with a short generation time, are best for this purpose. A myriad of eukaryotic cell cultures that have been purposefully altered or carefully isolated from the affected organs of diseased patients and that show an atypical phenotype have been widely used as host cells for functional cloning. The applications for the functional cloning of new cDNAs from higher organisms also depend on a selectable phenotype or activity to isolate the host cell that harbors the relevant genetic material. As an example, the anchorage-dependent phenotype of nearly all primary tissue cells is not exhibited by many tumor cells that will grow in suspension (6). When the genetic material used is cDNA, the details of the selection method must be designed so that the cDNA library contains the cDNA encoding the deficient host activity, and so that the cDNA is incorporated into the host cells and expressed functionally. With expression of a cDNA library in eukaryotic host cells, the selection of a desired clone depends on acquisition of a new phenotype. In the example of the anchorage-independent phenotype exhibited by some tumor cells, the induction of the anchorage dependency allows selection for a cDNA-encoded activity related to the anchorage phenotype and possibly to the cause of tumor formation (7, 8). For any selection where the desired cDNA is of an mRNA that is in low abundance, the selection will require a large-scale transformation of host cells, in order to produce even a single positive clone.

Acquiring a cDNA opens up many types of experimental approaches for the analysis of gene expression and studies of the protein encoded by the cDNA. As an example, protocols are available to target a single codon in a cDNA for site-directed mutagenesis. By using available methods to express the altered cDNA, the effects of the mutation on the encoded protein's activity may be measured, and in this way, a structure–function relation is probed.

Although the methods to prepare and make use of cDNA are advanced and commercially available, it remains a challenge to select a completely new cDNA clone from a cDNA library. This may limit the uses of cDNA technology to better characterize known cellular processes rather than uncharacterized cellular processes. The successful recovery of a novel cDNA depends on a specific selection strategy that ultimately will test each cDNA for an encoded activity. The task of individually testing each clone in a cDNA library is nearly overwhelming. If a screening method designed to test each cDNA in a collective manner cannot be designed, it forces the need for biochemical methods to purify the protein activity in order to provide enough sequence information to obtain the cDNA by more conventional methods, such as library screening with a sequence probe or selective **PCR** library amplification with degenerate oligonucleotide primers. Evolving methods of protein expression have demonstrated the potential of cDNA selection as a possible alternative to protein purification. However, functional cloning may not always be possible. An alternative approach, which can temporarily bypass the challenge presented by the need to design or apply a new isolation strategy for each new cDNA, is to randomly isolate and analyze cDNA clones first and then subsequently to identify the encoded function. The use of sequence information derived from randomly selected cDNA samples has become part of the Human Genome Project as a way of providing an aid for the physical mapping of expressed genes, as gene tags (9, 10). The cDNA sequences obtained are collected into the expressed sequence tag (EST) database, which is a collection of nonrepetitious human cDNA sequences of randomly selected cDNAs from 250 cDNA libraries from RNA isolated from 37 distinct human organs and tissues (11). The EST information is providing genetic markers for physical gene mapping and also information about the expression pattern of the mapped genes as the cell lineage is known for each sample analyzed. Some hints about the encoded function of the mapped genes may be revealed by the expression pattern. Furthermore, the large volume of sequence information produced by random sequencing may be compared to the available sequence information of the growing number of fully sequenced genes, in order to identify the presence of conserved protein domains with established activities in a process that has come to be known as *functional genomics* (12, 13). This process of extending available information about function to randomly acquired new sequence information, which necessarily requires a unified, large-scale approach, will undoubtedly contribute greatly to the identification of the encoded functions of previously unknown human genes.

2. Preparation of cDNA

2.1. Isolation of RNA Template

The preparation of cDNA begins with the isolation of the RNA that will serve as a template to direct the cDNA synthesis. Since cDNA is representative of the RNA template, an inciteful choice of a cellular source of RNA, such as a tissue that is known or at least thought to contain the specific mRNA of interest, is important. In some cases, the RNA might be tested for the presence of an RNA of interest. In a simple case, the RNA sample could be analyzed prior to use for cDNA preparation by use of a sequence probe. This sort of analysis requires, of course, some definite sequence information about the mRNA of interest. In a more complex case, when no sequence information about the mRNA is available, but detection of the encoded protein is possible, the RNA source could be analyzed for the ability to direct synthesis of the protein. Detection of a protein may be accomplished by any known function, such as **enzymatic** activity or **ligand binding** activity. The presence of a protein in a cell does not insure the presence of the protein-encoding mRNA, as the protein could be present as a stable form from an earlier expression of an mRNA that is now degraded. On the other hand, a mRNA encoding a protein of interest could be present in a tissue, but remain untranslated. One technique that can be used to insure the presence of the mRNA of interest in an RNA preparation is to translate the total RNA in an *in vitro* translation reaction and then assay the total resulting protein product for the expected protein. The two high-activity *in vitro* translation systems in common use are those prepared from rabbit reticulocytes and wheat germ (14, 15).

Given that a tissue source can be identified that contains the RNA of interest, there may be a possibility of enriching for the desired mRNA. Only a small fraction of total cellular RNA is mRNA that is directed to ribosomes for translation into protein (Table 1). The majority of cellular RNAs function in other ways to aid translation, often with structural roles. Enrichment methods aim to remove the more abundant structural RNAs selectively from the mRNAs. Enrichment of polyA + mRNA by hybridization with immobilized oligo (dT), followed by stringent washing to remove the abundant, structural, poly A – RNAs, is a common method used to prepare the mRNA template for synthesis of cDNA representing protein-encoding mRNAs (16). To reduce contamination by mitochondrial poly A + RNA, the mitochondria may be removed by cell fractionation prior to total RNA extraction, although the extra time and handling of cells required could lead to some loss or degradation of RNA. Isolation of full-length mRNA of nuclear origin based on the unique m^7G cap structure might also serve as an alternative to cell fractionation to reduce those RNA messages of mitochondrial origin often present in RNA preparations (17). Translational inhibitors have been used to stabilize ribosome-bound mRNA that is degraded during translation (18), and as selective RNA degradation pathways are increasingly well characterized, there is an increasing promise of specific inhibitors of RNA degradation for use in preparing mRNA that normally has a relatively short half-life.

Table 1. Cellular Distribution of RNA in HeLa Cells

Cellular Location	% of Total	Average $t_{1/2}$
Nucleus	**10**	
hnRNA	4.0	20 min
snRNA	2.5	100 hours
pre-rRNA	3.5	15 min
Cytoplasm	**85**	
mRNA	2.0	8–10 hours
rRNA	75.0	107 hours
tRNA	8.0	80 hours
Mitochondrion	**5**	
mit-mRNA	0.5	8–10 hours
mit-rRNA	3.5	107 hours
mit-tRNA	1.0	80 hours[a]

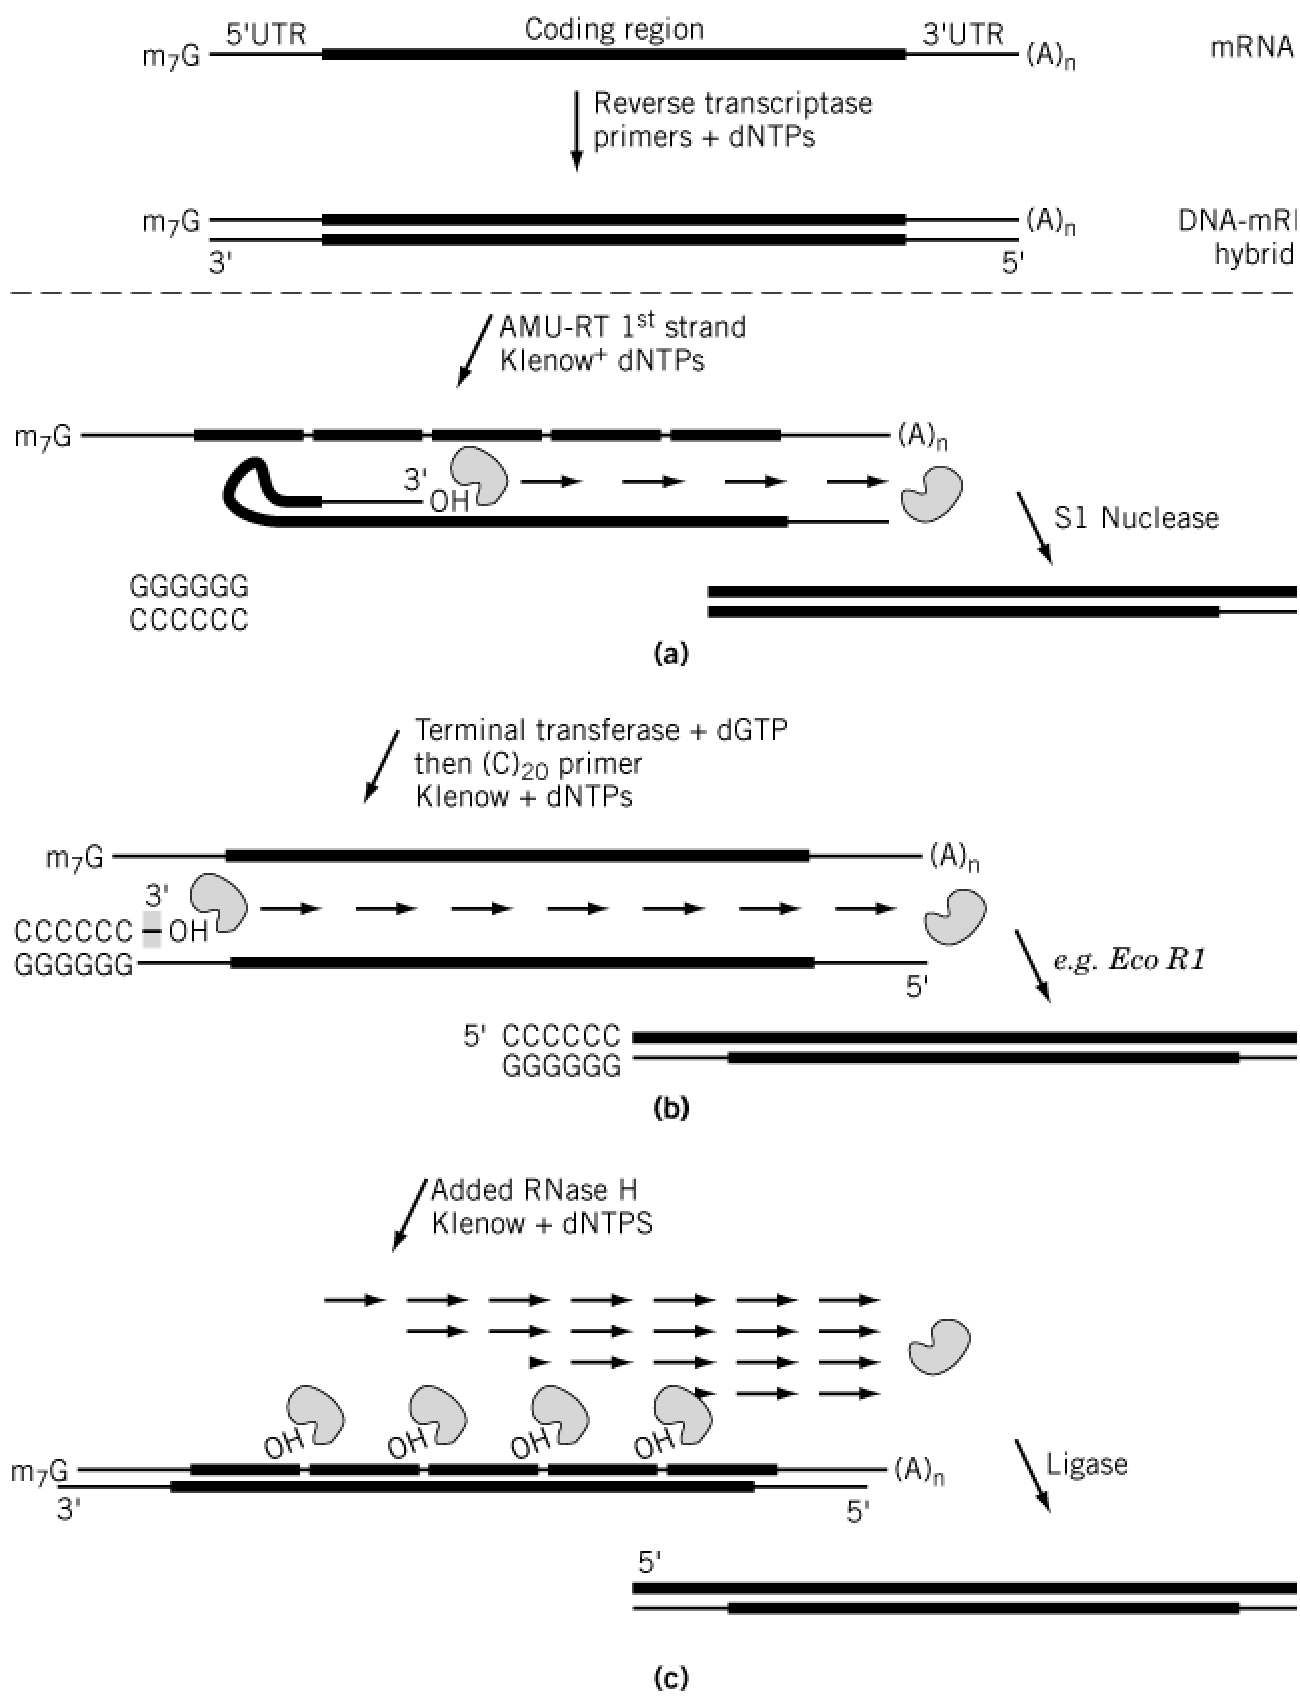
[a] *Note*: These values are approximate ones based on experimental observations made during repeated isolation of RNA from HeLa cell cultures.

Among poly A + RNA, there are messages of low, middle, and high abundance. The process of normalizing cDNA is used to reduce the relative number of high- and middle-abundance mRNA represented in the cDNA product. In this way, relatively fewer cDNA clones need to be screened in order to isolate a low-abundance message copy from a cDNA library. Preferred removal of cDNAs representing high- or middle-copy abundance mRNA is based on the rate of strand reannealing in a denatured cDNA sample (19). The two strands of a cDNA representing a high-abundance message have a higher probability of finding each other in a mixture and anneal before those of low-abundance cDNA. When annealed or double-stranded, the cDNA is separated from unannealed or single-strand cDNA by the use of hydroxyapatite chromatography. After a short annealing time, the low-abundance cDNA will remain in the single-strand chromatography fractions. These fractions are collected and allowed to anneal fully for use as normalized cDNA. Alternatively, subtractive hybridization is a technique used for the enrichment of, eg, tissue-specific or developmental stage-specific mRNA in the preparation of subtraction cDNA libraries.

2.2. Synthesis of the cDNA First Strand

The two cDNA strands are prepared independently. In the first-strand synthesis, the use of an RNA-dependent DNA polymerase results in a mixture of cDNA–RNA hybrid molecules in which the DNA strand is complementary to the original RNA, but possibly of shorter length (Fig. 2). The reverse transcription systems in common use are based on the avian myeloblastosis reverse transcriptase (AMV-RT) prepared from purified avian myeloblastosis virus particles or on the Moloney murine leukemia virus reverse transcriptase (MMLV-RT) prepared from a recombinant *Escherichia coli* strain (20). The purified AMV-RT has a stronger endogenous RNAse H activity than the cloned MMLV-RT, thus increasing the possibility of unwanted side reactions when using AMV-RT. However, purified AMV-RT may be more stable than MMLV-RT at the elevated temperatures used to reduce premature termination caused by **secondary structure** in the RNA template. RNase H is an endoribonuclease that specifically hydrolyzes the phosphodiester bonds of RNA in a DNA–RNA hybrid to produce products with terminal groups 3′-OH and 5′-P. Both AMV-RT and MMLV-RT have a tendency to begin second-strand synthesis prematurely through a reaction in which reverse transcriptase uses DNA rather than RNA as a template by forming a hairpin structure that serves as a template-primer substrate (21). Hairpin formation may be inhibited by the addition of sodium pyrophosphate and **spermidine**, although the RNase H activity is not inhibited with these conditions. The RNase H activity present in AMV-RT may provide a better opportunity for favorable hairpin formation by leaving single-stranded regions of DNA available for self-hybridization; this side reaction is more of a problem when AMV-RT is used. Heat-stable DNA polymerase isolated from *Thermus thermophilus* is capable of reverse transcription in the presence of MnCl *2*, which is a common alternative to the use of reverse transcriptases (22). Each system of reverse transcription has some advantages, as will be discussed, and should be considered with a view of how the second-strand synthesis will be performed. In addition to reverse transcriptase, first-strand synthesis requires deoxyribonucleotide triphosphates, dATP, dGTP, dTTP, and dCTP (or 5-metyl dCTP which may be substituted for dCTP in order to protect the cDNA from 5-methyl dCTP-sensitive restriction enzymes that may be used in subsequent cloning steps). The first-strand synthesis reaction also requires primers.

Figure 2. Three separate schemes of second-strand cDNA synthesis from the DNA–mRNA hybrid. (**a**) A classic methoc makes advantage of a looped back first strand as a primer for second-strand synthesis. After second-strand synthesis, S1 nuclease digestion of the single-strand loop structure results in an available free end for vector incorporation. (**b**) Termin transferase-directed extension of the 3′ end of the first strand results in a dG stretch that provides a binding sight for an oligo dC primer to initiate second-strand synthesis. The undesired dG stretch on the first-strand oligo dT primer is remov by restriction endonuclease digestion targeted to a site present in the oligo dT primer or in the recipient vector if vector priming is used. (**c**) Added RNase H degrades the RNA in the DNA–RNA hybrid product of first-strand synthesis, result in a series of RNA primers that are extended during second-strand synthesis. Subsequent ligation may aid the recovery o full-length cDNAs.



Unlike **RNA polymerases**, which bind a recognition sequence in a double-strand DNA template to initiate polymerization, replicative-type DNA polymerases require primers with a free 3′-OH group and a short double-stranded sequence. Note that a consideration of the primers to be used for the first-strand synthesis may serve to direct a more representative cDNA or cDNA better suited to the research aim. Because all mRNA, except animal histone mRNA, terminate with a 3′ poly A tract, the use of a $p(dT)_{10–15}$ oligonucleotide as a first-strand primer ensures that the synthesis begins at the 3′ end of mRNA, even when total RNA is used as a template for reverse transcription. A disadvantage of this primer is that the 5′ end of longer mRNA may be underrepresented in the cDNA product, since the chance that processive synthesis will continue to the 5′ end decreases with product length. The mRNA 3′ terminal poly A tracts with undesirable average lengths of ≈200 nucleotides can be avoided by the use of an "anchored p(dT) oligo," which has an equal concentration of dA, dC, or dG at the 3′ end of $p(dT)_{12}$ dN. Such an oligo mixture initiates first-strand synthesis at the position immediately adjacent to the beginning (5′) of the poly A tract, with an expected reduction in the length of the poly A tract captured in the cDNA. A random primer of six oligodeoxynucleotides used in place of $p(dT)_{10–15}$ may result in a more representative first-strand synthesis, since at least some of the primers should find matching hybridization sequences near the middle and 5′ end of the RNA and thus are frequently extended to the 5′ end of the template. A random primer is a better choice for use with poly A(–)RNA, which is not complementary to $p(dT)_{10–15}$. A technical consideration for random primed first-strand synthesis is the amount or ratio of primer to template that should be used, since more than one primer for each template could lead to interference between polymerase initiating on different primers hybridized to the same RNA template molecule. This will result in premature termination and a smaller average cDNA product length in the sample. Mixtures of random-primed and oligo dT-primed first-strand synthesis products should equally represent the length of RNA.

Another choice of primer to initiate first-strand synthesis is a sequence-specific primer, a primer complementary to a known sequence within the mRNA of interest. The design of a sequence-specific primer depends, of course, on some available sequence information. A very conserved sequence common to a group of possibly related mRNAs used for the preparation of a limited cDNA library is an example of the application of a sequence-specific primer. Whichever type of primer is used for the initiation of first-strand synthesis, extra sequence at the 5′ end of a primer, such as a restriction site sequence or a second primer-binding site, should not interfere with polymerase-directed extension of the 3′ primer end. Thus, the 5′ end of the primer may serve as a "sticky end" to incorporate the cDNA into a vector or as a primer target for subsequent amplification of the cDNA by PCR.

2.3. Synthesis of the Second Strand

As for first-strand synthesis, second-strand synthesis requires a polymerase, dNTPs, and a primer added to a template. In this case, the template is the product of the first-strand synthesis reaction. Since the template is DNA, a DNA-dependent DNA polymerase, most commonly *E. coli* DNA polymerase I or the **Klenow fragment** of DNA polymerase I, is used for second-strand synthesis. Additionally, reverse transcriptase added as a "chaser" reportedly facilitates second-strand synthesis through obstructions caused by secondary structure in the template (23). The product of the second-strand synthesis reaction is double-strand cDNA ready for steps leading to recombinant vector integration. The choice of primers that might serve to direct the synthesis of the second strand is limited, since the 3′ terminal sequence of the first strand varies greatly among the first-strand synthesis product population; there is no common sequence at the 3′ end of the first-strand product available for primer hybridization. Primer design for second-strand synthesis has conventionally been approached in one of three ways: (1) the classic method of hairpin-loop priming followed by S1 nuclease digestion, (2) RNAse H treatment to generate RNA primers, or (3) homopolymeric tailing, also known as vector priming (see Fig. 2). RNAse H is commonly available in a pure form for the second-strand synthesis reaction (Fig. 2**c**). Added RNAse H is used to generate short RNA primers that are extended to form the second strand (24, 25). The relative technical simplicity, high yield, and large average product length achieved with the RNAse H method have proven it to be the superior approach generally, although other methods may continue to have specific applications and certainly have had a central role in characterization of the potential side reactions that affect the yield and average size of the cDNA product.

The classic method of second-strand synthesis (26, 27) takes advantage of the tendency for the 3′ end of the first strand to fold back and form a DNA duplex with sequences located further 5′ or upstream on the same DNA strand (Fig. 2**a**). A consequence of the duplex or hairpin formation is availability of the self-primed template for second-strand synthesis. After removal of the RNA, reagents for second-strand synthesis are added, and so the second strand is generated. The product is double-strand cDNA covalently closed at the end corresponding to the 5′ end of the original mRNA. The addition of S_1 nuclease, a single-strand-specific nuclease, results in cleavage of the single-strand loop to produce free 5′ and 3′ ends, which are necessary for subsequent integration into a cloning vector. Although the use of S_1 nuclease, which has a potential of hydrolyze double-stranded DNA when used in excess, is often cited as the major disadvantage of the classical method, it is the necessary loss of sequence information that is the true technical fault in the method. Since at least some sequence is involved in the hairpin formation, the sequence of the 5′ end of the original mRNA is not represented in the cDNA product when this classical method of second-strand synthesis is used.

The method of homopolymeric tailing or vector priming relies on the use of *terminal deoxynucleotidyltransferase*, an enzyme that catalyzes the sequential addition of available nucleotide triphosphates to the free 3′ end of a DNA strand. Thus, a homopolymer tail made by extension of the free 3′ end of the cDNA strand resulting from the first-strand synthesis reaction serves as the primer site for second-strand synthesis (Fig. 2**b**). The application of homopolymer tailing to second-strand synthesis preserves the cDNA sequence representing the original 5′ end of the mRNA template, since priming is from sequence added by terminal transferase (28, 25). After first-strand synthesis initiated from a T-tailed vector, the 3′ end of the newly formed cDNA strand is the target for homopolymer tailing. The use of dGTP for the tailing reaction consistently results in an average of 20 G nucleotides on both the 3′ end of the cDNA first strand and on the free 3′ end of the vector. The consistent length of the tail with use of dGTP is apparently due to structural constraints, which cause decreased tailing after 20 Gs (29, 30). A restriction site in the vector is used to remove the G-tail from the vector, without affecting the G-tail on the cDNA, which as a DNA–RNA hybrid is a poor substrate for restriction endonucleolytic cleavage (31). Finally, an oligo $p(dC)_{20}$ primer is added, along with other reagents required for second-strand synthesis. The $p(dC)_{20}$ primer may be designed to have a 5′ end complementary to the overhang of the vector restricted end to aid in subsequent circularization of the recombinant DNA; otherwise, both the cDNA and vector ends may be made flush or blunt prior to circularization. Many variations of the vector priming method briefly described here have been described in detail elsewhere, but all make use of terminal transferase (32). The disadvantages of being more technically difficult and having more steps, as well as having a stretch of 20 G nucleotides at the vector-cDNA boundary (which could require special techniques for sequencing and subcloning), might be balanced by the important potential of increasing the number of full-length clones when using this method of second-strand synthesis.

Isolation of a cDNA corresponding to the intact full-length mRNA molecule often presents a challenge. Methods that increase the frequency of obtaining full-length clones in a cDNA synthesis reaction are often preferred. Losses of cDNA may occur at each step of the synthesis, from RNA isolation to vector incorporation. Losses of full-length cDNA may also occur due to incomplete replication of template by polymerase. For example, the presence of secondary structure in the RNA template may impede the progress of reverse transcriptase during first-strand synthesis, resulting in the formation of a partial cDNA beginning at the primer site and ending at the site where the secondary structure is encountered by the polymerase. Technical manuals that contain detailed protocols for cDNA synthesis often describe ways to monitor the progress of cDNA synthesis to give an indication of the reaction yields, or the incurred losses, and also the average size of the cDNA strand. A method designed to extend a partial cDNA isolated by a selection procedure called RACE (rapid amplification of cDNA ends) may be used to obtain the corresponding full-length clone (33). The actual 5′ end of an mRNA should, however, be mapped against the gene and/or correlated with the N-terminal sequence of the protein where possible. Primer Extension is frequently used to determine the precise 5′ end of an mRNA, and this method only requires enough sequence information for primer design.

3. Uses of cDNA

The final steps in cDNA synthesis are often those leading to vector integration. The use or application of cDNA is largely determined by the type of vector that is chosen to contain the cDNA. Vector integration is, therefore, the first step toward fitting the cDNA to the type of application that will be made or toward developing a selection strategy for the isolation of a cDNA of interest from a library. Recent progress in the development of cloning vectors for specialized applications and of methods of efficiently adapting the cDNA ends to fit the vector ends have resulted in a lot of flexibility in the combination of available vector features when making a choice from the long list of commercially available cloning vectors. The immediate aim of retaining all the newly synthesized cDNA through the process of vector integration and host transformation, while keeping the desired vector features, is frequently satisfied by the use of a **phagemid** (34). A phagemid vector combines features of lambda phage, filamentous phage, and plasmid vectors into one cloning vector (35, 36). The efficiency of host cell transformation through packaging of cDNA into viral particles, and subsequent viral infection as performed with the use of a l phage cloning vector, cannot be matched by even the optimal conditions for direct host-cell transformation with plasmid DNA. There is consequently less potential for cDNA loss during host cell transformation with a l phage system when compared to a plasmid system. The lower background that results from the screening of plaques rather than colonies with sequence hybridization probes or antibody probes offers another significant advantage to the use of viral vectors. Plasmid vectors offer advantages over l phage vectors for the characterization of the cDNA inserts, due to the necessarily large size of l phage vectors. Phagemid vectors contain a plasmid vector within a l phage vector and additional sequences derived from filamentous phage that contribute to the *in vivo* excision of the plasmid from the l phage vector. Thus, for characterization of individual selected cDNA clones, the original phage clones are converted to plasmid clones. Although it is technically straightforward to subclone a single cDNA clone from one vector to another, it is technically difficult to subclone an entire cDNA library from one to another vector without some loss of cDNA. Whichever type of vector is used to receive newly made cDNA, consideration of the vector features required for selection of a cDNA of interest from a library and the efficiency of the process of integration and host-cell transformation should be given prior to vector integration of cDNA as a library.

Possibly the greatest benefit of aquiring a new cDNA of interest from a cDNA library is the sequence information that can be derived from it. In addition to the encoded protein sequence, comparison of a cDNA sequence with the corresponding gene sequence reveals or confirms the location of any introns present in the gene. Analysis of a set of positives identified by rescreening of a library with the now available hybridization probe may provide some indication of the variability of the gene transcripts, eg, the presence of alternate splice sites or multicopy genes with minor sequence variations. The presence of viral RNA polymerase recognition sequences, most commonly SP6 and T7 **promoters**, in many cloning vectors are useful for the *in vitro* production of anti-sense RNA probes that may be used for the high-sensitivity detection of gene expression. Likewise, PCR primers may be designed from the sequence information to provide an alternate method of sensitive or quantitative gene expression analysis. The presence of potential post-transcriptional regulatory elements in the untranslated regions represented in the cDNA may be identified through computer-assisted sequence analysis and database comparisons. Although any number of extremely sophisticated uses for cDNA sequence information may be envisioned for a particular application, a generally useful benefit is the possibility to generate peptide antibodies to encoded peptide epitopes predicted to be on the protein surface.

Vectors are available with many combinations of features. A particularly useful vector feature for many types of applications is the inclusion of sequences that support cDNA expression. As the sequences required for correct initiation of translation differ among organisms, expression vectors, or an expression cassette within a cloning vector, are designed for use as a set with a matching host cell. The promoter sequences included to drive the transcription of the expression cassette and efficient transcriptional termination signals are likewise active in the same host. As there are no introns to be removed, expression of many encoded eukaryotic proteins is supported in strains of *E. coli*, provided that these proteins are not toxic to the *E. coli* host strain used. In order to avoid the possible toxic effects of some eukaryotic proteins, expression vectors with inducible promoters are available to postpone the cDNA expression to a point of vigorous growth so that significant protein production is accomplished before the host culture dies. The activity of eukaryotic proteins produced in prokaryotic host cells may be deficient due to the absence of factors required for proper protein folding in vivo, for post-translational modifications essential for the activity, or even for correct intracellular localization. Eukaryotic expression systems may better support the production of eukaryotic proteins with natural levels of activity and are designed for maximum protein production. Such expression systems may support continued replication of the vector containing a cDNA insert, in addition to containing an **expression cassette** with an active promoter and signals for transcription termination and translation initiation. Both prokaryotic and eukaryotic expression systems with matched vector and host are designed to produce proteins in quantities required for their structural characterization from manageable volumes of cell culture. Accurate physical measurements that require purified proteins may take advantage of "built-in" purification aids available in some expression vectors. Expression of a cDNA as a **fusion protein** aids in the isolation of protein from cell cultures. Provided a cDNA is cloned in-frame in relation to a vector sequence that encodes a polypeptide chain with a known ligand affinity, the resulting fusion protein may be purified from cell lysates by passage through an affinity chromatography column containing the immobilized ligand. The presence of a proteinase peptidase recognition sequence facilitates proteolytic removal of the vector-encoded polypeptide and elution of the cDNA-encoded protein from the affinity column.

An additional type of expression vector that is adapted to cDNA selection is one designed for use with a yeast host strain. The yeast 1, 2, and 3-hybrid systems have been designed to isolate a cDNA clone from a library based on the encoded protein's recognition or specific binding to a DNA, protein, or RNA sequence, respectively (37-39) (see Two-Hybrid Systems). In this way, cDNA selection is facilitated by its expression inside a yeast host cell that has been genetically altered for the selection. In order to perform the selection, an entire cDNA library is cloned into a shuttle vector that will support replication in *E. coli*, as well as replication and expression (as a fusion protein) in the yeast host. The library is amplified for transformation into the recipient yeast host strain, which is altered in such a way that specific binding of a target sequence or "bait sequence" results in a positive selection. The yeast hybrid systems typify advances in the use of traditional genetic strains adapted for functional cloning of cDNA from higher organisms, and yeast has consequently become a tool for functional cloning through molecular recognition, extending the use of cDNA as an aid to the selection of novel factors. Thus, a factor that binds to a DNA sequence, such as a transcription factor that binds to a gene promoter element, may be difficult to isolate by biochemical means due to its low intracellular abundance, but it might be cloned with the yeast 1-hybrid system. Likewise, a factor that binds to a protein might be cloned with the 2-hybrid system, or an RNA-binding protein with the yeast 3-hybrid system.

4. Summary

cDNA is a faithful double-stranded DNA copy of RNA and, as such, can represent those genes that are expressed as RNA in a source tissue. When integrated into an appropriate cloning vector to form recombinant DNA, cDNA may provide a continuous renewable source of genetic material for hybridization probes, designed reporters of biological activity, or pure encoded protein. The benefits of protein production and a myriad of specific research applications have made cDNA a universal tool for basic and applied cell and molecular biology research. The potential for using cDNA in molecular methods designed to select for activities that contribute detectable cellular phenotypes has provided possible alternatives or improvements to genetic and biochemical approaches.

Complementation

The term complementation usually refers to the situation where two defective genomes in the same cell together support a normal or nearly normal **phenotype**, each supplying the function that the other lacks. Another meaning of the term, in the context of DNA manipulation, is the repair of a mutational deficiency in an organism or cell culture by artificially introducing a **gene** that supplies the missing function. This is a potent way of cloning genes selected according to function. In either sense, complementation provides a way of discriminating between gene functions and of defining genes as functional units.

1. Complementation and the definition of the functional gene

Classical genetics was based upon clear-cut heritable variants, either induced by mutagenic treatments or, in earlier days, just turning up as "sports" in wild or cultivated populations. The geneticists' favorite organisms, notably **maize** (*Zea mays*) and the fruit-fly (***Drosophila*** *melanogaster*), were **diploid**. Most mutations were recessive to **wild type**, which is what would be expected if they mostly represented losses of function that could be more or less adequately supplied if one gene out of two was normally active.

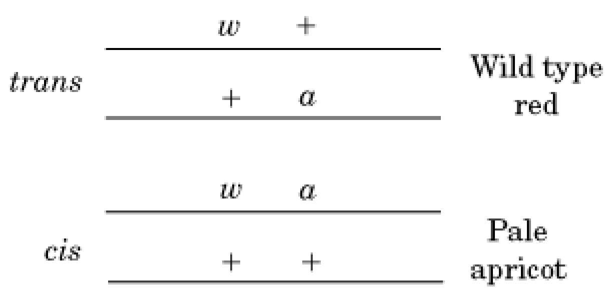
As mutants accumulated, they were attributed to the same or different genes on the basis of two criteria. First, it was supposed that mutations in the same gene were inseparable by recombination. A diploid that carries two different mutant **alleles** (ie, alternative forms) of a particular gene should never produce nonmutant or double-mutant germ cells by free reassortment or **crossing-over** at **meiosis**. According to the second criterion, mutations in the same gene should affect the organism in similar or at least related ways. Similarity or overlap of functional effects was judged by individual appearance (phenotype) and also and more rigorously by failure of the mutant chromosomes to complement each other's defects in the hybrid diploid. (In fact, the term complementation did not come into use until the late 1950s, and I use the word with hindsight.)

A classical example of using the complementation criterion, and one of the first in which it was thrown into doubt, involves the sex-linked *white* (*w*) gene of *Drosophila*, one of several genes governing eye color. A considerable number of recessive mutant *w* alleles had been identified. They diluted the normal red-brown eye pigment to various degrees when the same allele was present on both X-chromosomes (***homozygous***) in females, or on the single X in males. Females that had two different mutant *w* alleles (***heterozygous***) had dilute eye colors generally intermediate between the colors of the two homozygotes. Thus females of constitution *white/ apricot* (w/w^a) have pale apricot eyes, not wild-type red as would be expected if each mutant X-chromosome could provide the pigment-forming function lacking in the other.

In 1952, E. B. Lewis (1) found that, at very low frequency (about 1 in 10,000), w/w^a females produce eggs of recombinant types, with neither mutation or both. By the attached-X technique, which need not be described here, he showed that these recombinants arise by crossing-over between the X-chromosomes, just as if *white* and *apricot* were mutations at distinct, though very closely linked loci. Accordingly he gave them different symbols, *w* and *a*, and rewrote the constitution of the female parent wa^+/w^+a, where the + superscripts denote the respective wild-type alleles.

The remaining anomaly was what Lewis called the *cis* /*trans* position effect (Fig. 1). Two kinds of doubly heterozygous constitution could be compared, the original so-called *trans* arrangement wa^+/w^+a, that has the two mutations on opposite chromosomes, and the *cis* arrangement, $w^+ a^+/wa$. They had identical overall gene content, but the former had pale apricot eyes and the latter was fully wild type. w^+ and a^+ could act cooperatively to promote normal levels of eye pigment only when they were together on the same chromosome. Lewis called their relationship ***pseudoallelic***: allelic according to their failure to complement each other but nonallelic according to their ability to recombine. A formally identical situation at the *Drosophila lozenge* locus had already been reported by M. M. Green (2).

Figure 1. Lewis's (1) *cis-trans* comparison using two mutations in the *Drosophila melanogaster* X-linked *white* (*w*) gene. The mutations *white* (*w*) and *apricot* (w^a, shown here as *a*) are each recessive to wild type in females but do not complement one another in *trans*. By this criterion they are allelic in spite of being separable at low frequency by recombination.



For Lewis and Green at that time, the recombination criterion for allelism took priority, and the reason for the position effect was a matter for speculation. Before long, however, high-resolution recombination analysis of series of mutants in the microbial world, first in the fungus ***Aspergillus*** *nidulans* (3) and then in the bacterial virus (**bacteriophage**) T4 (4), revealed that pseudoallelism, in Lewis's sense, was much more the rule than the exception. It was rather rare for independently occurring mutations to be “truly” allelic. Almost all pairwise combinations of noncomplementing mutants showed some low frequency of recombination when crossed together. Soon afterward, the same was shown to be true in two bacterial species, *Escherichia coli* and *Salmonella typhimurium* (5), which have no regular diploidy or meiosis but other means exist for obtaining partial diploids and tests for complementation and recombination (see Complementation Tests). In one example after another, it was shown that most mutations within functional genes are at different mutually recombinable sites which, by different methods in different organisms, could be mapped in a closely spaced linear sequence that was continuous with the much longer sequence of the whole chromosome.

Following his very extensive analysis of the *rII* series of mutants in phage T4 ((4), see Complementation Tests), S. Benzer proposed replacing the word gene with a new term, **cistron**, meaning the unit of function as defined by Lewis's *cis*/*trans* comparison. When the *cis* and *trans* phenotypes are identical (wild type, if the mutants involved were recessive), the mutations are in different cistrons, affecting different functions. If *trans* is mutant and *cis* normal (or relatively so) the mutants are in the same cistron. The concept has been universally accepted, but the term cistron has dropped out of use. Now “gene” is generally used in the same sense, and the full *cis-trans* test is rarely applied. The theoretical reason for the comparing *trans* ($m1 + / + m2$) with *cis* ($m1m2/ + +$), rather than just *trans* with the wild type, is that it controls the possibility that the cumulative effect of two heterozygous mutations in different genes could be a sub-wild phenotype, even though each is individually recessive to its wild-type allele. In practice, however, recessive alleles usually remain recessive even when several of them are present together, and so the *trans*/wild comparison, the simple complementation test, is usually deemed sufficient.

Although diploidy provides the means for complementation testing in higher plants and animals and also in budding **yeast**, alternative methods, described under Complementation tests, have to be used for habitually haploid organisms, such as bacteria, viruses, and most fungi.

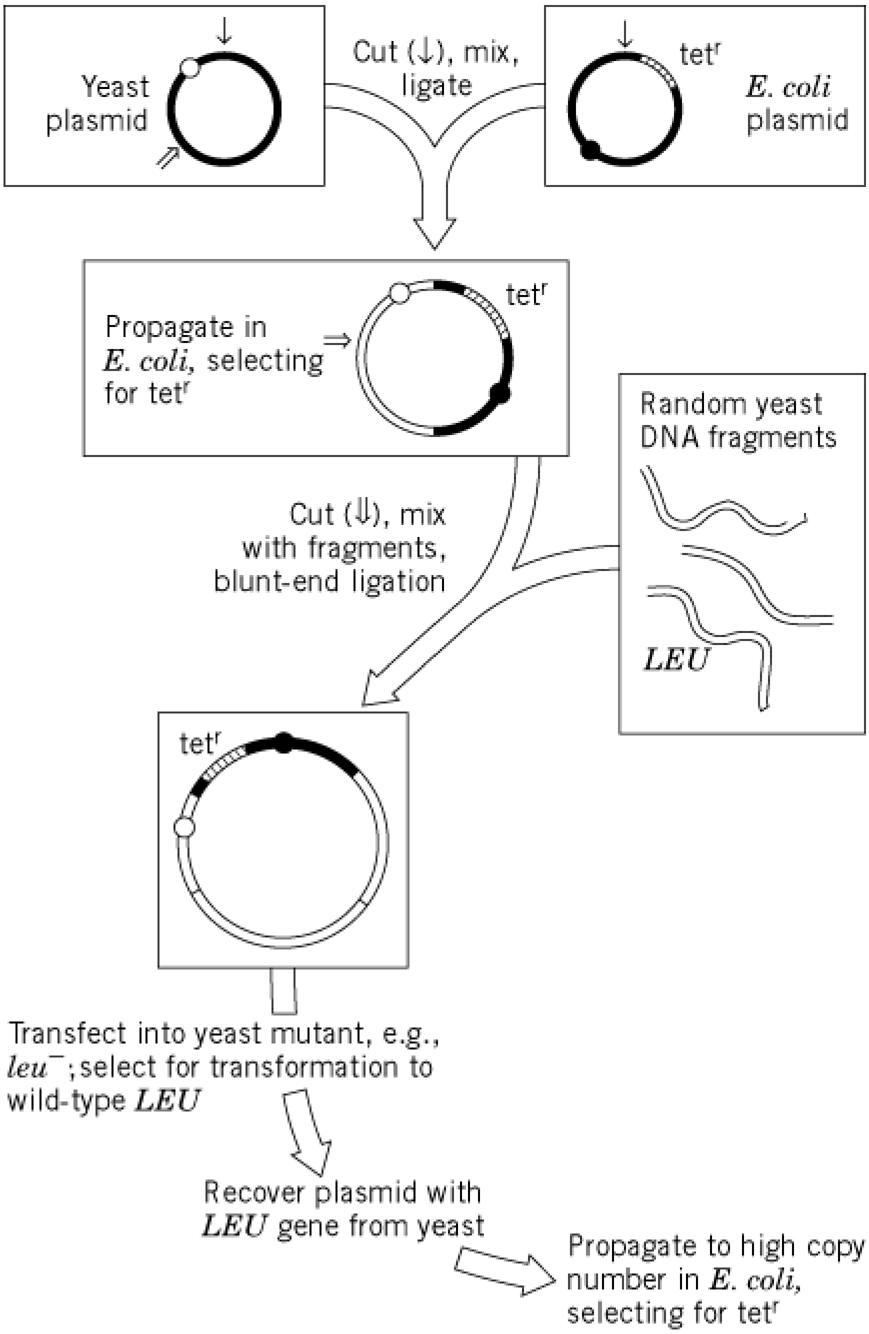
1.1. Complementation and gene cloning *in yeasts*

Cloning wild-type alleles of yeast genes with metabolic functions and mutating to give **auxotrophic** phenotypes, became straightforward following the development of the Saccharomyces two-micron (2-µm) **plasmid** as a cloning vehicle (7). This plasmid also replicates in the other major experimental yeast species, the fission yeast *Schizosaccharomyces pombe*. It has been most useful as a component of a series of hybrid **shuttle vectors**, capable of replication either in yeast or in *Escherichia coli*. These usually incorporate the replicative origin of the *E. coli* plasmid ColE1 and a gene for antibiotic resistance (e.g., to **tetracycline**) that can be selected for in the bacterial host.

To select and clone a yeast gene, fragments of total yeast DNA, produced by digestion with a **restriction endonuclease** (or sometimes by sonication), are ligated into the closed-loop, double-stranded DNA of a shuttle vector and introduced en masse by one of the standard transformation procedures into mutant yeast cells, which then are plated on a medium on which they grow to form colonies only if their mutational deficiency has be repaired. (see Cloning) The first yeast genes to be cloned were selected because they conferred on auxotrophic (nutritionally exacting) mutants the ability to form colonies on a minimal (unsupplemented) growth medium. But any gene that mutates to give a conditional no-growth phenotype can be cloned in essentially the same way. Temperature sensitive mutants have been a particularly rich source of cloned genes. Almost any essential protein can be mutated to a temperature-sensitive form, functional at, say, 30°C but not at 36°C. Mutant cells grown at the permissive temperature are transformed with a gene “library” and selected for repair of function at the restrictive temperature.

The shuttle vector bearing the selected gene replicates autonomously either in yeast or after transfer to *E. coli*. The bacterial host is more efficient for mass propagation of the clone. When sufficiently amplified, the cloned gene is cut out of the vector, and its structure and function are analyzed in various ways, most obviously by DNA sequencing. The general method is outlined in Fig. 2.

Figure 2. Cloning and amplifying a yeast gene in a shuttle vector selected by its complementation of a yeast auxotrophic (leucine-requiring) mutant. Open and filled circles indicate replication origins for propagation in yeast and *E. coli*, respectively. Based on Beggs' first demonstration of the method (7).



The complementation of yeast mutants is used for cloning yeast genes and also genes from such distant organisms as *Drosophila* and humans. One good example is cloning the human equivalent of the *Schizosaccharomyces pombe* (fission yeast) *CDC2* gene (8). *S. pombe* temperature-sensitive *cdc2* mutants cannot complete their cell cycle at elevated temperature (36°C) because the mutant *cdc2* gene product, a protein kinase that provides a signal essential for initiating cell division, is inactivated at this temperature. Transformation of mutant cells with a human cDNA library cloned in a replicating plasmid led to the isolation of a few colonies that harbor hybrid plasmids carrying the desired cDNA sequence. The cloning plasmid used in this instance differs from that illustrated in Fig. 2 in that its replication in fission yeast depends on a DNA sequence from the monkey **SV40 virus**, which replicates well in *S. pombe*, not on the yeast 2-mm plasmid. To clone mammalian gene sequences in yeasts, it is generally necessary to use cDNA rather than genomic DNA. Mammalian **introns** are not effectively spliced out in yeast cells and, in any case, often make the gene too long for cloning in one piece.

1.2. In Neurospora

Although yeast species that have a single-cell, colony-forming habit and are accessible to replicating plasmids are especially convenient for cloning genes, the complementation principle can also be applied to filamentous fungi and has been particularly successful in *Neurospora crassa*. This species has the disadvantage that it has no convenient plasmid that stably replicates without integration into the chromosomes. Consequently, although auxotrophic mutants are "rescued" by transformation with fragments of total *Neurospora* DNA, it is not so easy to recover the transforming sequences from the transformed cultures. This difficulty was overcome by sib selection (9).

The method is making a library of *Neurospora* DNA sequences in some suitable vector (sufficient in number so that it is probable that the great majority of genes are represented), dividing the clones into a number of pools, and testing DNA isolated from each pool for its ability to repair the mutant of interest. Then a pool that works (and there is usually at least one) is subdivided into smaller pools for further tests, and then to still smaller pools, until the hunt is narrowed down to a small number of clones that can be tested individually. Though obviously laborious, the method has been very successful. It has been used for cloning genes of metabolic function and also for the loci (actually gene complexes) that govern fungal **mating type** by complementation of mating-deficient mutants (10, 11).

1.3. In Drosophila

Many gene functions involved with basic cellular processes are common to yeast and mammals. Then it is not surprising to find that others, more to do with tissue differentiation, are common to most animals. Because the genetic control of development is better understood in *Drosophila* than in any other animal, it is of interest to ask whether some of the relatively well-characterized *Drosophila* genes have mammalian equivalents. Flies cannot be used for the kind of mass screening of gene libraries that is possible with yeast, but it is not difficult to find out whether some particular mouse gene or cDNA clone complements a *Drosophila* mutant.

It is relatively easy to get exotic DNA into the *Drosophila* genome by inserting it into the transposable P element and injecting the construct into early embryos. Thus the mouse gene M33, cloned on the basis of its sequence similarity to the *Drosophila polycomb* (*Pc*) gene, was successfully introduced into *Pc* mutant flies (12). The mutants, which usually have sex combs on all legs of the male instead of just on the front pair as in the wild type, were partially normalized by inserting one copy of M33 into their genome and were restored almost to wild type by two copies. *Pc* protein is one of a group of chromosomal proteins that act together to prevent certain developmentally important genes from being expressed in the wrong places or at the wrong times. This experiment strongly indicates that there is a mammalian gene that has a similar function.

Complementation Tests

The **gene** is best defined as an integral unit of genetic function, in the sense that none of its parts functions normally in isolation from the others. If so, two different forms (**alleles**) of the same gene, both more or less inactivated by mutation, should not make good each other's defects when together in the same cell. They should not, in other words, show complementation. On the other hand, two genomes that have mutations in different genes should complement each other to produce a wild-type phenotype, provided that each mutant allele is recessive to its **wild-type** counterpart. This complementation criterion is of great importance because it permits assigning mutations to the same or to different genes without a detailed analysis of gene functions. When mutations are closely linked and have fairly similar phenotypic effects, it is always likely that they are in the same gene. But it is not uncommon to find close linkages of separate genes whose function is related. A complementation test provides much stronger evidence.

The interpretation of complementation tests is itself subject to certain difficulties, which are discussed separately under the heading **Allelic complementation**. Here we make the simplifying assumption that complementation between recessive mutations means that they are in different genes.

For a complementation test, it is necessary to bring two mutant genomes, or at least relevant parts of genomes, together in the same cell. In organisms including animals, higher plants and budding **yeasts**, that have a stable **diploid** phase in their life cycles, this can be simply achieved by making a sexual cross between mutant strains. In microorganisms that have no stable diploid phase, various other means have to be employed. In haploid filamentous **fungi**, heterokaryons that have two genetically different kinds of nuclei in a common cytoplasm provide a satisfactory substitute for diploidy. In **bacteria**, where neither diploidy nor heterokaryosis is usually available, there are various ways of introducing fragments of the genome from one cell to another to make partial diploids (merodiploids). This makes it possible to test for complementation of genes located within the duplicated fragment (Fig. 1). In **viruses**, especially bacterial viruses (**bacteriophages**), complementation tests can be carried out simply by mixed infections.

Figure 1. Three general ways of making complementation tests: (**a**) by diploidy (higher plants, animals and the budding yeast *Saccharomyces cerevisiae*); (**b**) by heterokaryosis (fungi, such as *Neurospora crassa* and sometimes cultured mammalian cells); (**c**) by addition of a genomic fragment to a haploid genome (bacteria, such as *Escherichia coli* and *Salmonella typhimurium*). In each diagram, 1 and 2 are different mutations, and + stands for the corresponding nonmutated sites.

1. Complementation Tests in Diploids

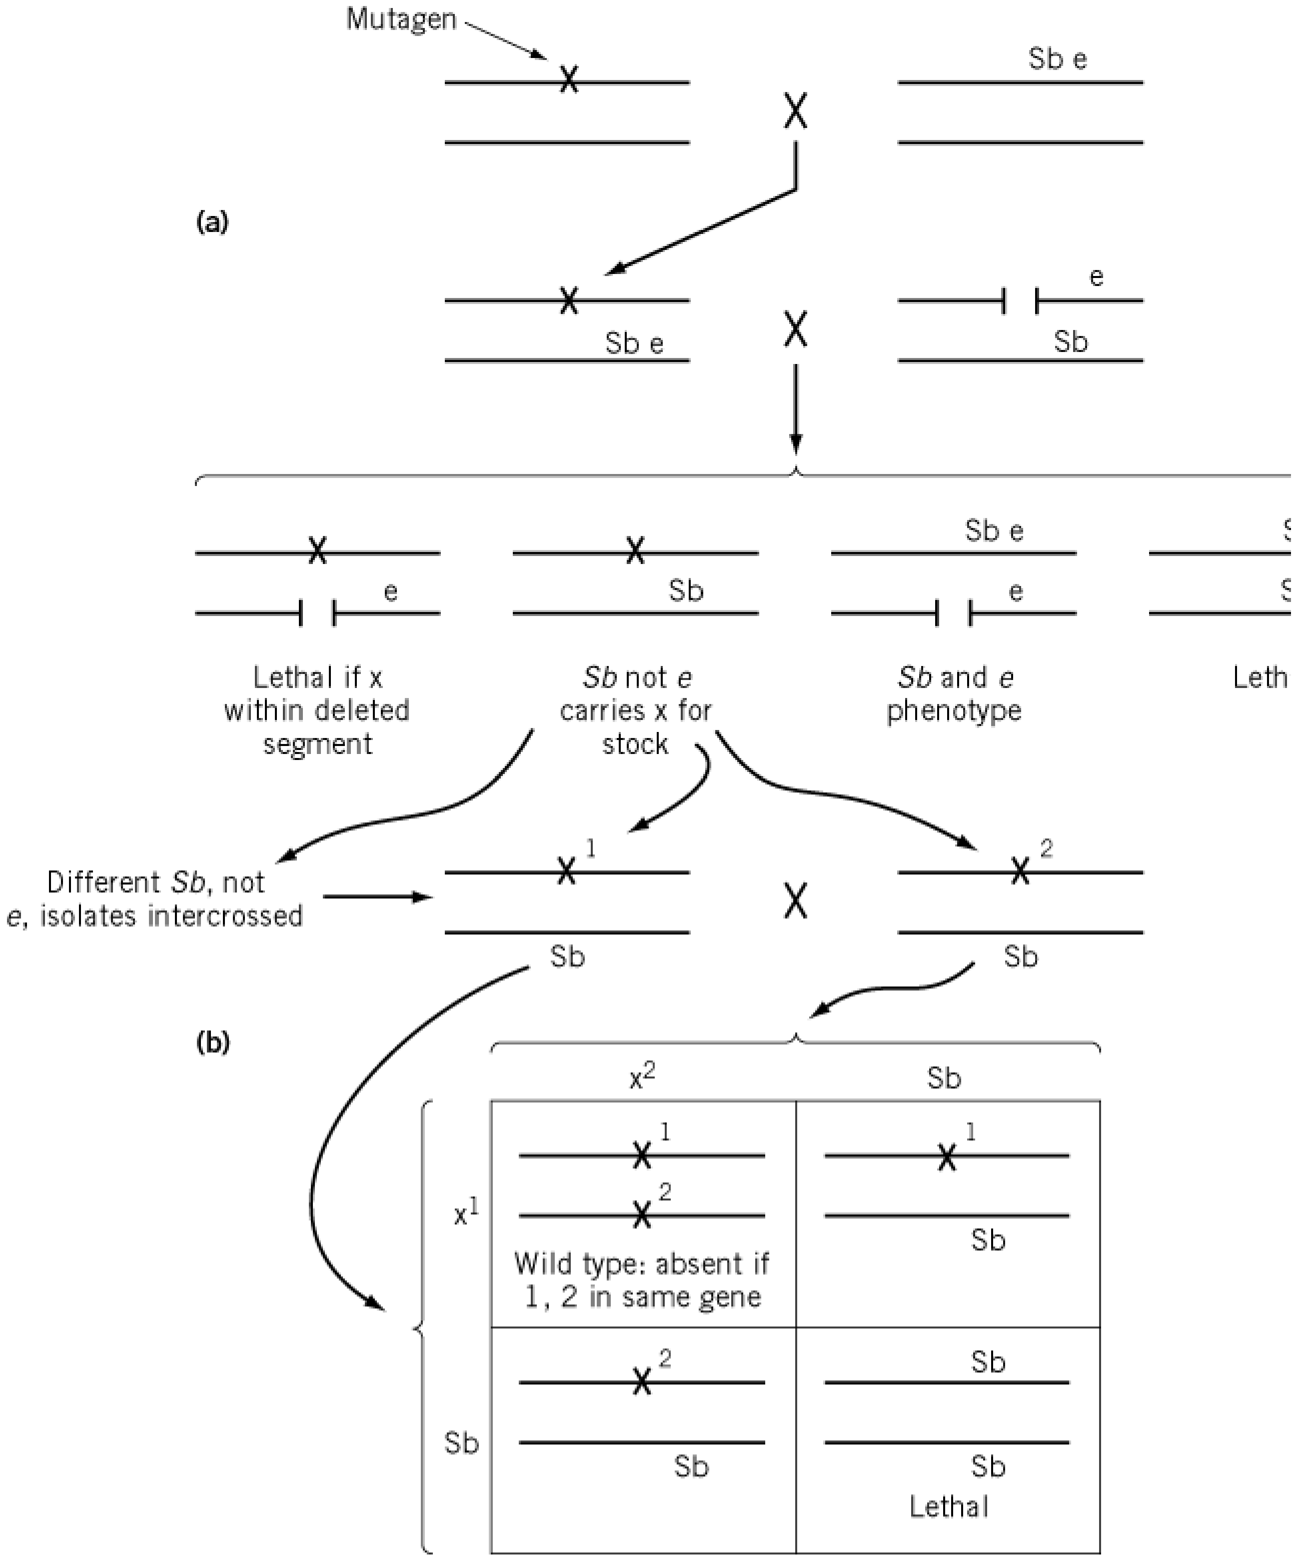
The most extensive complementation testing using diploids has been carried out in the budding yeast *Saccharomyces cerevisiae* and the fruit fly ***Drosophila*** *melanogaster*. These are the diploid organisms that have most experimentally induced mutants sorted into genes.

Saccharomyces has the great advantage as an experimental organism of propagating itself equally well as a haploid or a diploid. Haploid cells are of two different mating types, called *a* and a. In wild strains, the cells are constantly interconverted by a genetic switching mechanism but are stabilized in nonswitching laboratory strains. Most yeast genetics is based on the use of **auxotrophic** mutants that grow only if given some specific nutritional supplement which they can no longer synthesize—most commonly an amino acid, a **purine** or **pyrimidine** base, or a vitamin. Such mutants can be readily obtained in haploid strains. For comprehensive complementation testing, it is necessary to isolate each mutant in both mating types from a cross to wild type. Then haploid cells of pairs of mutants of opposite mating types are mixed at marked positions on plates of unsupplemented agar growth medium. Sexual fusion to form diploid cells occurs almost immediately, and the diploids grow if the two mutations complement each other's nutritional deficiencies. The result is quite clear after overnight incubation. Auxotrophs that have different nutritional requirements always complement, but mutants that have the same requirement may or may not do so because several different genes acting in sequence are usually necessary to synthesize a single end product. The results split the mutants that have a common requirement, say, for the amino acid histidine, into clear-cut complementation groups - *his1*, *his2*, *his3*, etc. Every member of one group complements every members of any other group, but only sporadic and fairly infrequent complementation occurs within groups (see Interallelic Complementation). In general, complementation groups equate to genes, and each one is deficient in one enzyme of the biosynthetic pathway.

In the fruit-fly, *Drosophila melanogaster*, which is certainly the most intensively investigated multicellular organism, many mutants have been assigned to allelic series based on the mutant phenotypes of their heteroallelic combinations. The famous example of multiple alleles of the *w* (white-eye) gene is referred to under Complementation. Most of the allelic series have consisted of viable mutants, all within the same short chromosome segment, and obviously related phenotypes that made their allelic relationship are very likely even without complementation testing. However, nonvisible mutations, **recessive lethals**, have been much used in attempts to establish the total number of genes that have essential functions residing within a particular chromosome segment. Complementation is the only guide for classification of lethals.

A broadly applicable experimental scheme is shown in Fig. 2. The method is selecting, after heavy mutagenization, a large number of **recessive lethal** chromosomes based on their failure to complement a deletion of a short, defined chromosome segment, and maintaining them in breeding stocks combined with a "balancer" chromosome. A *Drosophila* balancer chromosome carries a dominant viable mutation to show that it is present and a recessive lethal mutation to ensure that any fly that carries it also has the chromosome against which the balancer is supposed to be balanced. The balancer chromosome also contains an inverted segment, or complex of inverted segments, to inhibit its recombination with the mutagenized chromosome, or else has genetic markers to ensure that recombination within the mutagenized region can be avoided. Crosses between flies that have different recessive lethals, each in combination with the same balancer, produce a predicted one-third of their progeny free of the balancer, if the two are in different genes and therefore complement one another, but no progeny without the balancer if they are in the same gene.

Figure 2. The isolation of recessive lethal mutations in *Drosophila* and testing them for complementation. (**a**) Male flies treated with a mutagen and mated to females carrying a balancer third chromosome that has the marker mutations *Sb* (do bristle phenotype, recessive lethal) and *e* (recessive ebony body colour). Flies in the next generation that have mutageniz chromosome 3 covered by the balancer, are crossed to flies that have a third-chromosome deletion and the *e* marker, bala against *Sb*. If the mutagenized third chromosome has a recessive lethal mutation (x) at a site within the deletion, there ar viable progeny that do not carry *Sb*. Then, the recessive lethal is present, balanced against the *Sb* chromosome in all viab progeny that are not ebony (*e*/*e*). (**b**) When *1*/*Sb* and *2*/*Sb* flies are crossed (*1* and *2* are two different lethals), one-third o viable progeny should be wild type (without *Sb*) if *1* and *2* are in different complementation groups (equivalent to genes) exhibit *Sb* if *1* and *2* are in the same complementation group. Based on Ref. 1.



In the study on which Fig. 2 is based (1), a total of 268 recessive lethals that fall within a segment of chromosome 3 comprising 26 polytene chromosomal bands could be assigned to 25 complementation groups. The numbers were sufficiently great to make it likely that most, if not all, of the genes that have essential functions and therefore can mutate to recessive lethality had been identified. The gene number was probably underestimated because there are certainly genes that can be deleted without lethality. Nevertheless, the agreement between chromosome band number and the apparent number of essential genes (now found in several different experiments) is too close to be without significance.

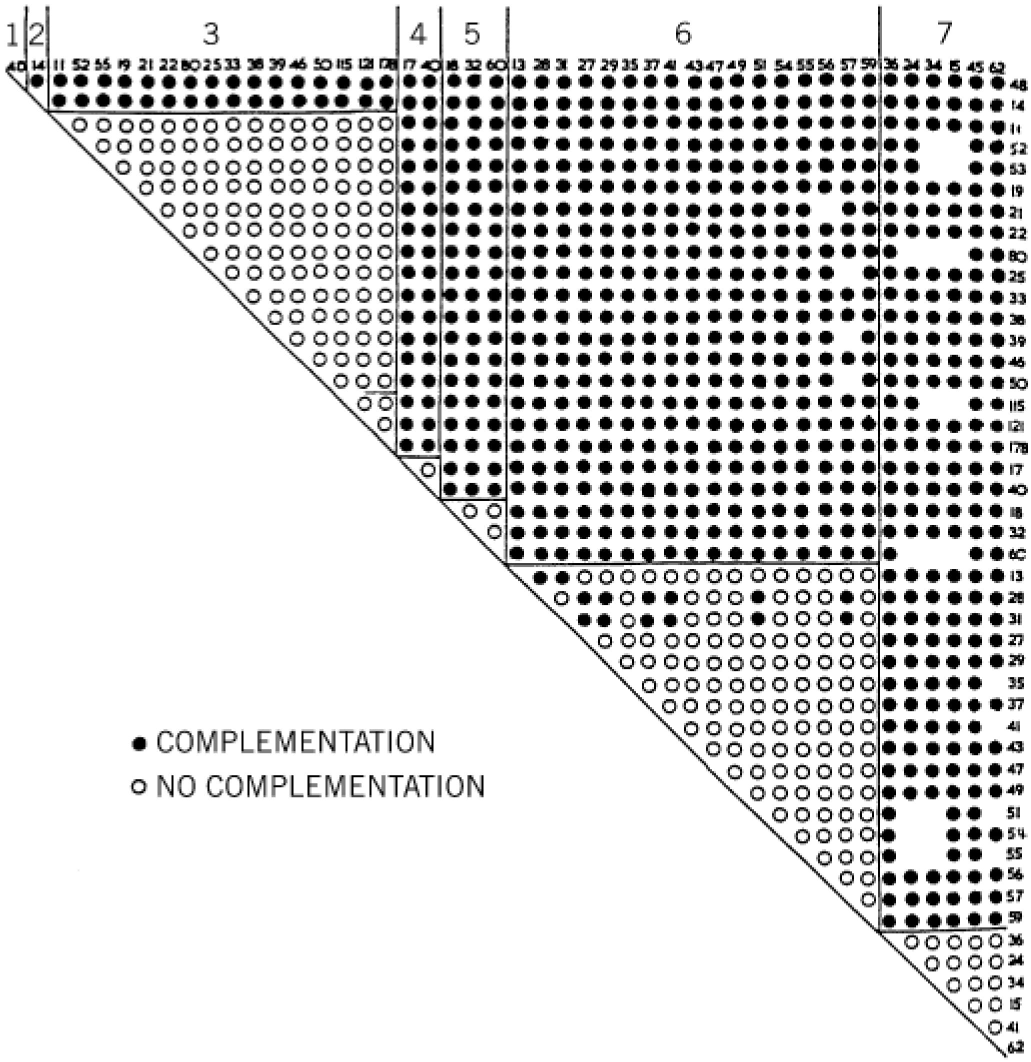
2. The Use of Heterokaryons

Filamentous fungi, or at least those (eg, ***Neurospora*** *crassa*, ***Aspergillus*** *nidulans*) that have been well studied genetically, are naturally haploid except for the immediate product of sexual fusion, which immediately undergoes meiosis to provide nuclei for haploid **spores**. In *Aspergillus*, however, rare vegetative diploids are obtained by selection (2). In *Neurospora*, where this is not possible, complementation tests are easily carried out with haploid heterokaryons, mixed cultures in which the filamentous hyphae have undergone fusions to bring the two different kinds of haploid nuclei together in the same cytoplasm (3).

For heterokaryon formation, *Neurospora crassa* strains have to be of the same mating type, and identical with respect to a number of other genes governing vegetative compatibility. These requirements are automatically met if the mutants under test have all been isolated in the same wild-type strain, as is usually the case. Given vegetative compatibility, fusions occur readily as soon as mixed mutant inocula of conidia (asexual spores) begin to germinate. *Neurospora* filaments (hyphae) are coenocytic. Numerous nuclei are present together in each cytoplasmic compartment, and the nuclear ratio in a heterokaryon is quite variable but is determined at least approximately by the ratio of the two kinds of conidia in the initial mixed inoculum. The nuclear ratio is, in fact, not usually critical. If, as is usually the case, the mutants under test are auxotrophic (ie, have special nutritional requirements) and the mixed inoculation is on a minimal medium on which neither mutant grows by itself, the heterokaryon grows vigorously if the mutants complement one another.

At least in *Neurospora*, different genes can complement each other perfectly efficiently in heterocaryons even though they are separated in different nuclei. This is not at all surprising. Genes act, after all, by exporting their messenger RNA to the **cytoplasm**. Reports indicate that complementation in *Aspergillus* is more efficient in diploids than in heterokaryons, but one suspects that this is because, in this fungus, the different nuclear types are not sufficiently closely intermingled. A large number of *Neurospora* auxotrophic mutants have been efficiently classified into complementation groups, equivalent to genes, by heterokaryon testing. An example is shown in Fig. 3 (4).

Figure 3. The result of complementation tests by heterokaryon formation on 46 *Neurospora* mutants that cannot utilize acetate. Nearly all possible pairwise mixtures of mutant conidia were inoculated into a medium containing acetate as the sole carbon source. Growth occurred only if the mutants showed complementation. In the matrix shown, the mutants, designated by their original isolation numbers, are divided into seven different complementation groups. All intergroup combinations showed complementation and grew like wild type. Most or all combinations within a group did not grow. The growth shown by a few pairs of mutants within group 6 is evidence for *inter* **allelic complementation**. From Ref. 4.



Humans, of course, are diploid, but complementation testing by controlled sexual crossing is obviously out of the question. Here again, heterokaryosis may provide an alternative, and cells in culture may serve as surrogates for people. One good example is an analysis of the human *xeroderma pigmentosum* syndrome, caused by genetic deficiency in DNA repair (5). Cultured cells isolated from different patients were induced to fuse by treating them with heat-inactivated Sendai virus. Complementation in the resulting heterokaryotic cells was assessed by their ability or inability to incorporate a radioactive precursor into their DNA following damage by UV light. The results permitted assigning the different mutations to four different complementation groups, putatively different genes (Fig. 4).

Figure 4. The use of heterokaryosis for complementation testing of cultured cells from human Xeroderma Pigmentosum (XP) patients (5). The syndrome that is excessive sensitivity to uv light is a consequence of failure to repair damaged DNA by excision followed by new synthesis. (**a**) Cultured fibroblasts from different patients were mixed and induced to undergo fusions. The resulting cells, some now heterokaryotic, were irradiated and cultured in the presence of tritiated **thymidine** to see whether they responded to the DNA damage by incorporating this radioactive DNA precursor into their nuclei. The original XP mutant cells, or noncomplemented heterokaryons, incorporated no tritium, but certain pairs of mutant cells showed complementation. (**b**) The complementation matrix with the division of 12 XP mutations into four complementation groups A-D. Here the cells are diploid and homozygous for the different mutations instead of haploid as in the *Neurospora* example (Fig. 3), but the principle is the same. +, complementation; 0, no complementation; –, test not done.

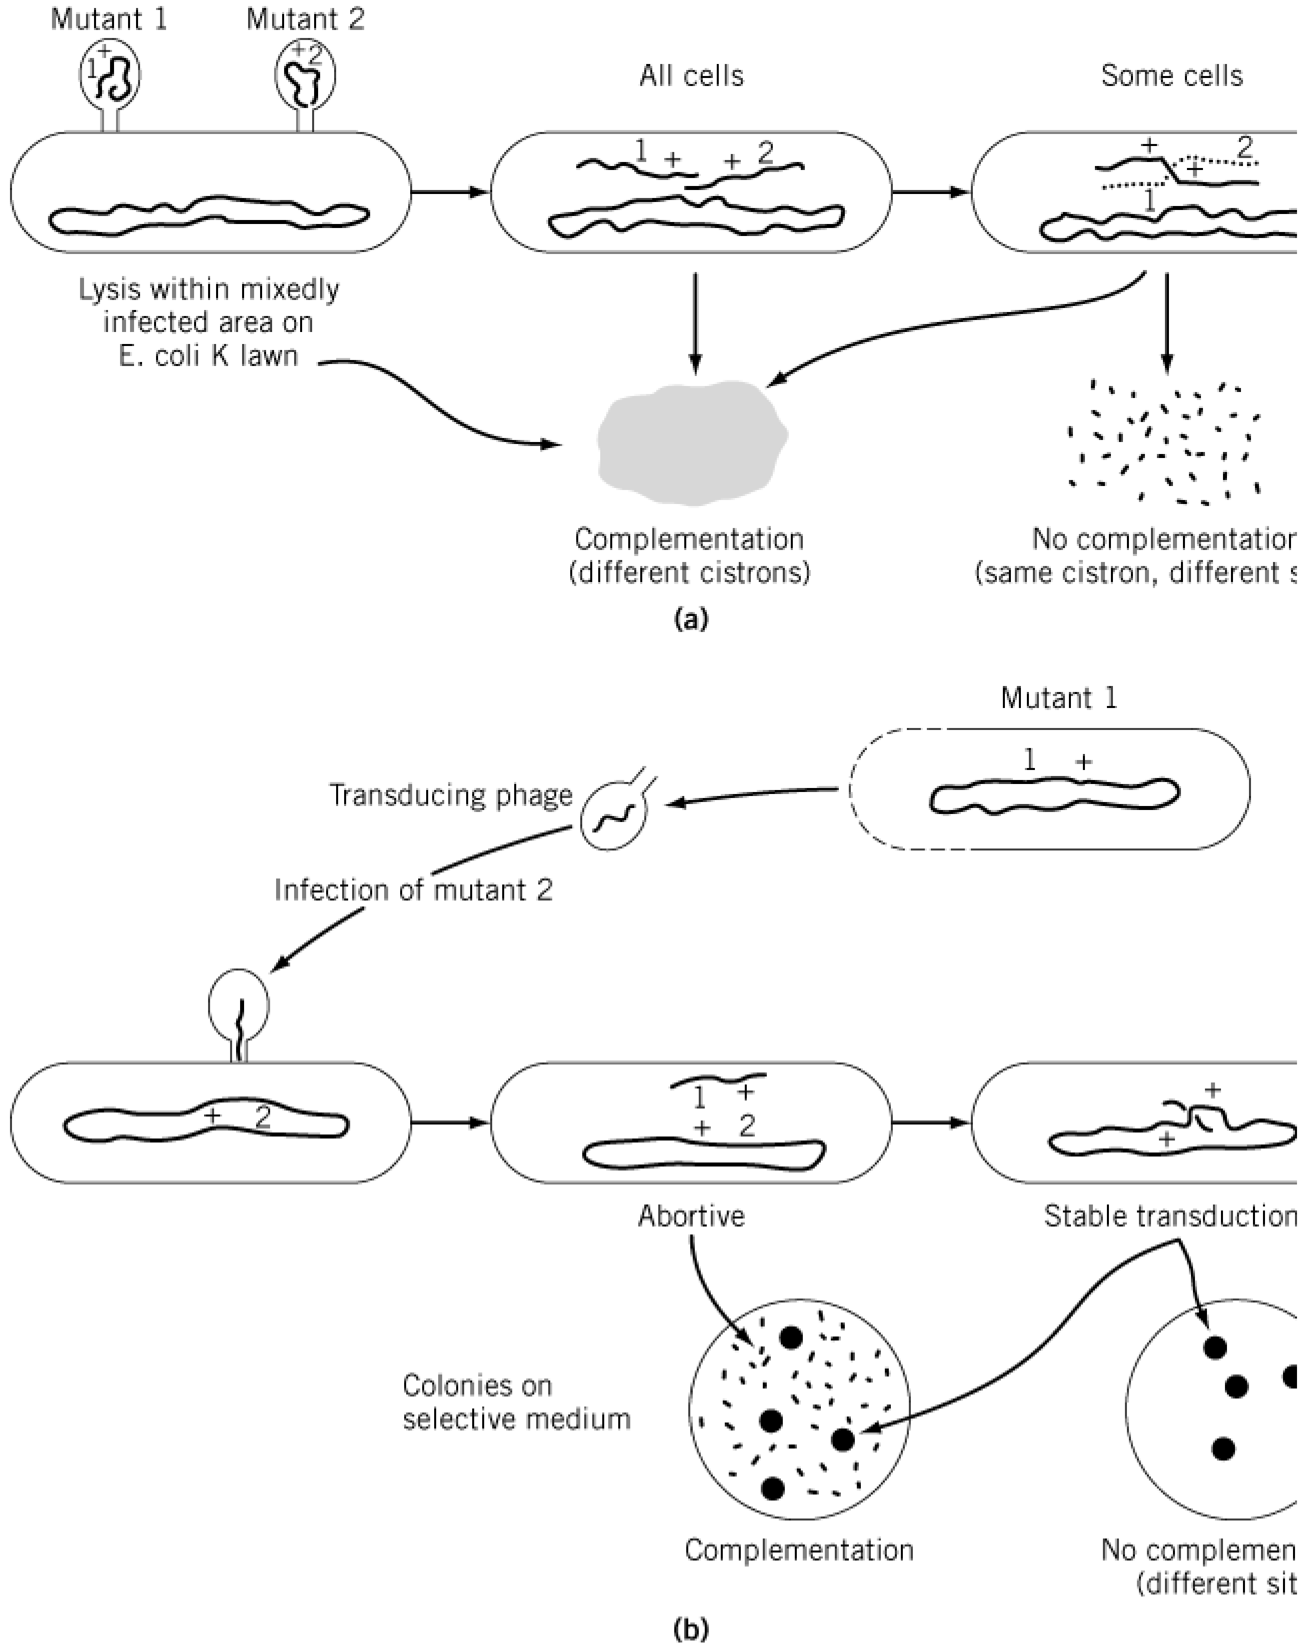
2.1. In Viruses by Mixed Infection

S. Benzer's very extensive complementation testing of bacteriophage T4 mutants (see also Complementation) depended on infection of bacterial cells with mixtures of phage particles (6). Mixed infection is analogous to heterokaryosis because two different whole genomes are present in a somewhat indeterminate ratio, but the difference is that the simple viral genomes are not enclosed in **nuclei**. The mutants under study (class *rII*) were distinguished by growing on one *Escherichia coli* strain (B) but not on another (K). Complementation between pairs of mutants was checked by superimposing *rII* phage inocula on lawns of K cells, usually with a small admixture of B cells to allow at least some viral propagation. Three results were clearly distinguished: (1) complementation of the two mutants—total clearing of the mixedly infected patch due to lysis of all the cells in that area; (2) no complementation, but some formation of wild-type phage by recombination during mixed growth, shown by scattered spots of lysis; and (3) much less commonly, neither complementation nor recombination—no lysis at all (Fig. 5**a**). These results were interpreted to mean that (1) mutant sites are in different cistrons (ie, different functional genes); (2) mutants are at different sites in the same cistron; and (3) mutants are at the same site, or one is a deletion overlapping the other. The complementation results split the *rII* mutants cleanly into two mutually complementing groups or cistrons. Recombination analysis using a set of overlapping deletion mutants showed that these two cistrons correspond to two adjacent, nonoverlapping segments of the phage “chromosome”, which is not actually a chromosome in the cytological sense but a single molecule of **double-stranded DNA**.

Figure 5. Two examples from bacteria of complementation tests that distinguish between complementation and recombi (**a**) Testing for complementation between *rII* mutants of bacteriophage T4. These mutants grow well in *Escherichia coli* B but not at all in strain K12(l). Mixed infections on a lawn of K cells that have a minor admixture of B cells to permit s joint growth give total clearing (lysis) if mutants *rII-1* and *rII-2* are in different genes (cistrons), and lysis only in spots b of recombination, if they are at different sites in the same gene. Based on Ref. 6. (**b**) Abortive transduction as a criterion complementation in *Salmonella typhimurium*. Phage P22 grown on histidine-requiring (*his-*) mutant 1 was used to infect mutant 2. Surviving bacteria were tested for their ability to grow on a histidine-free medium. Rather numerous tiny (abo colonies showed that a nonreplicating fragment of DNA from mutant 1 complements mutant 2. The absence of such tiny colonies signifies no complementation. In either case, vigorously growing colones arise by recombination between the b chromosome and the incoming fragment, provided that 1 and 2 are at different sites. Based on Ref. 7.



2.2. By Partial Diploids (Merodiploids) in Bacteria

It is not possible to test in bacteria for complementation between whole genomes because, at least in those species that are well-analyzed genetically, there is neither a stable diploid phase nor any sexual process that transfers a whole genome from one cell to another. However, bacteria acquire extra genomic fragments in three general ways: (1) by infection with defective bacteriophages which, “by mistake", have picked up bacterial DNA (**transduction**); (2) by joining a fragment of bacterial DNA to the DNA of a plasmid that brings about its own intracellular transfer (**conjugation**); and (3) by uptake of free DNA (transformation). The first two methods have been important in complementation analysis.

Transduction has been the principal means of classification and mapping of auxotrophic mutants of the bacterium *Salmonella typhimurium*. Bacteriophage **P22** grown on one mutant strain (the donor) is used to infect a second mutant strain, perhaps requiring supplementation with the same nutrient, such as an amino acid. Most of the infected bacteria are lysed, but some survive, are now lysogenic, and harbor the phage in latent form (see Lysogeny). Some survivors have acquired some fragment or other of the genome of the donor bacterium by infection from defective bacteriophage. The donor DNA is replicated in the recipient cell only if it recombines into the recipient chromosome and replaces the equivalent recipient segment. More commonly the donor DNA persists without replication, and its genes are expressed only in the primary recipient cell and in a few surrounding cells by diffusion of gene products. The appearance of tiny colonies of cells (abortive transductants) that grow transiently without the nutritional supplement, demonstrates complementation between the recipient genome and the donor genomic fragment. Usually a much smaller number of large strongly growing colonies results from chromosomal integration of a donor fragment and recombination between donor and recipient mutational sites to reconstitute a wild-type gene. The presence of large colonies without abortive ones shows that the mutations are at different sites within the same gene or cistron (Fig. 5**b**). Failure to form any colonies at all means (apart from possible experimental error) that the two mutations are at the same site or that one is a deletion overlapping the other (7).

The plasmid that is used to bring about partial diploidy in *E. coli* is the transmissible "sex factor" F, a closed-loop DNA molecule that replicates autonomously in the bacterial cell and is occasionally integrated by **crossing-over** into the much larger loop of the bacterial chromosome. The integrated plasmid DNA undergoes occasional excision, usually precisely, but sometimes carries with it an adjacent segment of bacterial DNA, the nature of which depends on where the plasmid happened to have been inserted. This modified F is called F′ and, like F itself, is transmitted from cell to cell. F′-*lac* plasmids that carry segments of DNA from the lac operon of the bacterial chromosome, were of great importance in elucidating the complementation relationships of *E. coli lac* mutants (a topic dealt with separately under cis-dominance).

Complex Loci

In classical **genetics**, the word locus referred to a position on a chromosome marked by a **gene** difference that has a **phenotypic** effect. Neither the locus nor the gene were thought to be subdivisible by recombination, and so locus and gene were treated almost as synonyms. The idea of complex loci arose from examples, especially from *Drosophila* and **maize**, of different mutations, apparently at the same chromosome locus, that give a range of different phenotypic effects, suggesting that the locus harbors some rather complex kind of gene.

With our modern knowledge, the word locus can take either of two very different meanings. It may mean just the genetically mapped site of a mutation, which, at the molecular level, is quite likely to be no more than a single base-pair change within the long DNA sequence of a gene. But, in the context of complex loci, it can mean a relatively short chromosomal segment (not frequently split up by genetic recombination) that contains a cluster of genes among which there is some functional connection. So complex loci, though of somewhat confused etymology, is a useful heading under which to review the evidence for chromosomal units of function at a level higher than that of the individual gene.

This article does not cover examples of loci that mutate to give various phenotype effects when the varied effects are due to mutations in a single gene that has multiple functions. Such genes that encode "multiheaded" enzymes (see Multifunctional Proteins) are sometimes called "cluster genes" in fungal genetics to distinguish them from the gene clusters with which they may initially be confused. Some examples are reviewed under **Allelic Complementation**. Nor are we concerned with single genes that have multiple modes of **intron** splicing, which yield alternative messenger RNAs (see examples under Gene Structure). And we obviously cannot include groups of functionally diverse genes that just happen to be very closely linked, for that would make virtually all genes parts of one complex locus or another. To qualify as a complex locus, in our present sense, a gene cluster must have some kind of unity in structure, in function, or in both.

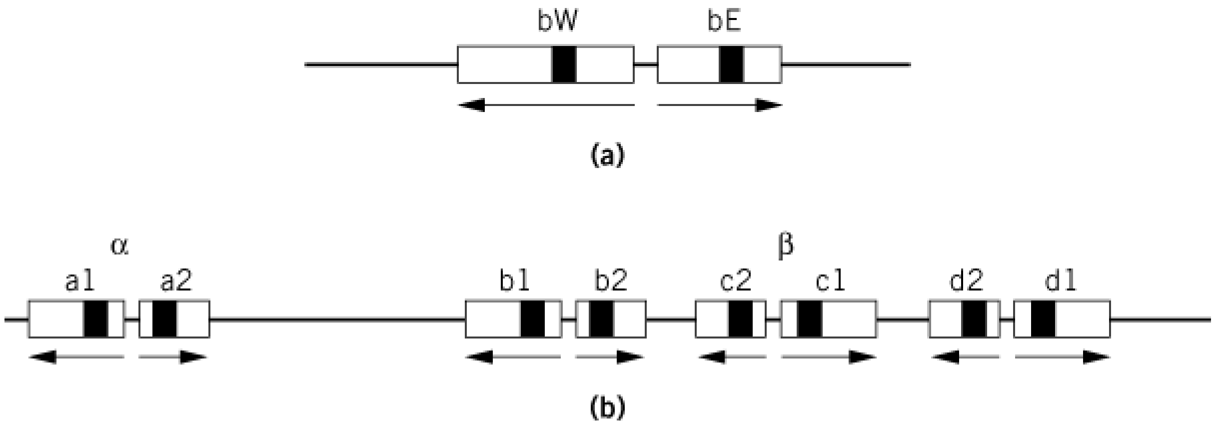
Gene clusters that fulfil this criterion have been found in **fungi**, flowering **plants**, *Drosophila* and mammals, and this article reviews examples from each of these kinds of organisms. We do not deal here with **bacteria**. Operons, which might be viewed as complex loci but are not usually so termed, are dealt with under their own heading. Also excluded from this article are highly repetitious tandemly arrayed genes required by the cell in very high dosage. The preeminent example is **ribosomal** RNA genes in the **nucleolus organizer** chromosomal regions of eukaryotes. Histone genes are also highly repetitive and are concentrated in clusters in some organisms, including *Saccharomyces* yeast. This is arguably more repetition than complexity.

1. Fungi

In fungi, the self-incompatibility and cross-compatibility in sexual mating in many species is determined by **mating-type** loci, which virtually always consist of more than one gene. A relatively simple example is the maize smut fungus, *Ustilago maydis*, whose two loci, *a* and *b*, control the specificity of sexual fusion and the formation of an invasive dikaryotic mycelium after fusion, respectively. The *a* locus has two "**alleles**," *a1* and *a2*, each of which consists of two genes, one that encodes a polypeptide pheromone and the other a pheromone **receptor**. The *a1* pheromone is recognized by the *a2* receptor and the *a*2 pheromone by the *a*1 receptor. There is no close homology between *a1* and *a2*, and they do not recombine with each other. The *b* locus exists in numerous alternative forms. Each consists of two closely spaced, divergently transcribed genes called *bE* and *bW* that encode the two components of a dimeric transcriptional activator. But dimerization occurs only between *bE* and *bW* products of different mating types (1).

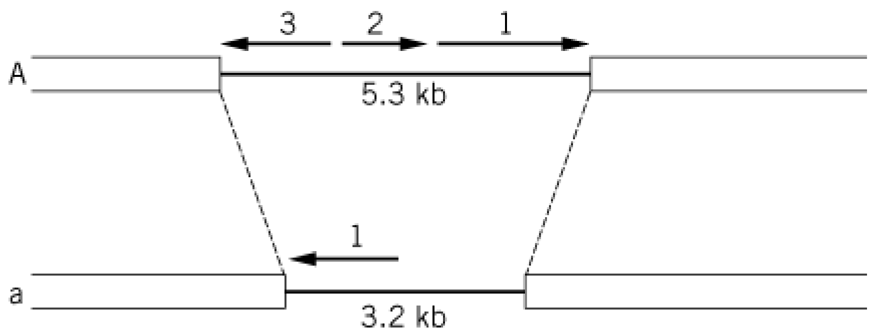
The ink-cap mushroom fungus, *Coprinus cinereus* (like *Ustilago*, a member of the Basidiomycete class), also has two mating-type loci, *A* and *B*. The *A* locus, which controls the ability to form a fruiting dikaryon, is the most thoroughly investigated. Here the situation resembles that at the *Ustilago b* locus, except that genes that encode dimerizing monomers, thought to be transcriptional activators on the basis of their **homeobox**-like sequence motifs, are distributed in multiple copies between two subloci, *A*a and Ab, between which rare recombination occurs (2) (Fig. 1). Again, dimerization occurs only between the products of different mating types.

Figure 1. The structures of mating type loci in Basidiomycete fungi. (**a**) The *b* locus of *Ustilago maydis*. The *bW* and *bE* gene products form W-E protein dimers to activate transcription of genes necessary for sexual development. Each exists in multiple allelic forms. Effective dimers are not formed by W-E combinations from the same strain. Gene segments that encode homeodomain-like protein sequences are filled. (**b**) The archetypal *A* mating type locus of *Coprinus cinereus*. The system works in principle as in the *Ustilago b* locus, except that here there are four pairs of genes, *a*, *b*, *c*, and *d*, any one of which can function in promoting fertility. The archetype is a composite of known mating-types, all of which are missing one or another part of it. From Refs. 1 and 2 by permission.



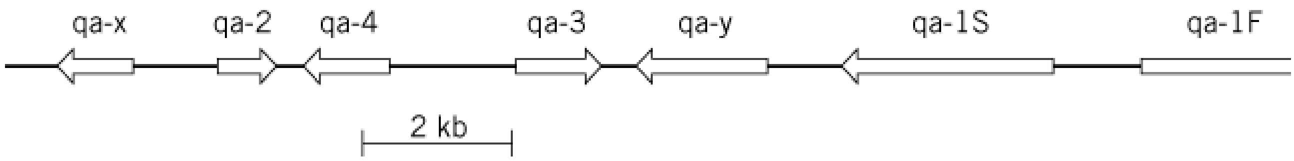
Ascomycete fungi, such as *Neurospora crassa* and *Saccharomyces cerevisiae*, simpler than Basidiomycetes, have only two mating types (*A* and *a* in *Neurospora, a* and a in *Saccharomyces*), but the genetic loci that determine them are still complex. *Neurospora A* contains three genes (Fig. 2) and *Saccharomyces* a contains two, though each of the *a* mating-type loci has only a single gene. The two alternative mating-type loci in both organisms are completely nonhomologous, and the same is true for the *Ustilago a* locus. It has been customary to call the alternative occupants of these mating-type loci "alleles," but in the light of present knowledge this terminology is inappropriate because it implies different forms of a single gene. The new word idiomorphic has been suggested for the relationship between quite different genes or gene clusters that are alternative occupants of the same locus (3). Much the same applies to the yeast mating-type system that has the additional complication of mating-type switching.

Figure 2. The mating type loci of the Ascomycete fungus *Neurospora crassa*. *A1* and *a1*, quite unrelated in sequence, act in a complementary way to permit sexual reproduction. *A2* and *A3* function in postfertilization fruiting-body development. From Ref. 3 by permission.



Fungi also provide examples of another kind of locus complexity, the tight clustering of separate genes that co-operate in a particular area of metabolism. The *Neurospora crassa Qa* cluster is a particularly good example (Fig. 3). Here a DNA segment of only 18 kbp harbors seven different genes, the transcription of which is increased 50- to 1000-fold when the fungus is forced to grow using quinate as a sole carbon source. Three of these genes encode the three enzymes that, acting in sequence, oxidize quinic acid to protocatechuic acid. Two genes encode regulatory proteins that control the transcription of the whole cluster. One gene is a transcriptional activator and the other a repressor that cancels the function of the activator but whose own effect is nullified by binding to quinate. The remaining two genes have no identified function and are recognized solely as **open reading frames** (4). The significance of the gene clustering is not fully understood, but it seems plausible to suggest that derepression of transcription is facilitated by an induced unfolding of **nucleosomal** structure that extends across the entire complex.

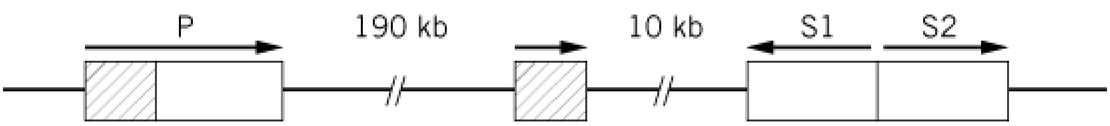
Figure 3. The *Qa* (quinate-utilization) gene cluster of *Neurospora crassa*. The genes *qa-3, qa-2*, and *qa-4*, respectively, encode quinate dehydrogenase, catabolic dehydroquinase, and dehydroshikimate dehydratase, which act sequentially to degrade quinate. *qa-1S* and *qa-1F* encode regulatory proteins, that respectively repress and activate transcription of the whole cluster. *qa-Y*, it is thought, encodes a quinate transporter protein, and *qa-X* has no known function (4).



2. Flowering plants

A long-standing example from what used to be, pre-*Arabidopsis*, the geneticists' favorite plant, is the *R* locus of *Zea mays* that is necessary for pigmentation and encodes transcriptional activators for genes that encode pigment-synthesizing enzymes. It was an early example of locus complexity because it has two independent functions. Some recessive loss-of-pigment alleles affect only the red color in the plant whereas others affected only the seed. Analysis at the DNA level has revealed the situation shown in Fig. 4 (5). The *R* locus contains three genes. One gene (*P*) is specific for plant pigment, and the other two (*S1*, *S2*) apparently duplicate the function in seeds. Presumably their distinct tissue specificities are due to different promoter/**enhancer** sequences. There is also a partial and presumably functionless duplication of *P*. An origin by **duplication** and subsequent partial **divergence** of function is the most obvious explanation for the clustering of these functionally related genes, although the opposite orientations of *S1* and *S2* are a puzzle.

Figure 4. The complex *R* locus of *Zea mays*. *P* controls red pigment synthesis in the plant generally and the duplicate *S* genes in the seed. *S1* and *S2*, transcribed divergently, are each similar to *P* except that they lack the segment shown hatched. This segment is present as a tandemly duplicated fragment, presumably nonfunctional. Sequence information suggests that this scrambled arrangement is due to the activity of a transposable element (5). “Alleles” of *R*, R^g (red seed, green plant), and r^r (colorless seed, red plant) are, respectively, due to loss of *P* and *S* function. The *P* and *S* components can be separated by meiotic crossing over at frequencies on the order of 10^{-4} to 10^{-3}.

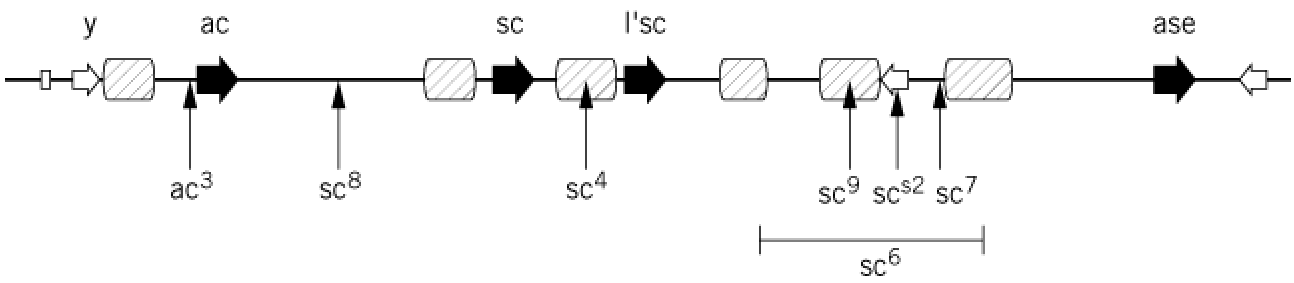


A long-standing problem in plant biology has been the various systems of self-incompatibility, often controlled by what are multiple alleles at a single locus, usually called *S*. The general principle is that pollination is prohibited if the pollen grain and stigma (or, in the *Brassica* family, the pollen mother cell and stigma) have an allele in common. The *Brassica S* locus, one of the best analyzed, contains two genes, each present in the population in multiple allelic forms, that control the incompatibility response of the stigma. A third S locus gene, expressed in the pollen and determining pollen specifity, has also been identified (6). Here, as in the analogous self-incompatibility in fungi, the functional reason for the multiple genes all in the same locus is obvious. For the system to work, the different specificities have to be mutually exclusive in the haploid genome.

3. Drosophila

In the fruit fly, *Drosophila melanogaster*, a classical example of locus complexity, perhaps originally generated by tandem duplications, is provided by the scute (*sc*) and achaete (*ac*) families of mutations (7, 8). These affect the bristles in the wings and mid-thorax of the fly, really parts of the fly's neural system, the origin of which can be traced back to the transcription of scute and achaete, usually both together but sometimes one more than the other, in rather precisely positioned bristle mother cells in the wing imaginal disc of the larva. It seems that *sc* and *ac* largely duplicate each other's functions and, before molecular analysis, the basis for recognizing two different genes was not clear. Different mutations in the *sc/ac* locus eliminate different bristles or different combinations of bristles, and, to the extent that their effects are nonoverlapping, complement one another in *trans*. Now that the *sc/ac* locus has been analyzed at the DNA level, it is seen that there are six genes within the approximately 100 kbp that comprise the *sc/ac* complex (7, 8) (Fig. 5), of which at least four are involved with the neural/bristle system. *sc* and *ac* apparently have the major roles. Most of the mutations that affect the positioning of bristles actually fall between the genes. Several are chromosomal rearrangements that have breakpoints within the *ac/sc* complex, and it is thought they exert their effects by separating *ac* and/or *sc* from enhancer sequences, several of which have been identified in the *sc/ac* region. The patterns of transcriptional activation of *sc* and *ac* and hence the positioning of bristles, it is thought, reflect the distribution of a number of enhancer-binding proteins, the identity of which remain to be established. The genes and the enhancers together may be seen as an integrated system for responding to a pattern of positional information set by the products of other genes.

Figure 5. The *scute-achaete* (*sc/ac*) complex at the tip of the *Drosophila melanogaster* X-chromosome. Genes that have functions in neural/bristle development are shown as filled arrows, and other genes, apparently unrelated in function, as (arrows (*y* = *yellow*). Thin vertical arrows indicate the breakpoints of segmental rearrangements that affect the bristle phe (*sc*^{6} is a deletion). Regions that include enhancer sequences are shown hatched. The different bristle phenotypes are beli be due to separation of *sc* and/or *ac* from enhancers. Redrawn and simplified from Ref. 8 by permission.



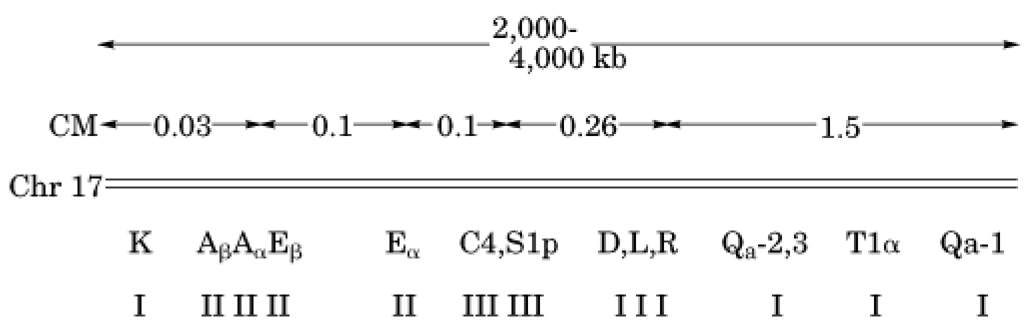
4. Mammals

Many clusters of related genes have originated through tandem duplication and subsequent functional divergence. Obvious examples are the globin gene clusters in animals and humans (see under Globins, Gene Structure). The b-globin gene cluster has a common ancestral origin and is also functionally integrated through the locus control region.

The clustered **HOX genes**, which are of profound importance in animal development and encode homeobox-containing proteins, were discovered in mammals and now in other animal groups through their significant similarities to the genes of the linked *bithorax* and *Antennapedia* complexes of *Drosophila*. Five unlinked clusters of HOX genes in mouse and humans each consist of up to 13 tandemly arranged genes within a region on the order of 100 kbp of DNA. Through their homeobox-encoding segments, the genes of one cluster have only a very limited degree of sequence similarity to each other but have a greater resemblance to genes in corresponding positions in other clusters in the same species or even in different species. Because they were not identified through the classical genetic route of mutation mapping, the HOX clusters of mammals are not usually called loci though, confined as they are within chromosomal segments that correspond to a small fraction of a **centimorgan**, they are sufficiently tightly linked to qualify for that title, and they also fulfil the criterion of functional integration. The almost uncanny correspondence between the linear sequence of genes within each cluster and the anterior-posterior order of the body segments that the genes affect clearly indicates some function for the clustering and ordering of the genes, though this is still mysterious.

The mammalian major histocompatibility complex (MHC), intensively investigated in mouse, and its human equivalent the human leucocyte antigen (HLA) complex, is encoded by genes spread over rather too large a section of chromosome to be called a locus. Indeed, the positions of individual antigen-encoding genes within it are themselves often called loci. In humans it encompasses about four megabases of DNA and 3 to 4 centimorgans. But it may be regarded as at the upper end of the size range of clusters of functionally related genes, and so it is relevant to mention it here. A diagram showing of the structure of the complex, and its scale in relative to the whole chromosome is shown in Fig. 6. Because there is significant homology among the different genes, at least within each of the two main subclusters, the close linkage is likely to be due to duplication by short-range transposition and subsequent diversification. But it may also have been maintained by natural selection, because their continued coupling is advantageous if certain combinations of alleles of different genes confer disease resistance (10).

Figure 6. The arrangement and spacing of genes within the major histocompatibility complex (MHC) of mouse. Class I genes encode transplantation antigens mediating graft rejection (K, D, L), or other cell-surface antigens (Qa, Ti). Class II genes encode antigens involved in the immune response. Class III genes encode components of the complement system. Meiotic recombination within the complex is infrequent but not very rare (genetic map distances are shown in centimorgans, cM). After Ref. 9 by permission.



An entirely different kind of complex locus is involved in determining hypervariable proteins of the mammalian immune system, immunoglobulins and T-cell receptor proteins. These are not really gene clusters but rather banks of gene components that are assembled by DNA splicing reactions in a large number of different ways to provide coding sequences for proteins of almost any required specificity. In mammals, as exemplified by mouse, there are six known rearranging complexes of the mouse immune system, three (heavy-chain and two light-chain) for immunoglobulin components and three (a, b and g polypeptides) for T-cell receptor components. A diagram to scale of the completely sequenced human b-chain locus that extends over 600 kb is shown in Fig. 7 (11). Here the functional reason for clustering is obvious. It is only surprising that the sequences destined to be spliced together are as widely separated as they are. Presumably they are brought close during the splicing process by the formation of some very extensive DNA loops.

Figure 7. The arrangement and spacing of the part-genes which, when appropriately spliced together, encode b-chains of the human T-cell receptor. Splicing of DNA during T-cell differentiation brings together one C “constant”, one J (“junction”), one D (“diversity”), and one V (“variable”) sequence to encode a large number of alternative b-chains. J on the map stands in each case for six or seven short alternatively used junction sequences. The other marked elements are all single units. All are transcribed/translated from left to right, except for the rightmost V which is inverted and doubtfully functional. The splicing occurs in stages, first D to J, then DJ to V, and finally VDJ to C. The diagram has been simplified by omitting the pseudogenes and incomplete V sequences, which approximately equal the functional genes in number and are interspersed among them. T = trypsinogen gene, the presence of which, in multiple copies, within the b-chain complex, has uncertain functional significance. After Ref. 11 by permission.

Compressibility

Compressibility is an important measure of the atomic packing and flexibility of protein molecules. Measurement of this quantity is possible, in principle, only for proteins in solution. The partial specific compressibility of a protein in solution b is defined as the change in the partial specific volume v_2^0 with increasing pressure. Since the atomic van der Waals volume, v_c, may be assumed to be incompressible, the experimentally determined b of a protein can be mainly attributed to its cavities v_{cav}, and to changes in hydration Dv_{sol}:

$$\bar{\beta} - (1/\bar{v}_2^0)(\partial \bar{v}_2^0/\partial P) = -(1/\bar{v}_2^0[(\partial v_{cav}/\partial P) + (\partial \Delta v_{sol}/\partial P)] \qquad (1)$$

(see Partial Specific (Or Molar) Volume). The first term on the right-hand side contributes positively, and the second term negatively, to b. Thus, a positive b value can be ascribed to a large cavity effect overcoming the hydration effect. There exist two types of compressibilities, depending on the experimental conditions: adiabatic and isothermal. Most compressibility studies of proteins have been of adiabatic compressibility because of its accuracy and technical convenience.

1. Adiabatic Compressibility

The partial specific adiabatic compressibility b_s is calculated with the Laplace equation, $b_s = 1/u^2d$, where u is the sound velocity and d the density of the protein solution. The sound velocity is usually measured with an accuracy of 1 cm sec^{-1} by using a resonance or sing-around pulse method at 3 to 6 MHz. All amino acids show large negative b_s, with values between -62.5×10^{-12} cm^2 dyn^{-1} (for glycine) and -21×10^{-12} cm^2 dyn^{-1} (for tryptophan) at 25°C, because they have a negligibly small amount of cavity. Data for b_s have been reported for about 40 different proteins; some values in water (or in dilute buffer at neutral pH) are listed in Table 1. Fibrous proteins show negative b_s, indicating the dominant effects of the surface on hydration relative to internal cavity volume. On the contrary, most globular proteins have positive b_s, due to the large contribution of the internal cavities overcoming the hydration effect. This is consistent with the fact that more than 50% of the total surface area is buried in the interior of a folded protein molecule.

Table 1. Partial specific volume (v_2^0), compressibility (b_s and b_T), and volume fluctuation (dV_{rms}) of proteins in water at 25°C (1, 4)

Protein	**v_2^0 (cm^3 g^{-1})**	**b_s (10^{-12} cm^2 dyn^{-1})**	**b_T[a] (10^{-12} cm^2 dyn^{-1})**	**dV_{rms}[b] (cm^3 mol^{-1})**
		Globular proteins		
Cytochrome c	0.725	0.07	4.27	30.8 (0.34)
Soybean trypsin inhibitor	0.713	0.17	4.44	41.1 (0.20)
Trypsin	0.717	0.92	5.16	46.0 (0.28)
Ribonuclease A	0.704	1.12	5.48 (5)	36.2 (0.38)

Peroxidase	0.702	2.36	6.70	68.3 (0.24)
a-Chymotrypsin	0.717	4.15	8.32	62.2 (0.33)
Lysozyme	0.712	4.67	7.73 (12.3)	44.2 (0.43)
Carbonic anhydrase	0.742	6.37	10.5	76.0 (0.34)
a-Lactalbumin	0.736	8.27	12.4	56.9 (0.54)
b-Lactoglobulin	0.751	8.45	11.8	63.6 (0.46)
Myoglobin	0.742	8.98	13.1	64.1 (0.51)
Ovalbumin	0.746	9.18	12.1	101 (0.30)
BSA	0.735	10.5	14.6 (13.4)	135 (0.27)
		Fibrous proteins		
Gelatin	0.689	–2.5		
F-actin	0.720	–6.3 (20°C)		
Myosin	0.724	–18 (20°C)		
Tropomyosin	0.733	–41 (20°C)		

[a] The values in parentheses represent the experimental data; the other values were calculated with Equation 2 of the text.

[b] The values in parentheses represent the ratio (%) of dV_{rms} to the total protein volume.

Some assumptions are necessary for estimating separately the contributions of cavities and hydration to b_s. A rough estimation suggests that the intrinsic compressibility of globular proteins free from hydration is of the order of (10 to 20) × 10^{-12} cm^2 dyn^{-1}. This value is comparable to the adiabatic compressibility of normal ice, suggesting that an internal protein structure is as rigid as ice.

As can be seen in Table 1, the value of b_s varies over a wide range and is sensitive to the structural characteristics of individual proteins. For example, lysozyme has a considerably smaller b_s than does a-lactalbumin, in spite of their great similarities in primary and tertiary structures. However, the compressibility-structure relationships of proteins have been scarcely discussed on a molecular level, because of the complicated contribution of hydration. The contributions of some structural factors have been deduced by the statistical analyses of b_s data on globular proteins (Ref. 1). From the ratio of accessible surface area to volume, b_s would be expected to increase with increasing molecular weight, but there appears no definite correlation between b_s and molecular weight. Instead, a positive correlation is found between b_s and the partial specific volume. Hydrophobic proteins show large positive b_s, probably due to an enhanced imperfect packing of nonpolar residues localized in the interior of the molecule. Typical a-helical proteins, such as myoglobin and bovine serum albumin have very large b_s, even though the a-helix itself is rigid, predominantly nonhelical proteins, such as **trypsin** and soybean trypsin inhibitor, have small b_s. These results suggest that the a-helix could be a dynamic domain for the thermal fluctuation of proteins. Four amino acids (Leu, Glu, Phe, and His) show statistically a strong ability to increase b_s, whereas another four (Asn, Gly, Ser, and Thr) decrease it, although the meaning of this is obscure. A single amino acid substitution can bring about a noticeable change in b_s, probably due to modified atomic packing, even though it is rare to observe any visible changes in the tertiary structures of mutants by X-ray crystallography.

Adiabatic compressibility data for nonnative conformations and for unfolding processes, in combination with partial specific volume, also present useful information on the principles of protein structure that cannot be obtained by spectroscopic techniques. Unfolding of a protein with strong denaturants such as **guanidinium** chloride decreases the compressibility and specific volume, but it is known that the compressibility increases and the partial specific volume decreases on thermal and pressure denaturation.

2. Isothermal Compressibility

The volume fluctuations and the pressure-dependent properties of proteins are theoretically related to the partial specific isothermal compressibility b_T, rather than the adiabatic one b_s. To determine b_T, the solution density or partial specific volume must be measured as a function of pressure, under hydrostatic pressure or centrifugal force. Such an experiment is very difficult, however, and few b_T data are available for proteins, because high pressure may cause protein denaturation and modify preferential solvent interactions. Approximate values of b_T may be estimated from b_s by utilizing the relationship

$$\beta_T = \beta_s + \alpha^2 T / C_p d \tag{2}$$

if the thermal expansion coefficient a and the **heat capacity** at constant pressure C_p, are known or can be reasonably inferred. Such assumed b_T values are listed in Table 1, along with some experimental data. Despite many assumptions, the calculated values of b_T are not so very different from the experimentally observed ones. The value of b_T is greater than b_s by (3 to 4) $\times 10^{-12}$ $cm^2\ dyn^{-1}$; these differences are comparable to those found for the amino acids.

There are some other methods to evaluate the isothermal compressibility of proteins, although the value obtained is not a partial quantity in solution. Kundrot and Richard (2) reported 4.7×10^{-12} $cm^2\ dyn^{-1}$ for b_T of lysozyme by comparing its X-ray crystallographic volume at atmospheric pressure and 1000 atmospheres. Contraction of the molecule was distributed nonuniformly; one domain was essentially incompressible, but another had a large compressibility. Computer simulations, such as molecular dynamics, **Monte Carlo**, and normal mode analyses, are also available. Normal mode analysis of myoglobin yielded $b_T = 9.37 \times 10^{-12}$ $cm^2\ dyn^{-1}$.

According to statistical thermodynamics, the volume fluctuation dV_p of a protein with volume V_p is related to its isothermal compressibility b_T (Ref. 3):

$$\overline{\partial V_p^2} = kTV_p\beta_T \tag{3}$$

where k is the Boltzmann constant and T the absolute temperature. The root-mean-square fluctuation of the partial molar volume dV_{rms}, which was estimated by using b_T instead of b_T, is listed in the last column of Table 1. The volume fluctuation is only about 0.3% of the overall dimensions of protein, but the dV_{rms} values estimated by this method are the lower limit of the probable fluctuations, since the solvation factor is still included in the value of b_T that was used. If the intrinsic isothermal compressibility of a protein itself, which is not easy to determine, is used instead of b_T, a greater volume fluctuation (up to 50% greater) might be expected for a protein without hydration. Although many assumptions are used in estimating b_T and the fluctuation of volume, the values obtained are considered to be reasonable; if concentrated in one area at one particular moment, the fluctuation in volume could produce sufficient cavities or channels to allow the entry of solvent or probe molecules to account for phenomena such as hydrogen exchange and fluorescence quenching observed with folded proteins.

Computer Simulation of Biological Molecules

Biological molecules are systems of enormous complexity. This makes it exceedingly difficult to elucidate the details of biological activities using only experimental techniques. Despite enormous progress in structural studies of proteins, it is hard to determine uniquely how the particular function is determined by the given structure. A mathematical description of the energy of a macromolecule in terms of its atomic coordinates is, in principle, sufficient to predict relevant biological properties. However, such a description can only be handled by powerful computers. Having the proper model of a macromolecule should allow one to simulate its properties as if one is dealing with the actual molecule. Such an approach, called *computer simulation*, offers what is probably the best way of describing the function of macromolecules.

The relationship between the energy of molecules and the position of its atoms is called a potential function or a *force field*. A reasonable potential function provides the first step for modeling a molecule. In principle, one can obtain potential functions by using quantum mechanical methods that describe the entire molecule as a supermolecule. However, such methods are not yet practical for describing macromolecules. Some progress can be made using **hybrid QM/MM approaches**, but, in general, it is essential to use approximated potential functions whose parameters are based on empirical information (1-5).

Potential functions can be based on **all-atom molecular models** that describe the interactions between all the atoms of the given molecule or on **simplified models** where the forces due to several atoms are described by a single interaction center. Examination of molecular properties using the corresponding potential functions is known as molecular mechanics. This term is usually reserved for the use of **energy minimization** and **normal mode analysis** methods. The use of potential functions to solve the equation of motion of atoms is known as molecular dynamics (MD). This method gives the atomic position as a function of time and provides a powerful way of obtaining dynamical and time average properties. In some cases one can obtain useful insight by using **Brownian dynamics**. Frequently it is sufficient to know the properties of macromolecules at their minima. Generating starting configurations in the search for such minima can be done by **Monte**

Carlo methods Monte Carlo calculations and other sampling approaches. Apparently, the most important biological properties are reflected in most cases by thermodynamic properties and not dynamical properties. In particular the **Free Energy** provides the most important connection between structure and function, while the knowledge of the individual contributions to free energy from **enthalpy** and **entropy** is less critical for reproducing functional properties of macromolecules. The free energy of macromolecules can be evaluated by several approaches and, in particular, by the free energy perturbation (FEP) and linear response approximation (LRA) methods. Free energy calculations are frequently based on the use of **thermodynamic cycles** (3, 4, 6).

The potential functions that describe the energetics of macromolecules reflect different types of interactions. This includes **bonding** and van der Waals interactions that determine the steric properties of the given molecule and electrostatic interactions (that include hydrogen bonding and other **dipolar** and **ionic interactions**). The free energy of macromolecules is largely dependent on electrostatic energies, which reflect the effect of polar and ionized groups and its compensation by the polarization of the solvent around the protein (6, 7). These energies involve **long-range interactions,** whose accurate evaluation present a major challenge. Electrostatic energies can be modeled by using **implicit models** where the solvent molecules (and sometimes the protein dipoles) are represented implicitly. The use of a **dielectric constant** in an electrostatic model is a form of implicit model, and, in fact, the dielectric constant in many electrostatic models is not related at all to the true protein dielectric constant but to the properties that are not simulated explicitly (6, 8). *Computer simulations of biological molecules has been particularly effective in studies of the following subjects.*

1. Energetics (Thermodynamics and Equilibrium Properties)

Simulation of the free energies of different biological processes provide the “missing link” between the corresponding structures and functions. This is particularly true with regard to electrostatic free energies. However, obtaining reliable free energies by computer simulations is very challenging and requires validation by discriminative benchmarks. One of the most effective test in of calculations of free energies in proteins in general and electrostatic models in particular is provided by calculations of absolute **pK_as of ionizable groups** in proteins (8). The basis for calculating this quantity is the relationship (6)

$$2.3RT(pK_a^p - pK_a^w) = \Delta\Delta G_{sol}^p(AH \rightarrow A^-) - \Delta\Delta G_{sol}^w(AH \rightarrow A^-) \qquad (1)$$

where the superscripts *p* and *w* denote protein and water, respectively, and $DDG_{sol}(AH \rightarrow A^-)$ is the difference in solvation energy between the protonated and deprotonated states of the acid. Although early models only considered the change of pK_as due to the effect of protein ionized groups (9), it is now recognized that the most important factor is the self-energy (6) (or “solvation energy”), which is the energy of forming the charge in its protein environment when the other charges are turned off. The modulation of this effect is largely determined by the protein permanent dipoles (6). Obtaining reliable estimates of the self-energy by Free Energy Perturbation is very challenging, but significant progress has been made (3, 10). Apparently, it is essential to treat long-range effects in a consistent way in order to obtain meaningful results in pK_a calculations (10). It is frequently simpler to obtain better results by simplified solvent models (6) and by models that treat the solvent as a dielectric continuum (11). However, one must bear in mind that models that treat the protein in a uniform dielectric without considering the microscopic nature of the protein permanent dipoles cannot reproduce the correct physics of ionized groups in proteins (6, 8).

Redox energies of biological cofactors play a major role in **electron transfer** processes. Such energies can be evaluated by simulation methods using a similar approach to that used in equation 1 and evaluating the change in solvation energy upon moving the charge from water to the protein. FEP calculations of redox energies were reported by several workers, and related studies in photosynthetic reaction centers were also presented. Here the proper treatment of the solvent around the protein is quite crucial (12). As in the case of pK_a calculations, one finds that simplified models (13) and continuum models (14, 15) are quite effective.

Reliable calculations of free energies of **ligand binding** are crucial for quantitative progress in rational drug design. FEP has been used extensively in studies of binding free energies (3). Most early studies involve simple cases of small changes in the ligand (16). Calculations of absolute binding free energies are much more challenging (3, 17) and involve major convergence problems. Here the use of the LRA has been found to be quite effective (17-19). Extensive progress has also been made with simplified models (17, 19, 20) and with more phenomenological approaches (21, 22).

The permeation of ions through membrane channels plays a major role in biophysics. Here, the challenge is in evaluating the energy of an ion in the channel relative to its energy in solution and using the energetics in determining the conductance of the channel. Reliable simulation of such systems requires one to properly represent the channel and its surrounding membrane and water environment. The energy contribution of the membrane-induced dipoles must be included in consistent calculations. Consistent FEP studies of the energetics of moving an Na^+ ion to the center of the **gramicidin A** channel have been reported with a reasonable result (23). Incomplete modeling of the boundaries of the simulated system and long-range interactions can lead to significant overestimates of the penetration barrier (eg, the results of ref. 24). Semimacroscopic studies of ion channels are quite useful and much less challenging than full microscopic calculations (10, 25, 26). The recent emergence of the structure of a bacterial **potassium channel** (27) have highlighted the need for reliable FEP calculations, and some progress has been already made (28).

2. Structural Properties

Molecular simulations can be used to refine, and sometimes predict, structural properties. Energy minimization approaches were the first to be used successfully in relaxing bad steric contacts in X-ray crystallography (29). Such approaches were also used in more systematic refinements of protein structures (30). The emergence of powerful computers allows one to use more rigorous statistical mechanical approaches coupled with MD simulations in exploring structural properties (31).

Simulations are also very useful in evaluating and analyzing temperature factors and interpreting the meaning of the corresponding experimental results.

All-atom simulation approaches are still quite ineffective in predicting protein-structures, and one has to resort to simplified models. Even when one starts from the X-ray structure, it is not trivial to have the simulated structure identical to the observed one. The problems involved include the need for reliable potential function and, perhaps more importantly, the need to have a realistic description of the solvent (32) and proper treatment of long-range forces.

3. Dielectric Properties

Although proteins cannot and should not be described as a medium of a uniform dielectric constant, it is important to understand the dielectric properties of proteins. Experimental attempts to determine local dielectric constants are far from being unique, and simulation studies can provide great insight. In relating the simulated dielectric constant to experimental observations, one should take into account the effect of the solvent around the protein, which is also referred to as the *reaction field* (33). Consistent simulations of the overall dielectric constant of solvated proteins have been reported by several workers (34-36). It has been found that the local dielectric at protein active sites is quite large and quite different than the low value usually deduced from dielectric measurements (37). Simulations are also very effective in analyzing the fast time components of dielectric **relaxation times** (34, 36).

4. Dynamical Properties

MD simulations and related approaches provide powerful ways of evaluating dynamical properties. Many of these properties can be casted in terms of the **corresponding time correlation function** (38).

$$C_A(t) = \frac{1}{\tau}\int_0^{\tau} A(t')A(t+t')dt' \tag{2}$$

where A is the property of interest and t is a sufficiently long simulation time. For example, the diffusion constant, D, can be obtained from the velocity autocorrelation, $C_v(t)$, by

$$D = \frac{1}{3}\int_0^{\infty} C_v(t)dt \tag{3}$$

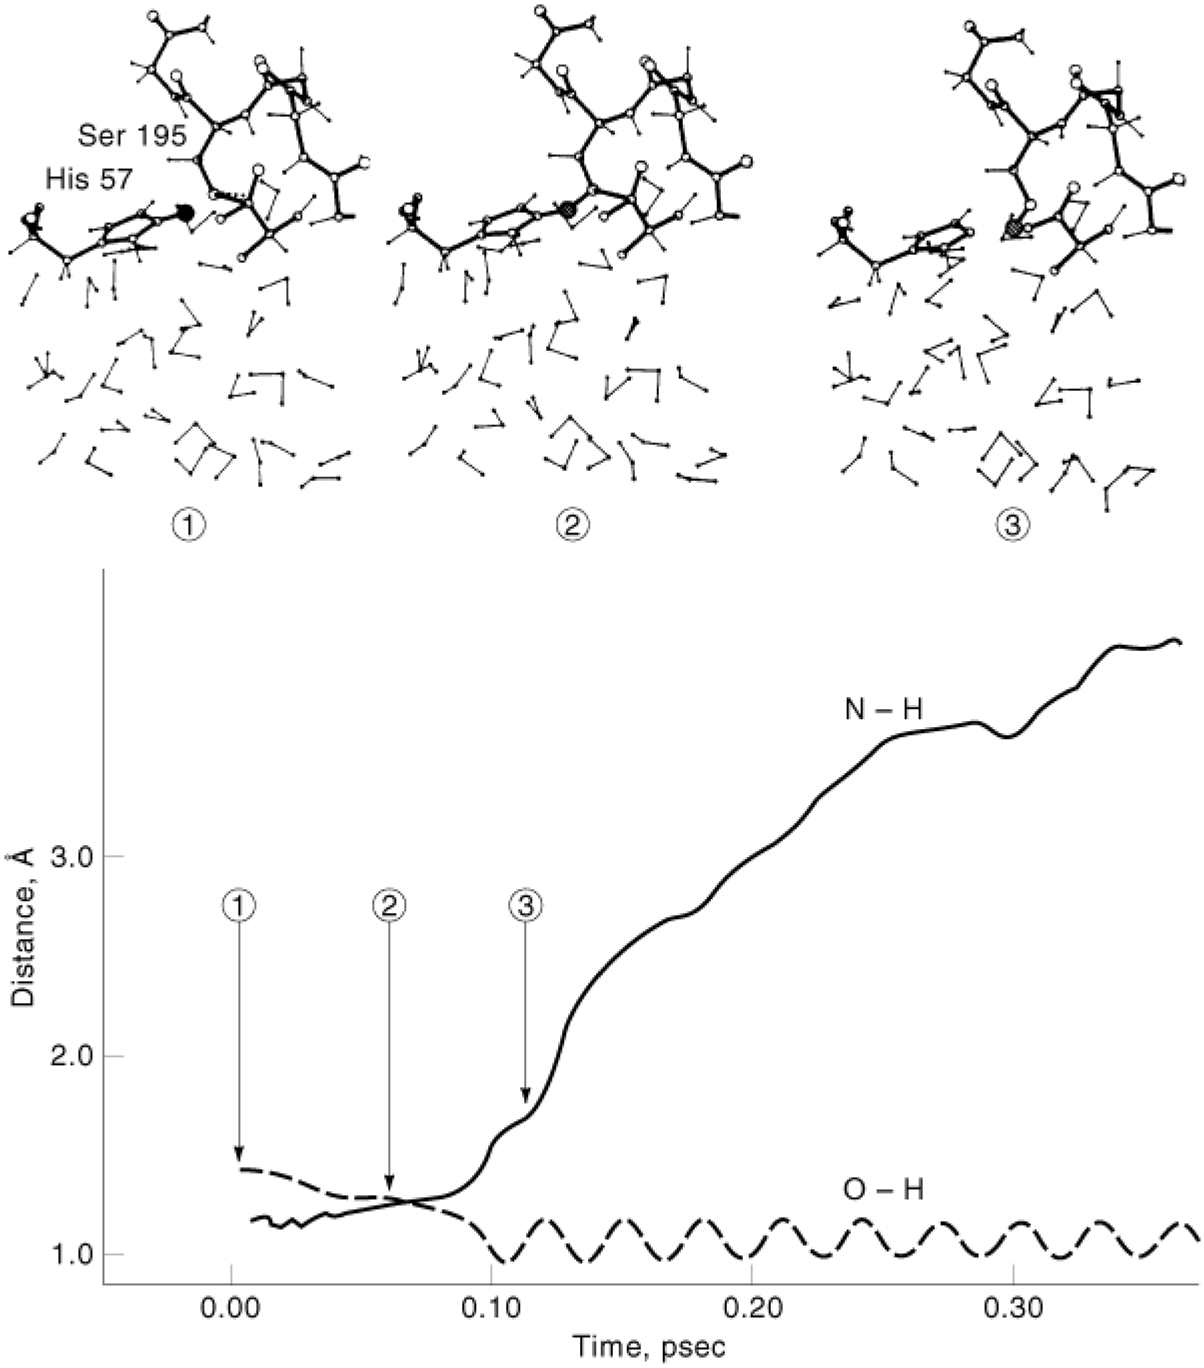
This relationship can be used in comparing simulations to experiments and in analyzing the microscopic meaning of experimentally deduced parameters. The dynamical range accessible to simulation studies can be probed by several approaches, and significant progress has been made in comparing simulations to the results of inelastic **neutron scattering** (39).

Molecular fluctuations are characterized by correlation times, which are closely related to the underlined relaxation processes. Relevant relaxation times can be evaluated by simulation studies using:

$$\tau_A^{-1} = C_A(0)^{-1}\int C_A(t)dt \tag{4}$$

The fluctuations of the macroenvironments of proteins can play an important role in fast reactions. This is true in particular with regard to the effect of electrostatic fluctuations on charge transfer processes such as electron transfer reactions. The rate of such reactions is determined by the effect of the protein fluctuation on the difference between the energies of the reactant and product state. Such an approach has been used in studies of the dynamics of the primary event in photosynthesis 26, 40-42. The same approach can be used in studies of photoisomerization processes, although in such cases one needs to account for a large coupling between the electronic states. As much as rate constants of regular chemical reactions are concerned, the most important factors are activation energies (see below) and not dynamical effects. Nevertheless, the chance that a trajectory that reaches the transition state will lead to reaction of the transmission factor is a dynamical effect. This factor can be evaluated using MD simulation by running trajectories downhill from the transition state (43) (Fig. 1). However, the transition factor is usually close to unity in reactions with significant activation barrier (4, 26) (Fig. 1).

Figure 1. A downhill trajectory for the proton transfer step in the catalytic reaction of trypsin. The trajectory moves on the actual ground state potential, from the top of the barrier to the relaxed enzyme–substrate complex. 1, 2, and 3 designate different points along the trajectory, whose respective configurations are depicted in the upper part of the figure. The time reversal of this trajectory corresponds to a very rare fluctuation that leads to a proton transfer from Ser 195 to His 57. (adapted from ref. 4).



5. Rate of Biological Processes

The rate constant of processes in condensed phases can be expressed as:

$$k = F(k_B T/h) \exp\{-\Delta g^{\neq}/k_B T\} \quad (5)$$

where k_B is the Boltzmann constant, T is the absolute temperature, h is the Planck constant, F is the **transmission factor** of section 3, and $Dg^{\ddagger}$ is the activation-free energy. For most reactions with large $Dg^{\ddagger}$, one finds that F is close to unity and, thus, the most important factor is $Dg^{\ddagger}$. Enzymes catalyze their reactions by reducing activation-free energies (44), and one of the most important questions in structure function correlation is how this reduction of $Dg^{\ddagger}$ is accomplished (4).

Molecular simulations should allow one to evaluate activation free energies and transmission factors and to probe the molecular origin of enzymatic reactions. However, such reactions involve bond making and bond making processes that cannot be described by simple force fields. It is also impractical to describe the complete enzyme/substrate complex by high level quantum mechanical approaches. A possible alternative is provided by **hybrid Quantum mechanics/molecular mechanics (hybrid QM/MM)** methods 4, 45-49. Such methods describe only parts of the reacting system quantum mechanically, while treating the rest of the protein classically. QM/MM approaches are very promising, but the corresponding results are not yet quantitative (26). An alternative, which is, at present, the most reliable way of simulating enzymatic reaction, is provided by the Empirical Valence Bond (EVB) approach (4, 26, 50, 51). The EVB method describes the reaction potential surface by a valence bond method that considers the different resonance structures of the reactant and product fragments and their interaction with the surrounding protein and solvent. This method is calibrated by considering the reference reaction in water so that it focuses on the difference between the reaction in protein and solution, which is much easier to obtain than to predict the reaction potential surface in the protein by a first principle approach.

The EVB approach can be used to calculate conveniently and efficiently activation-free energies of enzymatic reactions using a combination of FEP and umbrella sampling approaches (4, 50). The activation energies can be converted to rate constants of enzymatic reactions using equation 5.

6. Protein Folding

Models that use **simplified representation** of the protein amino acids (52) have provided a powerful understanding of the protein folding process (53-56). Such models are sometimes classified as *on-lattice* and *off-lattice* models. On-lattice models consider the simplified representation along a regular cubic lattice (thus allowing exact enumeration at the expense of somewhat unrealistic structure), while the off-lattice models try to provide more realistic representation (52). Simplified models are used extensively in understanding the relationship between sequence to folding probability and to the specific folded structure (52-56) and in deducing the sequence of events in the folding process (53). The gradual increase in computer power makes it tempting to use all-atom simulations in studies of folding processes. Some advances have been made (57-59), and more will follow. A promising effective approach is the use of the simplified representation as a reference potential for all-atom calculations (60).

Concatemers

A concatemer is a multimeric molecule of **DNA** formed by identical monomers arranged linearly in the same head-to-tail orientation. Closure of a **bacteriophage** DNA molecule upon entry into the bacterial host cell is a relatively simple process. The complementary single-stranded ends anneal in a reaction that is thermodynamically favored and by conditions that restrict diffusion and keep the ends close to each other. **Annealing** is followed by covalent joining, catalyzed by the host DNA Ligase, which forms phosphodiester bonds. Opening of the circular DNA molecule, coupled to its encapsidation to form mature phage particles, however, is rather complex.

Capsid precursors interact with the newly replicated DNA molecules in the form of concatemers (1, 2), which are the product of DNA replication proceeding in two stages. First, the DNA injected into the host is circularized and covalently closed, as previously described. In the case of the lambda phage, the DNA undergoes several stages of DNA replication in which the circular DNA rings generate daughter rings. Then, during phage vegetative growth, **rolling-circle** replication gives rise to *linear* concatemers of l DNA. These concatemers, which in the absence of packaging may be up to 10 chromosomal units long, are the normal substrates for packaging.

RNA primers for DNA synthesis are excised during the process. This raises the question of how the extreme ends of linear DNA can be completed. Not only must a small RNA fragment initiate at the 3′ terminal nucleotide of the template strand, but the sequence must be filled in after ribonucleotide removal. This dilemma was resolved using phage T7 DNA, which has the property of having redundant ends. The sequence of about 160 bp found at the left end is repeated exactly at the right end of the molecule. When the linear T7 molecules replicate, they do not generate unit-length progeny molecules, but very long concatemers (units linked end to end) containing the complete genome sequence repeated over and over.

Conditional Lethal Mutations

Mutations that cause lethality under one condition (the restrictive or nonpermissive condition) but not another (the permissive condition) are called conditional lethal mutations, or loosely, conditional lethals. Conditional lethal mutations have an honored position in molecular biology. The recognition that a **gene** is not indivisible, the determination of the triplet nature of the genetic code, and the discovery of **nonsense codons**, all resulted from studies of a particular class of conditional lethal mutants of **bacteriophage** T4. T4 *rII* mutants grow on *Escherichia coli* strain B (the permissive host) but not on *E. coli* strain K-12 when it is **lysogenic** for bacteriophage **lambda** (the nonpermissive host). Interestingly, the function of the proteins encoded by the two *rII* genes remains unknown. The conditional lethality of the *rII* mutants allowed geneticists to grow the phage, to perform genetic crosses on the permissive host, and then to analyze the results on the nonpermissive host.

Conditional lethal mutations are the only genetic way to identify essential genes in haploid organisms or cells. By definition, a mutant with a null mutation in an essential gene cannot be isolated in the haploid state (in **diploid** organisms, recessive lethal mutations on autosomes are **complemented** by the other functional **allele**). Conditional lethal mutations are usually identified by screening mutant clones for growth under permissive conditions but not under restrictive conditions. Lethal in this case does not always mean conveying death. For example, auxotrophies are considered a class of conditional lethals because the auxotrophic cells grow only in the presence of the required growth factor, although they do not necessarily die in its absence. The more typical classes of conditional lethals are host-range mutants (described above), **temperature-sensitive mutants**, and cold-sensitive mutants. Nonsense mutations are considered conditionally lethal because the mutation is suppressed when a suppressor transfer RNA is present.

Conditional lethal mutations are a powerful way to identify protein–protein interactions. A mutation that renders a protein inactive at high or low temperature, for example, may be suppressed by a compensating mutation in the gene encoding a protein that interacts with it. To conclude that the two proteins interact, the suppression must be allele-specific, ie, not caused by general suppression (as in the case of tRNA nonsense suppressors). In addition, other events, such as gene duplication, suppress conditional lethals. Interacting proteins are also identified by synthetic lethal mutations, which are mutations in each of two genes, neither of which is lethal alone but which are lethal when together in the same cell.

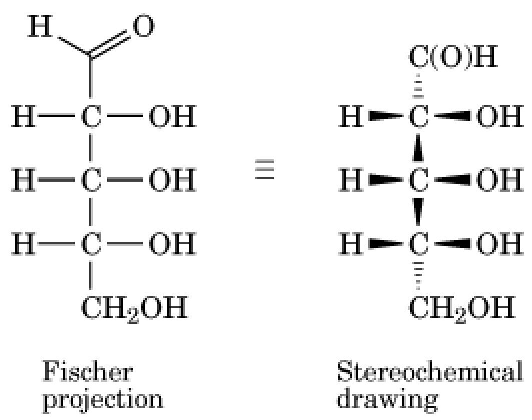
Configuration

Although configuration and conformation are listed as synonyms in the *Oxford English Dictionary* (1), in chemistry and biochemistry they have specific and separate meanings differentiated by time or energy. Both terms refer to the organization of atoms in space, but configuration refers to the element that remains invariant in time in the absence of any covalent bonds being altered, whereas conformation refers to the relative orientation in space of atoms that can vary by rotation about single bonds and consequently varies in real time for biological molecules. The absolute configuration identifies the arrangement of atoms that generates **chirality** in a molecule. Following Pasteurs identification of the two chiral forms of tartaric acid, it was only known that they differed by being nonsuperimposable mirror images. This ambiguity was resolved when the crystal structure of (+) tartaric acid was determined by Bijvoet and co-workers (2). By this means, the absolute configuration of many related molecules became identifiable.

The designation of the configuration of a chiral center was problematic for nearly a century. Fischer introduced a general procedure that identified enantiomers as either D- or L- (3) based on whether the nonhydrogen substituent was on the right or left when the molecule was drawn as a “Fischer projection” (Fig. 1). This nomenclature permeates biochemistry through the now colloquial names of amino acids, carbohydrates, and lipids.

Figure 1. A Fischer projection. By convention, it has the vertical bonds directed away from the viewer and horizontal bonds directed out toward the viewer. The configuration of each chiral carbon in D-ribose is D because the nonhydrogen substituent is drawn to the right. For sugars, the enantiomer is defined by the bottom chiral carbon when the carbon chain is oriented vertically with the carbonyl carbon at the top; thus, D-ribose is pictured.

D-ribose

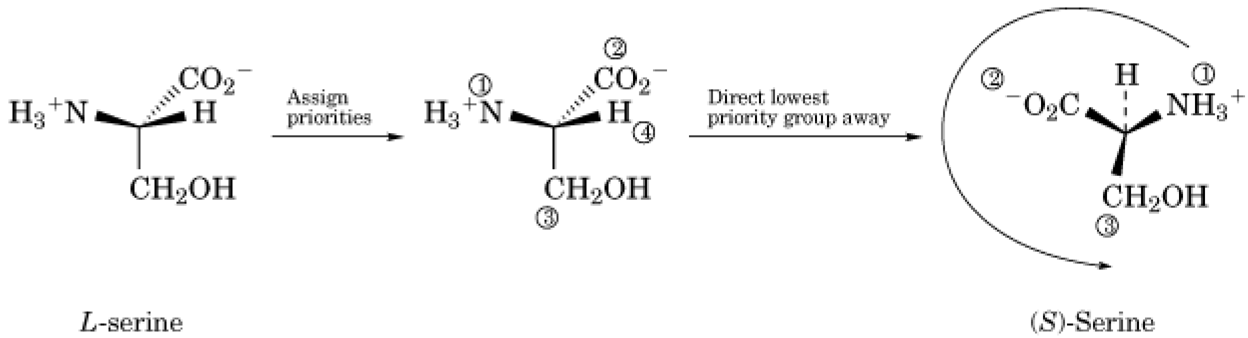


The Fischer nomenclature leads to ambiguities (4). A rigorous and unambiguous method of identifying configuration proposed by Cahn et al. has been adopted for specifying absolute configuration as either (*R*) or (*S*) for chiral tetrahedral centers (5). The procedure requires the assignment of priority to the four substituents that generate a chiral center, followed by a procedure to identify the arrangement as either (*R*) or (*S*). The four rules for assigning priority are:

1. Substituents are assigned their priority in order of decreasing atomic number of the atom directly bonded to the chiral center.
2. If two or more atoms receive the same priority in step 1, the atoms bonded to each of the equal priority atoms are examined one at a time. If the two groups are not differentiated by the atom of greatest priority, the second and third atoms are compared successively.
3. Heavier isotopes take precedence over lighter isotopes, eg, ^{2}H over ^{1}H and ^{14}C over ^{12}C.
4. Double bonds are counted as two bonds to the same atom.

Once the relative priorities of the four substituents are assigned, the bond to the lowest priority group is oriented directly away from the observer, and the remaining three groups are viewed in a plane. If the arc connecting the three groups in order of highest to lowest priority is clockwise, the chiral center is assigned the (*R*) configuration (from the Latin rectus), whereas if the arc is counterclockwise, the center is assigned the (*S*) configuration (from the Latin sinister). These assignments are shown in Figure 2.

Figure 2. Assignment of the relative priorities of the four substituents on the chiral a-carbon of serine. The carboxylate carbon takes precedence over the hydroxymethyl carbon because it has three bonds to oxygen. The assignment of the (*S*) configuration results from the counterclockwise arc that connects the substituents in order of precedence.



. Assignment of the relative priorities of the four substituents on the chiral a-carbon of serine. The carboxylate carbon takes precedence over the hydroxymethyl carbon because it has three bonds to oxygen. The assignment of the (*S*) configuration results from the counterclockwise arc that connects the substituents in order of precedence. [Full View]

Confocal Microscopy

Confocal microscopy is now a well-established tool for the examination of subcellular structure and function and complements light and electron microscopy. Because of its high temporal resolution, confocal microscopy allows for the visualization of living as well as fixed tissues and cells, and therefore dynamic processes can be examined and analyzed quantitatively as they actually occur. Confocal microscopy offers several advantages over conventional light microscopy, among which are an increase in contrast, resolution, and clarity (1). Conventional light microscopy provides a two-dimensional (2-D) image of the specimen in the focal plane of the objective lens, but this image is contaminated by out-of-focus images of the specimen above and below the focal plane. Confocal microscopy provides a 2-D image in the focal plane without the out-of-focus information. Furthermore, the resolution of images from a confocal microscope is improved by a factor of 1.4–1.75 (2). Through computer control of the focus and acquisition of images, modern confocal light microscopes can collect a series of 2-D images (or "optical sections") through the specimen producing a three-dimensional (3-D) image. Four-dimensional imaging (4-D), defined as 3-D imaging over time, is a recently developed extension in which 3-D images are recorded at periodic time intervals (3).

The basic principle of the confocal microscope is to eliminate the scattered, reflected, or fluorescent light from out-of-focus planes by making the illumination, specimen, and detector all have the same focus, ie, they are confocal. In effect, this microscope will image only the very thin optical section on which the beam is focused. Matched pinholes are used, one at the light source which is imaged onto the specimen to function as a probe that is scanned over the specimen, and one at the detector to capture only a narrow plane of focus. Thus, the out-of-focus blur from areas above and below the focal plane are eliminated. The matched pinhole apertures improve the lateral resolution over conventional light microscopes by a factor of 1.4 with the use of circular apertures and 1.75 with annular apertures (2). Confocal microscopes are often designed to scan in a raster pattern over the sample in which the microscope illuminates one spot at a time, scanning the spot along parallel lines in the focal plane. Lasers are an ideal illumination source for raster scanning because they provide an intense beam of monochromatic radiation that can be condensed onto a small spot. Hence many confocal microscopes are laser scanning (LSCM).

Applications of LSCM include (i) determining the location of proteins, lipids and nucleic acids, cytoskeletal structures and organelles within cells (4, 5), using fluorescent dyes, antibodies, phalloidin, and lectins, (ii) observing ionic fluctuations, such as calcium, magnesium, and pH, in cells and organelles (6), and, (iii) measuring membrane potential using fluorescent dyes (7). The power of 4-D imaging in molecular biology was illustrated by the noninvasive monitoring by LSCM of mitotic events, and cleavage and migration patterns of fertilized sea urchin eggs labeled with $DiOC_6$ (8). Macromolecules and subunits can be characterized by immunocytochemical fluorescence probes, which involves the use of antibodies labeled with fluorophores (9). When more than one fluorophore is used, 3-D multilabel (multicolor) imaging can be used to map the 3-D relationship of the labeled structures. For example, z-series collected from two different channels, fluorescein and rhodamine, can be merged into a single reconstruction. By rotating the rendered volume, particular nuances of the structural relationships highlighted by the bound fluorophores may be revealed (10, 11). It is not only important to know that a particular compound is present in a specific cell type or subcellular component, but it is also important to detect and quantify changes in local concentrations of such compounds. Quantitative immunocytochemistry utilizes the principles of stereology and statistical analyses (12) and can be coupled to LSCM to detect differences in immunoreactivity. This method has been used to measure the distribution of integral membrane proteins in the vertebrate retina and to determine the distribution of transport vesicles (13).

Many of the advantages of a confocal light microscope can be achieved with a standard light microscope equipped with a digital camera interfaced to a computer, which controls the microscope stage and focus control as well as run rapid deconvolution algorithms (14). With knowledge of the 3-D point spread function of the microscope, the deconvolution algorithms remove out-of-focus signal to produce images comparable in quality to LSCM images. The advantages of the deconvolution confocal microscope are that (i) the system expense is a fraction of the cost for a LSCM system, and (ii) lower illumination levels can be used, since all of the light emitted from the specimen is used in forming the 3-D image. Lower illumination minimizes the problem of photobleaching of fluorophores used to label the specimen. A disadvantage of this approach is that the full 3-D deconvolution process can take significantly more time to produce a 3-D image than does a confocal microscope.

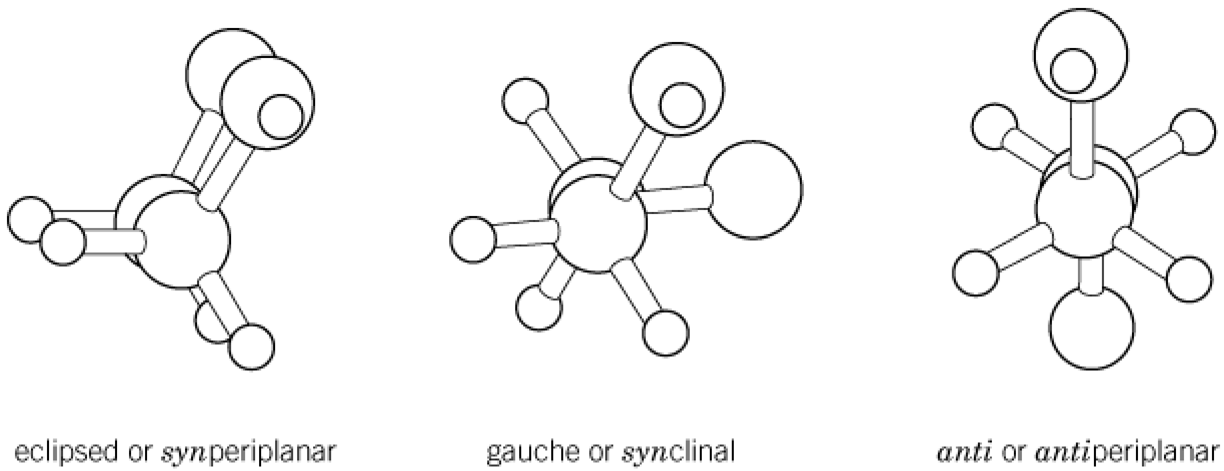
Conformation

Nonidentical spatial arrangements of the atoms of a molecule achieved by rotation about single bonds are referred to as different conformations (1). Two molecules differing in their conformation may be referred to as conformers . Because rotations about single bonds are usually rapid, conformers are rapidly interconverted, making it difficult to separate individual conformers. Note one exception to this rule is rotation about the C–N single bond of the peptide bond of polypeptides, which has partial double-bond character, so it is planar and the *cis* and *trans* conformations are only slowly interconverted (see Cis/Trans Isomerization). The conformation of a molecule may then be largely specified by characterizing the rotations about its single bonds. These rotations are quantified by determining the torsion angle or dihedral angle. Individual torsion angles may be qualitatively described as eclipsed, **gauche**, or **anti** (Fig. 1), or more formally named *syn* periplanar, clinal, and *anti* periplanar; they are quantified, as described in Torsion angle.

Figure 1. The common description of a conformation, illustrated by ethylene glycol. When the substituents are superimposed, the conformation is described as *eclipsed*; when they are staggered, the conformation is *gauche* if the large substituents are roughly separated by 60° and *trans* or *anti* if they are opposite.



Other common combinations of torsion angles lead to descriptive names for common groups of atoms, eg, the 2′-endo conformation of **ribose** describes all five of the torsion angles of the furanose ring. This practice extends to larger biomacromolecules. The conformation of a small repeating segment of a biomacromolecule is characterized by its torsion angles along the backbone. Thus specification of the phi (f) and psi (y) angles for an oligopeptide (see Ramachandran Plot) describes its conformation as alpha-**helical** or beta-**sheet** (2). The specification of the torsion angles along the phosphodiester backbone of a polynucleotide also will determine whether the conformation is of the A, B, or Z type (3) (see DNA Structure).

A stable three-dimensional structure of a biological macromolecule is referred to as its conformation. Because rotation about single bonds is energetically easy, a unique conformation does not exist, as at least one single bond will be changing rapidly. A cooperative change of several torsion angles, such as occurs in the protein unfolding or melting of double-stranded DNA, may have a significant energetic barrier. The interconversion of the two conformations is then identified as a *conformational change* , where the implication is that the macromolecule has been converted from one family of conformations to an experimentally distinguishable family of conformations.

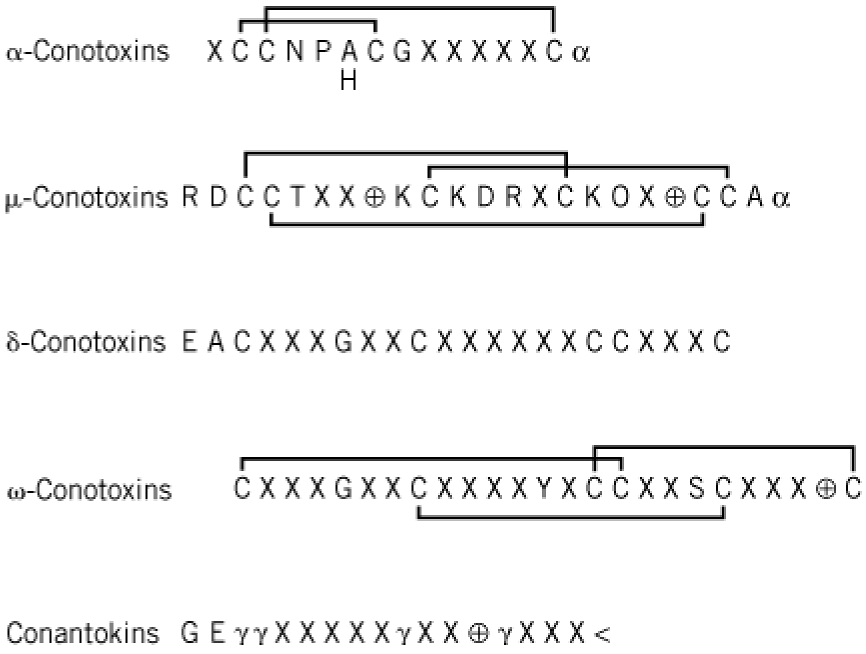
Conotoxins

Perhaps the largest array of **channel**-binding toxins is produced by marine gastropods of the genus *Conus*, which includes more than 500 species (1, 2). These animals appear to have developed the ability of generating a very large number of toxin variants starting from a basic peptide structure consisting of relatively few residues (Fig. 1). In such a way, they produce venoms containing complex mixtures of toxins, capable of binding and blocking the activity of several ion channels. Moreover, some conotoxins are capable of binding differentially to the various **isoforms** of an ion-specific channel, thus providing precious tools to pharmacologists and neuroscientists (1).

Figure 1. Peptide toxins contained in *Conus* venoms. *Conus* spp. produce a highly complex mixture of toxins. Shown here are the consensus sequences and disulfide connections of toxins specific for the acetylcholine receptor (a-conotoxins), sodium channels (m- and d-contoxins), calcium channels (w-conotoxins), and the NMDA glutamate channel (conantokins). O indicates *trans*-4-hydroxyproline, plus a positively charged residue, g a g-carboxyglutamate, and a an amidated a-carboxyl. The disulfide connectivity of d-conotoxins is not established.



The m-conotoxins are 22 residue-long basic peptides and include three hydroxyproline residues and six cysteines that form three disulfide bonds (Fig. 1). These conotoxins have an ellipsoid shape with the basic residues, which are essential for the binding activity, clustered on one side of the molecule (2, 3). m-conotoxins bind to the tetrodotoxin binding site of the **sodium channel**, thereby inhibiting the propagation of the action potential and causing flaccid paralysis. Another family of conotoxins specific for sodium channels is that of the d-conotoxins, whose binding causes an increased conductance of such voltage-gated channels (4).

w-conotoxins act on voltage-gated **calcium channels** and inhibit calcium entry through the presynaptic membrane, thus preventing the release of neurotransmitters. Their peptide chain consists of 24 to 30 residues and three disulfide bonds (Fig. 1). A frequently used w-conotoxin is G_{VIA}, a 27 residue-long peptide that is very specific for calcium channels containing the a1B subunit, such as the N-type calcium channel present at the neuromuscular junction of vertebrates. The specificity of different w-conotoxins for different vertebrates is exploited in studying the function and anatomical distribution of calcium channels (1).

The largest family of conotoxins is that of the a-conotoxins, 13 to 18 residue-long peptides, whose folding is dominated by two disulfide bonds (Fig. 1). These paralytic neurotoxins bind specifically to the nicotinic acetylcholine receptor and different a-conotoxins are able to distinguish between different neuronal isoforms of the receptor. *Conantokins* are *Conus* peptides with yet another channel specificity: They bind to the NMDA-sensitive glutamate channels. They are peptides of 17 to 21 residues with no cysteine but four **gamma-carboxyglutamate** residues (1) (Fig. 1). Very short *Conus* peptides are conopressins, which consist of nine amino acid residues with a single disulfide bond and are specific for the vasopressin receptor.

Conservative Substitutions

Missense mutations cause the substitution of one amino acid for another in the protein encoded by the mutant **gene**. The effect of such a change on the protein's function will often depend on how similar the new amino acid is to the original one. Amino acids are classified by their acidity, polarity, hydrophobicity, and structure. Substitutions are considered conservative if the change is between amino acids of the same class. However, a better criterion is whether the substitution has occurred during the evolution of related proteins. The mutations that give rise to conservative amino acid substitutions are considered evolutionarily neutral mutations, or nearly so. Lists of likely conservative substitutions are found in many laboratory manuals, for example (1).

Constant (C) Region

The heavy and light chains of immunoglobulins contain (a) **variable (V) regions** of approximately equal size (ie, about 110 amino acid residues), and (b) constant (C) regions that contain a multiple of 110 residues, one for the L chain and three or four for the H chains, depending upon the isotype. Whereas the V regions are involved in antigen recognition, C regions are devoted to effector functions, such as **complement** fixation, transplacental passage, or attachment to various cell types. C regions are organized on a basic **domain** structure, corresponding to the 110-residue subunit of Ig with an autonomous three-dimensional protein structure, as shown by X-ray crystallography (see Immunoglobulin Structure). This structure, known as the immunoglobulin constant domain fold, provides the basis for the general organization of a large number of proteins, known as the Ig superfamily.

The existence of different C regions was first shown by immunochemistry, because specific antisera could distinguish two types of light chains, known as l) light chains, and five discrete isotypes of H chains, which dictate the organization into the five classes of immunoglobulins (IgA, IgD, IgE, IgG, IgM). Definitive understanding of the basis of isotype structure was obtained by protein sequencing and finally by DNA sequencing. Within each Ig class, one may distinguish subclasses, as in the case of the g chain or the a chains in humans.

Most of the effector functions of immunoglobulins are supported by the last two or three COOH-terminal domains of the heavy chains, depending upon the class. The most interesting feature of constant regions is their ability to bind to a receptor family, termed **Fc receptors** (FcRs), because binding involves the Fc region of Ig. FcRs represent adaptors that can confer on a variety of cell types any antibody specificity, depending on which Ig will bind to the receptor. There is an FcR specific of each soluble isotype, IgG, IgA, and IgE. One distinguishes FcRs of high affinity (FcR type I) that fix Ig monomers and FcRs of low affinity (FcR type II) that bind Ig only when aggregated or as multivalent complexes. Depending on which cell type FcR is anchored, they express an cytoplasmic tail of variable size, which may result from alternative splicing and that contains various signaling motifs such as an immunoreceptor tyrosine-based activation motif and an immunoreceptor tyrosine-based inhibition motif. $Fc\epsilon RI$, present on mast cells, basophils, and eosinophils, plays a major role in anaphylaxis, because it will fix monomeric IgE. Upon cross-linking by antigen, this FcR is triggered, leading to the cascade of events that are responsible for degranulation of the corresponding cells and thus to the liberation of pharmacologically active molecules that account for immediate hypersensitivity. $Fc\epsilon RII$ (CD23) binds aggregated IgE, or IgE already cross-linked by antigen. It is present at the surface of many cell types, including B cells. It may also be cleaved and release several soluble products that have a **cytokine**-like activity. FcgRI is found on monocytes, eosinophils, and neutrophils and binds to monomeric IgG, whereas FcRaI is present on macrophages, neutrophils, and T and B cells.

This demonstrates the extraordinary plasticity and amplification of molecules of the immune system and illustrates the huge diversity of functions that are linked to the constant regions of immunoglobulins.

Contact Inhibition

Cultured cells, particularly when grown as a monolayer attached to a substrate, will go through a reproducible growth cycle following subculture (1) (see Cell Line). The phases normally defined are (1) the lag phase, before the culture starts to proliferate; (2) the exponential , or log , phase, when the cells are dividing rapidly and the population doubles over a fixed time; and (3) the plateau phase, when the cell number remains stable with further time in culture. As a culture reaches the end of the exponential phase and enters plateau, it responds to cell contact, reduced substrate availability, a reduction in nutrients, and a number of other stimuli that inhibit a further increase in cell numbers. These have been divided into two major components: contact inhibition and density limitation of cell proliferation . Contact inhibition is the cessation of cell motility that occurs when a cell culture reaches confluence. It was first described from observations of randomly migrating fibroblasts made in time-lapse cinemicrography (2). Normal fibroblasts cultured at low cell density show a spindle-shaped morphology, with a reversible polarity along their long axis, which is also the direction of cell migration. When the cell encounters another similar cell, contact induces a reversal of the polarity; the ruffling in the leading tip of the cell ceases and transfers to the opposite tip, which then becomes the anterior end, and migration resumes in the opposite direction. When contact is made with another cell, the process of reversal of polarity is repeated, unless the cell is surrounded by other cells, when membrane ruffling ceases and cell migration is inhibited. In the cases of normal human or chick diploid fibroblasts, the cell assumes a parallel array that gives the appearance of whorls in the cell monolayer under low power microscopy or naked eye observation.

At the time that motility ceases, the cells are still capable of proliferation, but the culture becomes crowded following one or two population doublings, the cells assume a narrower spindle shape, and cell spreading is reduced beyond the point where the cell is able to re-enter the cell cycle (3). At this point, proliferation ceases in a normal cell culture, and the culture remains as a monolayer. Further growth is inhibited by density limitation of cell proliferation , and the culture enters the plateau phase of the growth cycle (see Cell Line). Density limitation of cell proliferation is distinct from contact inhibition, which affects primarily membrane ruffling, polarity, and cell migration. The mechanisms are, however, similar, although the detail remains obscure. Subconfluent cells have many more adhesions to the substrate than to other cells, favoring motility and proliferation. When the culture becomes confluent, the number of cell–cell adhesions (cadherins) increases, but they are still exceeded by cell–substrate adhesions (integrins), which inhibit cell motility but not proliferation. When the culture becomes crowded, the number of cell–cell adhesions increases, and cell–substrate adhesions are reduced, maintaining inhibition of motility but now inhibiting re-entry into the cell cycle. As contact with adjacent cells and contact with the substrate are mediated via different classes of **receptors** (4), the signaling that results from activation of these receptors is potentially different, although exactly how remains unclear.

In addition to alterations in cell spreading, adhesion receptors, and the actin cytoskeleton when cells reach a high density, the cells are also exposed to reduced nutrient levels, due to a higher rate of utilization, and increased levels of catabolites, both of which will tend to inhibit proliferation. In a static culture, this may generate a depleted layer above the cells, across which nutrients and growth factors must diffuse to reach the cells. The diffusion rate will be significantly slower with higher molecular weight components of the medium, including growth factors and peptide hormones such as insulin. Support for this diffusion boundary layer hypothesis was provided by experiments where local irrigation was increased, by means of a micropump, and resulted in a localized increase in the frequency of labeling with [^{3}H]-thymidine (5). As the range of the diffusion boundary was short, it was proposed that the limitation was principally in growth factors, depleted by binding to cell-surface receptors and endocytosis, which was confirmed by the observation that addition of growth factors or serum to the medium will induce further proliferation (6).

On the other hand, one of the main observations that confirms that contact inhibition and density limitation of cell proliferation are not simply evidence of environmental deterioration is the result of the so-called “wounded monolayer” experiment (7). If a confluent, growth-arrested monolayer is scored with a sharp instrument, creating a bare patch devoid of cells, the surrounding cells respond as follows. The edge cells start to show ruffling of the cell membrane bordering the wound, spread out, and migrate into the space. When they have spread beyond a critical point, they enter the cell cycle and divide, and they continue to do so until the space of the wound is filled. They then stop migrating, but continue to proliferate until the cell density in the wound matches the crowded state of the rest of the monolayer; at this point they stop dividing. Meanwhile, no other cells distant from the wound show any sign of entering the cell cycle. This confirms that a major component of density limitation of cell proliferation is due to geometry and cell shape, rather than simply nutritional or growth factor limitation.

If a culture of normal fibroblasts that is growth arrested at high density is fed with medium containing serum or growth factors, many of the cells will reenter the cell cycle, resulting in the formation of a second cell layer over the first; if this is repeated, multilayered cultures can be produced. It has been proposed that the first layer of cells secretes a collagen overlay (which may produce a further diffusion barrier) and the second cell layer grows on top of this, technically not disobeying the rules of contact inhibition and density limitation of cell proliferation. This second layer, however, is still limited by contact and density, and when it reaches confluence, it will form a second layer of parallel arrays of cells, not colinear with the first. If perfused, these cultures may continue to increase up to 20 or 30 cell layers deep (8).

When cultures of normal epithelium reach confluence, they also become contact-inhibited. In less dense cultures, however, they do not show the random migration seen in cultures of fibroblasts, but tend to grow in patches with ruffling of the membrane, cell spreading, and proliferation restricted to the outer edge of the patch (9). Their motility is limited, but when it occurs, it tends to involve the whole patch, which moves as a unit. Multilayering in normal epithelial cultures also occurs, but tends to imply maturation perpendicular to the substrate, rather than overgrowth. Epidermal cells, for example, will become stratified, with the upper layers of cells becoming progressively more keratinized. This is accentuated if the cells are grown on collagen, particularly in the presence of dermal fibroblasts and due to integrin down-regulation. Epithelial cells, which are derived from simple epithelium that is only one cell thick *in vivo*, tend to be obligate monolayers in culture. Likewise, normal endothelium from the lining of blood vessels will not pile up in culture, although after some time at high density it will tend to curl up and form secondary structures resembling capillaries (10), particularly if grown on an extracellular matrix, such as Matrigel.

Transformation allows cells to escape from the restrictions of contact inhibition and density limitation of cell proliferation (see definition of transformation in Immortalization). On one hand, they often lack, or have modified, the appropriate receptors or cell-adhesion molecules to recognize each other on contact; on the other hand, they are no longer dependent on cell spreading to allow entry into the cell cycle. Many transformed cell lines will propagate in suspension, without any substrate attachment. In addition, transformed cells often produce autocrine growth factors or have permanently active steps in the signal transduction cascades that promote cell proliferation (11-13). Hence, transformed cells will grow to a higher density and form multilayered cultures quite readily. The limitations imposed by density now tend to be diffusion-related, principally nutrient, catabolite, and gaseous (dissolved O_2 in and CO_2 out). One major limitation is the release of lactic acid by the cells, as they are generally more anaerobic in their metabolism than normal cells, and this depresses the pH, initially inhibiting proliferation and ultimately killing the cells. Although transformed cell cultures enter a plateau phase of culture when they reach a high density, the growth fraction in transformed cultures in plateau can be quite high (10–20%), unlike the plateau in normal cell cultures, where the growth fraction is very low (<5%). A steady state is reached when cell proliferation is matched by cell necrosis or apoptosis, and the cells deteriorate rapidly and irreversibly if the medium is not replenished.

The differences in response to high cell density between normal and transformed cells has been exploited in the isolation of transformed foci. If a monolayer of 3T3 cells is **transfected** with an **oncogene**, especially in the exponential phase of growth, when transfection is more efficient, it will show foci of transformed cells when the culture reaches confluence, because of the lack of contact inhibition of cell motility and density limitation of cell proliferation in successfully transformed cells (14). Likewise, transformed cells plated on a confluent monolayer will continue to grow and may form foci, or they may infiltrate the monolayer. Normal cells plated on a confluent monolayer will give a varying response, depending on the cell lineage of the confluent monolayer. If the plated normal cells are of the same lineage as the confluent monolayer, they will not grow; for instance, fibroblasts will not grow on a confluent monolayer of fibroblasts, and normal glial cells will not grow on a confluent monolayer of normal glial cells (15), whereas their transformed counterparts will. On the other hand, normal glial cells will grow on a confluent monolayer of fibroblasts, and normal keratinocytes will grow on a monolayer of normal 3T3 cells (16).

Cultures that are propagated in suspension will, of course, not encounter contact inhibition. Nevertheless, they are subject to density limitation of cell proliferation. Part of this is undoubtedly due to nutrient depletion, catabolite buildup, and pH depression, but even if limiting nutrients are replaced and the pH is stabilized, high density suspension cultures do not increase significantly above $1–2 \times 10^6$ cells/ml. Quite often suspension cultures, such as hybridomas, will remain in the plateau phase for only a short time and then deteriorate rapidly, leaving few viable cells in the culture. The reason for this appears to be that the cells tend to enter apoptosis when they reach a high density. Some moderate success has been achieved overexpressing *bcl* in these cells to inhibit apoptosis (17).

Contact Maps

Contact maps are two-dimensional representations of three-dimensional protein structures. A three-dimensional description of a protein structure composed of N structural units could be expressed as an $N \times N$ array of the pairwise distances (see Distance Geometry). This could be done for all pairs of atoms, for selected types of atoms (eg, Ca atoms), for groups of atoms (eg, side-chain centers of mass), or for entire amino-acid residues. Contact maps are generated from such matrices by taking a certain cutoff value for the pairwise distances. For example, the $N \times N$ matrix of the distances between protein Ca atoms (1, 2) can be transformed into a Ca-based contact map (3). Those Ca atoms that are closer to each other in the protein structure than the chosen cutoff distance are considered to be “in contact.” This produces a binary $N \times N$ matrix—a so-called black and white contact map. Alternatively, one may assume a set of several critical values for the distances between Ca atoms (or for other atoms or groups of atoms) and generate an integer matrix—the equivalent of a contact map with a colored or gray scale. A map of main-chain hydrogen bonds could also be considered as a variant of a protein contact map. The choice of structural units being mapped and the choice of cutoff distances determine the quality and range of structural information being stored in a contact map (see Fig. 1).

Figure 1. Schematic drawing of the structure of the B domain of protein G and its contact maps. (a) Three-dimensional structure of the B domain. (b) Ca-based contact maps: above the diagonal, the black and white map with a cutoff distance of 8 Å; below the diagonal is the gray-scale map where various shades of gray correspond to three values of the cutoff

distance, 8 (darkest), 10, and 12 Å. (c) Side-chain-based contact map. Above the diagonal, the dark squares correspond to the pairs of side chains for which the distance between at least one pair of heavy atoms is less than 5 Å. Below the diagonal, a 6.25-Å cutoff criterion has been applied to the centers of mass of the side chains. (d) The main chain hydrogen bond map for the same structure. The amino acid sequence of the protein is given along each axis in one-letter code, and the secondary structure is indicated as follows: E is extended b-strand, H is helix, and S and T are two types of turns.

1. Contact Maps as a Fingerprint of Protein Three-Dimensional Structure

A contact map constitutes a structural “fingerprint” of a protein (4). Each protein can be identified based on its contact map. The **secondary structure**, fold topology, and side-chain packing patterns (for side-chain contact maps) can be visualized conveniently and read from the contact map. Furthermore, structural similarity between a pair of proteins is immediately apparent by a very pronounced similarity of their contact maps; in comparing two protein structures, there is no need to search all their possible relative orientations. The reconstruction of a protein structure from its contact map is more complex, although low-to-moderate resolution three-dimensional models can be easily built, even from a fragmentary contact map (5). The accuracy of the model depends on the type of contact map and the computational tools employed. A combination of protein nuclear magnetic resonance NMR spectra (see NOESY Spectrum; COSY Spectrum) constitutes a hybrid contact map of a protein, and model building from these data is an example of a map-to-structure modeling procedure (6, 7).

2. Ca-Based Contact Maps

Ca-based contact maps and distance matrices were perhaps the first commonly used maps for visualization of protein structures (3, 8, 9). An example is given in Figure 1b. These contact maps reflect well the overall topology of the protein fold, but only rather coarse structural details can be read from them. This is due to the fact that the Ca–Ca distance distributions extracted from protein structures have several convoluted peaks. These peaks correspond to various distances between pairs of various secondary structure elements (a-helices, beta-strands, etc.). Thus, a single cutoff distance is always inadequate: Too small a value would miss some helix-to-helix contacts, while too large a value may create some problems with identification of the secondary structure patterns. Gray scale maps (several cutoff ranges) communicate much more detailed structural information.

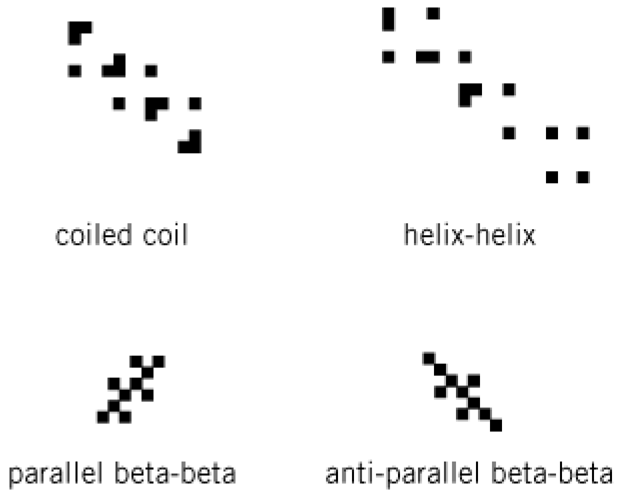
3. Side-Chain Contact Maps

Side-chain contact maps contain much richer information, not only about the topology of a protein fold and its secondary structure, but also many fine details about the packing patterns of the protein side-chains. Various conventions can be used to build side-chain contact maps; two are illustrated in Figure 1. In one case, two residues are assumed to be in contact when any two heavy atoms (ie, all except hydrogen) are a shorter distance from each other than some assumed cutoff. Due to the comparable size of all the united atom types constituting the side chains (eg, CH_2, CH, NH_2, etc.), a good choice of cutoff distance is between 4.5 and 5.0 Å (4, 10). In this range, the number of detected contacts is not sensitive to the particular choice of cutoff, and the packing pattern of the side chains is always described with high fidelity. Characteristic patterns of contacts between elements of secondary structure are an important and useful feature of these contact maps (11). Alternatively, one may build a side-chain contact map using the side-chain centers of mass as a reference. In this case, a larger value of the cutoff distance needs to be used. These cutoff values for the distance between side-chain centers of mass could be made specific for certain amino acid pairs, on the basis of the different sizes of the side chains, which produce different average contact distances for various pairs. As seen in Figure 1, the two approaches (atom based and center of mass based) lead to very similar protein representations. The patterns of the atom-based contact maps are slightly better defined.

4. Regularities of the Contact Maps Reflect Regularities of Protein Structures

Different types of contact maps reflect different aspects of the regularities seen in protein structures. The side-chain-based contact maps are a very good example (10). Near the diagonal of the map, the distinct features of the protein secondary structure can be easily read. Indeed, for extended fragments of the polypeptide chain, only residues i and i + 2 can be in contact. For a-helices, the i, i + 3 and i, i + 4 patterns of contacts are well pronounced. Furthermore, characteristic clusters of contacts further away from the diagonal reflect the packing between particular pairs of b-strands within the b-sheets. Parallel and antiparallel structures have very different features on the contact patterns. Very characteristic patterns could also be observed for other pairs of secondary-structure elements. It is even very easy to distinguish between the patterns for two helices in a helical or a/b protein and in the coiled-coil structural motifs. Figure 2 shows some typical side-chain contact map patterns.

Figure 2. Representative patterns of side-chain contact maps describing interactions between a-helices (top) and between b-strands in parallel and antiparallel beta-sheets (bottom).



5. Application of Contact Maps in Modeling Protein Structure

Contact maps provide a very convenient way of identifying pairwise interactions within protein structures. This has been applied in various algorithms for threading protein sequences, where contact maps are actually used as ersatz template structures (4). In computer simulations of biological molecules, contact maps provide a convenient way of displaying structural changes. Also, regularities of the patterns seen in all classes of proteins can provide a guideline for designing knowledge-based multibody potentials (12, 13) and for protein modeling in a reduced (and perhaps also in all-atom) representation (13, 14). Such potentials may be necessary to reproduce the all-or-none character of protein folding transitions in model simulations (15).

One can easily recognize the distinct features of well-defined contact maps, with their characteristic patterns, after inspecting several maps of various proteins. This is an excellent example of a pattern recognition problem that could be learned by **neural network calculations**. Then such a trained network can be used for the automated recognition of good versus poor models of protein structure (16).

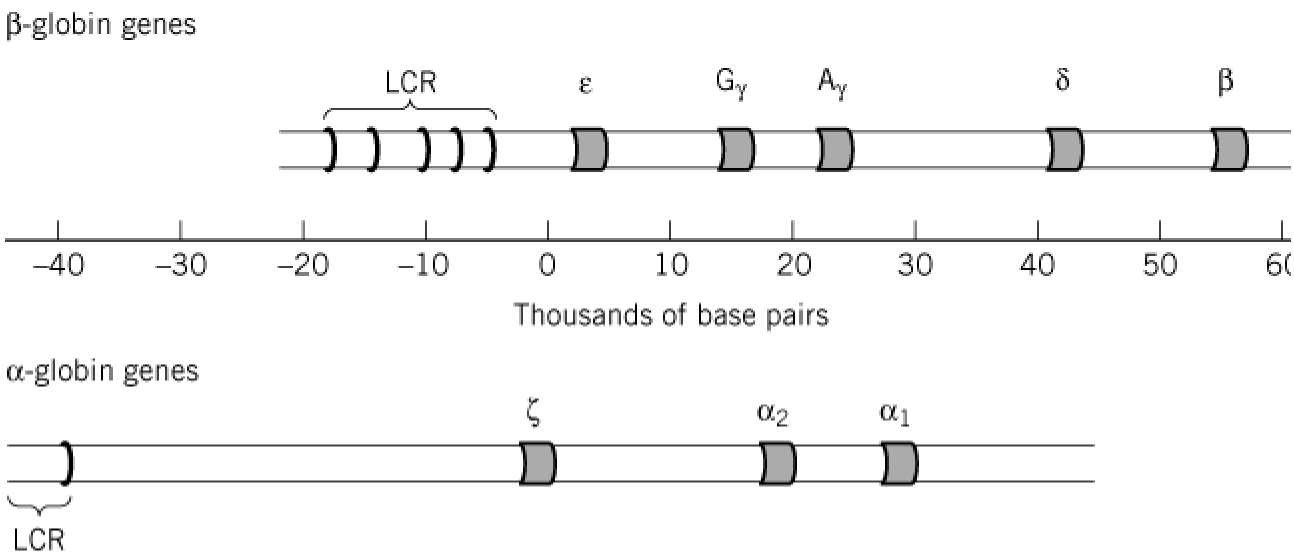
Contiguous Genes

The order of genes on a chromosome and the existence of directly contiguous genes can be useful in understanding their individual functions and in mapping the genome to understand the function of chromosomal **domains**. In **prokaryotes** there is often a close linkage of genes involved in a common metabolic pathway. This type of linkage is uncommon in **eukaryotes**, although examples exist, including five genes in *Neurospora crassa* involved in synthesis of chorismic acid (1) and two genes in *Drosophila* melanogaster involved in purine metabolism (2).

There are several families of closely linked genes in humans. These include genes for alcohol dehydrogenase, a-amylase, the major histocompatibility complex, a-globins, b-globins, chorionic gonadotropin, luteinizing hormone, and growth hormone. Every chromosome has at least one family cluster of undispersed genes. These clusters vary in size from several thousand base pairs to millions of base pairs with a large cluster like the major histocompatibility complex. The members of a single **gene family** are derived from the gene duplication of single ancestral genes. Whereas gene families are rare in prokaryotes, the more complex differentiative states in eukaryotes require similar gene products with subtle differences in function. An example of a well-studied locus, where genes with closely related functions are linked together, occurs at the a- and b-globin loci. At these chromosomal sites, globin genes specific for embryos, neonatal and adult animals are linked together and expressed in a sequential fashion during development (Fig. 1). The globin loci also present interesting examples of where gene linkage helps understanding the chromosomal function. All of the globin genes depend on a super enhancer known as a **locus control region** (LCR), which functions over an entire chromosomal **domain**.

Figure 1. The b-globin gene cluster, which is on the short arm of chromosome 11 in humans and includes five genes tha are sequentially expressed during development. Its locus control region (LCR) consists of five short stretches of DNA extending over a span of 12 bp. Similarly, there are three a-globin genes on the short arm of chromosome 16, but that LC comprises only one DNA sequence far upstream.



The relative order of genes is often conserved within a chromosome.This is termed linkage conservation. Linkage conservation often occurs in chromosomes isolated from distinct species. For example, in the X-chromosome there are many genes that have the same order along the chromosome in both mouse and humans. This is a useful aid in mapping new genes. There are several potential evolutionary advantages to linking certain genes together, which include common regulatory mechanisms, at the level of establishing a functional chromosomal domain, as described for the globin genes (3), or in terms of coordinate expression, as described for two genes involved in a particular metabolic pathway. There may also be regulatory mechanisms where genes compete with each other for a common regulatory element, as occurs in the globin genes at certain times in development (4).

Contrast Variation

"Contrast" in scattering and diffraction experiments is defined as the difference between the mean scattering density of a component and its background, which can be a solvent or other components of an assembly of biological molecules. The greater the contrast, the more readily a component can be distinguished from its surroundings. "Contrast variation" involves the manipulation of the contrasts of specific components in a system in order to extract structural information on individual components. Contrast variation used in combination with small-angle scattering is a powerful method for examining the shapes and interactions of biological molecules in solution. If one has ordered samples, then contrast variation used in combination with **neutron diffraction** experiments can give important information on the location of disordered components that cannot be seen in X-ray diffraction experiments.

1. Contrast Variation with Neutrons

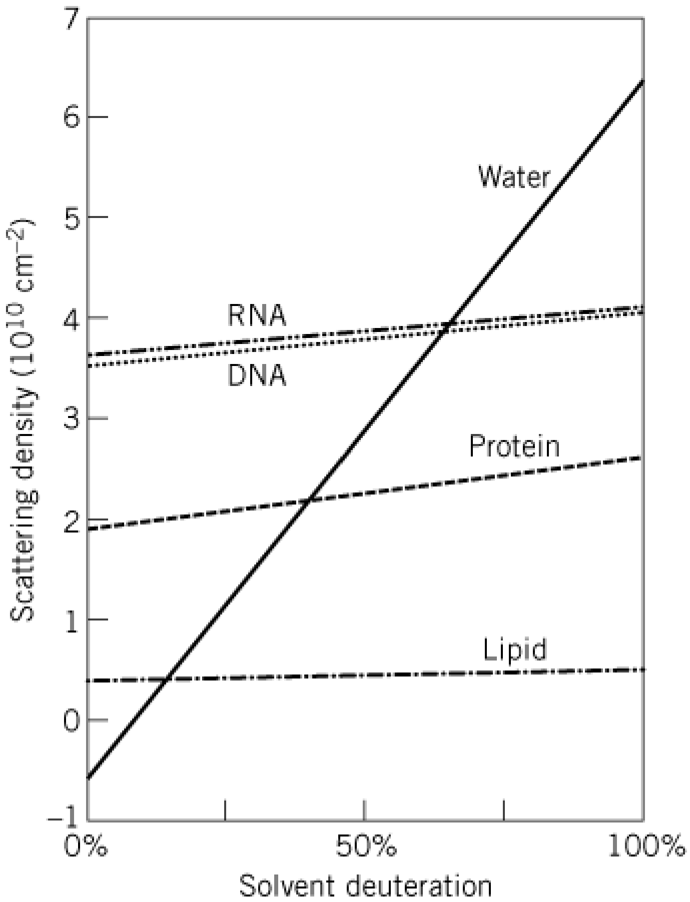
Either contrast variation experiments take advantage of inherent differences in scattering density between components of a complex or assembly, or the experimenter introduces contrast into the system by manipulating the scattering density of a specific component. Scattering densities are calculated by summing the scattering amplitudes of each atom within a volume and dividing by that volume. Because X-rays are scattered by electrons and the X-ray scattering amplitudes of atoms increase monotonically with the number of electrons, it is difficult to change the scattering density of a biological molecule in a benign way. On the other hand, neutrons provide extremely elegant and practical means for contrast variation. Neutrons are scattered by atomic nuclei in a sample. Hence neutron scattering amplitudes depend upon the complex properties of the neutron–nucleus interaction, and they show no systematic dependence on atomic number. Furthermore, isotopes of the same element can have very different neutron scattering properties. For neutrons, one of the largest differences in neutron scattering amplitude is between the isotopes of hydrogen (^1H and ^2H). Table 1 lists the coherent, elastic neutron scattering amplitudes for the atoms commonly found in biological systems. Note that the scattering amplitudes for most nuclei are positive and approximately equal. The exception is the scattering amplitude for ^{1}H which is negative, resulting from a 180° phase shift between neutrons scattered by ^{1}H compared to the other nuclei. As a consequence, the neutron scattering density of a particle depends strongly on its mean hydrogen content. The basic biological constituents, proteins, polynucleotides, and lipids, each have quite different mean neutron scattering densities (Fig. 1). Furthermore, the scattering densities for pure $^{1}H_2O$ and $^{2}H_2O$ bracket the values for biological constituents. Thus by simply varying the $^{2}H_2O$:$^{1}H_2O$ ratio in the solvent, one can do a contrast variation experiment on a protein–DNA complex, or a membrane protein in a bilayer. For a complex of proteins, selective deuteration of individual proteins provides a way of altering their mean neutron scattering densities for contrast variation studies. Recently, it has been demonstrated that one can obtain dramatically increased contrast effects using a novel method of "spin contrast variation." This method uses polarized neutron scattering from samples labeled with dynamically polarized nuclei and has been demonstrated to be effective for studying biological systems by locating RNA (1) and proteins (2, 3) in ribosomes.

Table 1. Coherent Neutron Scattering Lengths, b_{coh}, and Corresponding X-Ray Scattering Factors, $f_{X\text{-ray}}$, for Biologically Relevant Nuclei

Atom	Nucleus	(10^{-12} cm)	f_X for q = 0(10^{-12} cm)[a]
Hydrogen	^{1}H	–0.3742	0.28
Deuterium	^{2}H	0.6671	0.28
Carbon	^{12}C	0.6651	1.69
Nitrogen	^{14}N	0.940	1.97
Oxygen	^{16}O	0.5804	2.25
Phosphorous	^{31}P	0.517	4.23
Sulfur	mostly ^{32}S	0.2847	4.5

[a] X-ray scattering amplitudes are normally given in units of electrons, but have been converted to cm here for comparison with neutron scattering amplitudes. At very short wavelengths and low-Q, the X-ray coherent scattering cross-section of an atom with Z electrons is $4p(Zr_0)^2$, where $r_0 = e^2/m_e c^2 = 0.28 \times 10^{-12}$ cm.

Figure 1. Average scattering length densities for biological molecules as a function of the fraction of D_2O in the solvent. The slope of the lines arises from the exchange of labile hydrogens.



2. Small-Angle Scattering with Contrast Variation

The scattering intensity distribution from a homogeneous solution of monodisperse particles in a solution can then be expressed as

$$I(Q) = \int\int \Delta\rho(\mathbf{r}_1)\Delta\rho(\mathbf{r}_2)\frac{\sin Q|\mathbf{r}-1-\mathbf{r}_2|}{Q|\mathbf{r}_1-\mathbf{r}_2|}d\mathbf{r}_1 d\mathbf{r}_2 \qquad (1)$$

The integration is taken over the volume of the particle. Q is the momentum transfer or scattering vector amplitude and is equal to 4p(sin q)/l, where q is half the scattering angle, and l is the wavelength of the incident neutron radiation. Dr(**r**) = r(**r**) – r_s is the "contrast," or neutron scattering density difference between the particle and the solvent. For uniform scattering density particles, if one can "match," or make equal, the scattering density of a particle and its solvent, then the small-angle scattering from that particle will be zero; that is, the particle will become "invisible" in the scattering experiment. For a multicomponent assembly, one can use this technique to study the shape of an individual component within the assembly. Rigorous solvent matching can be difficult, however, and is made more difficult when there are significant internal density fluctuations within the component being matched.

For a two-component complex in solution, one can conduct a series of measurements at different contrast points ("contrast series") to extract the basic scattering functions of individual components. Ignoring internal scattering density fluctuations, the scattering from a two-component complex in solution can be written as

$$I(Q,\Delta\rho_1,\Delta\rho_2) = \Delta\rho_1^2 I_1(Q) + \Delta\rho_1\Delta\rho_2 I_{12}(Q) + \Delta\rho_2^2 I_2(Q) \qquad (2)$$

The subscripts 1 and 2 refer to each component; and $Dr_{1(2)} = r_{1(2)} - r_s$, where $r_{1(2)}$ is that mean scattering density for component 1 (or 2). $I_1(Q)$ and $I_2(Q)$ represent the scattering of components 1 and 2, respectively, while $I_{12}(Q)$ is the cross term. A set of scattering measurements with different solvent scattering densities, or contrasts, gives a set of equations in the form of equation 2, which can be solved by linear least-squares regression to give the three basic scattering functions $I_1(Q)$, $I_2(Q)$, and $I_{12}(Q)$. Using these functions, the individual structural parameters for each component such as molecular weight, radius of gyration, R_g, and the pair distribution function, $P(r)$, can be calculated, as well as information on the relative dispositions of the individual components (see Small-Angle Scattering and Radius Of Gyration for details). $P(r)$ is the probable frequency distribution of all vector lengths between pairs of volume elements within the scattering component, weighted by the product of the scattering densities of each pair of volume elements. $P(r)$ is calculated as the indirect Fourier transform of the basic scattering function for each component, and its second moment gives R_g for that component. The indirect Fourier transform of the cross term $I_{12}(Q)$ gives the pair distribution function containing intercomponent vector lengths, which can give information on the distance between the two components.

Ibel and Stuhrmann (4) proposed an alternative approach to determining the relative dispositions of components in a complex. They showed that the $R_g^{\,2}$ dependence on the scattering contrast can be written as

$$R_g^2 = R_m^2 + \frac{\alpha}{\Delta\rho} - \frac{\beta}{\Delta\rho^2} \qquad (3)$$

where R_m is R_g at infinite contrast; and $Dr = r - r_s$, where r is the mean scattering density for the complex and r_s is the scattering density of the solvent. The coefficient a is related to the second moment of the scattering density fluctuations about the mean value for the complex, while b is related to the square of the first moment of the density fluctuations about the mean. If the sign of a is positive, the lower scattering density component is more toward the inside of the complex than the higher scattering density component. A negative a indicates the reverse. b is proportional to the square of the separation of the centers of mass of the two components. If b is zero, then the centers of mass are coincident.

3. Deuteration of Biological Molecules

Neutron scattering and/or diffraction experiments using contrast variation frequently depend upon the ability to reconstitute complexes with specific components labeled uniformly with deuterium. Deuteration of biological molecules is achieved by growing microorganisms on deuterated media. Relatively high average levels of deuteration (50% for nucleic acids, 70 to 80% for proteins) can be achieved by growing organisms on ^2H_2O with normal protiated carbon sources (5). Typically, however, the aromatic groups are not highly deuterated using this approach. Higher levels of enrichment (> 99%) are achieved using deuterated nutrients and ^2H_2O (5). Deuterated algal hydrolysate provides an excellent rich growth medium for *E. coli* containing an expression system with a specific protein of interest. If the expression is sufficiently robust, deuteration can be achieved in minimal growth media with deuterated glucose, glycerol, or succinate in ^2H_2O. Intermediate levels of uniform deuterium labeling can be achieved by diluting ^2H with ^1H in the growth medium.

4. Examples of the Application of Contrast Variation

4.1. Small-Angle Scattering and Contrast Variation

Examples of significant advances based on small-angle neutron scattering with contrast variation include: the solution structure of the nucleosome core particle showing the DNA winding around the outside of the histone core (6, 7); mapping the radial distribution of protein and nucleic acid components in the influenza virus (8); determining the subunit structure of DNA-dependent **RNA polymerase** (9) and its relationship to a 130-bp DNA fragment (10); the subunit structure of a ribosome particle, showing the dispositions its components (11, 12) (see Neutron Diffraction And Scattering); and the determination of the conformations and dispositions calmodulin complexed with its target enzymes (13) and of the evolutionarily related muscle protein troponin C (TnC) complexed with its regulatory target troponin I (TnI) (13) which acts as a calcium-sensitive “switch” to regulate the contractile apparatus. Figure 2 illustrates this latter experiment, showing the model derived from a neutron contrast series on complexes of TnI with deuterated TnC in its calcium-saturated form (14). The neutron data show TnC in the complex has the unusual dumbbell shape evident in the TnC crystal structure (15, 16), while TnI forms a spiral structure that passes through two hydrophobic clefts in each globular domain of TnC. The diameter of the TnI central spiral is close to that expected for an a-helix. The model suggests a mechanism for the action of the calcium-sensitive TnC/TnI molecular switch. The hydrophobic cleft of the *N*-terminal regulatory domain of TnC alternately opens and closes (in response to calcium binding and release) and thus binds and releases TnI, which in turn switches “off” and “on” TnI's inhibition of the interactions between the muscle fibers required for contraction.

Figure 2. Model structure for the muscle protein complex troponin C/troponin I derived from small-angle neutron scattering and contrast variation (14). Troponin C is represented as a space filling model based on its crystal structure, and the green crosses represent the volume occupied by the troponin I. This figure is based on work done at Los Alamos National Laboratory. See color insert.

4.2. Diffraction Experiments with Contrast Variation

In crystals of large biomolecular complexes, there are frequently disordered regions, even when the diffraction data extend to relatively high resolution. The scattering from the disordered components is seen predominantly at low-*Q*—that is, in the "small-angle" region where the contrast effects can be strong. Deuteration strategies similar to those used in small-angle neutron scattering allow for contrast manipulation. Phase information can be derived for the low-*Q* data using contrast-variation procedures (17), beginning with starting phases from a X-ray crystallography or a model structure and using the contrast-variation relationships to produce the best scattering-density maps (18). Examples of experiments using contrast variation and low-resolution neutron crystallography include the determination of the location of 25% of the protein and the RNA in crystals of the Tomato Bushy Stunt Virus (19) that were "missing" in the 2.8 Å resolution X-ray structure. The most important conclusion of this study is that at the virus radius where the protein and RNA interact, the quasi-equivalence of the 180-protein subunits breaks down, and the RNA interacts preferentially with 60 of the subunits. This observation favors a model for self-assembly in which the RNA interacts with trimers of protein to form an icosahedral scaffolding in which the gaps are filled by the other 120 subunits which have nonspecific contacts with the RNA (see Capsids, Viral). Another example of the application of low-resolution neutron diffraction and contrast variation is in membrane protein crystallography, where it has been used to locate and orient detergent molecules with respect to the protein (20, 21). These experiments take advantage of the inherent high contrast between detergent and ^2H_2O; and they provide information on the role of detergent in membrane protein crystallization, as well as the potential lipid–protein interactions.

Controlling Element

Controlling element is the term used by Barbara McClintock (1) to describe the new genetic elements she found in the late 1940s that "can modify and control the action of the genes themselves" and "may move from location to location within the chromosome complement without losing its identity." We now know such elements as transposable elements—that is, discrete pieces of DNA that can move from place to place within a genome. Such elements are extremely widespread and have been found in virtually all organisms that have been examined. It is interesting that she discovered these elements that we now know to be mobile DNA before the structure of DNA was established in the early 1950s. The first molecular characterization of transposable elements came nearly 20 years later, after their discovery in bacteria, where DNAs containing them could be isolated and characterized (2).

McClintock was a maize geneticist and cytogeneticist. Her discovery of controlling elements resulted from the study of irregular patterns of pigment in maize kernels (ie, variegations of pigment patterns) that arose in some ears. Such variegation results in changes in pigment gene expression during kernel development. We now know that such variegation reflects the insertion of a transposable element to inactivate a gene and the subsequent excision of the element at a later time, restoring gene function. Having earlier studied chromosome breaks that resulted from unusual chromosome fusions, she was also quick to appreciate that some variegation resulted from chromosomal breakage at a particular site. She proposed that there was an element *dissociation* (Ds) at the breakage site and suggested that variegation results from the loss of genes downstream of this site following chromosome breakage.

Identification of an element that could cause chromosome breaks was novel, but even more dramatic was her finding that the element could move to another chromosomal site and again cause instability via chromosome breakage. McClintock realized that another element in addition to Ds was required to cause breaks at Ds and also to promote the translocation of Ds to another chromosomal position—that is, that another element encodes a product that promotes the movement of Ds. She named this other element *activator* (Ac) and also established that Ac could move from place to place.

We now know that Ac is an intact (autonomous) element (about 2.9 kbp) encoding a recombinase, a transposase, that acts on special sequences at the tips of the element to promote its translocation; Ds is a deleted version of Ac that lacks the transposase but still has the special terminal recombination sequences, so that Ac transposase can promote movement of Ds. Ds is called a **nonautonomous element** because it requires the presence of transposase provided by another element.

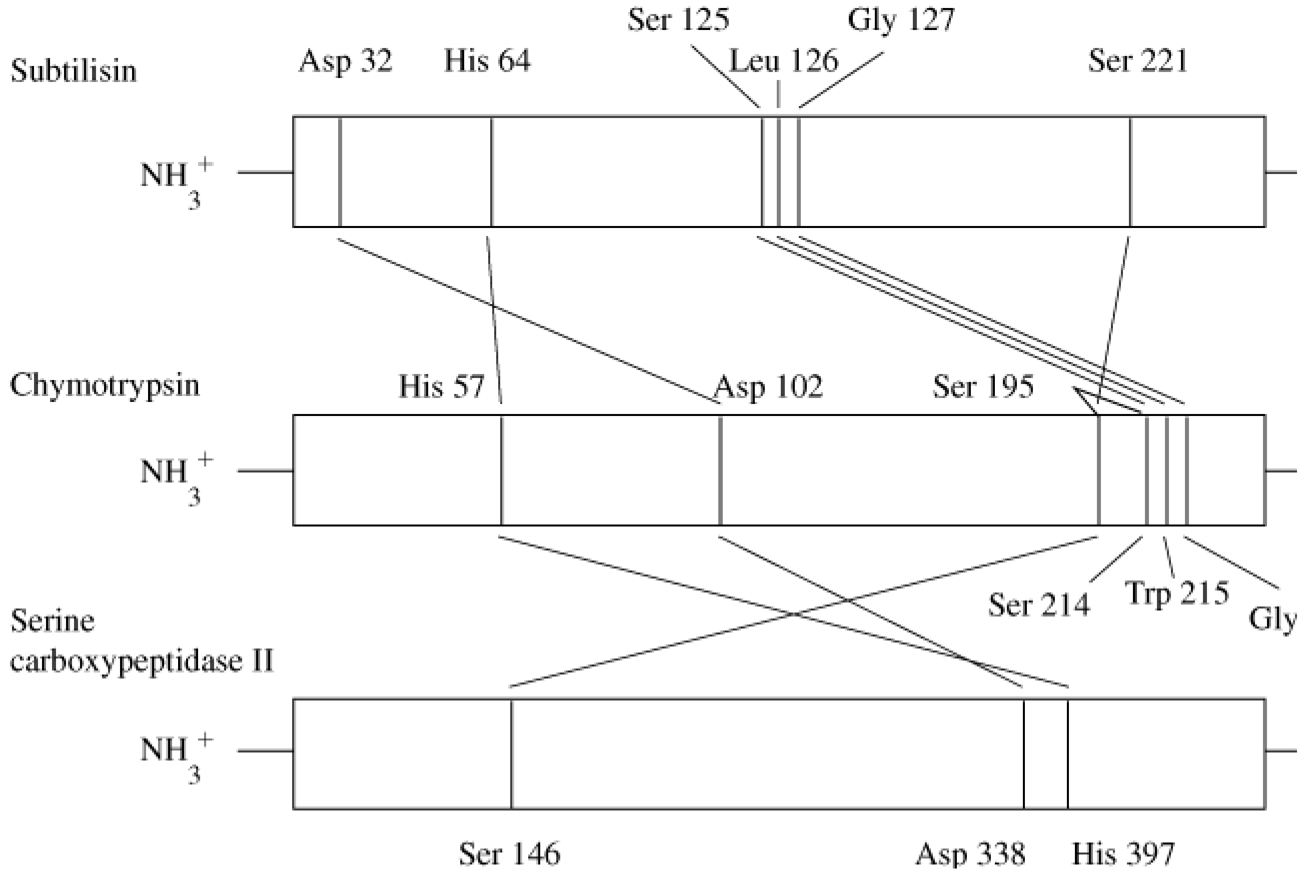
Convergent Evolution

Convergence is defined as an evolutionary event in which two morphological or molecular traits become similar during evolution due to a similarity in environment or selection pressure, even though these traits have independent ancestors or origins. In the case of amino acid or **nucleotide sequences**, there is little known evidence for convergence; the probability of two sequences becoming similar by convergence seems vanishingly small, and any similarities in sequence are attributed to divergent evolution. Yet even the absence of sequence similarity cannot be taken as evidence of convergence, as this will also result from extensive divergence between two sequences that originated from a common ancestor. In many such cases where proteins related functionally have no detectable sequence homology, their three-dimensional protein structures are very similar; protein structure appears to change more slowly than does the primary structure, and such cases seem to be further examples of divergent evolution.

There are, however, some examples of convergence that are apparent in the protein structure and the active sites of enzymes. For example, there are several kinds of serine proteinases. One family of these proteinases, represented by **chymotrypsin**, has very similar tertiary structures and active sites, containing a catalytic triad of serine, histidine, and aspartic acid residues. The serine proteinase subtilisin also contains an extremely similar triad structure, even though the rest of its tertiary structure and sequence is unrelated to the chymotrypsin family (Fig. 1) (1). Moreover, the three residues constituting the catalytic triad occur in different orders in the primary structures, making it virtually inconceivable that the two families of proteins arose from a common ancestor. Furthermore, serine carboxypeptidase II also contains a catalytic triad at its active site, even though its catalytic mechanism is entirely different. It is considered that the very similar triad structures of these different protein families emerged from their respective and independent ancestors by positive natural selection. This is one of the best characterized examples of convergent evolution.

Figure 1. Convergent evolution of the active site residues in subtilisin, chymotrypsin, and serine carboxypeptidase II. Al relative positions of active-site residues differ in the amino acid sequences among subtilisin, chymotrypsin, and serine carboxypeptidase II, they have a common catalytic triad consisting of Ser 221, His 64, and Asp 32 in subtilisin; of Ser 1 and Asp102 in chymotrypsin; and of Ser 146, His 397, and Asp 338 in serine carboxypeptidase II. Thus, they are conside examples of convergence or convergent evolution (2).



There are other examples of enzymes with the same functions but sufficient differences to make it clear that they have not arisen from the same ancestor, but that the same function has arisen independently by a type of convergent evolution (Table 1) (2).

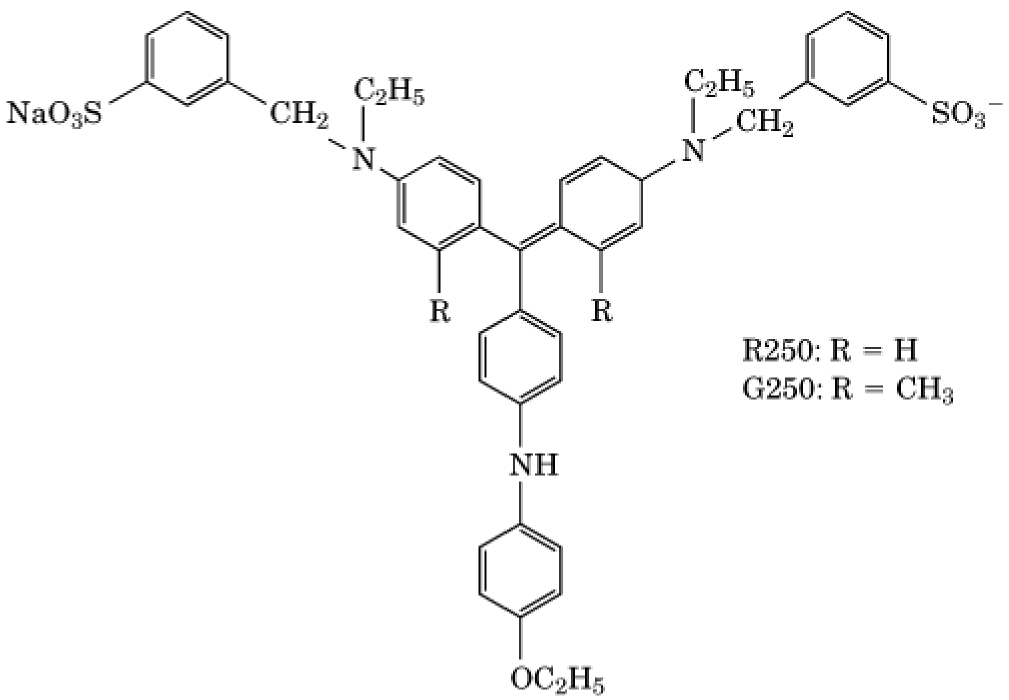
Coomassie Brilliant Blue

Proteins are most frequently detected after gel electrophoresis by fixing them in the gel, so that they do not diffuse further, and then staining them to produce a colored zone. The most sensitive stain is silver stain, but the stain used most frequently is Coomassie Brilliant Blue. It has two frequently encountered forms, R250 and G250, whose structures are depicted in Figure 1. Although the two dyes are structurally very similar, they require different physical and staining procedures and are not interchangeable in any particular protocol. These two dyes do not react chemically with proteins but merely form noncovalent complexes. The interaction with proteins is believed to be primarily ionic and involves the acidic sulfonate groups on the dye and basic groups on the protein, but nonpolar **van der Waals** forces are probably also involved. Consequently, the dyes do not bind equally to all proteins, so two electrophoretic bands with the same blue color need not contain the same amount of protein (1).

Figure 1. The chemical structures of the R250 and G250 forms of Coomassie Brilliant Blue. They differ only in the nature of the group R.



Electrophoresis gels are readily stained by placing the gel in a liquid containing the Coomassie dye plus an agent to fix the protein bands, usually acetic acid plus methanol; a solution of 10% (w/v)

trichloroacetic acid plus 10%(w/v) sulfosalicylic acid is very effective for fixing and staining. Fixed and insoluble proteins bind the dye tightly. It is usually necessary to remove the excess dye from the staining mixture before the bands on the gel can be seen. This is usually accomplished simply by washing the gel in the fixative solution, but it can also be accomplished by adding an agent, such as polyurethane foam, that binds the excess dye tightly. It is important not to remove all of the excess dye from the solution because then the dye bound to the protein bands dissociates and the gel becomes bleached. The procedure is simplified if the Coomassie dye is only slightly soluble in the original staining mixture; the protein takes up the dye from the solution, but the background color remains weak.

A number of other dyes, such as Ponceau S and Amido black, can be used in the same way, but they are not as sensitive as the Coomassie dyes. Coomassie Brilliant Blue detects approximately 0.1 µg of protein in a band on a polyacrylamide gel.

Coomassie Brilliant Blue, particularly G250, is also used to quantify the amount of protein in solution, which is known as the Bradford assay (2). The dye complexed to protein has an altered **absorbance** spectrum. Under certain acidic conditions, the absorbance maximum shifts from 465 to 595 nm upon binding to a protein. Even though different proteins give somewhat different responses in this assay, its simplicity makes it widely used.

Cordycepin

Cordycepin is 3′-deoxyadenosine, but is normally used in molecular biology as the triphosphate form. 3′-Deoxyadenosine triphosphate is a chain-terminating nucleotide analogue of ATP that can be incorporated into an **RNA** by polyadenylate polymerase. This inhibits further elongation of the poly A tail due to the absence of the 3′-hydroxyl group. The cordycepin triphosphate has been used primarily to study the polyadenylation reaction *in vitro*, where it has allowed this reaction to be resolved into two distinct steps: cleavage of the messenger RNA precursor and the addition of the poly A tail (see Polyadenylation) (1, 2).

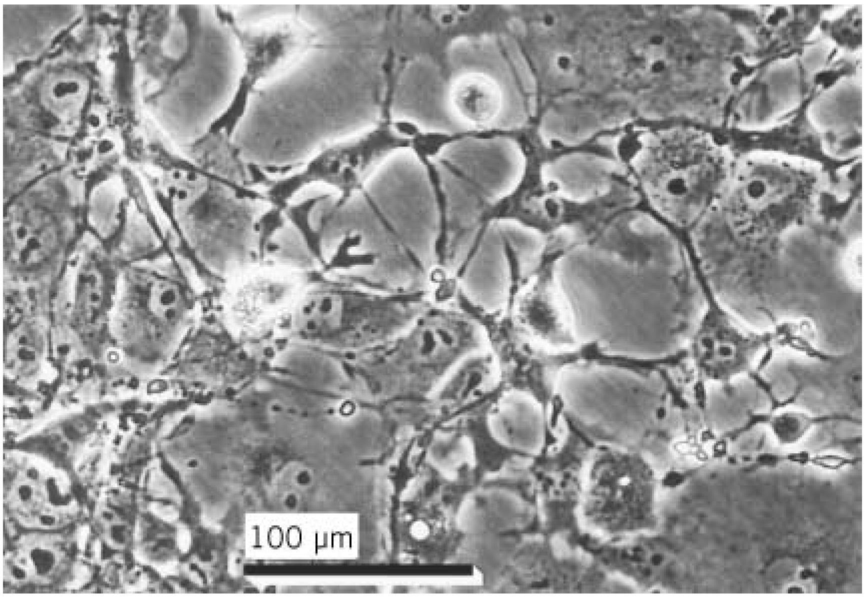
Corepressor

A corepressor is a molecule that binds to a sequence-specific DNA binding protein and enables that protein to direct transcriptional repression. The term is used to apply to two types of mechanism. In the first case, a small molecule binds to and effects a conformational change in a DNA-binding protein, thus, enabling binding to a specific DNA sequence. One example of this mode of action is the binding of tryptophan to the tryptophan repressor. The second type of corepressor is a protein that forms a specific complex with a sequence-specific DNA binding protein and then itself inhibits transcription either directly or indirectly. One example of such an activity is the complex formed in eukaryotes between histone deacetylases and DNA-targeted regulators via an adaptor protein.

COS Cells

COS cells are monkey kidney fibroblasts (Fig. 1); they have become popular in recent years because they support certain strains of replication-deficient animal **viruses** (1, 2) and can be **transfected** easily (3, 4). Two lines are in common use, COS-7 (ATCC CRL-1651) and COS-1 (ATCC CRL-1650).

Figure 1. Confluent culture of COS-7 cells. Phase contrast, Olympus CK microscope, 20× objective.



1. Origin

Both cell lines were derived from CV-1 cells (ATCC CCL-70), an established cell line of simian fibroblasts, by transformation with an origin-defective mutant of **SV40 virus** (1). Both are **T-antigen**-positive, permit lytic growth of SV40, and support the replication of temperature-sensitive mutant SV40 tsA209 and of SV40 mutants with deletions in the early region. COS-1 cells contain a single integrated copy of the complete early region of the SV40 genome.

2. Properties

COS cells are propagated as a monolayer in the alpha modification of Eagle's minimal essential medium (a-MEM) supplemented with 10% fetal bovine serum (see Serum Dependence) or in Dulbecco's modification of Eagle's medium. They grow rapidly, with an approximate population doubling time of 18 h.

3. Usage

COS cells have been used extensively in DNA transfer studies (5-7) and have been transfected by a number of different methods, including calcium phosphate (8), DEAE (4), and lipid transfection (9).

COSY Spectrum

Correlation spectroscopy (COSY) was among the first two-dimensional (2D) nuclear magnetic resonance (NMR) experiments to be developed. In COSY–type experiments, cross peaks arise in a 2D map at the intersections of two chemical shifts if a resolved spin-coupling interaction exists between the nuclei characterized by the two shifts. The cross peaks have considerable fine structure, consisting of positive and negative signals if the lines of the spectrum are sufficiently narrow.

The appearance of the cross peaks in a COSY–type experiment relates to a quantum-mechanical phenomenon known as coherence transfer. In NMR, a coherence is characterized by a specific Larmor precessional frequency that is essentially defined by the magnetic field of the spectrometer and the chemical shifts of the spins involved in the creation of the coherence. A cross peak in COSY–type experiments develops because magnetization that was initially characterized by one precessional frequency is converted at some point to a coherence that precesses at a different frequency, defined by another chemical shift. The COSY 2D experiment in effect measures the precessional frequency of the coherence during both parts of the experiment. Coherence transfer occurs only if spins are J-coupled to each other. In peptide and protein systems, the appearance of a cross peak in proton-proton COSY experiments generally identifies sets of protons that are adjacent to each other in the covalent structure. With sufficiently narrow lines, it is possible to analyze the structure of COSY cross peaks to obtain values for the spin-spin coupling constant involved in the coupling interaction signaled by the cross peak.

Many variations on the basic ideas of the COSY experiment are now available, including DQFCOSY (double quantum filtered COSY). The advantages of the DQFCOSY experiment include a much narrower set of diagonal peaks (so that cross peaks close to the diagonal can be detected more readily) and drastic reduction of the intensities of singlets. Such singlets tend to be very intense and can cause noise and various artifacts in a 2D spectrum.

Note the requirement that a resolved spin-coupling interaction be present for optimum detection of a COSY–type cross peak. With greater molecular weights of samples, proton NMR spectral lines increase in width. Under these conditions, the positive and negative components of COSY cross peaks can begin to cancel one another, with the detection of the cross peak relative to noise becoming more difficult. Thus, although the presence of a cross peak in a COSY–type spectrum indicates mutual spin coupling between (probably) adjacent groups of protons, the absence of a cross peak in a COSY–type spectrum cannot be taken as evidence that two nuclei are not coupled to each other.

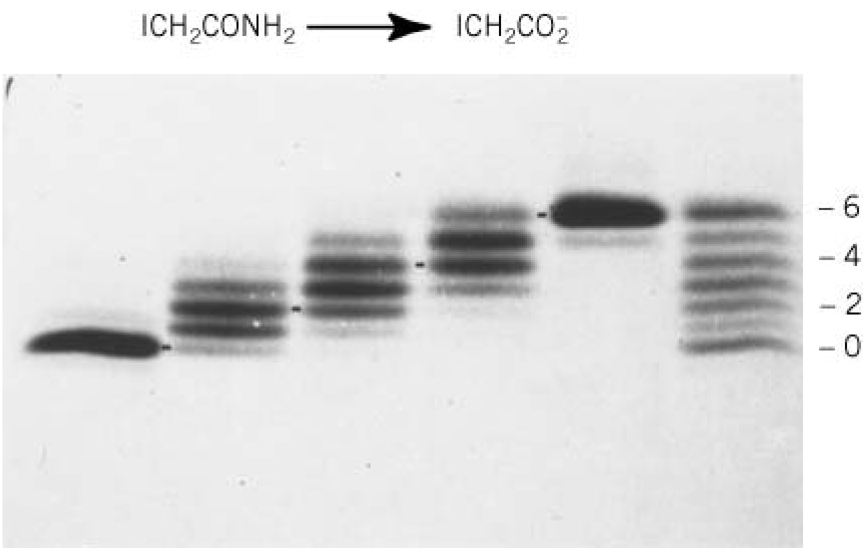
Counting Residues

Natural proteins have integral numbers of each of the twenty amino acids in a polypeptide chain, but most currently accepted methods of determining this number by amino acid analysis yield only a nonintegral ratio of moles of amino acid per mole of protein. This value is rarely close to an integer because of experimental error and uncertainty about the **molecular weight** of the protein. The method described here determines the integral number of residues of certain amino acids, independently of any other property of the polypeptide chain, including its molecular weight. Then this information is combined with amino acid analysis to determine a more accurate value for the molecular weight and the number of other amino acids. The method also provides information about the net charge on a protein.

The general procedure is to modify the *N* residues of a given amino acid gradually and specifically, so as to generate a complete spectrum of molecules with 0, 1, 2, 3, ¼, *N* of the groups modified. A single modification reaction can be used, varying the average extent of the reaction. Alternatively, one uses the competition with a related, but distinguishable reagent and carry out the modification to completion. Then the modified species generated are counted after separating them by a technique sensitive only to the number of groups modified by the particular reagent. The most useful modifications are those that alter the electric charge of a residue. Then the number of modifications introduced is determined by separating the various species by electrophoresis, isoelectric focusing, or ion exchange chromatography. The separation must be sensitive only to the number of groups modified in charge, not which particular ones in the polypeptide chain. This is usually accomplished by carrying out the modification and the separation on unfolded molecules, where differences between the *N* residues are minimized. There should be (*N* + 1) species present.

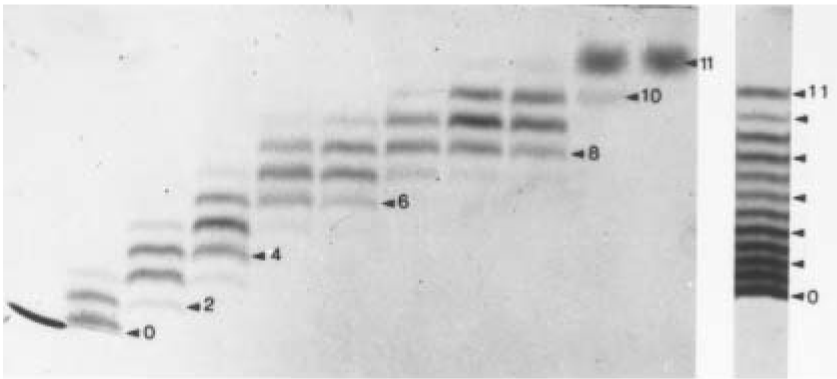
The thiol groups of cysteine residues are reacted with a reagent like **iodoacetic acid**, which introduces an acidic group. This reaction competes with that with the closely related iodoacetamide, which is neutral and does not introduce a charged group. The reaction of the thiol groups is taken to completion, and the number of acidic groups introduced is varied by varying the ratio of iodoacetic acid to iodoacetamide (Fig. 1). The number of acidic groups introduced is determined by electrophoresis under denaturing conditions. In addition to the number of total cysteine residues or thiol groups, the number of disulfide bonds can be determined by counting the thiol groups present before and after reduction of the disulfide bonds.

Figure 1. Counting the six cysteine residues of reduced BPTI. The reduced protein was reacted with the neutral iodoacetamide (1st lane), acidic iodoacetic acid (5th lane), and mixtures of the two in the ratios 1:1, 1:3, and 1:9 in lanes 2, 3, and 4, respectively. Lane 6 contains a mixture of equal portions of the samples applied to lanes 1 to 5. Electrophoresis of the basic protein was in 8 *M* urea from top to bottom. The electrophoretic mobility is decreased in proportion to the number of acidic carboxymethyl groups on each molecule; the number for each of the electrophoretic bands is indicated at the right. The competition between the two reagents indicates that iodoacetamide reacts three times more rapidly than iodoacetic acid under the conditions used here. From Ref. 1.

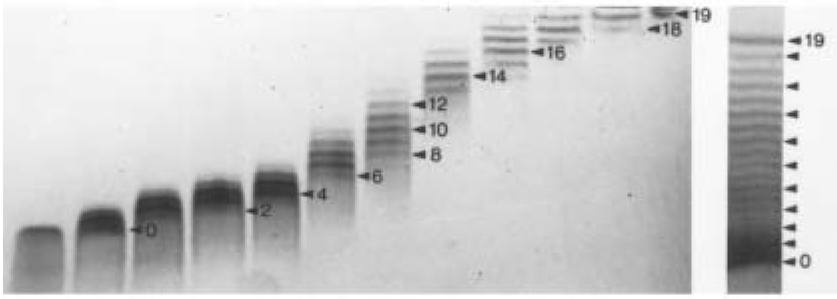


The amino groups of **lysine residues** and at the N-terminus can be modified specifically by reacting them with a reagent like succinic anhydride, which replaces a basic amino group with an acidic group. Consequently, the net charge of the protein can change by up two units for each amino group reacted. The reaction is varied in its extent by varying the amount of reagent added to the unfolded protein (Fig. 2).

Figure 2. Counting amino groups of bovine **ribonuclease A** (**a**) and horse ferri**cytochrome c** (**b**) by electrophoretically separating the mixtures produced by progressive succinylation. The original unmodified protein is on the left, and the degree of succinylation increases to the right. Electrophoresis was in 8 M urea at pH 3.6 from top to bottom. The separate lane on the far right is of a mixture obtained by combining all of the individual samples. In this case, electrophoresis was at the slightly lower pH of 3.45. Alternating bands are marked by arrows, and the number of succinyl groups is indicated for a few of the bands. The results confirm the presence of 11 and 19 amino groups in ribonuclease A and cytochrome *c*, respectively. From Ref. 2.



(a)



(b)

Other amino acids for which specific modifications are possible may be counted in the same way, in theory, but the specific techniques have not yet been developed.

In each of the previous procedures, the number of groups modified is counted by the number of new bands apparent by electrophoresis. Electrophoretic mobility is proportional to the net charge of the protein molecule, which is changed gradually by modifiying specific residues. Therefore, the net charge on the original protein molecule can be determined by measuring the degree of modification necessary to give the protein zero electrophoretic mobility or by using stepwise modification to establish a scale for electrophoretic mobility as a function of changes in net charge.

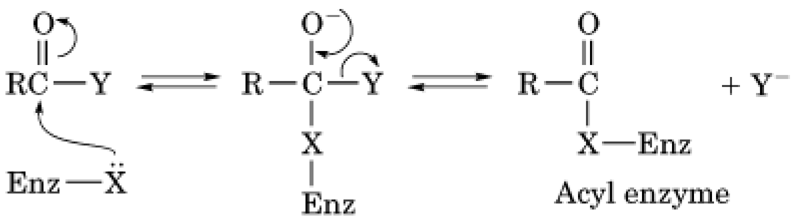
Covalent Catalysis

Covalent catalysis by an enzyme involves the formation, along the reaction pathway, of a covalent enzyme intermediate that can be formed and broken down at a rapid rate. Covalent bonds are formed most commonly as a result of the attack by an enzyme nucleophilic (electron-rich) group on an electrophilic (electron-deficient) moiety of the substrate that is bound at the active site. The nucleophilic groups that are present on the side-chains of amino acid residues are $RCOO^-$, RNH_2, R–OH, and the nitrogen atoms of the imidazole ring of histidine residues. The electrophilic moieties of substrates may be acyl, phosphoryl, or glycosyl groups, so the covalent intermediates would be acyl-, phosphoryl-, and glycosyl-enzyme complexes, respectively. The reactions involved in the formation of an acyl-enzyme are



The second step in covalent catalysis is the attack by a low-molecular-weight nucleophile on the covalent intermediate to release the second reaction product. If the attacking nucleophile is water, the enzyme would catalyze a hydrolytic reaction that conforms to a **kinetic mechanism** with the ordered release of products. If the attacking nucleophile were a second substrate, the reaction would have a ping-pong kinetic mechanism.

Enzyme molecules are poor in electrophilic groups. But electrophilic catalysis does occur with those enzymes that contain metals (see Metal-Requiring Enzymes) or prosthetic groups (see Coenzyme, Cofactor) that act as electron sinks during catalysis.

As a large number of enzymes catalyze reactions through the formation of covalent intermediates, it appears that the this type of catalysis offers some general advantages (1). It has been considered that the immobilization of a covalent intermediate should provide a significant **entropic** driving force and catalytic efficiency is increased by having multiple bond-making and bond-breaking steps occurring within a single active site.

CpG Islands

In some animals, cytosine bases occurring in the sequence CG are frequently methylated to 5-methylcytosine (see Methylation, DNA). Yet even in species where most such residues are methylated, there are genome segments, known as *CpG islands*, which are conspicuously not methylated. These are short, dispersed regions of DNA with a high frequency of CpG dinucleotides relative to the bulk genome, but they are not methylated. In the haploid human genome, it is estimated that there are some 30 to 45 × 10^3 CpG islands. Such regions of DNA are at least 200 bp in length and have a $G + C$ content greater than 50%. Outside these islands, the frequency of CpG sequences is depleted to about only 20% of that expected on a random basis. This bias against CpG sequences that would be methylated is believed to be caused by methylcytosine bases that deaminate spontaneously 10 to 20 times more readily than normal cytosine bases. Furthermore, the product of deamination of 5-methylcytosine is thymine, a normal base, so this mutagenic event is more difficult to repair than usual (see DNA Repair).

CpG islands are associated with the 5′ ends of **housekeeping genes** and of a few tissue-specific genes (highly tissue-specific genes usually lack islands). They have an open chromatin structure, and it has been postulated that they are sites of interaction between transcription factors and **promoters**. All known widely expressed genes are associated with more than one CpG island, which usually includes the transcription start site, and a few of these genes have an additional island in the 3′ direction. The average length of CpG islands is about 240 bp in widely expressed genes, but there is no typical size. Most are between 200 and 1400 bp, and a majority of islands are 200 to 400 bp. The average size of islands associated with genes with limited expression is slightly smaller.

Less than half of tissue-specific expressed genes and of those with limited expression are associated with CpG islands that occur in one or more exons. This implies that CpG islands may be used to identify transcripts, since they occur in exons. Furthermore, CpG islands cover the whole or part of the promoter regions containing canonical TATA box and CAAT box, and they include GC-rich promoters lacking a typical TATA box. Such promoters are considered typical of housekeeping genes.

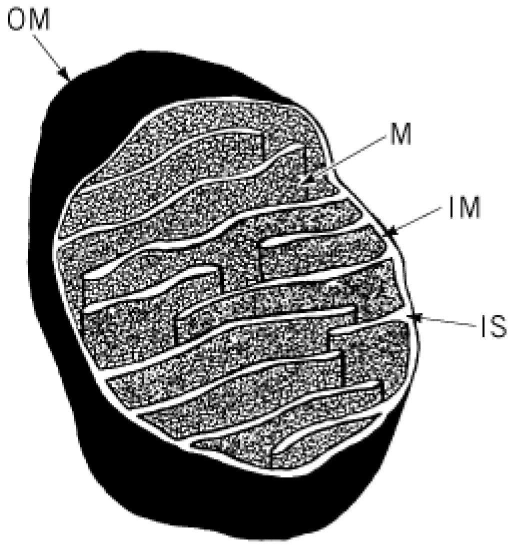
Cristae

Electron microscopy of mitochondria demonstrates that the inner mitochondrial membrane (IM) folds towards the inner part of the mitochondrion and then folds back (Figure 1), thereby forming structures that are called cristae (see Mitochondria). The same morphological evidence has shown that a relationship exists between the development of cristae and the functional activity of mitochondria, which is, in turn, related to the energy requirement of the cell. In fact, folding of the inner mitochondrial membrane is a prerequisite for the structural organization of respiratory enzyme complexes (see ATP Synthase). The IM defines the intermembrane space (IS) and the mitochondrial matrix (M), where most soluble enzymes and the **protein biosynthesis** apparatus are localized, while the respiratory enzyme complexes are localized in the IM. Recently, detailed analysis of mitochondrial inner and outer membranes (OM), of their contacts, and of the localization of proteins in the two membranes, in the intermembrane space, and in the matrix, has led to very important developments in our understanding of the essential aspects of mitochondrial transport. Since the IM and OM separate two distinct spaces in mitochondria, proteins encoded by the cell nucleus and targeted to the mitochondria can be destined to either one of these spaces, or to be integral components of the IM or OM.

Figure 1. Morphology of a mitochondrion derived from electron microscopy (OM = outer membrane; IM = inner membrane; IS = intermembrane space, M = matrix).



Sorting of proteins to mitochondria is generally mediated by presequences, which are by signals composed of 15–35 amino acid residues at the amino terminus (see Signal Peptide). Most proteins to be targeted to the mitochondrion are therefore synthesized on cytoplasmic ribosomes as precursors and then transferred to **receptor** proteins on the mitochondrial surface. The pre-sequences are then inserted across both membranes at contact points, through distinct outer and inner protein-conducting channels. Many components of this complex machinery for importing proteins have recently been identified (1).

Transport requires unfolding and refolding of proteins by chaperonins and is followed by removal of the presequence by a proteinase in the mitochondrial matrix. Signal peptides are needed not only for routing proteins to mitochondria but also to reach the correct mitochondrial location. Proteins may actually remain in the matrix, assemble with other proteins in the IM, or be transported to the IS through the IM. An inner membrane–associated proteinase is then used to cleave a second signal peptide from these proteins. However, this very interesting scheme is not general, since some proteins lacking a signal peptide can also be imported into mitochondria.

Critical Micelle Concentration

Many properties of a detergent in aqueous solution depend on its critical micelle concentration (cmc), which in turn is determined by the chemical structure of the detergent. In aqueous solution, detergents remain either in aggregated (micellar) or monomeric states, and the cmc is the maximum concentration at which the detergent molecules remain as monomers. An increase in detergent concentration above the cmc leads to the formation of micelles or mixed micelles with the solubilized lipid and protein molecules (see Detergents). Although the formation of mixed micelles of detergents with lipid and protein molecules is an important requirement in detergent solubilization of plasma membrane proteins and lipids, a low cmc may not be essential for efficient membrane solubilization because the cmc value alone does not always reflect a detergent's ability to dissociate membranes. For example, sodium dodecyl sulfate (SDS) is strongly ionic and has a cmc of ~0.23% at 25°C, whereas MEGA-10 is polar but nonionic and has virtually the same cmc of ~0.22%. Yet SDS is probably the strongest **denaturing** detergent known, whereas MEGA-10, just like MEGA-8, is much less disruptive to biomembranes (1, 2). A very similar picture emerges from comparing sodium cholate, which is strongly ionic and denaturing, with CHAPS, which is moderately zwitterionic and much less denaturing, even though both have a cmc of ~0.5% (2). Because the cmc values are also the result of certain more fundamental factors, such as structural features and ionic properties of the detergents (ie, nonionic, moderately ionic, or strongly ionic, and the membrane-dissociating property of a detergent is directly related to such factors), one effective way of classifying detergents is based on their structure and ionizability, rather than their cmc values (see Detergents).

Crosslinking

Crosslinking refers to linking separate chemical functionalities covalently. Crosslinking is usually achieved through use of a bifunctional crosslinking reagent, specifically, a compound having two reactive groups that react chemically with the two functional groups that become crosslinked. In this case, only two functional groups are usually crosslinked, but, with other types of reagents, higher order crosslinking is possible. Crosslinking can be either intramolecular (between separate functional groups on the same molecule) or intermolecular (between functional groups located on separate molecules). In the latter case, it is usually between two macromolecules or between a macromolecule and a relatively small molecule. Crosslinking is usually used to detect groups that are in much greater proximity than would be expected from just their bulk concentrations, due to the structures and associations of the molecules of which they are part. In biochemical applications, the chemical functions that can be crosslinked may be components of all classes of macromolecules (proteins, **nucleic acids**, carbohydrates, and lipids). For simplicity, this article focuses on crosslinking involving the functional groups of proteins, predominantly **amino**, **thiol**, imidazole and carboxyl groups (ie, the nucleophilic side chains of certain amino acids); however, the concepts are the same for the other classes of macromolecules. It should be noted that crosslinking also occurs naturally, resulting from oxidation, radiation, or the action of certain enzymes.

A distinction is sometimes made between the terms *crosslinking* and *conjugation* (or bioconjugation). In this case, crosslinking is used to denote the covalent linkage of only molecules that are associated naturally, such as the subunits of an oligomeric protein or a hormone and its **receptor**. Conjugation, in contrast, refers to the covalent linkage of molecules that lack affinity for one another. The resulting covalent complexes, referred to as conjugates, have a multitude of uses, especially in biotechnology (see Enzyme Immobilization And Conjugation). The distinction between crosslinking and conjugation is maintained in this article.

1. Uses of crosslinking

On the basis of the variety of the crosslinking reagents that are available and of the molecules that can be crosslinked, plus the types of experimental questions that can be answered, crosslinking is among the most versatile of biochemical techniques. In the case of proteins, for example, some information about their three-dimensional structure can be gained through identifying specific amino acid residues that are readily crosslinked intramolecularly (1). Crosslinking can also be used as a general conformational probe to detect structural changes in a protein, such as might be induced by **ligand binding** (2). Inasmuch as crosslinking can hinder conformational transitions and the dissociation of oligomers, it can also be used to stabilize the **tertiary** or quaternary structures of proteins. Thus, it can "lock" a protein into a particular functional state (3) or stabilize an oligomeric protein for subsequent physical studies, such as electron microscopy. A careful analysis of the mass and composition of crosslinked complexes allows a minimal subunit stoichiometry to be determined; this is especially useful for insoluble oligomers, such as those found in membranes (4). Information concerning the symmetry of oligomeric proteins can also be obtained from crosslinking (5, 6). One of the most common uses of crosslinking is to identify neighboring proteins in a complex (7), and this can be extended to include determination of the specific regions of each that are crosslinked (8). By varying the length of the crosslinker, one can also obtain a limit for the maximum distance that can separate neighboring proteins (6). In addition to giving both relative and absolute structural information, crosslinking can be used for general screening. For example, one can identify the receptor for a particular ligand, such as a hormone (9).

It must be emphasized that for all the above applications, interpretations can be made only for those crosslinked complexes that are generated. The absence of crosslinking does not mean that two molecules do not interact, only that they are not crosslinked under the specific set of experimental conditions chosen, which includes the crosslinking reagent used. Because crosslinking requires the proper positioning of those functional groups having the appropriate chemical reactivities, one cannot expect all interacting molecules to be crosslinked by any given reagent.

2. Crosslinking Procedures

Crosslinking, like chemical modification of proteins, is an empirical procedure, and both processes are influenced by the same variables, namely temperature, pH, concentrations of reactants, and time. In crosslinking, however, the influence of the latter two variables is more complex. Because nucleophilic side chains of amino acids are considerably more reactive when deprotonated, the pH of the reaction is important in controlling the extent of crosslinking and the selectivity for particular side chains. Regarding concentrations, the amounts of both the crosslinker and the proteins can influence crosslinking, with low concentrations of protein and crosslinker generally favoring intramolecular crosslinking. Adding the crosslinker over time, instead of as a single addition, favors a greater extent of crosslinking. Differences in selectivity of the reactive groups of bifunctional reagents, especially heterobifunctional crosslinkers, for protein functional groups can be maximized using a two-step reaction. In this procedure, one protein is first derivatized with the crosslinking reagent and then purified to remove excess free reagent before being exposed to the second protein. This two-step procedure, which allows for each of the two reactions to be performed under different conditions, is particularly useful for enzyme immobilization and conjugation, when the two molecules do not normally associate with each other.

Following crosslinking, the covalent complexes formed are commonly identified as new electrophoresis bands in sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE), with altered molecular weights, although care must be taken, because intramolecular crosslinking can alter the migration of individual polypeptides with this technique. Alternatively, in simple systems, covalently linked complexes can be identified as components with increased **Stokes radii** in size exclusion chromatography. If either the crosslinker or the crosslinked protein has identifiable physical or chemical characteristics, these can aid in the identification of complexes. Once crosslinked complexes have been identified, complete analysis of their composition and stoichiometry can still be challenging, especially when multiple proteins are present. One useful method for identifying the proteins composing a complex is to use a cleavable crosslinker so that the original components can be regenerated from the fractionated complex (7). Another useful method is to perform Western blots on the fractionated complex using antibodies against potential components (2). Once the components have been identified, their stoichiometry in the complex is deduced from its overall mass. The ultimate step in analysis is to determine directly the actual amino acid residues that are crosslinked. Using conventional protein sequencing by Edman Degradation, the sequences of the two crosslinked peptides are obtained simultaneously, with the crosslinked residues represented by gaps in the sequences; however, identification of crosslinked peptides by mass spectrometry is becoming increasingly common.

Cruciform (Holliday Junction)

A key intermediate in DNA recombination is the **Holliday junction** that involves the joining of four homologous DNA strands into a cruciform arrangement, as visualized by electron microscopy some years ago. **Supercoiling** also can induce the formation of the cruciform for inverted repeat sequences. Detailed structural analysis of the cruciform DNA structure became possible when specific sequences were designed to form a so-called immobile junction. Studies on those molecules using gel electrophoresis and **fluorescence** indicated that the structure has a stacked X shape (ie, not tetrahedral) in the presence of metal ions (eg, Mg^{+} or $Co(NH_3)_6^{3+}$). Models of the detailed structure at the junctions have been proposed. One such model involves a right-handed, antiparallel X structure, with two stacked helices crossing over each other with a crossover angle of ~ 60° (or 120°). Within each helix of the X structure, the two arms are collinear and the junction site is folded. A number of B-DNA structures determined by X-ray crystallography showed helix–helix packing contacts in the crystal lattice that are remarkably similar to the X structure. Recently the crystal structures of two proteins that are involved in the recombination process have been solved in the presence of their DNA substrate. The crystal structure at 2.4 Å resolution of Cre recombinase bound to a loxP DNA substrate showed that four recombinases and two loxP sites form a synapsed structure in which the bound DNA adopts a conformation similar to the four-way Holliday junction (1). The synapse assembly has a pseudofourfold symmetry, and the junction core is less compact than that proposed for the "free" Holliday junction.

Cryoelectron Microscopy

Cryoelectron microscopy can be divided into two classes, depending on whether the specimen is *hydrated* or *dry*. Table 1 provides a brief description of the possible methods of specimen preparation. In each method, the specimen is initially frozen and can subsequently be observed in a cryoelectron microscope, or can be further preserved by drying or making a replica for observation in a conventional electron microscope.

Table 1. Methods of Specimen Preparation in Cryoelectron Microscopy

Frozen Hydrated Specimens	**Dry Specimen Previously Frozen**
1. *Vitrified film of ice* A thin layer of macromolecules in aqueous suspension is rapidly frozen by plunging in a cryogen, eg, ethane, and transferred to a cryoelectron microscope.	1. *Freeze drying* Cells or tissues are frozen, then lyophilized. The remaining material is dried and stabilized for transfer to a conventional electron microscope. Alternatively, a replica is made.
2. *Frozen section* Cells or tissues are rapidly frozen by contact with a cold metal block, sometimes under high pressure, then sliced into thin sections at ~< –160 C°.	2. *Freeze fracture* Cells or tissues are frozen, then fractured. A replica of the fractured surface is made.
Subsequently, sections are transferred to a cryoelectron	3. *Freeze etching*

microscope.

Freeze fracture followed by freeze drying.

4. *Freeze substitution*

Tissues are frozen, then the ice is replaced at low temperature by an organic solvent. Conventional plastic embedment follows.

5. *Cryoimmunohistochemistry*

Tissues are first chemically fixed, then suffused with a cryoprotectant and frozen for sectioning. Immunolabelling of the thawed sections follows.

The development of techniques for visualizing frozen hydrated tissues and macromolecules has been a boon for studying structures in a state that closely approximates their native condition (1). Because freezing takes place very rapidly, these techniques offer the ability to examine dynamic events with high time resolution. For example, the structure of the open-channel form of the acetylcholine receptor was elucidated from membrane crystals that were briefly activated (< 5 ms) with droplets containing acetylcholine (2). Small conformational changes triggered by acetylcholine were detected in the frozen hydrated crystals. The spatial resolution of periodic structures, eg, protein crystals, can also be high, extending to 3.3 Å (3; Perkins, unpublished results). Moreover, these structures can be examined unstained by utilizing the intrinsic contrast difference between the biological specimen and vitreous ice. Thus, the effects of solvent composition on the structure and aspects of interacting components can be examined (2).

Fundamental to examining frozen hydrated specimens is the preservation of the environment by rapid freezing (4). Rapid freezing causes the water of the specimen and its environment to be trapped in a vitreous (amorphous or glass-like) state. This vitreous state prevents damage to the specimen caused by the formation of ice crystals when the specimen is frozen more slowly. The specimens preserved in thin films of vitreous ice generally retain a high degree of structural integrity. However, it is crucial to maintain the specimen at below ~ –140° C because vitreous ice tends to crystallize above this temperature (4).

A wide range of frozen hydrated specimens has been examined in cryoelectron microscopes. Most studies have concentrated on macromolecules and their assemblies hydrated and frozen in thin films. To a lesser extent cryosections of biological tissues have also been studied (5-9), but the difficulty of freezing of bulk material without formation of ice crystals has hampered progress. The first published results obtained of macromolecules were from viruses, fairly robust particles (10). Early work produced 3-D reconstructions at relatively low resolution, ~ 2–3 nm (10-13), although certain viruses produced data to ~ 1 nm resolution (14). Important new information about viral structures was obtained even at lower resolution. Recent work has extended the resolution of complex viruses beyond 1 nm (15, 16). By combining cryoelectron microscopy with X-ray crystallography, near atomic resolution detail of the overall architecture of large complexes and of the interactions between the components can be obtained. An instructive example is the 3-D structure of rhinovirus 14 complexed with Fab fragments determined at 0.4 nm resolution (17).

Although the contrast in frozen hydrated specimens is low compared to negatively stained specimens, the signal can be significantly boosted by averaging many identical particles together using Fourier averaging for crystals (2, 17) and correlational averaging for single particles as discussed below (15, 16, 18). Vitreous ice embedment is particularly useful for visualizing the specimen interior compared to negative stain, which accumulates around areas accessible to the aqueous phase, thus usually showing only the molecular envelope. Hence, in general only those portions of integral membrane proteins extending beyond the lipid bilayer are observed in negative stain. However, exceptions to this limitation of negatively stained membrane proteins have been found (19-22). In certain instances, frozen hydrated crystals of membrane proteins do not provide resolution as high as the same crystals in negative stain (23). Vitreous ice embedment of delicate specimens, such as chromosomes or DNA fragments (9, 24, 25) has provided impressive results, since this type of specimen is commonly poorly preserved in other embedment media. Another example is the direct visualization by cryoelectron microscopy of A-, P-, and E-site transfer RNAs in the *E. coli* ribosome (26).

Cryofixation of tissues is an alternative to conventional chemical fixation of subcellular ultrastructure. Vitrification of ice can frequently be achieved to a depth of 10–20 µm when tissues are frozen by slamming them against a polished copper block cooled to the temperature of liquid nitrogen or liquid helium (27). High-pressure freezing can freeze samples in vitreous ice to depths as great as 100 µm, since the increase in volume going from water to ice is impaired by a high-pressure environment inhibiting the growth of ice crystals. Cryofixation is usually the choice for immunocytochemistry because it retains the antigenic properties of the specimen better than chemical fixation. With good vitrification, freeze-etching or freeze-substitution (Table 1) can provide information about structures stabilized with a mechanism different from chemical fixation.

Crystallization

The determination of the three-dimensional structures of proteins by X-ray crystallography requires the availability of large, well-ordered crystals. These are difficult to obtain. The crystallization of any given protein requires long painstaking work, including much trial and error in the choice of environmental conditions (pH, temperature) and crystallizing agents.

The basic requirement is the availability of the protein in *very* pure form, free of all other molecules, such as traces of nucleic acids, in a single form (absence of **isoforms**), in a solution that is free of any dust particles. If liganded to any **coenzymes**, cofactors, or effectors, all molecules must be equally liganded; all molecules must be in the native state, and there must be no partial oligomer formation.

The basic approach is to prepare a protein solution at high concentration (10 to 100 mg/ml) in a crystallizing solvent at conditions at which the solution is close to saturation. Then the solution is gradually brought to supersaturation by, eg, slow variation in pH or temperature. All changes must be brought about slowly and the solution not subjected to shocks, such as mixing. This allows the formation of crystal nuclei. Amorphous aggregates must be totally avoided. Once nuclei are formed, the system is induced to crystallize further by the addition of protein to these nuclei, avoiding the formation of new ones, since the aim is to form large crystals. See the specialized literature for further details.

Typical crystallizing agents are (1) salts $(NH_4)_2SO_4$, Na_2SO_4, Na citrate, $MgSO_4$; (2) organic molecules [2-methyl-2,4-pentanediol (MPD), ethanol, isoproponal, acetone, dioxane, 1,3-propanediol]; (3) polyethylene glycols (molecular weight between 2,000 and 20,000). See also Vapor Phase Crystallization.

Crystallography

Crystals are very important for molecular biology because they are required for detailed structure determination of macromolecules using X-ray crystallography. The scientific study of crystals is very old. Its origin can be traced back to 1669 when Nicolaus Steno noticed that the angles between the faces in growing crystals remain constant. Individual crystals may differ in shape appreciably, but the angles between corresponding faces are always the same. A century later, René Just Hauy proposed that crystals are built from small units whose shape is a parallelepiped. An extensive review of the history of crystallography is given in Ref. 1. The physical properties of crystals are, generally not equal in all directions. Their optical, magnetic, and electric properties vary with crystal direction, and this is the reason that crystals are widely used for physical measurements and in industrial processes, for instance, a quartz crystal in a clock or watch. The wealth of variable characteristics is a consequence of the regular packing of the ions, atoms, or molecules in the crystal. This internal regularity had been suggested since Hauy, but it could only be proven with the introduction of X-ray crystallography. In this technique, the crystal acts as a grating and diffracts X-rays in directions specific for the repeating distances in the crystal. In addition, it became possible to elucidate the internal structure of crystals, that is, the arrangement and structure of the molecular composition.

In the regular packing inside the crystal, three repeating vectors can be recognized: **a**, **b**, and **c**, with angles a, b, and g between them. These three vectors define a unit cell in the crystal lattice. From morphological crystal symmetry considerations, that is, the rotational axes, mirror planes, and centers of symmetry observed in the shape of crystals, 32 combinations of these symmetry elements (point groups) are possible. They can be assigned to seven, and not more than seven, crystal systems (2): triclinic, monoclinic, orthorhombic, tetragonal, trigonal, hexagonal, and cubic. Internally, a crystal has more symmetry operators. Translational symmetry is added to the symmetry axes and the mirror planes. These operators can be combined in 230 different ways, leading to 230 space groups, introduced by Schoenflies and Fedorow at the end of the nineteenth century (Ref. 1, p. 114; 2).

Because biological macromolecules have an asymmetrical structure, they can only form crystals without mirror planes or centers of symmetry. This restricts the number of space groups appreciably for these molecules.

C_0t Curve

A C_0t curve describes the sequential complexity of a DNA sample. It describes the kinetics of reassociation and re**annealing** of a sample of double-stranded DNA that has been (*1*) fragmented to small pieces, approximately 400 nucleotides, (*2*) denatured to single strands, and (*3*) then permitted to reanneal. The extent to which two complementary DNA strands reassociate is proportional to C_0t. C_0 is the original molar concentration of the complementary strands of DNA, and *t* is the incubation time. $C_0t_{1/2}$ is the value of C_0t required for completing half of the reannealing reaction. If the sequences of all initial DNA fragments were identical, complementary fragments encounter each other readily and the mixture reanneals readily at a low value of C_0t. At the other extreme, reannealing is very slow and occurs only at high C_0t values if the original DNA contains many different sequences, so that the concentrations of complementary strands are very low and they encounter each other only infrequently. The value of $C_0t_{1/2}$ is a measure of the sequential complexity of the original DNA.

Such studies on genomic DNA were one of the first indications that genomes often contain repetitive DNA. Such DNA segments are present in higher concentrations than those segments present in only one copy per genome, and this fraction of the DNA reanneals at a correspondingly lower C_0t value. The results indicate that different sequences are present in widely varying frequencies throughout the genome, and only a fraction occurs only once per genome.

Cubitus Interruptus **Genes**

In Drosophila development, the **phenotype** associated with a gain-of-function mutation of the *cubitus interruptus* (*ci*) gene was first described in 1971 by Hochman (1). Later, this gene was categorized as a segment polarity gene because the loss of *ci* function results in the loss of naked regions in the segments of larval cuticle (2). The *ci* gene encodes a **zinc-finger** protein, CI, that stimulates transcription in response to the ***hedgehog*** (*hh*) signal transduction cascade, which helps to establish the anterior-posterior positional information in the embryonic segments and imaginal discs. The morphogen in vertebrates, Sonic hedgehog (*Shh*), induces and patterns many developmental processes, at least in part through regulating the expression of the vertebrate *ci* **homologues** *Gli1*, *Gli2*, and *Gli3*, which then transcribe a second level of *Shh* target genes. The importance of these genes in growth and development is illustrated by the fact that the Gli1 protein is amplified in glioblastoma cells.

1. Protein Structure of CI and Gli

Both the *ci* and *Gli* genes encode proteins with five highly homologous, tandemly repeated zinc fingers that act as **DNA-binding** domains and are distinguishable from other zinc-finger domains (3-6). The protein products of these genes are required for the transcription of *hh* target genes during development. Because the *Gli* and *ci* genes respond to the same signaling pathway and share a common DNA-binding domain, they are considered to be homologues, even though there is very little conservation on the amino acid sequence level between CI and Gli proteins outside of the zinc-finger region. Three members of the *Gli* gene family (*Gli1*, *Gli2*, and *Gli3*) have been identified in mouse, chicken, and zebrafish (7, 8). Two *Gli* genes have been identified in ***Caenorhabditis elegans*** (9), four in Xenopus (10). They share various degrees of similarity with the zinc finger region, which represents the greatest degree of homology among the family. The zinc fingers are responsible for the DNA-binding activity of both CI and Gli proteins as demonstrated by both in vitro binding assays and in vivo experiments, in which expression of a transgene is driven by Gli binding sites (4, 5, 11, 12). The consensus DNA-binding site for CI and Gli proteins has also been characterized by isolating and comparing **genomic** DNA fragments that can bind to Gli1. The core sequences were further confirmed by DNase footprinting (13). The X-ray crystallography structure of the Gli1 zinc fingers bound to the DNA binding site has been solved (14). Zinc finger 1 does not contact the DNA, whereas the rest of the four fingers wrap around the DNA, with fingers 4 and 5 making most of the base contacts with the DNA. This structure might explain the higher homology shared by zinc fingers 3–5 among the members of the *Gli* gene family. **Bandshift assays** demonstrate that full-length Gli1, full-length Gli3, or a GST protein fused to the CI zinc finger domain translated in vitro can bind to the Gli DNA binding site **consensus sequence** (5, 11, 13). When the CI zinc-finger **domain** is fused to a heterologous activation domain, it functions as a transcriptional activator in fly imaginal discs and embryos (15). Furthermore, CI can transactivate a reporter gene driven by Gli binding sites in yeast (12) and in fly cell lines (16). All of these experiments suggest that *ci* functions as a transcription factor that binds DNA through its zinc-finger domain. The amino acid residues of CI that are N-terminal to the zinc-finger domain are rich in alanine residues, a characteristic of transcriptional repressor domains (17). When a CI protein that is truncated C-terminal to the zinc-finger region is expressed in the anterior compartment of the fly embryonic segments, it causes downregulation of *ci* target genes (15). This result supports the idea that the N-terminus of CI has a repressor function. The C-terminus of the CI protein is highly acidic, a characteristic of transcriptional activators (18). When introduced into Drosophila embryos, a CI protein in which the N-terminus is deleted can function as a transcriptional activator to enhance *ci* target gene expression, indicating that the activation domain resides in the C-terminus (15).

2. Expression and Function of *ci*

The repeating segments of the fly embryo are established during blastoderm stage through a series of hierarchical interactions among the maternal gap and pair-rule genes. The segment polarity genes specify the anterior-posterior polarity of each segment during gastrulation. Consequently, it is no surprise that most of the segment polarity genes describe interdependent signal transduction cascades. *Ci* is a member of the *hh* signal transduction pathway and encodes a zygotic gene that is not detected until early cellular blastoderm stage (stage 5). Before stage 11, expression of CI protein closely follows the pattern of *ci* transcripts. Both protein and message are detected initially on the dorsal surface of the embryo. As development progresses, the domain of *ci* transcription and protein expression extends ventrally and, by stage 10, encompasses the entire embryo. Coincident with the onset of ectodermal segmentation, both the message and the protein are restricted to the anterior compartment of each segment by the ***engrailed*** (*en*) gene, resulting in 15 broad, metamerically repeating stripes. At stage 11, the protein expression pattern no longer coincides with the transcript pattern. Although transcripts are still uniformly distributed throughout the anterior compartment of each segment, the protein stripe within each segment is graded so that higher levels of protein are detected in the rows of cells that define the posterior edge of the anterior-posterior (A/P) boundary and lower levels are seen in the middle of the CI-expressing stripe. This pattern of expression also exists in imaginal discs, where *ci* is uniformly transcribed in the entire anterior compartment and higher levels of CI are detected along the A/P boundary (3, 19). It should be noted that the protein staining patterns were obtained with antibody made against the C-terminus of CI and detected only the full-length protein. The discrepancy found between transcript and protein levels in the segments and discs indicates that CI is subject to post-transcriptional regulation.

The *ci* transcription pattern is regulated by various unidentified factors and is mediated through the regulatory sequences in the *ci* promoter. Using transgenic flies that carry the *LacZ* reporter gene under the control of different *ci* regulatory sequences, it has been shown that various elements in the *ci* promoter differentiate embryonic from disc expression (20). Although the sequences required for the repression of *ci* transcription in the posterior compartment of the embryonic segments and imaginal discs are different, they both contain binding sites for the *engrailed* protein, EN, consistent with the genetic data showing that *en* inhibits *ci* transcription in the posterior compartment. EN protein expressed in bacteria protects specific DNA sequences in the *ci* regulatory region that have been shown to mediate *ci* repression in the posterior compartment (20). In addition, EN binds the *ci* gene in polytene chromosomes, and misexpression of *en* by the **heat-shock** promoter greatly reduces *ci* mRNA levels (20). Furthermore, Eaton and Kornberg (21) have shown that *ci* transcripts expand into the posterior compartment of both embryonic segments and imaginal discs in *en* mutant flies (21).

Genetic epistasis experiments place *ci* within the *hh* signaling cascade. It acts downstream from the *hh* receptor *patched* (*ptc*) and *smoothened* (*smo*), a transmembrane protein that is coupled to *ptc* and transduces the *hh* signal. *Ci* also acts upstream of the *hh* target genes (see Hedgehog Signaling). CI is an activator of transcription in the cells that receive an *hh* signal. These cells abut the posterior edge of the A/P boundary where high levels of CI are expressed. The cells expressing lower levels of CI are outside the range of *hh* activity and, in these cells, CI is a repressor of the *hh* target genes (19, 22). Recently, great progress has been made toward understanding the cellular mechanism involved in determining whether *ci* is an activator or a repressor. The first insight comes from the observation that CI exists in two forms: the 155-kDa full-length activator form and a 75-kDa proteolytic fragment (22). In the absence of an *hh* signal, a proteolytic event generates the 75-kDa form by cleaving the sequences C-terminal to the zinc-finger domain from the full-length protein. Because the resulting 75-kDa proteolytic product has both the zinc-finger DNA-binding domain and the N-terminal repressor domain, it functions as a repressor, preventing the activation of *ci* target genes. Antibodies made against the N-terminus of CI (AbN), which detect both full-length CI and the proteolytic fragment, stain the entire anterior compartment of the embryonic segments and imaginal discs. On the cellular level, the antibody staining is distributed evenly in both the nucleus and the cytoplasm (15, 22). On the other hand, full-length CI resides primarily in the cytoplasm. The levels are very low in the cells of the anterior compartment that do not receive an *hh* signal and are very high along the A/P boundary that contacts the *hh*-producing cells (19). This expression profile suggests that *hh* signaling regulates full-length CI levels post-transcriptionally. Genetic and cell culture experiments support this hypothesis. The hh^{Mrt} mutation results in a dominant misexpression of *hh* in the wing disc. In these animals, high levels of CI protein are detected along the anterior wing margin, where ectopic *hh* is expressed (23). Suppression of *hh* expression by shifting a temperature-sensitive *hh* mutant (hh^{9k94}) to nonpermissive temperatures causes decreased levels of CI along the A/P boundary in imaginal discs (15). The transmembrane protein PTC, the product of the *patched* gene, is the receptor for HH and, in the absence of HH binding, inhibits the *hh* signaling pathway. The binding of HH to PTC relieves the inhibition of *ptc* on *smo*, the positive transducer of *hh* signaling (see Hedgehog Signaling). In *ptc* mutants, *smo* is constitutively active, and *hh* target gene expression becomes independent of a *hh* signal (24-28). As expected, high levels of full-length CI are distributed uniformly in the anterior compartment of *ptc* mutants (15). Overexpression of *ptc* in wing discs results in the downregulation of full length CI along the A/P boundary without changing the *ci* messenger RNA levels, providing further evidence that *hh* regulates CI protein levels post-transcriptionally (23).

The mechanism involved in the *hh* regulation of full-length CI levels is currently under intense investigation. It has been shown that a domain C-terminal to the zinc-finger domain and N-terminal to the sites **phosphorylated** by protein kinase A is responsible for the retention of the 155-kDa full-length CI in the cytoplasm (22). Because the 75-kDa repressor form of CI does not contain this domain, its nuclear localization is not regulated. The 155-kDa CI protein forms a complex with *costal2* (*cos2*), a protein related to kinesin, *fused* (*fu*), a **serine/threonine protein kinase**, *suppressor of fused* (*su*(*fu*)), and other unidentified proteins. This complex is tethered to microtubules, thus anchoring CI in the cytoplasm. When cells receive an *hh* signal, the complex dissociates from microtubules, releasing the full-length CI from the cytoskeletal structure and presumably making it more accessible to nuclear translocation. *Hh* signaling also inhibits CI proteolysis, which accounts for the increased levels of full-length CI detected along the A/P boundary (22, 29, 30).

Protein kinase A (PKA) antagonizes *hh* and negatively regulates *ci* activity (see Hedgehog Signaling). Recent studies have helped to elucidate the mechanism involved in this regulation. Loss of PKA function or inhibition of PKA activity increases the levels of full-length CI in both embryos and discs (23). Cell culture experiments have provided details about the mechanism involved in the PKA regulation of CI (31). CI has consensus PKA phosphorylation sites at four serine residues in its C-terminus. Substitution of the serine residue with alanine in any of the first three PKA sites inhibits CI proteolysis, thus increasing the levels of full-length CI and stimulating CI-mediated transcription, suggesting that CI is the direct target of PKA regulation. Recently an F-box/WD40-repeat protein encoded by *slimb* has been identified in flies (32). Loss of *slimb* function causes the formation of supernumerary limbs and the accumulation of high levels of full-length CI. Because *slimb* is related to a yeast protein, cdc4p, that is involved in targeting cell-cycle regulators to the **ubiquitin**-mediated **protein degradation** pathway, *slimb* has been hypothesized to mediate CI proteolysis.

Evidence obtained both *in vitro* and *in vivo* suggests that *ci* directly mediates transcription of the *hh* target genes. Consensus CI binding sites have been identified in the promoter regions of *ptc* and *wg*, and CI has been shown to bind to these sites both in vitro and in vivo (11, 12, 22). In cell culture, CI transactivates a reporter gene driven by the *wg* (***wingless***) promoter region that contains the CI binding sites (11). Both endogenous and ectopic *hh* signals transactivate a *lacZ* gene driven by the 758-bp minimal *ptc* promoter in a CI binding site-dependent manner in transgenic flies (12). These experiments support the idea that CI is a transcription factor that mediates the *hh* signal in the nucleus. *Ci* also functions as a suppressor of *hh* gene expression. *Ci* mutant clones generated in the anterior compartment of the imaginal discs ectopically express HH and induce the ectopic expression of *ci* and *hh* target genes in the surrounding wild type cells, presumably through the inductive function of the ectopic *hh* (33).

3. Gli Expression and Function in Vertebrates

A number of different *hh* homologues exist in vertebrates, and they also play important roles in the specification of cell fate. The transcription factors that respond to these vertebrate signaling cascades are considered homologues of *ci* because the zinc-finger motif that defines their DNA binding domains is more similar to that of CI than any other zinc-finger proteins. To date, three *ci* homologues, *Gli1*, *Gli2* and *Gli3*, have been studied in detail.

In mouse, all three *Gli* genes are detected initially during gastrulation at 7.5 days postcoitum (dpc) in broad domains in both ectoderm and mesoderm. As development progresses, the expression patterns of the three genes become more restricted and, by the completion of organogenesis, their expression is no longer detected. *Gli1* expression overlaps with *Sonic hedgehog*(*Shh*) expression initially in the ventral midline; however, by 9.5 dpc *Gli1* is excluded from *Shh*-expressing cells and is restricted to a narrow stripe of cells that lies along the caudal-rostral axis of the ventral neural tube and lateral to the *Shh*-expressing floor plate cells. The *Gli2* and *Gli3* expression patterns are widespread within the dorsal neural tube in domains that do not overlap with regions of *Gli1* expression. While *Gli2* expression is relatively homogenous and broad, *Gli3* is expressed as a gradient, with highest concentrations found in the dorso-lateral cells of the neural tube. This dorsal-ventral pattern of expression is maintained throughout the development of the brain and spinal cord (7, 34, 35). In the somites, all three *Gli* genes are expressed in the dorsal-lateral mesochymal cells (dermomyotome), suggesting that the *Gli* genes are involved in myogenesis. The *Gli1* message is also detected in the ventral medial somite (sclerotome), whose development is patterned by *Shh*. *Gli3* is expressed throughout the newly formed somite, and its expression becomes restricted to the dorsal medial myotomal cells as development progresses (7, 36). As in the developing neural tube, the initial *Gli1* expression pattern in the limb bud overlaps that of *Shh* in the posterior mesochyme and then becomes restricted to the posterior cells immediately adjacent to the ZPA (zone of polarization activity) that expresses *Shh*. Except in the posterior margin, *Gli2* and *Gli3* are expressed throughout the limb bud, with higher levels of *Gli3* expression detected in the autopod. During bone formation, *Gli1* is expressed strongly in the perichondrium surrounding the cartilage elements where *Indian hedgehog* (*Ihh*) is expressed, and *Gli2* and *Gli3* are expressed in the tissues surrounding the perichondrium (37). *Gli1* transcripts are also detected in developing lung, gut, gonad, and eye (7, 38).

That *Gli1* is expressed in cells adjacent to those that express *Shh* or *Ihh* is reminiscent of the relationship between *hh* and *ci* and suggests that *Gli1* is one of the *hh* target genes and may transduce the *hh* inductive pathways. Transgenic or Strong's luxoid mutant mice that misexpress *Shh* induce ectopic *Gli1* expression in the neighboring cells (37, 38). Removal of the notochord from wild-type quail embryos abolishes *Gli1* expression, and supplementing the same embryos with SHH restores *Gli1* expression (36), supporting the notion that *Gli1* is a target of *Shh*. Ectopic expression of *Gli1* induces ectopic expression of the ventral neural tube markers *HNF-3b* (hepatocyte nuclear factor-3b), *patched* (*ptch*), and *Shh*. In addition, ectopic *Gli1* expression in mouse and Xenopus suppresses the expression of the dorsal neural tube marker *Pax-3*. This phenotype is reminiscent of the ectopic floor plate differentiation obtained with a gain of *Shh* function. *Gli1* also induces ectopic ventral neuronal differentiation, as shown by its ability to induce the expression of the ventral neuron markers, serotonin and dopamine. This inductive activity may be a secondary effect of *Shh*, because *Gli1* also induces *Shh* expression (34, 35, 39). The promoter region of *HNF-3b* contains Gli binding sites that can bind to *Gli1 in vitro*. Tissue culture experiments demonstrate that *Shh* can transactivate a reporter gene that is controlled by the Gli binding sites found in the *HNF-3b* promoter. Mutating the Gli consensus binding site in the *HNF-3b* promoter abrogates the *Shh* response, showing that this site is required for *Shh*-dependent transactivation (40). The best evidence that *Gli1* is a mediator of *Shh* signaling comes from experiments in transgenic mice that express a *LacZ* reporter gene driven by the *HNF-3b* minimal promoter. In these animals, b-galactosidase expression is detected in the floor plate, and this expression depends on the presence of an intact Gli binding site (40). Taken together, these studies imply that the transcription of the *Gli1* gene is induced by *Shh*, whereupon the *Gli1* protein activates an array of genes needed to differentiate the floor plate and the ventral neurons. This pattern of regulation also exists in limb development. Marigo et al (8) have shown that misexpression of *Shh* in the anterior limb bud causes ectopic *Gli1* expression, and expression of a Gli-VP16 fusion protein activates the *Shh* target gene *ptch*. *Gli* is also a target for *Ihh* and mediates *Ihh* function in bone morphogenesis. In a developing bone, the prehypertrophic cells of cartilage express *Ihh* and the receptor for parathyroid/parathyroid related protein (PTH/PTHrP). On secretion, *Ihh* stimulates *Gli1* expression in the perichondrial cells, leading to the synthesis of PTHrP, which is then secreted and binds to its receptor on the *Ihh*-producing cells. Stimulation of the PTHrP signaling pathway ensures the proliferative state of the prehypertrophic cells and prevents their premature ossification (41, 42).

Our understanding of *Gli2* function comes mainly from experiments with *Gli2* knock-out mice. *Gli2* loss-of-function mutations result in the absence of floor plate differentiation, severe axial skeletal abnormalities, and downregulation of the *Shh* target genes, such as *ptch* and *Gli1*. These results suggest that *Gli2* functions as a transcriptional activator of *Shh* target gene expression in certain structures during development (43). Injecting frog embryos with *Shh* or *Gli1* causes ectopic expression of *Gli2*, implying that *Gli2* transcription is activated by *Gli1* in response to *Shh* signaling (35).

Gli3 has been proposed for several reasons to function as a repressor of *Shh*. First, the expression patterns of *Gli3* and *Shh* are mutually exclusive (8, 34, 35, 44). Second, *Gli3* can suppress the activation of the *HNF-3b* promoter by *Gli1* in cotransfection assays (40). Third, *Gli3* knock-out mice (*Xt*) misexpress *Shh* in the anterior limb bud and dorsal neural tube, domains that normally express *Gli3* (35). Genes that are involved in limb outgrowth and patterning, such as *ptch* and *Hox*, and those for fibroblast growth factors (FGFs) and bone morphogenic proteins (*Bmp*) are also ectopically expressed in *Gli3* mutant mice due to the misexpression of *Shh* (45). This cascade of misexpression might explain the extra autopods associated with the heterozygous *Xt* mouse. Whereas *Gli3* is a repressor of *Shh*, *Shh* acts to repress *Gli3*. The misexpression of *Shh* by viral infection downregulates *Gli3* in the chick limb, and the ectopic expression of *Gli1* in the dorsal tube of transgenic mice suppresses the normal dorsal *Gli3* expression (8, 39). These results support the notion that CI function is accomplished by two Gli proteins in vertebrates, with *Gli1* acting as an activator and *Gli3* as a repressor, respectively, of *Shh* target gene expression.

Although Gli proteins have distinct expression patterns and cause different phenotypes when disrupted individually, they share some functional redundancies. Both *Gli1* and *Gli2* can induce motor neuron differentiation, and this redundancy may explain the fact that motor neuron induction is unaffected in homozygous *Gli2* mutant mice (43).

From an evolutionary perspective, many interesting parallels exist between the Drosophila and vertebrate *hh* signaling pathways. In Drosophila, *hh* suppresses the activity of the CI repressor by inhibiting the proteolysis of the 155-kDa CI protein. *Shh* signaling suppresses the activity of the *Gli3* repressor by inhibiting its transcription. CI suppresses *hh* expression, and *Gli3* suppresses the transcription of *Shh* in the cells where CI or Gli is active. In the presence of an *hh* signal, the 155-kDa CI protein is an activator of *hh* target genes, and this activity has evolved in vertebrates into the functions of *Gli1* and *Gli2*. Clearly, continued studies of CI and the Gli family members will elucidate the evolution of the signaling systems that drive the developmental process.

Cyclic AMP (3′,5′-cyclic AMP, cAMP)

Nucleotides play a universal role in life, as components of nucleic acids, as forms in which chemical free energy is stored, and as regulators of gene expression or enzyme activity. Cyclic adenosine 3′,5′-monophosphate (cAMP) plays a universal role in the control of gene expression as well as in the integration of metabolic functions. It is present both in eucaryotes and in procaryotes (see 1 for early recognition of cAMP presence in bacterial genera). cAMP seems to be absent only from archaebacteria (but see Adenylate Cyclases). Its presence was controversial in plants, but a work from the J. Schell laboratory investigating opine catabolism in plants resulted in the cloning of a gene that appeared to specify cAMP synthesis in plants. It was, however, later reported that this work was a fake, so that it is now admitted that plants do not make cAMP (2). Cyclic AMP has been reported to exist in cyanobacteria and in algae. This ubiquity explains the major interest displayed in its mode of synthesis, and the vast amount of literature devoted to the enzymes that produce cAMP from ATP, the adenylate cyclases (E. C. 4.6.1.1). Because cAMP is a regulatory molecule, it must be either excreted in the environment or inactivated in order not to accumulate. This is performed by 3′,5′-cyclic-nucleotide phosphodiesterases (E. C. 3.1.4.17). These enzymes are generally specific for cyclic nucleotides (namely cAMP and cGMP) and sometimes specific for cAMP or cGMP alone. A variety of natural inhibitors modulate their activity (nucleoside triphosphates, pyrophosphate, and especially methylated xanthines, such as theophylline) by a variety of processes involving protein phosphorylation or calcium. Adenylate cyclases (see entry) form four independent classes of enzymes, and this raises the question of the origin of cyclic nucleotides as regulatory molecules, as well as their universal implication in regulatory networks. Because it is very polar and negatively charged, cAMP does not permeate easily into cells (unless through specific transporters, generally unknown at present). More lipophilic analogs such as N6,O2′-dibutyryladenosine-3′,5′ monophosphate are, therefore, used to modulate its concentration and mimic its effect in cell cultures *ex vivo,* but *in vivo* inhibitors of phosphodiesterase or specific mediators (neuromediators in particular) are used for therapeutic purposes where cAMP concentration must be altered.

Cyclic AMP was discovered in 1958 by E. Sutherland, who obtained a Nobel prize in 1971 for this and other discoveries on hormone action. As he has himself written, it is within the scope of molecular biology that cAMP was discovered: *"When I first entered the study of hormone action, some 25 years ago, there was a widespread feeling among biologists that hormone action could not be studied meaningfully in the absence of organized cell structure. However, as I reflected upon the history of biochemistry, it seemed to me there was a real possibility that hormones might act at the molecular level".* Sutherland built up a cell-free system where well-known hormones could control glycolysis *in vitro.* Using this system he isolated a small thermostable molecule that was able to activate glycogen phosphorylase. Chemical analysis of the molecule permitted its identification as adenosine 3′-5′ cyclic monophosphate. Synthesis of cAMP was shown to be the result of the action of an enzyme, adenylate cyclase, that generated cAMP and PPi from ATP, when activated by adrenaline (3). Since this pioneering work, the study of cAMP-mediated effects required the identification of the structure, function, and regulation of adenylate cyclases, the cAMP synthesizing enzymes. And, contrary to expectation, this did not yield a unifying picture of the role of cAMP, but, rather, demonstrated that this molecule has been used over and over again by living organisms for very different functions.

At the time of cAMP discovery, the aphorism of Jacques Monod, *"what is true for Escherichia coli is true for the elephant,"* induced biochemists to try bacterial systems to unravel cAMP function. After the discovery of cAMP by Sutherland in 1958, Mackman and Sutherland (4) demonstrated that glucose-starved *E. coli* cells accumulated cAMP. Ullmann and Monod (5) later established that part of the catabolite repression phenomenon (see entry) was controlled by cAMP. This discovery raised hopes that the study of this mediator in bacteria would help to understand what happens in eucaryotes (even perhaps in higher eucaryotes). However, it soon became clear that cAMP in eucaryotes was generally, as found by Sutherland, a "second messenger" that was used as an intracellular relay molecule to the action of extracellular hormones, while it acted directly on transcription via its receptor, the Catabolite Activator Protein (see entry) in *E. coli* (6). Study of the slime mold *Dictyostelium discoïdeum* revealed another function of cAMP, phylogenetically linked to is hormone-mediated action in higher eucaryotes, namely a pulsatile synthesis and degradation used by bacteria as a signal to control their aggregation properties as a differentiating multicellular organism (7).

The universal role of cAMP in controlling such diverse metabolic processes is puzzling because the enzymes needed for its synthesis, adenylate cyclases, are extremely varied and submitted to a wide variety of regulations (see entry). Why does this result in the synthesis of the same molecular species, cAMP? Is not all the regulatory process lost in this way? How can the cAMP signal generated by one enzyme type be distinguished from another? Compartmentalization is often invoked in this process, but, while this is relatively easily accounted for in the case of macromolecules, this is difficult to see in the case of small molecules such as cAMP. Another usual answer is to say that it is the combination of hormonal receptors of differing types and cAMP—and not cAMP alone—that is required for specificity. But would not cAMP synthesized from different sources also be recognized? Another answer is to remark that cAMP is known to be only one among many second messengers: cGMP has been added to the list as well as inositol phosphates, phosphatidyldiglycerides, calcium, etc (see corresponding entries). This certainly permits generation of a combinatorial control of activities, but would be very sensitive to accidental synthesis of cAMP. Cyclic AMP is not synthesized in a steady state way (even in bacteria). It is, therefore, important not to consider cAMP as such, with some average concentration, but to consider the shape of its time-dependent variation in concentration. In fact, observations are accumulating that strongly suggest that cAMP does not have the same effect when it is delivered in a steady state fashion, rather than in a pulse (or a series of pulses) (7).

The motile and aggregating amoeba *D. discoïdeum* has been used as a paradigm for cell differentiation because undifferentiated cells start to differentiate into specific tissues some time after starvation. Secreted in the external medium, cAMP is necessary for aggregation. The genetics, biochemistry, cellular biology, and physiology of phenomena involving cAMP have been investigated in detail in this organism, where it controls, as in higher eucaryotes, a protein phosphorylation cascade, initiated after a regulatory cAMP-binding subunit of a protein kinase detaches from its target enzyme. This cascade is necessary not only for chemotaxis and aggregation but also for the triggering of genes involved in differentiation. The regulation of cAMP pulsatile concentration is mediated by two sets of enzymes adenylate cyclases and phosphodiesterases. In contrast with the situation with higher eucaryotes, however, cAMP and phosphodiesterase control operates not from the interior of the cell but from the external medium. This requires specific membrane receptors for cAMP and a process of signal transduction (see entry). In *D. discoïdeum* the pulses are generated by an appropriate coupling between adenylate cyclase activity, phosphodiesterase activity, and diffusion. The main observation is that variation in the cAMP pulse frequency changes the response of the cell. Many biochemical models can account for such cAMP pulses. These models require simple enzyme properties (in particular standard nonlinear features, such as self-activation and desensitization after saturating activity). They do not require the existence of many gene products, but only a specific behavior of enzymes (appropriate Vm and Km of biosynthetic and degradative enzymes). Assuming that cAMP concentration modulation in time is the control event is, therefore, not a biochemical paradox.

In bacteria, Utsumi et al (8) have investigated cyclic AMP synthesis during the cell cycle of *E. coli* on synchronized cells, and they have given an unambiguous demonstration that there was a strong correlation of cAMP synthesis and replication or cell division, suggesting that the molecule may play some role in the cell cycle. This is also correlated with the position of the adenylate cyclase gene near the chromosome's origin of replication and with its very low level of expression, suggesting that expression is strongly coupled to DNA replication. This observation has long been overlooked because cells deficient for adenylate cyclase or CAP are viable, suggesting that cAMP is dispensible. Specific time-dependent variation of the concentration of cAMP for fine coordination of replication and division in *E. coli* is achieved by excretion of the nucleotide, rather than coupling to the activity of a phosphodiesterase (6). In this respect it is interesting that high concentrations of cAMP produced by foreign genes in *E. coli* are not toxic until they reach a very high level (at least 10-fold the normal concentration), whereas much lower concentration of cAMP produced by the endogeneous adenylate cyclase are toxic (9). Cyclic AMP has been formally linked to catabolite repression, but there are many catabolite sensitive operons that do not respond to cAMP. In addition cAMP synthesis is very strong in *E. coli* when cells enter the stationary phase of growth, suggesting that it could be a cell-to-cell signal as it is in *D. discoïdeum.* This may be one of its function in other bacteria (such as Rhizobium species), where it is clearly not linked to catabolite repression.

In the same way, intracellular and extracellular levels of cAMP vary during the cell cycle of *Saccharomyces cerevisiae.* Using centrifugal elutriation, Smith et al (10) showed that the intracellular cAMP concentration followed the stages of the cell cycle, being highest during the division cycle and lowest immediately before or just after cell separation; at the same time the external cAMP concentration did not vary. Therefore, in yeast, as in *E. coli,* it appears that the role of the external medium is to behave as a sink. These observations substantiate the demonstration that, under normal conditions, appropriate enzyme systems can generate a specific time-dependent pattern of cAMP concentration. As in the case of *E. coli,* it is known that in *S. cerevisiae* adenylate cyclase is dispensible in mutants of the cAMP receptor, and in *S. pombe* adenylate cyclase is dispensible during vegetative growth (11). But, as in this former case, cells that carry the mutation and are deficient in adenylate cyclase have several growth defects. In this respect, the function of the time-dependent cAMP pattern could be optimization of transient processes, in particular cell division and chromosome segregation.

In all these cases cAMP is recognized on the cell surface by a specific receptor. It is, therefore, interesting to identify cases where membrane targets of cAMP have been demonstrated (*D. discoïdeum* aside). Nerve cells typically generate and are sensitive to transient signals; they also have very involved patterns of adenylate and guanulate cyclase regulation (see entries). In this respect it is important to observe that cGMP (but also cAMP) has been shown to be involved as a central molecule in vision, taste, and olfaction. In particular, in addition to their role as second messengers in protein phosphorylation cascades, cyclic nucleotides are involved at the membrane surface, but intracellularly, in gating ion channels in olfactory and taste neurons. This certainly permits generation of a variety of time-dependent patterns for cAMP regulation, as a function of environmental inputs as well as of the fine molecular structure of the enzyme or its subunits (12, 13). Because ion channels are involved in the main functions of neurons (firing patterns), this makes cyclic nucleotides important in learning processes.

Indeed, many experiments have demonstrated that cAMP is involved as a mediator of learning and memory in invertebrates [*Aplysia* (14) and *Drosophila melanogaster* (15)], as well as vertebrates (16, 17). The study of mutants of *D. melanogaster* that are defective in learning or memory has been of major importance in our understanding of the physiology, biochemistry, and anatomy underlying conditioned behaviors. *D. melanogaster* learning mutants have been separated into two general classes: those with structural defects in the brain and those without obvious brain alterations. From studies of mutants affected in the brain structure, two areas have been found to be involved in conditioned behavior: the mushroom bodies and the central complex. Analysis of the mutants has shown that many types of molecules are involved in learning, but the cAMP-mediated phosphorylation cascade has emerged as especially important. During learning, time-dependent processes are involved in the stabilization of synapses, a general view being that they are created during growth as transient entities that can either regress or be stabilized. In this process, the evolution of the synaptic pattern is dependent on the pattern of neurotransmitter delivery. Analysis of the minimal requirements for synapses stabilization suggests that neurotransmitter release must be coupled to some other transient metabolic process in a retrograde manner in order to yield a stable geometry (18). In the cases where cAMP is involved, one can, therefore, speculate that the role of this mediator is to trigger an appropriate biochemical process when the proper time-dependent control of its synthesis is at work (19). Accordingly, once again, it is not the cAMP concentration that is important, but, rather, the time-variation of its concentration. In the process of learning, the regulation of adenylate cyclase activity would, therefore, be exquisitely tuned to permit delivery of the molecule in the proper time-dependent manner.

In *D. melanogaster,* five different genes have proven important for normal learning: *dunce* (a cAMP phosophodiesterase), rutabaga (an adenylyl cyclase), amnesiac (a product similar to adenylate cyclase activating peptides), *DCO* (protein kinase A), and *dCREB2* (a cAMP-response element binding protein). The products of many of these learning mutants are enriched in mushroom bodies. A process involving control of transcription by the cAMP response element binding protein (CREB)-responsive plays a central role in the formation of long-term memory in *D. melanogaster, Aplysia* and mammals. This is one of the examples where cAMP is involved in the control of transcription in eucaryotes, as it is in eubacteria, although through a different chain of events. Agents that prevent CREB activity interfere with the formation of long-term memory, whereas agents that increase the amount or activity of the transcription factor accelerate the process, thus indicating that CREB is essential for the switch from short-term memory to long-term memory (protein synthesis dependent) (20). Further work involving inbred mice strains as well as knock-out mutants affecting the hippocampal region demonstrated that both the genetic background and the temporal pattern of synaptic activity affects the cAMP-dependent synaptic plasticity (21).

Cyclic Amp Receptor Protein (CRP)/Catabolite Gene Activator Protein (CAP)

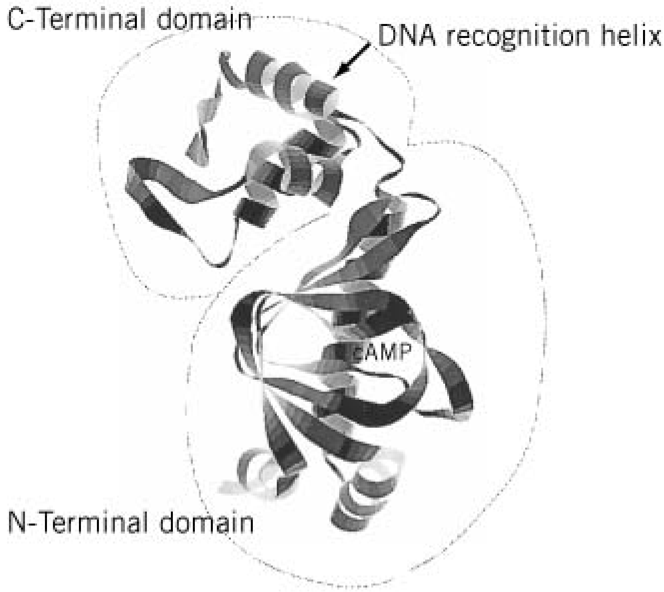
The cyclic AMP receptor protein (CRP), or catabolite gene activator protein (CAP), of *Escherichia coli* is one of the best characterized transcription factors. It was discovered more than 25 years ago as a protein that binds **cyclic AMP** (cAMP) and stimulates **gene expression** of the lac operon (1, 2). Since then, CRP has attracted attention as the paradigm of gene activator proteins. It is now known that CRP, in conjunction with cAMP, participates as a global transcription factor in a wide regulatory network, both activating and repressing a large set of operons. One mechanism of catabolite repression is due to the reduction in the intracellular concentrations of both cAMP and CRP.

The CRP protein is composed of two identical subunits of 209 amino acid residues each. It is active when complexed with cAMP, which behaves as an **allosteric** effector. It is a prototype of sequence-specific DNA-binding proteins containing a helix–turn–helix motif. The cAMP–CRP complex binds to specific DNA sites in various operons. On binding DNA, it bends the DNA and interacts with **RNA polymerase** and/or other regulatory proteins to regulate transcription of the target operons.

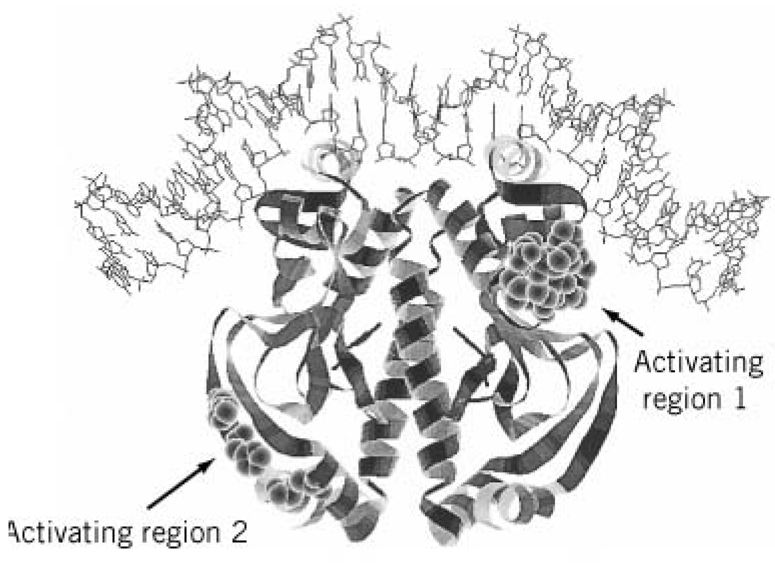
Following early studies on the properties of purified CRP, the *crp* gene was **cloned** and sequenced in

1982 (3, 4). The X-ray crystallography structure of CRP complexed with cAMP was solved in 1981 (5). This confirmed the dimeric nature and **domain** structure of CRP deduced from biochemical studies. The subunit has two domains (Fig. 1**a**). The larger *N*-terminal domain is responsible for cAMP binding and for dimerization. The smaller *C*-terminal domain contains a helix–turn–helix DNA-binding motif. CRP is one of the first regulatory proteins where the helix–turn–helix motif was identified. CRP alone is able to bind to DNA nonspecifically. The binding of cAMP induces a conformational state that binds to specific sequences with a dyad symmetry. The detailed nature of the structural changes in CRP caused by cAMP remains unknown.

Figure 1. Structures of the CRP monomer and the CRP-DNA complex. The crystallographic coordinates were obtained from the Brookhaven Protein databank (accession code 1CGP). The images were generated by Protein Adviser (FQS). (**a**) The two domains of a CRP monomer. The larger *N*-terminal domain is responsible for cAMP binding and for dimerization. The smaller *C*-terminal domain contains a helix–turn–helix motif that is involved in DNA binding. (**b**) The CRP dimer bound to a consensus DNA site. The positions that are responsible for transcription activation (activating regions) are highlighted by space-filling models. Activating region 1 contacts the *C*-terminal domain of a subunit of RNA polymerase (8), while activating region 2 contacts the *N*-terminal domain of a subunit of RNA polymerase (9).



(a)



(b)

The DNA sequences of many CRP binding sites, and a resulting **consensus sequence**, have been determined. They include variations of the 22-bp palindromic sequence, 5′-AAATGTGATCTAGATCACATTT-3′, in which the two TGTGA motifs are relatively well conserved in different promoters. The binding of cAMP–CRP to target DNA induces bending of the DNA (6). The structure of cocrystals of cAMP-CRP bound to a 30-bp DNA target was determined in 1991 (7). It shows the helix-turn-helix motifs of the two subunits inserted into successive major groves of a DNA that is bent by 90°C (Fig. 1**b**).

In promoters where CRP alone is sufficient to activate transcription, the role of the cAMP–CRP complex is to enhance functional binding of RNA polymerase (8, 9). Binding of cAMP–CRP or RNA polymerase to these promoters stimulates the other's binding. An example is the *lac* promoter, where the CRP-binding site is centered on base pair –61, which is one of the preferable positions for CRP action. Another position where CRP activates transcription efficiently is –41, as in the *gal* promoter (see Gal Operon). Changing these two standard distances reduces or eliminates CRP action. Only when this change is by an integral number of turns of DNA double helix is the ability of CRP to activate transcription retained to some extent, suggesting that both CRP and RNA polymerase must bind to the same face of the DNA (10, 11). Genetic and biochemical analysis revealed that cAMP–CRP activates transcription by directly contacting RNA polymerase at these simple promoters. A surface-exposed loop in the *C*-terminal domain of CRP and the *C*-terminal part of the a subunit of RNA polymerase are primarily responsible for the contact between two proteins (8). An additional contact between the *N*-terminal domain of CRP and the *N*-terminal domain of a subunit is also involved in transcription activation at the promoters where the CRP site lies at –41 (9). The interaction between CRP and RNA polymerase is needed transiently to stimulate events leading to the formation of an open complex in these simple promoters (12). The contribution of CRP-induced DNA bending to transcription activation is still unclear. The CRP-binding site lies well upstream in several CRP-dependent promoters. In these cases, CRP acts as a coactivator of a second activator that is presumed to be responsible for the direct interaction with RNA polymerase. In the example of the *araBAD* promoter, CRP binds around –94 and the second activator AraC binds in the region between the CRP and RNA polymerase sites (13) (see ara Operon).

CRP also acts as a repressor or a corepressor in several operons. A simple example is the *cya* promoter, where cAMP–CRP inhibits the action of RNA polymerase by binding a target site located within the promoter (14). A more complex mechanism of repression is found in the operons that are coordinately regulated by CRP and CytR. Most of these promoters possess tandem CRP-binding sites that flank the CytR operator. An example is the *deo* promoter, where the CRP-binding sites are located at –41 and –94. The binding of cAMP-CRP to these sites dramatically enhances the binding of CytR to its operator, resulting in the formation of a repression complex containing both cAMP–CRP and CytR (15).

Although many studies have been identifying the regions of both transcription factors and RNA polymerase that are responsible for protein–protein and protein–DNA interactions, how these interactions lead to transcription activation is largely unknown. CRP, along with its target promoters, will continue to be a useful system for further understanding of molecular mechanisms of transcriptional regulation, including this fundamental question.

Cyclic GMP (Cyclic Guanosine 3′,5′-Monophosphate, cGMP)

Cyclic GMP, a structural analog of **cyclic AMP**, occurs at similarly low concentrations (*i.e.*, in the micromolar range) in many animal tissues. It is synthesized by guanylate cyclases, which correspond to the adenylate cyclases that synthesize cyclic AMP, and is destroyed by specific **phosphodiesterases**.

A functional role for cyclic GMP in **bacteria** is controversial. It is present in *Escherichia coli* but at such a low intracellular concentration (nanomolar, corresponding to about one molecule per cell) that hardly makes it a significant molecule. In addition, the sequence of the *E. coli* genome does not reveal any gene product that could code for a guanylate cyclase. There are many reports suggesting the presence of cGMP in bacteria (1), but its presence is perhaps most likely in myxobacteria, where it could be involved in cell aggregation and differentiation.

In contrast, cGMP is universally in **eukaryotes** (except in **plants**). It is generally involved in processes leading to activation of specific regulation cascades, which are differentially controlled by appropriate mediators, or leading to control specific processes for neuronal activation of sense organs, such as the sensitivity to light of retina receptor cells and the triggering of olfaction and taste (2-4). The organization of guanylate cyclase and the control elements is sometimes similar to but distinct from the organization of hormonally regulated adenylate cyclase. In particular, **G-protein**-mediated regulation of vision operates on the phosphodiesterase rather than on the cyclase.

Phototransduction systems in vertebrates and invertebrates share a great deal of overall strategic similarity but differ significantly in the underlying molecular machinery. In the dark, vertebrate retinal rod cells synthesize a high level of cGMP that keeps gated **sodium channels** open in the plasma membrane of the outer segment (5). Light closes these channels by activating an enzymatic cascade that leads to rapid hydrolysis of cGMP by cGMP-specific phosphodiesterase (6). This hyperpolarizes the cell and modulates transmitter release at the synaptic buttons. Photoexcited rhodopsin triggers a transducer protein (transducin), which is related to G-proteins by catalyzing the exchange of GTP for bound GDP. Subsequently, the activated GTP-form of transducin switches on the phosphodiesterase. The cascade that has an overall gain of 10^5, is turned off by the GTPase activity of transducin and by the action of two proteins, rhodopsin kinase and arrestin . The kinetics of the reactions in the cGMP cascade limit the temporal resolution of the visual system, and statistical fluctuations in the reactions limit the reliability of detecting dim light. Together with **calcium** ions and **inositol phosphates**, cGMP controls visual excitation and adaptation. A light-induced fall in the internal free Ca^{2+} concentration subsequently stimulates resynthesis of cGMP, antagonizes the catalytic activity of rhodopsin, and restores the high affinity of the light-regulated sodium channel for cGMP, allowing the cell to adapt to background light (7).

The initial events in mollusks and arthropods are probably similar to those of vertebrates. However, whereas light activation of vertebrate photoreceptors leads to activation of cGMP-phosphodiesterase and generation of a hyperpolarizing response, activation of photoreceptors of invertebrates like Drosophila leads to stimulation of phospholipase C and generation of a depolarizing response (8). Cyclic GMP has also been implicated in modulating behavior in insects (9).

Cyclic GMP is also a second messenger in regulation mediated by natriuretic peptide hormones, but it is probably in the recently discovered nitric oxide (NO) regulation cascade that cGMP has the most unexpected role. Nitric oxide and atrial natriuretic peptide hormones play key roles in a number of neuronal functions, including learning, memory, and in blood circulation. Most experiments suggest that they exert converging actions by elevating of intracellular cGMP levels by activating soluble and membrane-bound guanylate cyclases. Cyclic GMP is the starting point for multiple signal transduction cascades, which are now beginning to be unraveled (10). In more than a quarter of a century since the discoveries of atrial granules and volume receptors in the heart atria, the search for natriuretic hormones has led to the isolation and identification of many atrial natriuretic factors (ANF) [(11), as a specific example see (12)]. In the heart, for example, ANF peptides are synthesized and stored in the Golgi apparatus of cardiac myocytes and are released in response to atrial wall stretch following acute plasma volume expansion and increased central blood volume. The mechanisms of the renal action of these potent natriuretic hormones are not yet completely unraveled. The renal hemodynamic, tubular, and adrenal, and systemic vascular effects are related to enhanced cGMP synthesis in specific medium-sized arteria, in the glomeruli and specific tubular segments, and in adrenal tissue. Specific ANF-binding sites have been detected in these target organs. A primary action of elevated cGMP levels is stimulating cGMP-dependent protein kinase (PKG), the major intracellular receptor protein for cGMP, which phosphorylates substrate proteins to trigger a regulation cascade (10).

Cyclic GMP-dependent protein kinases (PKG) also mediate some of the neuronal effects of cGMP (13), but unfortunately few PKG substrates are known in the brain. In striatonigral nerve terminals, for example, NO mediates phosphorylation of the protein phosphatase regulator, dopamine- and cyclic AMP-regulated phosphoprotein by PKG. PKG substrates are critically placed in the protein phosphorylation network and regulate protein phosphatases, intracellular calcium levels, and the function of many ion channels and neurotransmitter receptors. Nitric oxide is a signaling molecule in the nervous system of both mammals and insects. In contrast to classical transmitters, NO permeates membranes and acts on neighboring targets normally limited by diffusion barriers. This diffuse signaling is evolutionarily highly conserved. The NO forming enzyme, NO synthase, is present mostly in the nervous system, especially the brain. A soluble form of guanylate cyclase is the major target of NO action. Usually there is cellular separation of the release site and target site of NO, although exceptions to this rule exist.

As with cAMP, cGMP is important for memory in insects. In the honeybee, for example, the NO/cGMP system in the antennal lobes is implicated in the processing of adaptive mechanisms during chemosensory processing, and experimental data support a specific role of the NO system in memory formation (14).

Signal transduction in gastric and intestinal smooth muscle is mediated by receptors coupled via distinct G-proteins to various effector enzymes. Calcium is implicated in signal transduction in different ways according to the cell type (e.g., circular and longitudinal muscle cells). The initial steps involve Ca^{2+}/calmodulin-dependent activation of myosin light-chain kinase and the interaction of actin and **myosin**. Relaxation is mediated by cAMP-and/or cGMP-dependent protein kinases. A specific cascade involves G-protein-dependent stimulation of Ca^{2+} influx, leading to Ca^{2+}/calmodulin-dependent activation of a constitutive NO synthase in muscle cells that activates soluble guanylyl cyclase. The resulting activation of protein kinase A and PKG is jointly responsible for muscle relaxation (15).

Therefore, cyclic GMP is a secondary messenger that acts on targets that are sometimes similar to those of cAMP but proceed through a completely different cascade, in which the diffusible NO (and sometimes carbon monoxide) play a major role.

Cyclins

From a simple start as a family of proteins with interesting patterns of accumulation during the cell cycle, the cyclins have grown to become key regulators of diverse cellular processes, in particular the cell cycle. Most cyclins, whether they are present only at specific times during the cell cycle or constitutively, exert their functions through their associated cyclin-dependent kinase (Cdk) binding partners. Binding to cyclins is one of the required steps in the activation of Cdks. The degradation of many cyclins by the ubiquitin system provides a means of inactivating the associated Cdk following completion of its function. A large number of cyclins have been identified including some, like the original cyclins, that have roles in cell cycle progression, and others that don't cycle and that activate Cdks involved in very different activities, such as transcription.

The first cyclins were found during studies of translational control before and after fertilization of sea urchin eggs conducted as part of the Physiology course at the Marine Biological Laboratory in Woods Hole (1). These proteins were synthesized continuously, and accumulated until their abrupt degradation during mitosis. This sawtooth pattern of accumulation hinted that cyclins might play an important role during the cell cycle, either as inducers of cell cycle transitions or, perhaps less interestingly, as proteins that responded to cell cycle states to perform functions important for that stage. Later work showed that the injection of cyclin mRNA caused frog oocytes to mature into eggs (2), that is, to progress through meiosis and to arrest in second meiotic metaphase, ready for fertilization. This result suggested that cyclins were actually inducers of the transitions into meiosis and mitosis. Subsequent work revealed that the mitotic cyclins are the regulatory subunits of maturation promoting factor (MPF) (3, 4). MPF had been characterized as a proteinaceous activity that, when withdrawn from the cytoplasm of an egg and injected into an oocyte, caused that oocyte to mature into an egg. The catalytic subunit of Xenopus MPF had recently been determined to be Cdc2, a protein kinase first identified by genetic studies in the fission yeast *Schizosaccharomyces pombe* as the key regulator of the G2-M phase transition. The following years rapidly revealed large families of proteins showing sequence similarity to the original, mitotic cyclins, and to Cdc2. The cyclins are referred to by letter (cyclin A, cyclin B, ¼) and the kinase partners have been called cyclin-dependent kinases (Cdk2, Cdk3¼). (For further discussion of these and other aspects of cyclin function, see Cell Cycle.)

One of the irreversible ratchet steps in the cell cycle is the degradation of cyclins by the ubiquitin system (5). Ubiquitin is a 76-aa protein whose covalent attachment to proteins can target them for proteolysis by the proteasome, a huge multiprotease unwinding and degrading machine. Ubiquitin is activated by its ATP-dependent covalent attachment to a cysteine side chain on an enzyme called E1. E1 then transfers ubiquitin to a cysteine of one of many E2 enzymes. The E2s can ubiquitinate substrates, often with the help of an E3. The E3s may be the most diverse and interesting components of this system. Some E3s receive the covalently bound ubiquitin; others serve as matchmakers that bring together a substrate and the appropriate E2. For the mitotic cyclins, the E3 was first termed the cyclosome, though it is now generally termed the anaphase promoting complex (APC), which consists of 8 to 12 subunits. The APC is the regulated component of the ubiquitin system for the degradation of the mitotic cyclins and serves as the target for checkpoint signals that can block cyclin degradation. Proteolysis of cyclins that act earlier in the cell cycle has been best studied in the budding yeast *S. cerevisiae* and, though mediated by the ubiquitin system, uses an “SCF complex” as the E3 component, rather than the APC.

The cyclins now comprise a large family of proteins with diverse functions, each bound to a cyclin-dependent kinase (Cdt) catalytic partner. All cyclins resemble the first mitotic cyclins (cyclin A and B) in sequence, but not all cycle during the cell cycle. Cyclins A, B, D, and E play major roles in regulating cell cycle transitions. The cell cycle stage at which each kinase functions is largely determined by when each cyclin partner accumulates during the cell cycle. Quite a few cyclins (and their associated Cdks) function in transcription. For instance, cyclin H is one of the subunits of TFIIH, a general transcription factor for RNA polymerase II involved in the phosphorylation of the C-terminal domain (CTD) of the large subunit of the polymerase. Cyclin C is a subunit of the RNA polymerase II holoenzyme, which can also phosphorylate the CTD. As more cyclins are discovered (and the alphabet is exhausted!) the majority of all cyclins will probably be noncycling regulatory subunits of protein kinases functioning in processes other than the cell cycle. The observation that the first cyclins had cyclic patterns of accumulation and were involved in cell cycle control may represent more a historical footnote owing to their relative ease of discovery than a reflection of fundamental properties of this family of proteins.

Direct roles of cellular cyclins in diseases are extremely rare. For instance, some tumor cells contain cyclin gene amplifications. Many tumors overexpress cyclin messenger RNAs, presumably a secondary consequence of increased rates of cell proliferation. Much more important, however, is the general circumvention of normal cell cycle controls that is a hallmark of cancers. This topic is discussed in Cell Cycle. Interestingly, some viruses have co-opted cyclins to subvert normal cell cycle controls (6). For instance, the Kaposi Sarcoma Associated Herpesvirus encodes a D-type cyclin. Following infection, this cyclin associates with Cdk6, which is involved in progression through the G1 phase of the cell cycle, and activates it in a manner that makes it resistant to Cdk inhibitor proteins that normally restrain G1 progression. The infected cell is thereby pushed into S phase, allowing the virus to replicate and to produce progeny virus. This situation provides yet another example of how viruses have adapted normal cellular proteins for their own ends.

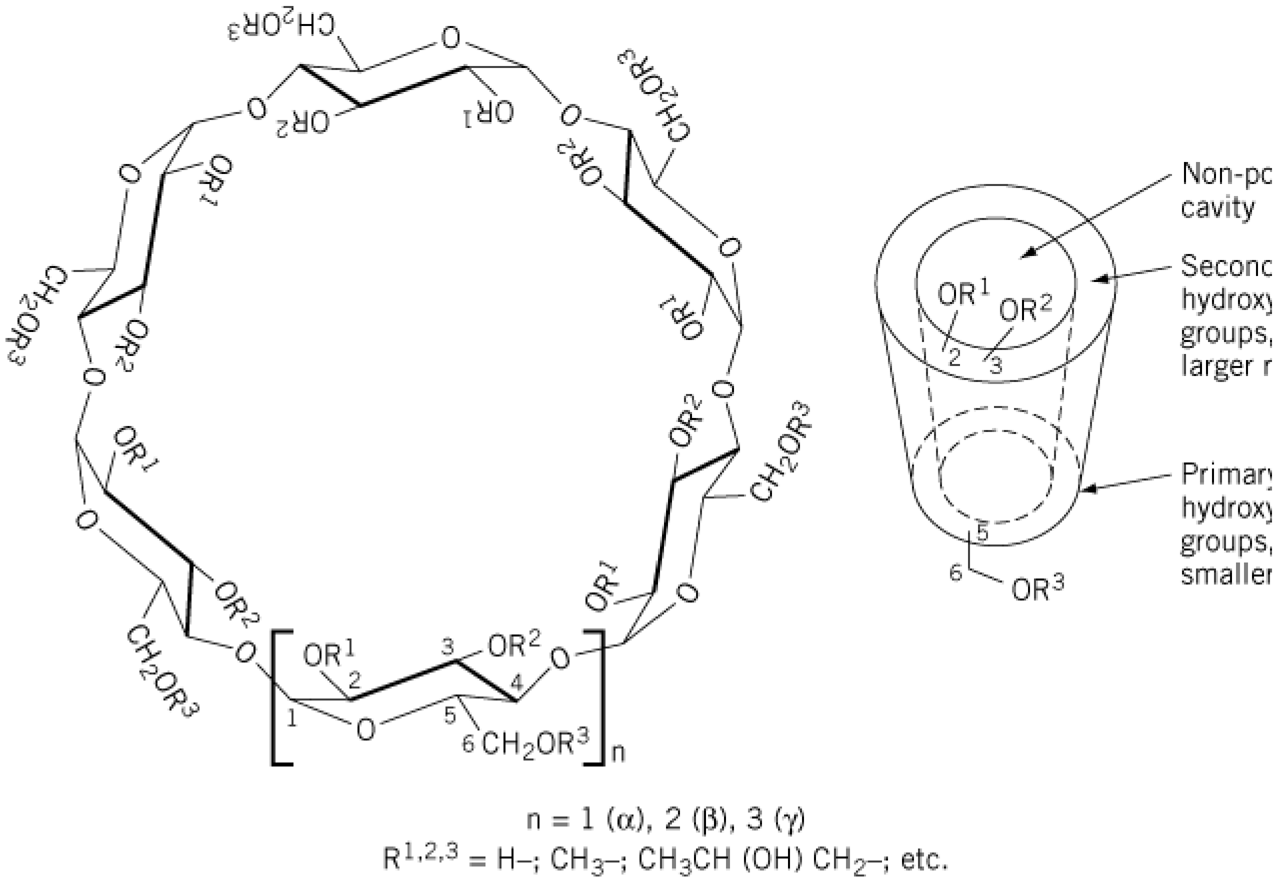
Cyclodextrins

Cyclodextrins are cyclic oligosaccharides with a truncated cone shape and an axial void cavity (Fig. 1). The diameter and the volume of the cavity vary with the number of glucose units in the cyclodextrin ring (1). The most commonly used cyclodextrin is b-cyclodextrin, which has seven glucose units and a cavity with a diameter of 0.78 nm and a volume of approximately 35 nm^3. Other natural cyclodextrins, such as a- and g-cyclodextrin, with six and eight glucose units and 0.57- and 0.95-nm cavity diameters, respectively, are also frequently used. The outer surface of the cyclodextrin molecule is hydrophilic, because the majority of the hydroxyl groups project outward, resulting in good water solubility. The internal cavity is relatively nonpolar, and it can encapsulate nonpolar solutes of appropriate dimensions, with binding occurring through various nonpolar interactions. Such binding is known as *inclusion complexation*.

Figure 1. Cyclodextrin structure.



The conformation of cyclodextrins in aqueous solution is believed to be that of the truncated cone of Figure 1. Molecules of **hydrophobic** compounds of appropriate size and shape penetrate into the cavity and are bound mainly through hydrophobic interactions, whose strengths depend on the efficiency of the contact. The edge of the torus of the larger circumference consists of secondary hydroxyl groups that are attached to **chiral** carbons (C2 and C3 of the glucose units). This structure results in variable binding affinities for different enantiomers, probably due to interactions of the chiral solute with the chiral entrance to the cavity (2). The primary hydroxyl groups of the glucose monomers make up the smaller edge of the cone. Chemical derivatization of natural cyclodextrins via modification of their hydroxyl groups is currently an area of very active research (3-6). Such modifications are yielding materials of varying complexation selectivities and physicochemical properties, such as improved solubility (7).

Hoffmann and Bock (8) have examined complex formation between different cyclodextrins and **nucleotides**. They found that adenosine, cytidine, guanosine, uridine, inositol, and deoxythymidine monophosphates (AMP, CMP, GMP, UMP, IMP, and dTMP) did not form a complex with a-cyclodextrin, but b-cyclodextrin readily bound AMP and IMP. It was concluded that that these six nucleotides are too bulky to fit into the cavity of a-cyclodextrin. When a complex is formed with b-cyclodextrin, the ribose and phosphate groups of the nucleotides exert a stabilizing effect by establishing hydrogen bonds with the outer rim of the cyclodextrin molecules. The position of the phosphate group is not important; increasing distance of the phosphate group from the base increased the stability of the complex. Larger oligonucleotides exhibited decreasing tendencies for complex formation, but the extent of complexation depended significantly on their base composition. Interestingly, polynucleotides with double- or triple-helical structures did not show any complexation with b-cyclodextrin (9). Transfer RNA, which comprises both helical and nonhelical structures, can interact with cyclodextrins, and these complexes have been used extensively for tRNA studies.

Cyclodextrins have also been used in labeling nucleic acid molecules in various biochemical analysis applications, especially in DNA sequencing. Cyclodextrin labels provide potentially high signal efficiency and versatility in label colors, while maintaining uniform chemical and physical properties. Cyclodextrin tracers are prepared by coupling the cyclodextrin to specific binding substances, such as nucleic acids, and forming inclusion complexes with the fluorophores. Then the DNA molecules are sequenced using cyclodextrin-labeled chain terminators. This method allows DNA sequencing with high sensitivity and high throughput (10).

Ikeda et al. (11) reported the use of anthryl(alkylamino)–cyclodextrin complexes as chemically switched DNA intercalators that were allosteric. On adding a ligand that is tightly bound in the cyclodextrin cavity, such as 1-adamantol, the host molecule releases the anthryl unit, which then leads to strong intercalation with the double-stranded DNA molecule. This principle could be extremely useful in nucleic acid reactions of medicinal and biotechnological importance, particularly in view of the established methods to modify cyclodextrins for specific interactions with a wide range of substances, for new drug delivery systems.

Cyclodextrins and their analogs can also be used as carriers to increase cellular uptake of phosphorothioate antisense oligonucleotides. Cellular uptake of phosphorothioate oligodeoxynucleotides in the presence of various cyclodextrin analogs was found to depend on the concentration and the time. In particular, 2-hydroxypropyl-b-cyclodextrin (HPbCD), 2-hydroxyethyl-b-cyclodextrin (HEbCD), and a mixture of various HPbCDs having different degree of substitution were observed to increase the uptake of phosphorothioate oligodeoxynucleotides two- to threefold in 48 h (12).

Cyclodextrins and derivatives are used to enhance the bioavailability of many water-insoluble pharmaceuticals (13). The solubilization results in fast and quantitative *in vivo* delivery for intravenous and intramuscular dosing. A decrease in irritation at the administered site can be observed (14). The solubility of hormones such as hydrocortisone was enhanced 72-fold using randomly methylated b-cyclodextrin (15). Sublingual administration of g-cyclodextrin complex of testosterone avoided rapid first-pass loss of the hormone and directed it effectively into the circulation; administration of the complex into the stomach resulted in much lower circulatory hormone levels (16).

The relatively good water solubility of the cyclodextrins makes these materials useful in chromatography and electrophoresis separation methods, such as in HPLC (high-performance liquid chromatography) and capillary zone electrophoresis (CZE) (17, 18). Buffer systems, even with organic modifiers, can be used to control the pH or modify other secondary equilibrium. Temperature also has a significant effect on selectivity in cyclodextrin-mediated separation systems.

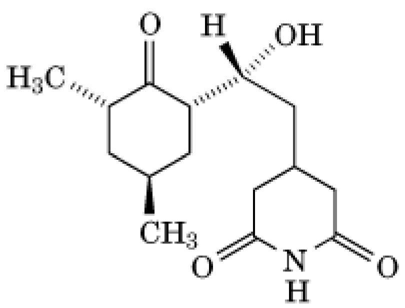
Cycloheximide

$C_{15}H_{23}NO_4$ (Fig. 1; molecular mass, 281.35). Cycloheximide is an antibiotic produced by *Streptomyces griseus*, and it inhibits protein biosynthesis in eukaryotes. Cycloheximide does not affect protein synthesis in prokaryotes or in mitochondria. It binds to the 60S subunit of eukaryotic ribosomes and inhibits the peptidyl transferase activity. The inhibition of peptidyl transfer causes a stack of ribosomes on the messenger RNA, generating polysome accumulation in cells. Cycloheximide is frequently used for the study of gene expression in eukaryotes as an inhibitor of protein synthesis *in vivo*, as well as *in vitro*.

Figure 1. Cycloheximide.



Cyclophilin

Historically, an 18-kDa cytosolic protein from pig kidney was the first peptidyl prolyl cis/trans isomerase (abbreviated PPIase) discovered and characterized enzymatically (1). These enzymes catalyze the rotation of a peptidyl prolyl moiety in peptides and proteins. In 1989 it was found that this protein is nearly identical in its primary structure to the already known cytosolic receptor of the immunosuppressive undecapeptide cyclosporin A in human T lymphocytes, previously named cyclophilin [Cyp18; for nomenclature see (2)] (3-5). This enzyme represents the archetype of cyclophilins in that it constitutes the catalytic **domain** of larger cyclophilin-like proteins. Now two additional families of such isomerases are known, those that bind FK506 (FKBP) and the parvulin family.

Alignment of amino acid sequences of the cyclophilin family defines residues that are highly conserved among vertebrates, plants, fungi, and bacteria. Nearly perfect conservation is located primarily in the central segment of the protein, including the sequences -Phe-His-Arg-Ile/Val-Ile-$(Xaa)_5$-Gln-Gly-Gly- at positions 53 to 65 and -Met-Ala-$(Xaa)_{9–10}$-Gln-Phe-Phe/Tyr-Ile/Val- at positions 100 to 114, where Xaa is any amino acid and / separates alternatives. These sequences are used as typical **motifs** to search for other cyclophilins. The three-dimensional structure of the archetypal cyclophilin consists of an eight-stranded antiparallel b-sheet barrel capped by a-**helices** (6, 7).

The characterization of 11 distinct cyclophilin genes in the genome of the nematode *Caenorhabditis elegans* demonstrates that organisms use numerous cyclophilins (8). As many as 12 human homologues have been identified thus far from the initial assessment of gene diversity by expressed sequence tag analysis. The C-terminal and/or N-terminal amino acid extensions of larger cyclophilins consist of additional **domains**, directing the proteins into specific cellular compartments, mediating protein/protein and DNA/protein interactions, or generating other biochemical functions.

The cytosolic Cyp18 often represents the major cyclophilin of cells. Kidney tubules and endothelial cells, for example, contain 10 µg of Cyp18 per mg total protein (9). Despite the numerous studies reporting the three-dimensional structures of Cyp18-bound oligopeptide substrates and inhibitors (10-12), a definite catalytic mechanism for cyclophilins and other PPIases is still lacking. It is currently believed that catalysis arises from a combination of desolvation of the substrate and substrate-assisted catalysis. Electrophilic assistance, for example, by the Arg55 residue of Cyp18, can also be envisaged to account for the more effective catalysis found for cyclophilins, compared to FKBPs. The positively charged side-chain of this amino acid residue is located within **hydrogen-bonding** distance and perpendicular to the plane of the substrate proline ring in Cyp18/substrate complexes. This environment may cause additional weakening of the reactive C–N linkage by immobilizing the lone pair of electrons of the nitrogen atom. Indeed, a Cyp18 variant in which Arg55 has been replaced retains only 0.1% of the wild-type enzymatic activity (13).

Because of the putative functional redundancy and overlapping of the many PPIases present in most organisms, gene deletion experiments often do not lead to a recognizable **phenotype** under normal growth conditions. Among the seven cyclophilins found in *S. cerevisiae*, deletions of only two are associated with any phenotype. Disruption of *Cpr3*, the gene encoding the **mitochondrial** isoform of yeast cyclophilin, affects growth on L-lactate medium (14), whereas *cpr7*D cells are defective in normal cell growth (15). The expression of many PPIase genes seems to be sensitive to **heat shock** and to the chemical **stress response**.

Recently, it was shown that host cell cytosolic Cyp18 is required for **HIV**-1 infection before **reverse transcription** but subsequent to receptor binding and membrane fusion in T cells (16). A proline-rich segment of the capsid domain of $Pr55^{gag}$ mediates incorporation of Cyp18 into HIV-1 virions

(17). This conserved segment that contains four proline residues occurs in the sequence -Pro-$(Xaa)_4$-Pro222-$(Xaa)_2$-Pro-$(Xaa)_5$-Pro-. Mutant proteins of HIV-1_{HXB2} that have **site-directed mutations** in which Pro222 is replaced by Ala or Gly221 by Ala, fail to bind to the **fusion protein** glutathione-S-transferase/Cyp18. Virions that contain these altered proteins cannot sequester Cyp18 into the released virions, emphasizing the importance of the Gly-Pro^{222} bond for $Pr55^{gag}$ /Cyp18 complex formation. The ability of many cyclosporin derivatives to dissociate the $Pr55^{gag}$/Cyp18 complex reveals a quantitative relationship between Cyp18 inhibition and complex decomposition. Obviously, the antiviral effect of cyclosporin A must be caused by a pathway distinctive from immunosuppression because cyclosporin A derivatives with negligible immunosuppressive activity, but high affinities for the active site of Cyp18, retain potent anti-HIV activity (18-20).

A genetic **cDNA** screen was used to identify the bovine homologue of the retina-specific cyclophilin NinaA of *Drosophila*. The membrane-localized PPIase of the secretory pathway of the fly is required for proper folding and trafficking of Rh1-6 opsin in photoreceptor cells (21). The bovine RanBP2 cyclophilin has a domain that binds to the GTPase Ran, as well as to red/green opsin. A still unknown modification of opsin, possibly a prolyl bond isomerization catalyzed by the Cyp-domain of RanBP2, augments and stabilizes the interaction between the Ran-binding domain and opsin. This modification is important in membrane trafficking of long-wavelength opsin in photoreceptors (22).

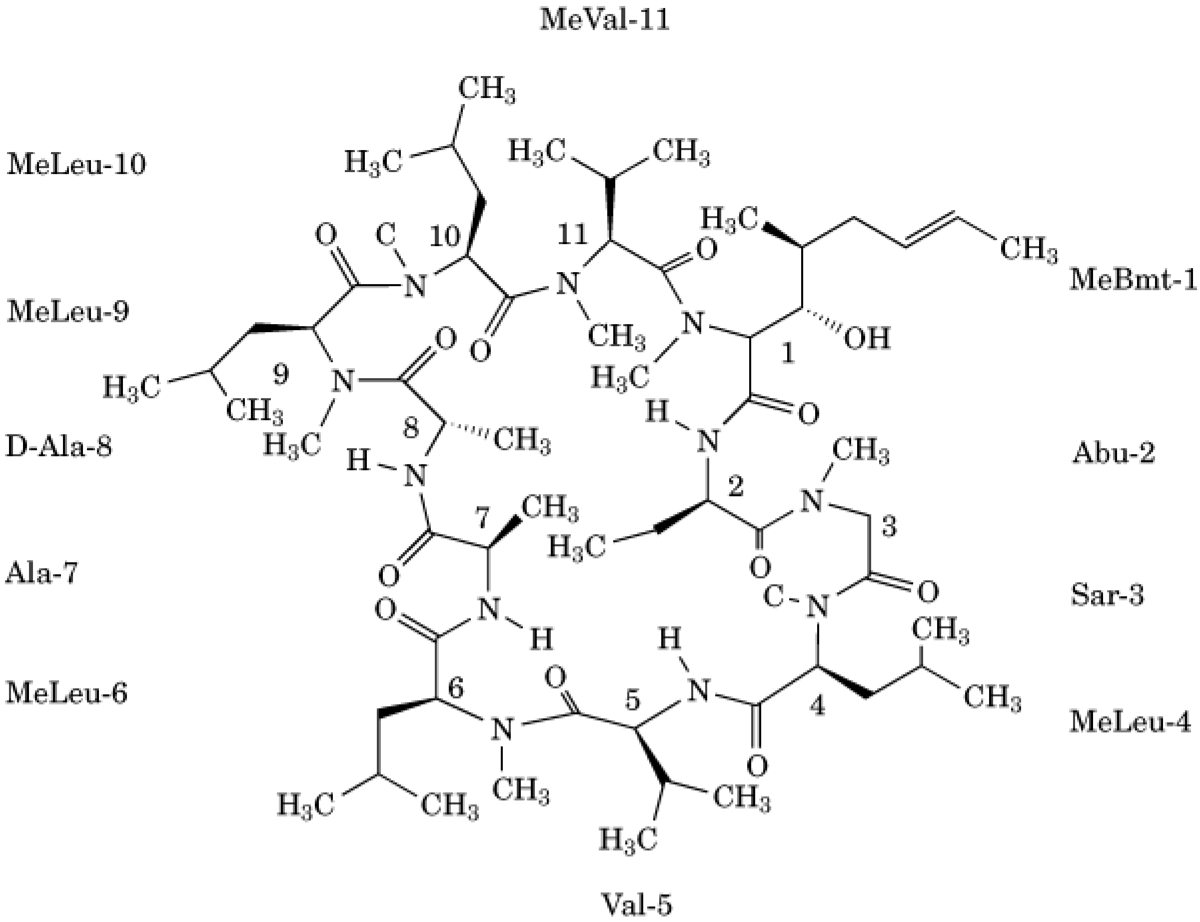
Cyclosporin

The cyclosporin family of secondary metabolites from the **fungus** imperfectus *Beauveria nivea* are cyclic undecapeptides characterized by an enormous spectrum of biological effects. The most widely used derivative, cyclosporin A (CsA), is immunosuppressive, antiinflammatory, and antichemotactic, and combats multidrug-resistance and viral, fungal, and parasitic infections, without being cytotoxic to mammalian cells (1, 2). Among a number of other *N*-methyl amino acids, CsA contains an uncommon amino acid at position 1, the (4*R*)-4([(*E*)-2-butenyl]-4-*N*-dimethyl-L-threonine (Fig. 1). Several minor congeners of CsA, designated CsB, CsC ¼ CsZ, have been found as by-products of the fermentation process. The [D-MeVal^{11}]-CsA derivative (CsH) is devoid of most biological effects, thereby serving as a control for nonspecific interactions. Other derivatives have been developed that exhibit a more restricted spectrum of biological activities compared to CsA. For example, [L-MeLeu(3-OH)^{1},MeAla^{4,6}]-CsA is nonimmunosuppressive but has enhanced antiviral efficacy (3). In the fungus, non-ribosomal synthesis of cyclosporins occurs on a huge, single-chain enzyme with a molecular mass of 1,689 kDa, termed cyclosporin synthetase . It utilizes unmethylated natural amino acids, ATP/Mg^{2+} and S-adenosyl-L-methionine as starting materials in biosynthesis (4). Beside its use as a powerful tool for unraveling the molecular basis of the cellular immune response, the therapeutic application of CsA has revolutionized the likelihood of success for organ transplantation since its introduction in 1983 (5). Other disorders with immune components, like psoriasis and juvenile diabetes, are relieved with the aid of cyclosporins.

Figure 1. Structure of cyclosporin A.



The dramatic effects of CsA on the cellular immune response, in which the T cells remain in a nonproliferative state, results primarily from the impaired expression of a number of lymphokine genes. This could include a variety of interleukins (IL-2, IL-3, IL-4), factors, such as granulocyte macrophage colony stimulating factor (GM-CSF), tumor necrosis factor a (TNF-a) and **g-interferon**, and the **oncogene** c-myc, all synthesized subsequent to antigen stimulation of T cells. Initial investigations identified cytosolic cyclophilin Cyp18 as the specific receptor for CsA in T cells, but minor **isoenzymes** cannot be completely ruled out yet.

The three-dimensional structure of the inhibitory CsA/Cyp18 complex was determined by X-ray crystallographic and NMR methods (6-8). The structure of Cyp18 is hardly affected by complex formation, whereas that of CsA bound to Cyp18 is dramatically different when in nonpolar organic solvents or in the solid state. In response to the altered conformation of CsA in the complex, the inhibition of the PPIase activity of Cyp18 by CsA is time-dependent, including a ***cis/trans* isomerization** of the peptide bond between MeLeu^{9}-MeLeu^{10}. Site-directed mutagenesis of Cyp18 indicates the involvement of a **hydrophobic** pocket of side-chains, with Trp121 as a major determinant, in the tight binding of CsA to Cyp18, with an inhibition constant, K_i of 2.3 nM. Comparison of Cyp18/substrate complexes with Cyp18/CsA indicates that the peptide chain of CsA runs in the opposite direction. The MeVal11 side-chain of the inhibitor occupies the place of the substrate proline ring.

In some cases, binding of cyclosporins to the targeted cyclophilin and inhibition of its PPIase activity may explain the biological effect of cyclosporins. In contrast, binding of CsA to Cyp18 is necessary, but not sufficient, to arrest signals for the cellular immune response. For example, [MeAla^{6}]-CsA is an excellent inhibitor of the PPIase activity of Cyp18 but has only 1% of the immunosuppressive effect of CsA, whereas the weak inhibitor [$MeBm_2t^1$]-CsA (K_i > 1 μM) still shows a considerable fraction of the CsA effect (9).

Thus, for immunosuppression CsA (like FK506 and rapamycin) is best viewed as a pro-drug that is activated functionally when bound to Cyp18 (10). Once formed from the components, the complexes CsA/Cyp18 or FK506/FKBP12 bind to and inactivate reversibly, in a noncompetitive mechanism, the Ca^{2+}- and calmodulin-dependent, heterodimeric protein **phosphatase** 2B (calcineurin). This enzyme catalyzes the dephosphorylation of Ser/Thr residues in phosphorylated proteins (11, 12). As a result of dephosphorylation, this enzyme induces the phosphorylated cytoplasmic subunit of NF-AT to translocate into the nucleus for association with the newly synthesized nuclear subunit of NF-AT to form a functional transcription factor (13).

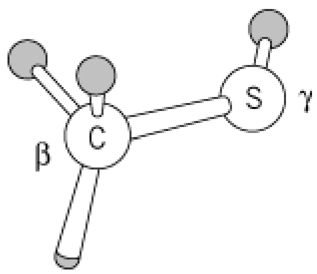
Cystatin

Cystatin is a protein inhibitor of cysteine proteinases from chicken egg white that gave its name to a family and superfamily of such inhibitors [see Cysteine (Cys, C); Proteinase Inhibitors, Protein].

Cysteine (Cys, C)

The amino acid cysteine is incorporated into the nascent polypeptide chain during **protein biosynthesis** in response to two **codons**—UGU and UGC—and represents only 1.7% of the residues of the proteins that have been characterized. The cysteinyl residue incorporated has a mass of 103.15 Da, a **van der Waals volume** of 86 Å^3, and an accessible surface area of 140 Å^2. Cys residues are one of the most conserved type of residue during divergent evolution; they are interchanged in **homologous** proteins most frequently with serine residues.

The thiol group of the Cys side-chain



is the most reactive of any of the normal amino acids. It undergoes numerous chemical reactions with a variety of reagents (see Thiol Groups). These reactions provide means for counting and measuring the number of Cys residues present in a protein (see Counting Residues and -Dithiobis-(2-Nitrobenzoic Acid), DTNB). It is the ionized thiolate anion that is reactive, and only it has **absorbance** in the UV region; the pK_a value of a typical exposed Cys thiol group is 8.7, but deviations as low as 3.5 and greater than 11 are known, depending on the environment (1).

In the nonionized form, the thiol group is not very polar or reactive, and thiol groups may be buried in folded proteins without the need for any hydrogen bonding. Approximately 40–50% of Cys residues are fully buried in folded protein structures. They occur predominantly in beta-sheet type of **secondary structure**. Cys residues can serve as efficient "capping" residues at the *N*-termini of a-helices in which their thiol group interacts with the hydrogen bonding groups of the backbone; the pK_a can then be decreased and the thiol groups made more reactive; probably for that reason, Cys residues occur at such positions in folded proteins only when important for function (2).

A notable tendency is for two Cys residues of the same or different polypeptide chains to form disulfide bonds. This occurs only if the protein conformation permits, and disulfide formation is a useful probe of **protein folding** *in vitro*. *In vivo*, disulfide bonds are usually inserted primarily into proteins to be secreted by the catalyst protein disulfide isomerase.

If a protein is hydrolyzed to amino acids under conditions in which the disulfide bond persists, two cysteine amino acids linked by a disulfide bond result, which historically was known as the amino acid cystine. Peptide bonds preceding Cys residues can be cleaved by cyanylation with 2-nitro-5-thiocyanobenzoic acid, followed by incubation at alkaline pH (3). The reaction is specific for Cys residues but has the disadvantage that the new *N*-terminus generated is blocked and not amenable to further **sequencing** by the Edman Degradation.

Thiol groups have intrinsic affinities for many metal ions, and they are used in proteins to ligate ions of zinc, iron, and copper. In an extreme example, metallothioneins about a third of the residues are Cys. The thiol groups of Cys residues are also used as nucleophiles in catalysis in the thiol proteinases.

Cys residues are the sites of several types of post-translational modifications, in addition to disulfide formation. **Farnesyl groups** and geranylgeranyl groups can be added to Cys residues at the *C*-termini of certain proteins, after removal of a few *C*-terminal residues. **Palmitoyl groups** can be attached in thioester linkages to the side chains of Cys residues.

Cysteine Proteinase Inhibitors

Cysteine proteinase inhibitors attracted wide attention and, after serine proteinase inhibitors [see Serine Proteinase Inhibitors, Protein], have the most frequently described members. Most but not all of these belong to the cystatin superfamily, which is frequently divided into three families: the stefin, the cystatin, and the kininogen families. The stefins are low molecular weight (about 100 residues) molecules without attached carbohydrate and without any intramolecular disulfide bridges. They are extremely stable intracellular proteins. The word *stefin* comes from the name of the J. Stefin Institute in Ljubljana (Slovenia), where the first stefin was discovered. Cystatins proper are only slightly bigger than stefins (120–130 residues). They contain two disulfide bridges near their COOH terminals and typically are secretory proteins. The family and superfamily are named after chicken egg white cystatin, which was discovered long before the other cystatins became popular. The third family of cystatins is the kininogen family. Proteins are assigned to it on the basis of the high molecular weights of its members, predominantly HMW (high molecular weight) (120 kD) and LMW (low molecular weight) (68 kD) kininogens. Kininogens are glycosylated and contain numerous disulfide bridges. Each contains three cystatin like repeats.

All cystatin family members inhibit only cysteine proteinases and only those related to papain but, within this broad group, they exhibit little discrimination between individual enzymes. In strong contrast to serine proteinase inhibitors, cystatins react with enzymes whose catalytic sulfhydryl group is significantly blocked. The mode of association was elucidated in detail from the three-dimensional structure of a complex of stefin A with papain.

In avian and mammalian cells, there are present cysteine proteinases called calcium-activated neutral proteinases (CANP), or calpains. These complicated multidomain enzymes are of great importance in the metabolism of muscles. They are controlled by a closely related family of molecularly complex endogenous protein inhibitors—calpastatins.

Cystine Knot

The cystine knot is a common protein motif that occurs in some protein structures. It incorporates an antiparallel b-sheet and three disulfide bonds, one of which passes through a ring formed by the other two disulfides (Fig. 1). Two families of cystine knot motifs have been identified. One is the growth factor cystine knot family (1, 2) that includes **nerve growth factor**, **transforming growth factor b2**, platelet derived growth factor, and human chorionic gonadotrophin. In this topology, the six cysteine residues (designated CI through CVI) form three disulfide bridges (CI-IV, CII-V, CIII-VI), with CI-IV passing through the ring formed by the disulfides of CII-V and CIII-VI. The size of the ring varies from 8 to 14 residues. The b-sheet is formed from four antiparallel b-strands. These cystine knot growth factors are all dimeric, but their dimer interfaces differ.

Figure 1. Schematic representation of the backbone structure of the growth factor cystine knot protein, nerve growth factor (4). b-Strands are shown as arrows, and the three disulfide bonds of the cystine knot are shown in gray, with the sulfur atoms depicted as gray spheres. The *N*- and *C*-termini are labeled. This figure was generated using Molscript (5) and Raster3D (6, 7).

The second group is the inhibitor cystine knot family (3) and includes the neurotoxin w-conotoxin GVIA and the uterotonic peptide kalata B1. The inhibitor cystine knot motif has the same disulfide bond pattern as the growth factor cystine knot, but in this case the knot is formed by CIII-VI passing through the ring formed by disulfides CI-IV and CII-V. The ring of the inhibitor cystine knot varies from 8 to 12 atoms, and the b-sheet is triple stranded and antiparallel.

Cytochalasin

Cytochalasins are a group of fungal metabolites that can permeate cell membranes and exert very strong effects on the cytoskeleton: ruffling and translocation are stopped, and cells round up (1, 2). In addition, cytochalasins A and B also inhibit glucose transport across the plasma membrane. Although it was originally believed that the main action of the cytochalsins on the cytoskeleton was binding with high affinity to the barbed, or fast-growing end of the actin filament, and inhibiting subunit addition and loss, it has become clear that the effects are more complex. The concentrations of cytochalasins used in cell biological experiments will have strong effects on actin monomers and may convert much of a cell's monomeric G-ATP actin to G-ADP actin (3). In addition, even at saturating concentrations cytochalasins do not completely block the fast-growing ends with respect to subunit addition or loss (3). Thus, the action of cytochalsin on a living cell is likely to be complicated and may affect the interactions of actin with many actin-binding proteins. Nevertheless, as a result of the large effect cytochalsins have on actin, they have been widely used to study the role of the actin cytoskeleton in cellular processes.

Cytochrome P450

Cytochromes P450 (designated here as P450) arise from a superfamily of **genes** that encode hemoproteins with molecular weights of 40 to 55 kDa and extraordinarily diverse properties and functions. P450 is nearly ubiquitous in the biotic world, with over 500 genes characterized in **plants**, animals, **fungi**, and **bacteria**, although it is not present in all organisms. Of the substrates of P450, 1000 are known, and there are perhaps as many as 10^6 in total; more than 40 different reactions are catalyzed (1). These enzymes play a critical role in:

1. Detoxification of bioactive molecules in vertebrates, insects, and plants
2. Metabolic activation of compounds that are both beneficial (drug precursors, hormones) and detrimental (carcinogens)
3. Biogenesis and catabolism of many endogenous compounds, including steroid hormones, vitamin D, biological insecticides, fatty acids, insect pheromones, and plant lignins and pigments

The P450 that metabolize xenobiotics appear to have no critical physiological functions, since mice with disrupted genes for these proteins had no obvious phenotypic abnormalities (2, 3). Most P450 proteins are membrane-bound in the endoplasmic reticulum (microsomes) or mitochondria, but soluble forms are present in bacteria. In mammals, the greatest concentrations of P450, particularly the detoxification forms, are present in the liver, but they are probably present in most tissues of the body, with relatively high concentrations in the intestines, lungs, nasal epithelia, and steroidogenic tissues. The genes for these enzymes differ in size, **intron** number, and **chromosomal** location. **Gene expression** of subsets of the P450 is regulated by a variety of substances, including xenobiotics such as aromatic hydrocarbons, barbiturates, and **peroxisomal** proliferators, and by endogenous steroid and polypeptide hormones.

The name cytochrome P450 is based on the characteristic increase in the absorbance of the protein heme group at 450 nm upon binding of CO and reduction of its iron atom. P450 differ structurally from most cytochromes because the fifth coordination group of the iron atom of the heme is occupied by a thiolate group from a cysteine residue and the sixth is occupied by water. They differ functionally because P450 are monooxygenases and not simply electron carriers (see Cytochromes).

1. Classification

On the basis of amino acid sequence similarity, the P450 are divided into more than 100 families and subfamilies (4). The various P450 within a gene family generally have >40% sequence identity, and members within a subfamily have identities >55% within mammalian species and >46% overall. P450 with >97% identity are arbitrarily considered **allelic** variants unless there is independent evidence for separate gene loci. Genes from animals, fungi, plants, or bacteria are assigned family numbers 1–49, 51–69, 71–99, and 101 and above, respectively. Family 51 is represented in plants and mammals, as well as fungi.

The recommended nomenclature for P450 genes is an italicized *CYP* (*Cyp* for mouse and *Drosophila*) followed by an Arabic number designating the family, a letter for the subfamily, and a second number for the member of the subfamily, eg, *CYP1A1* (4). Identical terminology is used for gene products, except that the name is not italicized. Trivial names of P450 and other designations of the proteins, such as cytochrome P450 1A1, P450 1A1 or 1A1, are also considered acceptable in publications so long as the official name is specified.

2. Catalytic Activity

The overall reaction catalyzed by P450 is

$$\mathrm{RH} + \mathrm{O_2} + \mathrm{NADPH} + \mathrm{H^+} \longrightarrow \mathrm{ROH} + \mathrm{H_2O} + \mathrm{NADP^+}$$

where R is an organic substrate. One oxygen atom of the O_2 is incorporated into the substrate and the other is reduced to water, so P450 is both a monooxygenase and mixed-function oxidase. Further reactions and rearrangements lead to more than 40 different types of chemical reactions, including aliphatic and aromatic oxidations, N-, S-, and O-dealkylations, oxidative deamination, and peroxidation.

The P450 reaction cycle starts with the binding of the substrate to the ferric form of P450, which is followed by reduction of the heme iron atom by acceptance of an electron, binding of O_2, activation of the oxygen by acceptance of a second electron, and scission of the oxygen molecule, followed by formation of water, a hydroxylated product, and ferric P450. The two electrons from NADPH are donated either to microsomal P450, through a flavoprotein, P450 reductase, or to mitochondrial and bacterial P450, sequentially through a flavoprotein (a ferredoxin reductase) and an iron-sulfur ferredoxin. In rare cases, the P450 and P450 reductase are fused into a single protein (5). Cytochrome b_5 increases the activity of some P450 *in vitro*, either as a source of the second electron or **allosterically** (6).

3. Structure

The catalytic domain of membrane-bound P450 is oriented toward the cytoplasm for the microsomal forms and toward the matrix for the mitochondrial forms. The microsomal P450 are inserted into the membrane in a cotranslational, signal recognition particle-dependent manner (7). The N-terminal 20 to 25 amino acid residues function as a membrane-insertion and halt-transfer signal and are not cleaved, so they anchor the protein to the membrane. The mitochondrial P450 contain standard cleavable mitochondrial targeting signals at their N-terminus, but the mode of insertion into the inner membrane of the mitochondria is not known.

The three-dimensional structures of soluble bacterial P450, but not any membrane-bound P450, have been determined. Although the primary sequence is dissimilar among these bacterial proteins, a common "P450 fold" is present in each (see Protein Structure), which suggests that a similar core structure will also be present in eukaryotic membrane-bound P450 (8). The P450 structure contains an **alpha-helical** region and a beta-sheet region, which constitute about 70 and 20%, respectively, of the polypeptide chain. The sequence FXXGXXXCXG, which includes the heme-binding cysteine residue, is conserved in nearly all P450. Structures of eukaryotic P450 have been predicted from amino acid sequence alignments and homology molecular modeling with bacteria P450 (see Protein Structure Prediction), and predictions of residues that interact with substrates have been generally consistent with the observed effects of mutations (9, 10).

4. Gene Structure

The sizes of the eukaryotic P450 genes, from the transcription initiation site to the polyadenylation site, vary dramatically, from about 3 kb for the *CYP21* genes to >70 kb for *CYP19* genes (11). In higher eukaryotes, the number of **introns** varies from 6 to 13, and the sites of insertion of introns are almost always conserved within a family, but only rarely between families. **Polymorphism** is common in P450 genes and underlies genetic differences in drug metabolism and congenital diseases in humans. The families of P450 genes are dispersed among at least nine chromosomes in humans and mice, but occasionally families cluster together, such as families 1, 11, and 19. Subfamilies within a family also may be dispersed to separate chromosomes or may cluster together, and members of the *CYP2A*, *CYP2B*, and *CYP2F* subfamilies are intermingled (4, 12). The gene duplication leading to the *CYP21A* locus included the C4 histocompatibility gene, so the two P450 genes alternate with the C4 gene. In spite of the diversity of P450 genes, their similarity in primary structures, the common three-dimensional fold, and some conserved intron sites among P450 genes support the idea that the P450 superfamily evolved by **divergence** from a common ancestral gene.

5. Gene Expression

P450 genes are expressed in tissue-, developmental-, and sex-specific patterns. The mechanisms regulating these patterns of expression are best understood in the liver and adrenal gland. An **orphan receptor** containing a **zinc finger**, termed Ad4BP or steroid factor-1 (SF-1), has been shown to be critical for the developmental and tissue-specific expression of P450 genes that are required for the biogenesis of adrenal and sex steroid hormones (13). The SF-1 gene has been disrupted in mice, with major effects on differentiation of the adrenal gland and gonads, pituitary gonadotropin function, and the ventral medial hypothalamus (14), so this gene has important developmental functions as well as effects on the expression of P450 genes. *CYP19*, aromatase, contains SF-1 sites, but its tissue-specific expression is also dependent on alternate **promoters** and transcription initiation sites (15).

All the known liver-enriched regulatory factors have been implicated in the expression of one or more P450 genes. Examples in which functional binding sites for liver-enriched factors have been demonstrated include HNF-1a for *CYP2E1*, HNF-4 for *CYP2C1/2/3*, DBP for *CYP2C6* and *CYP7*, HNF-3 for *CYP2C6*, C/EBPb for *CYP2D5*, and C/EBPa and C/EBPb for *CYP2B1/2* (16, 17). A variety of ubiquitously expressed factors also contribute to basal expression of the *CYP* genes. The developmental expression of *CYP2C6* correlates with the developmental activation of DBP (16), and the diurnal expression of DBP underlies the diurnal regulation of *CYP7* (18). Activation of *CYP2D5* by C/EBPb also requires the constitutive factor Sp1, which has a binding site near that of C/EBPb (16).

5.1. Sex-dependent Expression

The sex-dependent expression of several P450 genes in rodents may be mediated by more than one mechanism. In rats, the sex-specific expression of *CYP* genes is dependent on different patterns of growth hormone secretion in the two sexes. STAT transcription factors (19) and phospholipase$_{\mathbf{A2}}$ (20) may be involved in the growth hormone-regulated male-specific expression of specific *CYP* genes, but additional studies are required to establish the exact mechanism. In mice, a sex difference information (SDI) element is present in male-specific *Cpy2d9* and female-specific *Cyp2a4* (21). The SDI contains a CpG sequence that is **methylated** in a sex-dependent way, and a factor has been identified that binds in a methylation-dependent manner (22). The exact role of this factor is not yet resolved, as its tissue and developmental expression differs from that of the *CYP* genes.

5.2. Aromatic Hydrocarbons
The expression of subsets of the xenobiotic-metabolizing P450 genes is regulated by aromatic hydrocarbons, peroxisomal proliferators, and barbiturates. The induction of *CYP1A1* by aromatic hydrocarbons, including the halogenated aromatic hydrocarbon 2,3,7,8-tetrachlorodibenzo-*p*-dioxin, is best understood. Genetic differences in the induction of *Cyp1a1* in mice and in variants of cultured mouse hepatoma Hepa 1 cells contributed critically to the identification of a regulatory locus *AhR*, which encodes the aromatic hydrocarbon receptor, and a second gene, the Ah receptor nuclear translocator *Arnt*, which encodes a protein required for the **nuclear import** of AhR (23, 24). The AhR is complexed with the **molecular chaperone** hsp90 in the cytoplasm in uninduced cells, which is essential to maintain a functional AhR. Binding of the ligand results in the dissociation of hsp90 and localization of AhR in the nucleus. Arnt is a nuclear protein that binds to liganded AhR and is required for the binding of AhR to the DNA binding site (25). AhR/Arnt bind to multiple sites within an enhancer about 1 kb from the start site of transcription and disrupt the **nucleosomal** structure of the enhancer (23). In turn, the nucleosomal structure of the promoter region is also disrupted in a manner dependent on the **transactivation** domain of AhR, which then allows the binding of regulatory proteins to the proximal promoter. The core sequence of the binding sites, which have been designated xenobiotic-, dioxin-, or Ah-**response elements** by different investigators, is 5′-TNGCGTG-3′. Arnt binds to the core sequence, and AhR binds to the flanking sequence. Both AhR and Arnt contain (1) basic loop-helix-loop (bLHL) motifs near their N-termini; (2) PAS **domains**, which exhibit homology with the *Drosophila* proteins, Per and Sim; and (3) glutamine-rich, putative transcriptional activation domains in the C-terminal region (24). The ligand and hsp90 interact with sequences near the PAS domain of AhR, and the binding of AhR to Arnt involves the bHLH and PAS domains of each protein. Arnt is capable of transactivation independently, but AhR transactivation requires the association of AhR with Arnt.

5.3. Peroxisomal Proliferators
Induction of expression of the *CYP4A* genes by peroxisomal proliferators and fatty acids requires peroxisomal proliferator-activated receptor-a (PPARa), a member of the steroid hormone receptor family (26). CYP4A P450 catalyze the w-hydroxylation of fatty acids, including arachidonic acid, which may ultimately result in the degradation of the fatty acids by peroxisomes. The induction of *CYP4A* genes is defective in mice with disrupted PPARa genes (27). PPARa forms a heterodimer with retinoid-X-receptor (RXR) to activate the gene. The predominant sequence in *Cyp4A6* that confers the response to peroxisomal proliferators contains an imperfect repeat of the sequence AGGTCA, with a single base pair between the repeats and additional sequence to the 5′ side of the repeat. The 5′ sequence appears to be important for the specificity of binding of PPARa/RXRa to the nonconsensus, imperfect repeat of the peroxisomal proliferator response element present in *CYP4A6* (26).

5.4. Barbiturates
Induction of P450 genes by barbiturates is not well understood. Neither a barbiturate receptor nor specific barbiturate response elements in mammalian genes have been defined, and different mechanisms may be involved for different P450 (28). The system best understood is the induction by barbiturates of Bm-1, Bm-2, and Bm-3 P450 in ***Bacillus*** *megaterium* (29). In untreated cells, a repressor, Bm3R1, binds to a palindromic 20-bp sequence upstream of a promoter that drives the expression of both the repressor and Bm-3. In the presence of barbiturate, the binding is reversed,

which may result from direct effects on the repressor, but positively acting factors are also induced that compete for the binding of the repressor at the palindromic site and at sites termed "barbie boxes" present in the 5′ regions of the Bm-3 and Bm-1 genes. In the mammalian *CYP2B1/2* genes, evidence has been presented for phenobarbital responsive sequences in both the proximal promoter region, including barbie-box-like sequences (30), and in distal phenobarbital-responsive enhancers (31, 32). Identification of specific responsive elements and characterization of the cognate binding proteins will be required to establish the role of these regions in phenobarbital induction.

5.5. Glucocorticoids

A number of *CYP* genes are also modulated by glucocorticoids. In some cases, the effect is mediated through the classical glucocorticoid receptors, such as modulation by glucocorticoids of aromatic hydrocarbon induction of *CYP1A1* and phenobarbital induction of *CYP2B* genes (33). In other cases, such as *CYP3A* genes, the response to glucocorticoids occurs by nonclassical mechanisms that remain to be elucidated (34).

5.6. Cyclic AMP

Genes for P450 involved in steroid metabolism are induced by polypeptide hormones via **cyclic AMP**-mediated (cAMP) mechanisms (35). In the adrenal gland, *CYP11A*, *CYP11B*, *CYP17*, and *CYP21* are regulated in this way. Interestingly, even though each of these genes probably evolved from a common ancestor, different regulatory elements in the promoter of each gene mediate the cAMP response. A classical CREB binding site is present in *CYP11B*, but binding sites for proteins other than CREB are present in other genes, and different sites are present in ***orthologous** genes* in different species. In bovine *CYP11A*, a binding site for Sp1, a constitutive factor, mediates the cAMP response (36), and members of the **homeodomain** PBX family of helix-turn-helix motif proteins bind to the cAMP-responsive element in *CYP17* (37). Multiple proteins bind to many of these elements, and those that predominate *in vivo* remain to be identified.

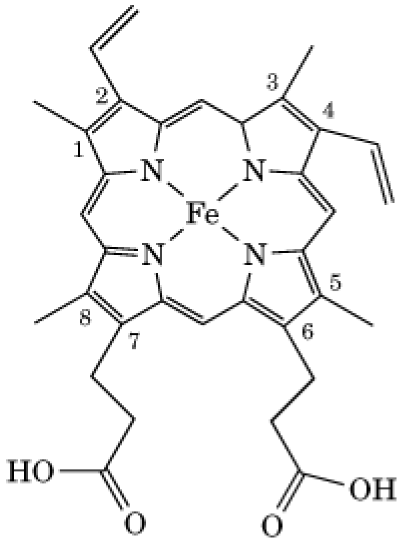
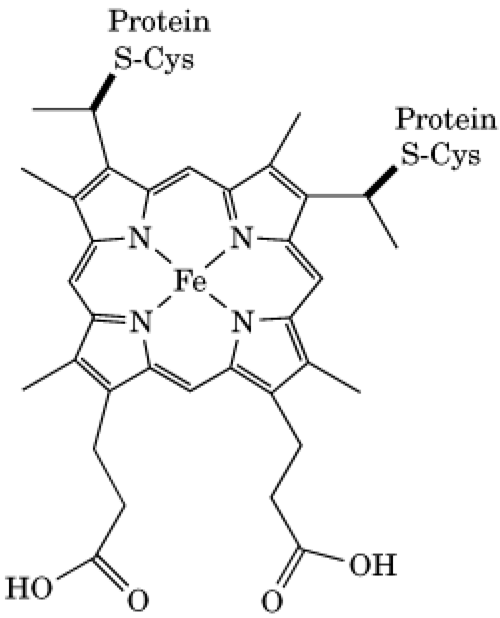
Cytochromes

Cytochromes are iron-containing proteins that facilitate the movement of electrons in a wide variety of metabolic processes (see Electron Transfer Proteins). Cytochromes are widely distributed throughout nature. They are found in all **eukaryotes** and in most, but not all, **prokaryotes**. The prosthetic group or chromophore of cytochromes is heme, an iron-containing porphyrin. The prototypic form of heme in cytochromes is protoheme IX, which consists of iron, two vinyl side chains, four methyl groups and two propionic acid side chains on a conjugated tetrapyrole ring (Fig. 1). Protoheme IX is the prosthetic group of *b*-type cytochromes and the family of proteins known as cytochrome P450. The *c*-type cytochromes have heme *c* as the prosthetic group, in which protoheme IX is covalently bound to the protein through one or, more commonly, two thioether bonds to cysteine side-chains. Heme *a*, found in *a*-type cytochromes, has a long isoprenoid tail substituted on one of the vinyl groups and a formyl group replacing a methyl. Further variations in heme structure are found in isolated cases, for example, cytochrome *d* and cytochrome *o* (1) but will not be discussed here. Cytochrome P450 and **cytochrome *c*** are discussed elsewhere in this volume.

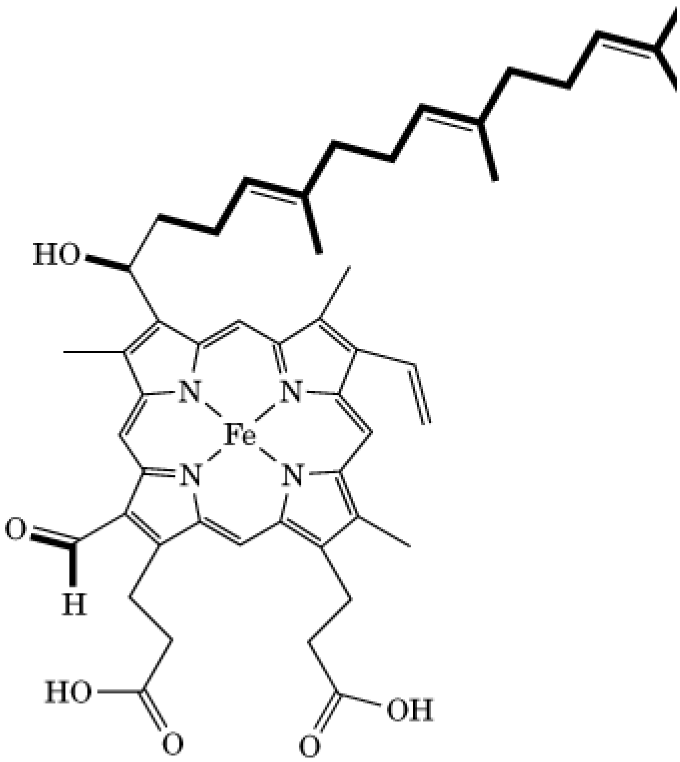
Figure 1. The structures of (**a**) protoheme IX, (**b**) heme *c*, and (**c**) heme *a*.



(a)



(b)



(c)

The iron in cytochromes, is either penta- or hexa-coordinate. Porphyrin nitrogen atoms fill four coordination positions (in-plane coordination, see Fig. 1) and appropriate ligands are positioned below the heme plane (5-coordinate) and, in most cases also above the heme plane (6-coordinate). The out-of-plane ligands in typical *c*-type cytochromes, are the N_3 atoms of histidine residues and the sulfur atom of methionine (Fig. 2). Ligation in the *b*-type cytochromes is generally by two His residues (Fig. 2) and by one or two His in the cytochromes *a*. Variations exist, however. For example, the out-of-plane ligation is by two His residues in cytochrome c_3, and by one His and an open position in cytochrome c'. Cytochromes are associated with the inner membrane of mitochondria, that of **microsomes**, the **thylakoid** membrane in chloroplasts, and the plasma membrane in **bacteria** (see Membranes). However, soluble forms (typically *c*-type cytochromes) are found in the space between the inner and outer mitochondrial membranes and in the **periplasmic** space in bacteria.

Figure 2. Stereo representations of the structure of tuna cytochrome *c* (upper stereo pair) and microsomal cytochrome b_5 (lower stereo pair). In cytochrome *c*, the N-terminal a-helix is at the *top*, the Met80 ligand is on the *left*, and the His18 ligand on the *right*. In cytochrome b_5, the N-terminus is at the lower *right* the His61 ligand is on the *left*, and the His37 ligand is on the right. The heme propionates are oriented toward the solvent.

The physiological activity in all cytochromes is the reversible oxidation and reduction of the iron atom, which cycles between the ferric (Fe^{3+}) and ferrous (Fe^{2+}) states. From a physiological standpoint, an important property of cytochromes is their oxidation-reduction **(redox)** potential, which is E_o' at pH 7. The redox potential measures the relative stabilities of the oxidized (ferric) and reduced (ferrous) forms and therefore their tendencies to donate and accept electrons, respectively. At pH 7 in aqueous solution, the redox potential of H_2 is –414 mV and that of O_2 is +816 mV. With relatively minor exceptions, these define the biological range. Cytochromes have redox potentials somewhere between these limits. In biological electron transfer, the direction of electron flow is from lower to higher potentials in the limit from hydrogen to oxygen. Thus the redox potential of a particular cytochrome determines, to a first approximation, where it is positioned relative to other redox compounds in electron transfer pathways (see Electron Transfer Proteins). The *c*-type cytochromes have redox potentials ranging from –400 to +450 mV, depending on the structural family and species, although they typically vary between only +200 and +300 mV in eukaryotic *c*-type cytochromes. The *b*-type cytochromes have redox potentials that range from –200 to +150 mV, and the *a*-type cytochromes have potentials in the +220 to +400 mV range.

The role of the protein moiety in cytochromes is threefold. First, the protein provides the out-of-plane ligands and, in the case of *c*-type cytochromes, the covalent attachment sites for the heme. Secondly, the protein provides the proximal environment for the heme, a nonpolar molecule that is not water-soluble, controls the exposure of the heme to the solvent, and interacts with the heme to modulate the redox potential. Thirdly, the protein surface provides the sites for the interaction with electron donors and acceptors because in all known cases the heme iron is buried in the protein's interior. Thus, the redox potential is modulated by a combination of the nature of the out-of-plane ligands, the immediate protein environment, and the solvent exposure of the heme.

The redox potentials dictate the direction of electron flow. For example, mitochondrial cytochrome *c* $(E'_o = +260\ \mathrm{mV})$ cannot significantly reduce oxidized pyridine nucleotide (NAD^+, $E'_o = -320\ \mathrm{mV}$). They do not, however, explain the specificity and efficiency of biological electron transfer. Within a biological milieu, a large number of redox compounds exist close to each other. These include small organic compounds, such as flavins and pyridine nucleotides (for example, NAD^+); oxygen (in aerobes); inorganics, such as nitrates, nitrites, sulfates, and sulfhydryls; and a variety of redox proteins, including non-heme-iron sulfur proteins, flavoproteins, cytochromes, and copper proteins (see Electron Transfer Proteins). Thus, from an energetic standpoint, substantial opportunities exist for electrons to flow in a great variety of directions. This does not happen, and electron flow occurs with very high efficiency (approaching 100%) only within specific pathways (for example, in respiration or photosynthesis). This incredible efficiency, the essence of life, is mediated by the surface of the protein, which provides recognition sites that determine which redox compounds interact on a physiological timescale, that is, it determines how fast electrons are transferred, and the direction of electron flow (2, 3). This kinetic control means that energetically equivalent reactions can take place on timescales that differ by many orders of magnitude. For example, reduced pyridine nucleotide reduces mitochondrial cytochrome *c* slowly (in seconds), whereas cytochrome c_1 $(E'_o = +220\ \mathrm{mV})$ reduces the same cytochrome in milliseconds, even though reduction by pyridine nucleotide is more strongly favored energetically in the first case (65.7 kJ/mol versus 3.8 kJ/mol).

The interactive domains of the cytochromes are defined by the amino acid side chains positioned on their molecular surface that dictate their sites of interaction. The structure of the complex between two electron transfer proteins determines the proximity and orientation of the relevant prosthetic groups (the two hemes in the case of electron transfer between two cytochromes). Three factors play a role in defining the interactive domains. First, the positioning of charged amino acid side chains on the surface of interacting molecules result in electrostatic interactions, either attractive or repulsive, that define the interaction domain (4). Secondly, the distance between redox centers (heme irons in the case of cytochromes) influences the rate of electron transfer. This distance is controlled by the size and nature of the amino acid side chains in the interactive domain (2). Third, two interactive domains that interact must be complementary physically and structurally, even if defined by nonpolar van der Waals interactions (2, 3). Apparently, during the course of evolution, mutations have occurred that optimize the rate of electron flow through relevant metabolic pathways by modulating the amino acid side chains defining the interactive domains, thus allowing competing redox reactions to occur in close proximity and channeling the flow of electrons through the appropriate pathway.

From the standpoint of solubility, cytochromes exist in three types of environments. Soluble forms are typically *c*-type cytochromes that are free to diffuse between electron donors and acceptors. Integral membrane proteins, that is, transmembrane proteins, have only part of the molecule exposed to solvent. The majority of the molecule is integrated into the membrane. Examples are *a*-type cytochromes and some *b*-type cytochromes. Peripheral membrane proteins are strongly associated with a membrane or with integral membrane proteins and have a substantial portion of the molecule in solution. Examples are cytochrome b_5 and cytochromes c_1 and *f*.

1. *A*-type Cytochromes

Cytochromes *a* and a_3 are components of cytochrome oxidase, or complex IV, of the mitochondrial electron transfer chain and are found in all eukaryotic organisms and many aerobic prokaryotes. Cytochrome oxidase catalyzes the four-electron reduction of O_2 to H_2O, utilizing cytochrome *c* as the electron donor. Cytochrome *a*, which is hexa-coordinate, mediates the transfer of electrons from cytochrome *c* to the penta-coordinate cytochrome a_3 (with the intermediate participation of a copper atom;), which provides the site for oxygen reduction. Variants of cytochrome oxidase are found in some aerobic bacteria that do not contain hemes other than heme *a*. Examples are cytochrome *bo*, which uses quinols as the electron donor in *Escherichia coli* and cytochrome cbb_3 in *Rhodobacter sphaeroides*, which has cytochrome *c* as an electron donor (1). Thus, the heme type can vary, although the function, the reduction of molecular oxygen to water, remains constant. Cytochrome oxidase is an integral membrane protein and couples the transfer of electrons and the corresponding redox energy with the movement of protons across the inner mitochondrial or periplasmic membrane, driving the synthesis of ATP (see Proton Motive Force). From an evolutionary standpoint, there is structural and amino acid sequence homology between eukaryotic and bacterial cytochrome oxidase (1). In addition, a variety of other enzymes exist that are structurally related to cytochrome oxidase and generally use cytochrome *c* or an electron donor, such as nitrous oxide reductase, which reduces N_2O to N_2 and utilizes copper as the prosthetic group, but has sequence homology with cytochrome oxidase and utilizes cytochrome *c* as its electron donor (1). Another example is nitric oxide reductase, which catalyzes the reduction of nitric oxide to nitrous oxide. Although it is a cytochrome *bc* complex, it has a transmembrane component and homology to portions of cytochrome oxidase (1).

2. *B*-type Cytochromes

The *b*-type cytochromes fall into two broad categories: (1) a family of relatively large cytochromes containing protoheme IX that are part of integral membrane protein complexes like cytochrome bc_1 and cytochrome b_6f; (2) a family of cytochrome b_5-like proteins that are peripheral proteins, typically anchored to a membrane, or are components of protein complexes like flavocytochrome b_2 and sulfite oxidase. The cytochrome bc_1 complex and its homologue in plants, cytochrome b_6f, catalyze the transfer of electrons from quinones to cytochrome *c* (in animals) or to plastocyanin (in plants) coupled with the movement of protons across the inner mitochondrial or the thylakoid membranes, which drives the synthesis of ATP (see ATP Synthase). The mitochondrial cytochrome bc_1 complex, also known as complex III, has the cytochrome *b* component integrated into the membrane through a number of transmembrane a-**helices** (5). The cytochrome c_1 component is anchored to the membrane and is the electron donor to cytochrome *c*. Cytochrome *b* is also a component of succinate dehydrogenase (also known as complex II), a complex integral membrane protein that participates in the mitochondrial electron transfer pathway (6). Succinate dehydrogenase oxidizes succinate to fumarate. The electrons reduce quinone and feed into the mitochondrial electron transfer chain.

Because of their large size and strong association with membranes, cytochromes *b* are not as well understood as the generally small and water-soluble *c*-type cytochromes (cytochromes c_1 and *f* are exceptions in terms of size and solubility). Thus the extent of structural and functional diversity among the cytochromes *b*, particularly in prokaryotes, remains an open question.

Proteins of the cytochrome b_5 family contain a cytochrome b_5 domain (Fig. 2) and, in the case of the mitochondrial and microsomal members, a hydrophobic tail or anchor that associates the cytochrome with the relevant membrane (7). The structure of cytochrome b_5 is shown in Fig. 2. In nitrate reductase, sulfite oxidase, and flavocytochromes b_2, the cytochrome b_5 domain is tightly associated with a flavoprotein that specifies the particular enzymatic activity. The cytochromes b_5 domain acts as an electron acceptor from the molybdenum (Mo)-pterin cofactor in sulfite oxidase or from protein-bound flavin in cytochrome b_5 reductase, nitrate reductase, P450 reductase, and flavocytochrome b_2. The cytochrome b_5 electron acceptor is cytochrome *c* in the flavocytochrome b_2 and sulfite oxidase systems, and a Mo-pterin cofactor in nitrate reductase. In microsomal systems, cytochrome P450 and a variety of acyl-CoA desaturases are the electron acceptors. In red blood cells, cytochrome b_5 reduces methemoglobin (see Hemoglobin). Thus, cytochrome b_5 has evolved the ability to function in a diverse group of electron transfer pathways and with a variety of electron donors and acceptors (7).

3. *C*-type Cytochromes

These cytochromes are discussed in more detail elsewhere in this encyclopedia, but it is important to note that this is a diverse group of cytochromes consisting of a variety of structural motifs and functions (8). Although restricted to mitochondrial cytochrome *c* and cytochrome c_1 (discussed previously) in eukaryotes and key components in the respiratory electron transfer chain, a variety of bacterial *c*-type cytochromes have evolved into a diverse and complex array of structures and function. In terms of structural families, the cytochromes *c* include the mitochondrial cytochrome *c* family and their bacterial homologies, cytochrome c_1 and *f*, and the cytochromes c_3, cytochromes c', flavocytochromes *c*, cytochrome c_4, and cytochromes c_5. Now, only cytochrome c_3 and *c*-type cytochromes that are related to mitochondrial cytochrome *c* are well understood in both structure and function.

The basic structural motif of the mitochondrial cytochrome *c* family has been maintained throughout evolution. Figure 2 presents the structure of tuna cytochrome *c*. In contrast to cytochrome b_5, the heme propionates are buried and not solvent accessible. Cytochromes utilizing the cytochrome *c* structural motif are found in almost all bacteria but differ primarily in their redox potentials, which vary from approximately +50 to +450 mV, and in the type and distribution of amino acid side chains on their molecular surfaces.

4. Summary

Cytochromes evolved early in the development of life on this planet, and they have retained the basic functional group protoheme IX (with relatively minor variations) throughout evolution. A number of basic structural motifs have evolved that are found in both prokaryotes and eukaryotes, including the mitochondrial cytochromes *c* and their bacterial precursors, the cytochrome b_5 family, the cytochrome oxidases, the membrane-spanning cytochromes *b*, and the cytochrome c_1/b_6 family. It is striking that a relatively small number of structural families have evolved to take advantage of diverse metabolic opportunities, capturing redox energy to produce ATP and adapting to available ecological niches.

Cytogenetics

Cytogenetics is the study of **genetics** by visualization of chromosomes and chromosomal aberrations, usually through light microscopy. There is a distinguished history of chromosomal visualization for analytical purposes. Longley defined the morphology of **maize** chromosomes (reviewed in Ref. 1), which opened the door for subsequent work on maize cytogenetics by McClintock (2). Staining of **prophase** and early **metaphase** maize chromosomes with acetocarmine allowed McClintock to identify 10 distinct linkage groups. In turn this laid the foundation for other maize cytogeneticists to identify chromosomal translocations and **inversions** visually. For example, it was possible to demonstrate that there is a correspondence between marker genes and cytologically defined chromosomal domains in crosses between heterozygous strains (3). Cytogenetics in *Drosophila melanogaster* received an enormous stimulus from the systematic study of the polytene chromosomes in salivary glands (4). These chromosomes have visibly distinct banding patterns under a phase microscope and after staining. Each of the four *Drosophila melanogaster* chromosomes have easily differentiated band patterns. The thousands of bands served as markers that allowed cytogeneticists to discern small deletions, duplications, translocations, and transpositions. Cytological experiments in *Drosophila* also allowed the discovery of the position effect, the phenomenon in which the position of a gene relative to heterochromatin influences the efficiency with which it is expressed (5).

Improvements in cytogenetics eventually allowed visualizing metaphase chromosomes in somatic cells in culture. Only in 1956 was it established by these methodologies that human cells contain 46 chromosomes (6). Likewise cytogenetic approaches allowed the discovery that children with Down's syndrome are **trisomic** for chromosome 21 (see Autosome). Medical cytogenetics has since been advanced by chromosome stains, such as Giemsa, that enable separating individual chromosomes in sufficient numbers for highly focused analysis of their biochemistry and genetics (see G Banding).

Cytokeratins

Cytokeratins form long filaments (they are one of the family of intermediate filament proteins; see also Keratins) that extend in a sinuous manner between the cytoplasmic surface of the cell nucleus and the plasma membrane of epithelial cells. The cytokeratin filaments appear to attach to the cytoplasmic side of the nuclear envelope, often close to the nuclear pore complexes. From there they radiate outward and link to or loop through the portions of the **desmosomes** or adhesion plaques that lie on the inner side of the cell membrane.

Cytokeratin chains can be divided into two groups: "acidic" Type I and "neutral-basic" Type II. In general, the Type II chains have higher isoelectric points and higher molecular weights than their Type I counterparts. Each chain comprises nonhelical end **domains** separated by a flexible rodlike structure. The *N*- and *C*-terminal domains in the epidermal keratins (or cytokeratins) have a characteristic substructure arranged about the rod domain with bilateral symmetry: E1, V1, H1 in the *N*-terminal domain and H2, V2, E2 in the *C*-terminal domain (1). The H1 and H2 subdomains, located respectively immediately *N*- and *C*-terminal to the rod domain, have sequences that are highly **homologous** regions within each chain type. The V1 and V2 subdomains are variable in length and sequence but always have a high content of glycine and serine residues. The E1 and E2 subdomains lie at the extreme ends of the molecule and are short, generally basic regions.

Between the terminal domains, the amino acid sequence has a heptad repeat substructure characteristic of a coiled-coil conformation (2). The latter thus consists essentially of coiled-coil rod domains (segments 1A, 1B, 2A, and 2B), joined by short linking domains (L1, L12, and L2), and results in a rod of total length 46.2 nm (Fig. 1). Each molecule contains a pair of different chains (Type I and Type II) aligned parallel to one another and in axial register (3-5). Segments 1B and 2 (= 2 A + L2 + 2B) each contain highly regular distributions of both acidic and basic residues (2). Thus each rod segment can be modeled as alternating bands of positive and negative charge, with a period of about 1.4 to 1.5 nm. Pairs of molecules aggregate through their rod domains in three antiparallel modes: (i) with their 1B segments largely overlapped, (ii) with their 2B segments largely overlapped, and (iii) with their entire lengths largely overlapped. In cytokeratins there is also a short head-to-tail overlap of about eight residues between parallel molecules (6). The antiparallel interactions originate in large part by the maximization of electrostatic interactions, which are possible as a consequence of the regular charge distribution in neighboring rod domains. They are also both specified and stabilized by interactions between the H1 (and presumably H2) subdomains, the head-to-tail overlap region, and the link L2. Cross-links formed between lysine residues in cytokeratins have been characterized (Fig. 2), thus confirming the modes of aggregation originally proposed on theoretical grounds (see earlier). This work also allowed the projected (axial) lengths of the links L1, L12, and L2 to be determined, together with the relative axial staggers between various coiled-coil rod segments (6, 7). These data allow a surface lattice structure to be constructed that predicts a near-axial period in the cytokeratin of 22.6 nm (the experimentally observed value is

22.7 nm). **Scanning transmission electron microscope** (STEM) data indicate that *in vitro* assemblies may contain about 16, 24, 32, or 40 chains, but it seems that only the 32-chain variant is present *in vivo*. The STEM data, nonetheless, would indicate that the cytokeratin may have a substructure in which an eight-chain entity, a protofibril, is present. *In vitro* two, three, four, or five of these protofibrils may aggregate in a nonspecific manner.

Figure 1. Schematic cytokeratin intermediate filament molecule. The rod domain is of approximate length 46 nm, with coiled-coil segments 1A, 1B, 2A, and 2B and non-coiled-coil links L1, L12, and L2. A break in the phasing of the heptad repeat, known as a stutter, occurs at the center of segment 2B. The *N*- and *C*-terminal domains contain E (end), V (variable but rich in glycine and serine residues), and H (homologous) subdomains arranged about the rod domain with bilateral symmetry. (From Ref. 8, with permission.)

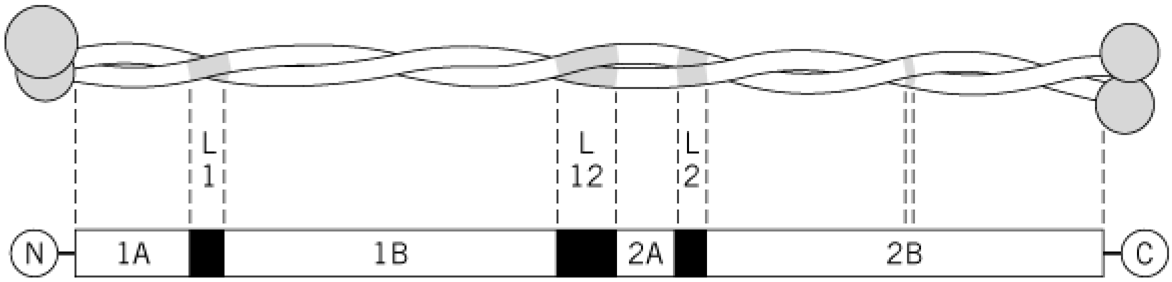

Figure 2. The cross-links induced chemically between lysine residues are shown for human K5/K14 epidermal keratin IF. The cross-links between the two polypeptide chains within a molecule (*left*) show that the chains are parallel and in axial register. Cross-links between molecules indicate that the molecules aggregate antiparallel through one of three modes, with (i) their 2B segments largely overlapped (A_{22}), (ii) the entire molecules largely overlapped (A_{12}), and/or (iii) their 1B segments largely overlapped (A_{11}). Combination of A_{22} and A_{11} results in a small head-to-tail overlap of about 1 nm between parallel molecules. (From Ref. 7, with permission.)

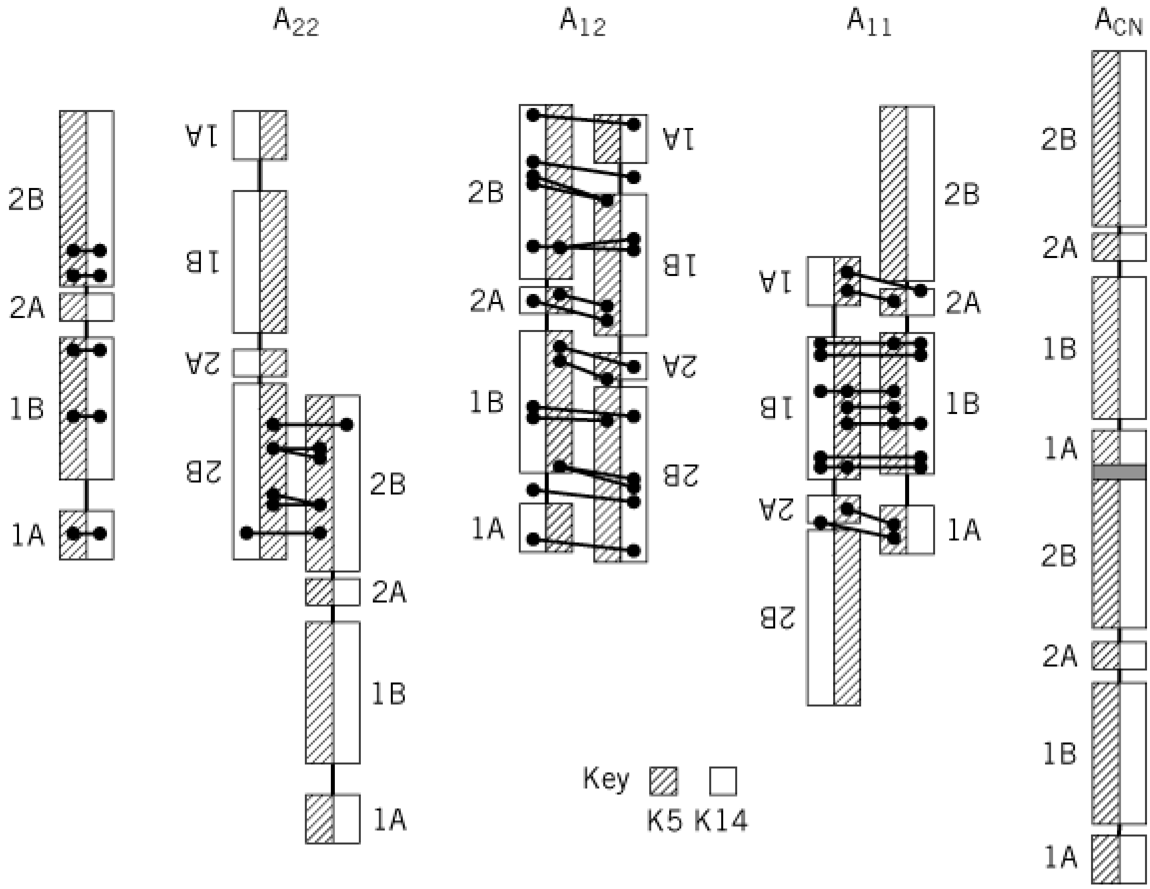

Characterization of a large number of gene mutations leading to keratinopathies has been achieved in recent years. The resulting sequence changes lie very largely in or close to the head-to-tail overlap region comprising the conserved sequences at the *N*-terminal end of segment 1A and the *C*-terminal end of segment 2B. A reasonable conclusion is that this interaction is subtly modified by the mutated residue and becomes less able to stabilize the cytokeratin *in vivo*.

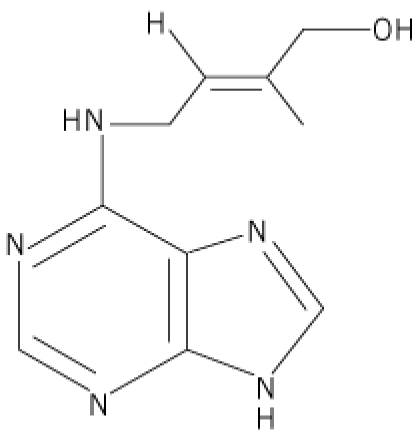
Cytokinins

1. History

The first discovery that plants make compounds that stimulate cell division dates back to 1913, when Haberlandt (1) demonstrated that an unknown substance present in vascular tissues of various plants caused cork cambium formation and wound healing in cut potato tubers. These molecules were later called *cytokinins*, from the Greek "cytokinesis" (cell division). In the 1940s, van Overbeek et al. (2) showed that similar compounds were also present in the milky endosperm of immature coconuts. In 1954, Miller et al. (3) isolated a substance, formed by partial breakdown of herring sperm **DNA**, that, in synergy with auxin, stimulated cell division in tobacco pith cells very actively. The molecule was called *kinetin* (6-furfurylamino purine). *Trans*-zeatin (6-(4-hydroxy-3-methylbut-*trans*-2-enylamino) purine) was the first cytokinin to be identified from maize endosperm (4) (Fig. 1).

Figure 1. Structural formula of *trans*-zeatin.



2. Biosynthesis and Metabolism

Natural cytokinins (CKs) are primarily purine derivatives with an N^6-substituted isopentenylated side chain (iP-type CKs) (5). However, a series of CKs with an aromatic side chain (eg, benzyl-adenine) have been demonstrated in certain species (6, 7). The most abundant naturally occurring CKs are CK nucleosides and CK nucleotides (5). Certain phenolic compounds also possess cell-division-promoting activity, but are not classified as true cytokinins (8).

The origin of CKs in plants remains a subject of debate. Roots are the primary sites of cytokinin biosynthesis, although limited synthesis in the shoot has also been demonstrated (9, 10). CKs have been proposed to be transported from root to shoot by the transpiration stream in xylem tissues, but conclusive evidence is lacking (11). Even though present throughout the plant, CKs have never been proven to be synthesized by endogenous, plant-borne enzymes. Because many root-associated bacteria are cytokinin producers, it has been hypothesized that CKs are made exclusively by these microbial symbionts (12).

Cytokinins can be synthesized via a direct (*de novo*) or an indirect (transfer RNA) pathway. The main source of free CKs is the *de novo* pathway. The key step is the formation of N^6-(D^2-isopentenyl) adenosine-5′-monophosphate from D^2-isopentenyl pyrophosphate and AMP catalyzed by isopentenyltransferase. The isopentenyl side chain originates from mevalonate, which also serves as a precursor to abscisic acid, gibberellins, and brassinosteroids. Isopentenyltransferase was first characterized from bacteria and slime molds (5, 7). Different constructs using the Agrobacterium isopentenyltransferase *IPT* (*tmr*) **gene** were used to generate constitutive or controlled cytokinin overproduction in **transgenic** plants (13-15). These studies mainly confirmed the classical view of cytokinin action in plants. Specific manipulation of senescence was achieved by placing the *IPT* gene under the control of a senescence-specific **promoter** (16). Recently, isopentenyltransferase activity was also demonstrated in plants (17), but the enzyme was never purified to homogeneity, nor have plant genes encoding isopentenyltransferase been **cloned**. This is the major reason why CK production by the plant itself is still questioned. An Arabidopsis mutant with sixfold elevated CK levels was isolated from a screen for seedlings with multiple cotyledons (18, 19). The **phenotype** of this *amp1* (*altered meristem program1*) mutant is reminiscent of several CK effects, including enhanced lateral branching, elevated rate of leaf formation, induction of flowering and floral morphological abnormalities, and delayed senescence. In addition, *amp1* displays a de-etiolated phenotype in the dark and is an **allele** of *cop2* (*constitutive photomorphogenic 2*). It was proposed that CK induces light-regulated genes in a light-independent fashion (19). The *AMP1* gene product may be required for CK degradation, or it could be a negative regulator of CK biosynthesis. A second mutant *cri* (*cristal*) that accumulates sixfold more CK than the wild type was recently identified (20). *Cri1* mutants are phenotypically different from *amp1* and show symptoms of vitrification.

The second biosynthetic route for CKs is via tRNA. Modified bases in tRNA, including isopentenylated bases, have been found in virtually all organisms investigated (21). CK modification in tRNA is always at the adenosine residue immediately 3′ to the anticodon of tRNAs that read codons starting with U (5). These CK residues in tRNA may serve as a direct, albeit not major, precursor of free CK, as a result of tRNA turnover. The rate of CK release in this way is dependent on the metabolic activity of the cell. The major CK in tRNA is *cis*-zeatin, with very low CK activity, but it can be converted to the biologically active *trans* isomer (Fig. 1) by a *cis–trans* isomerase (22) (see Cis/Trans Isomerization).

Several modifications can occur to the N^6-substituted side chain and purine ring. Formation of zeatin and its nucleoside and nucleotide derivatives, most probably by hydroxylation of the isopentenyl adenine moiety, is common in most plant tissues. The hydroxylase that mediates this conversion was isolated from cauliflower (23). O-Glycosylation of hydroxylated CKs is often observed, but leads to a considerable decrease in activity (5). CK-*O*-glucosides can be converted to free active CK by the action of b-glucosidases. In contrast, modification of the purine ring by *N*-glucosylation of the 3, 7, or 9 position yields inactive, stable derivatives that cannot generate free CKs. *N*-Glucosylation is thus expected to play an important role in regulating the levels of active CKs. An additional control is exerted by CK oxidase (24, 25). This enzyme catalyzes degradation of the N^6-(D^2-isopentenyl) side chain and irreversibly leads to loss of CK activity. CK nucleotides are not accepted as a substrate. A general role for CK oxidase is to contribute to CK homeostasis in plants (26).

3. Signal Perception and Transduction

A number of CK-binding proteins have been described, one of which is a potential CK **receptor** (27, 28). The latter is a cytosolic protein that reversibly binds zeatin and is involved in transcriptional activation in the presence of zeatin, but not in its absence. Only the *trans* isomer elicited the observed effect.

Two candidate plasma membrane CK receptors were identified by mutational analysis (29, 30). Mutants of *Arabidopsis* that exhibit shoot formation in tissue culture in the absence of CK were obtained by an activation-tagging approach. The *CKI1* (*cytokinin-independent 1*) gene was isolated and encodes a protein similar to two-component regulators of bacteria (29). As in the case of the ethylene receptor ETR1 (see Ethylene), CKI1 is a hybrid kinase with fused sensor and receiver domains. Based on this analogy and on the fact that constitutive overexpression of *CKI1* results in typical effects of CK action, CKI1 is hypothesized to encode a CK receptor. Overexpression would enable cells to sense endogenous concentrations below the threshold, which normally leads to CK response. Intriguingly, phytochromes also display similarities with two-component systems. It has been speculated that they might regulate other two-component systems, thus enabling cross-talk between the ethylene and CK pathways (31). A second candidate CK receptor is a seven-transmembrane domain receptor (7TM), characteristic in **G-protein** signaling and involved in transduction of extracellular signals (30). The *Arabidopsis GCR1* (*G-coupled receptor 1*) gene was isolated by polymerase chain reaction (**PCR**), and **antisense** mutagenesis with a 35S a*GCR1* construct resulted in reduced cotyledon and leaf expansion and a single flowering stem, a phenotype reminiscent of the *cyr1* (*cytokinin resistant 1*) mutant (see text below). However, *GCR1* and *CYR1* do not represent the same gene (30).

The above findings confirm the involvement of both phosphorylation and G proteins in CK signaling (32). Sense and antisense expression in tobacco of a gene encoding a small GTP-binding protein from rice resulted in a dwarf phenotype and abnormal flower development, correlating with a sixfold elevation of CK levels compared to wild type (33). **Phosphorylation** plays an important role in cell cycle control by CK (32). In addition, evidence was given for involvement of intracellular Ca^+ in CK signaling (see Calcium Signaling) mostly from studies in mosses (32). Finally, the similarity of a CK-binding protein to *S*-adenosyl-homocysteine hydrolase raised the possibility that some CK effects might be mediated through control of **methylation** of DNA and/or proteins (34).

Further progress in understanding CK Signal Transduction is expected from mutant studies. Several CK-resistant mutants have been identified, mainly in *Arabidopsis* (35). Five loci have been studied in detail. The majority were isolated using a root elongation response in the presence of CK. In certain cases, resistance to other hormones was found. For instance, the *ckr1* (*cytokinin resistant 1*) mutant is allelic to *ein2* (*ethylene-insensitive 2*), indicating cross-talk with the ethylene pathway. It was demonstrated that the inhibition of root elongation by CK results from an induction of ethylene biosynthesis (36). This was exploited by screening for the absence of triple response in the dark, in the presence of kinetin (37). The *cin5* (*cytokinin-insensitive 5*) mutant affects the 1-aminocyclopropane-1-carboxylate synthase gene *5* in *Arabidopsis*. Disruption of the carboxyl terminus of the same isoform leads to ethylene overproduction, previously identified as an *ethylene overproducer* (*eto2*) mutant. A third class of CK–resistant mutants is *cyr1* (38). In contrast to *ckr1* and *cin5*, *cyr1* displays an abnormal shoot phenotype: cotyledons and leaves fail to expand, a limited number of leaves are formed, and a single infertile flower is made. No resistance to other hormones was observed; however, *cyr1* is hypersensitive to abscisic acid (38). *Cyr1* is probably allelic to *emf2* (*embryonic flower 2*). *EMF* gene products might function in the maintenance of vegetative growth (39). The *stp1* (*stunted plant 1*) mutant has a reduced sensitivity to CKs, both in assays for elongation and radial swelling of the root (40). The general morphology was not affected, but a reduction in growth rate was observed. The function of the *STP1* gene product remains to be elucidated. Finally, a recent study describes identification of three loci involved in control of cell division and plant development (41). The corresponding mutants were called *pasticcino* (*pas*) and showed hypertrophy of their apical parts when grown on CK-containing medium, a phenotype reminiscent of abnormal shoots regenerated on media with unbalanced auxin/CK ratio and strikingly similar to the fasciation disease caused by *Rhodococcus fascians* (41). The altered embryo, root, and leaf development result from uncoordinated cell divisions. *PAS* genes are hypothesized to play a role in CK signaling, because no differences in CK levels were found compared to wild type.

4. Downstream Targets

Primary CK response genes have not yet been isolated, nor have CK responsive cis-acting elements or trans-acting factors been identified (42). A large number of genes that are either induced or repressed upon CK treatment have been described. Controls are exerted at a transcriptional or post-transcriptional level. Changes in gene expression were observed between 2 h and 48 h after treatment. Many of these secondary CK response genes are involved in light regulation and nutrition (32, 42).

5. Effects

Depending on temporal and spatial factors, a particular subset of downstream target genes is activated by CK treatment and results in one of many described effects. Cytokinins regulate many aspects of plant growth and development, including cell division, enlargement, and differentiation, as well as chloroplast development, release of apical dominance, nutrient mobilization, flowering, and delay of senescence (43, 44).

Cytomegalovirus

Cytomegaloviruses (CMVs) are a distinct subgroup of herpesvirus and are classified as subfamily *Betaherpesvirinae* in the *Herpesviridae* family. CMV forms a characteristic nuclear inclusion, which gives an “owl's eye” appearance to infected cells. Many animal species have their own species-specific CMV.

Human CMV maintains a collinear genomic organization, but no significant nucleotide sequence homology with other animal CMVs. Human CMV is also designated as human herpes virus 5 (HHV-5). A great majority of the human population are infected with CMV, without any symptoms by adulthood. CMV is excreted in the urine of infants and intermittently in saliva of healthy seropositive adults. Human CMV may cause diseases such as congenital cytomegalic inclusion disease and infectious mononucleosis. The importance of human CMV as a pathogen has been increasingly correlated with the rising number of immunodeficient patients due to immunosuppressive therapy after transplantation, acquired immune deficiency syndrome (AIDS), and so on.

Mature virions of CMV are 150 to 200 nm in diameter and have an envelope composed of a lipid bilayer and viral glycoproteins. Inside the envelope, a tegment or matrix surrounds an icosahedral capsid, which contains a double-stranded, linear DNA genome. Two types of noninfectious particles, in addition to infectious virions, are produced in cells infected with human CMV. Dense bodies do not contain nucleocapsid or viral DNA and are essentially enveloped tegment protein. Noninfectious enveloped particles have a capsid but no electron-dense DNA core.

Equine CMV has a genome of 180 kbp, while the genomes of human, simian, and murine CMVs are 230 to 240 kbp. Human CMV is unique among animal CMVs in that it has a genome structure similar to herpes simplex virus 1 (HSV-1, class E structure). Two unique sequences (UL and US) are flanked by inverted repeats. Inversion of the UL and US segments mediated by inverted repeats can give rise to four different genomes. Other animal CMVs are less complicated in genome structure, and genome inversion is not known for them.

The genome of the AD169 strain of human CMV has been sequenced. Two hundred and eight open reading frames (ORFs) with a coding capacity of at least 100 amino acid residues were identified in the genome. Although only a few of these ORFs have been actually shown to encode proteins, at least 40 have been shown to be dispensable for replication. ORFs have been designated by their location with regard to the unique and repeated sequences (TRL, UL, IRL, IRS, and US) and sequential numbers. By analogy to HSV-1, roughly one-quarter of these ORFs are predicted to encode proteins required for DNA replication and metabolism functions, and three-quarters for virion maturation and virion structure.

Human CMV shows a highly restricted host range and takes 48 to 72 h to yield detectable amounts of progeny virions. Primary human differentiated cells, such as skin or lung fibroblasts, as well as chimpanzee cells, support human CMV replication, but undifferentiated, transformed, or **aneuploid** cells are usually nonpermissive for CMV replication. The genes of CMV have been classified into three sequential, kinetic classes: a(immediate early), b(delayed early) and g(late) genes. Expression of the latter two relies on the a gene products. The b gene products mainly serve DNA replication and metabolism, while g gene products encode structural proteins.

Cytoplasmic Inheritance

Most of the genetic information of a eukaryotic cell resides in its nucleus, and some is found in the cytoplasm. Each **mitochondrion** and chloroplast contains several copies of specific DNA molecules that carry some of the genetic information for the organelle; the rest is encoded in nuclear **genes**. Organelle genes are **transcribed** and **translated** in the organelles themselves through a genetic code that diverges in many cases from the standard one, while the proteins encoded in nuclear genes are imported into the organelle after their **protein biosynthesis** on cytoplasmic ribosomes. As a consequence of this shared genetic determination, there are many cases of nuclear and organelle mutants that exhibit similar phenotypes.

Most organelle genomes consist of circular double-stranded DNA molecules (Table 1). After considerable controversy, it seems clear that many mitochondrial DNA molecules are linear rather than circular.

Table 1. Some Genomes from Mitochondria and Chloroplasts, with Indication of Their Size, Number of Confirmed or Putative Translatable Genes (Open Reading Frames, ORFs), and number of genes for transfer RNA and ribosomal RNA[a]

Species	Number	Size (kb)	ORF	tRNA	rRNA
Mitochondrial Genomes					
Saccharomyces cerevisiae	L36885	78	13	24	4
Schizosaccharomyces pombe	X54421	19	10	25	2
Drosophila melanogaster	U37541	20	13	22	2

Nicotiana tabacum	Z00044	156	107	37	8
Oryza sativa	X15901	135	113	46	8

[a] Data taken from the indicated EMBL sequence accession numbers.

Organelles may contain molecules of DNA other than their own chromosomes. Examples are the two linear plasmids of the mitochondria of *Zea mays* that result in the absence of functional pollen (androsterility); they are very useful for the commercial production of hybrid seed (see Heterosis). Another example is *kalilo*, a linear plasmid of *Neurospora crassa* that blocks mitochondrial functions when it integrates into the mitochondrial DNA; the result is senescence, the inability for indefinite vegetative growth.

Other cytoplasmic bodies with their own genetic information range from various self-replicating particles to **viruses** and complete endosymbiotic cells. Their genomes may consist of DNA or RNA. First to be discovered were the *kappa* particles of *Paramecium aurelia* (1), but many others are known, such as the *killer* particles in *Saccharomyces cerevisiae* and the s particles that render

Drosophila melanogaster specially sensitive to carbon dioxide.

1. Heteroplasmons and Mosaicism

A cell contains numerous copies of organelle DNA molecules, up to several thousand, and these need not be identical (heteroplasmon). Organelle genomes are notoriously unstable and suffer frequent point mutations and large rearrangements. Heteroplasmons can be produced by these spontaneous changes or by cell fusion. Contrary to the usual behavior of **heterozygotes**, the relative proportion of two variants in a heteroplasmon is not fixed, giving rise to mosaicism in cell clones.

In some cases, one of the variants imposes itself because of its faster reproduction. Thus, most *petite* mutants of the yeast *Saccharomyces cerevisiae*, lacking aerobic metabolism, carry changes in their mitochondrial DNA. Some of these are called *suppressive*, because mutant mitochondria displace wild-type mitochondria in heteroplasmons. Wild-type mitochondria, on the other hand, impose their phenotype when mixed with mitochondria that carry petite mutations called *neutral*.

In other cases, the two variants may be found in various relative proportions, or even pure, in different cells, as would be expected from random genetic drift. Many variegated ornamental plants exhibit patches or streaks of different colors in their stalks and leaves, ranging from normal green to whitish. This phenotype may have many causes; in the plant *Mirabilis jalapa*, the colors depend on the presence of mutant chloroplasts, mixed with the normal ones in various proportions.

Recombination can occur between the various forms of chloroplast DNA or mitochondrial DNA in heteroplasmons, as shown for example for chloroplast markers of *Chlamydomonas reinhardtii* and mitochondrial markers in *Saccharomyces cerevisiae*.

2. Heterokaryon Test

The fusion of two cells that differ in both nuclear and cytoplasmic markers results in cells that are at the same time heterokaryons and heteroplasmons. Vegetative multiplication of the heterokaryon produces three kinds of cells: heterokaryons and two homokaryons, one for each of the kinds of nuclei. Cytoplasmic traits may segregate in various ways, all independent of the segregation of the nuclei. Homokaryotic segregants may show new combinations of cytoplasmic and nuclear markers. This test requires that the nuclei in the heterokaryon do not fuse, but remain separate, so that they can segregate to different daughter cells. The test has been extended to the yeast *Saccharomyces* by the use of dominant *kar* mutations that block nuclear fusion after mating, thus giving rise to heterokaryons.

3. Reciprocal Crosses

The results of reciprocal crosses offer a test for cytoplasmic inheritance when the two parents do not contribute equally to the cytoplasm of the zygote. The most frequent case in animals and plants is *matrilinear inheritance*, in which all individuals inherit from their mothers only, because of the larger size and contribution of female gametes. Examples are the variegation in *Mirabilis*, the first report of this heredity pattern (2), androsterility in *Zea*, and several human diseases due to mitochondrial mutations, such as Leber's hereditary optic neuropathy.

The matrilinear rule is not absolute. The s particles of *Drosophila* are transmitted most often by the ova (egg), but sometimes by sperm. Chloroplasts may be provided by the male, as in the conifers, or by both parents, as in *Oenothera*. Mammals have powerful mechanisms to exclude the mitochondrial DNA of the sperm from the embryo, and the failure of these mechanisms might produce exceptions to the matrilinear rule.

Uniparental inheritance is observed with the *poky* mitochondrial mutants and the *kalilo* plasmid in the fungus *Neurospora crassa*. When two haploid strains of different **mating type**, *A* or *a*, are crossed, either can provide the large protoperithecia or the small conidia that fuse to produce the zygote. All offspring inherit the cytoplasmic markers from the protoperithecia donor, irrespective of its mating type.

Uniparental inheritance can occur even when the gametes are similar in size, as in *Chlamydomonas reinhardtii*. The zygote is formed by the fusion of seeming identical cells of the two mating types, called mt^+ and mt^-. Almost all the offspring inherit the chloroplast markers of the mt^+ parent only, because the DNA of the mt^- parent is usually destroyed (3).

There are cases of maternal inheritance that are not due to cytoplasmic genes.

Cytoskeleton

The cytoskeleton consists primarily of three types of filament: microtubules (about 25 nm in diameter), **actin**-containing microfilaments (initially thought to be 5 to 7 nm in diameter but now known to be about 10 nm in diameter), and intermediate filaments (about 10 nm in diameter). The latter were so named because they were intermediate in size between the long-established and well-characterized microtubules and microfilaments. Microtubules are filamentous structures often many microns in length that occur in the cytoplasm of eukaryotic cells. The actins are a highly conserved family of eukaryotic proteins, and actin filaments are perhaps best known for the highly specific interactions they make with **myosin** thick filaments that results in **muscle** contraction. Many actin-binding proteins play important roles in establishing the cytoskeleton *in vivo* and in allowing it to function appropriately. For example, fimbrin and a-**actinin** aggregate and cross-link microfilaments into bundles, severin severs actin filaments, b-actinin acts as an actin filament-capping protein, and ponticulin (a **transmembrane protein**) binds actin filaments and spectrin binds and links the microfilaments to the cell membrane. See Actin, Microfilament, Microtubules, Intermediate Filaments, Cytokeratins, and Keratins for further information on various components of the cytoskeleton.

Cytotoxic T Lymphocytes

The main interest to molecular biology of cytotoxic T lymphocytes is probably mechanistic. These cells are able to destroy other cells. How do they achieve this? The 40-odd year-old history of this field started with immunology and defense, and the cellular phenomenology that was possible at the time. It now culminates with the realization that the long-sought mechanisms of cytotoxicity convey in fact molecular signals of cell death. Thus, fundamental research on cytotoxic T cells now goes beyond immunology, becoming part of the booming research effort on programmed cell death.

It was shown in 1960 that white peripheral blood cells from alloimmune dogs were able to lyse *in vitro* target cells bearing the corresponding **alloantigens** (1). We now know that many different cell types have this ability to destroy other cells, in particular lymphoid cells, and among these T (i.e., *thymus-derived*) lymphocytes. There are two varieties: CD4+ and CD8+ lymphocytes. When activated, both varieties can be cytotoxic through a Fas-based mechanism, and in addition CD8+ cells can be cytotoxic via a perforin-granzyme-based mechanism. These two mechanisms will be considered in more detail below. A main role of cytotoxic T cells is to lyse syngeneic cells presenting surface determinants originating from **viruses** or other intracellular microorganisms. These, when within cells, are out of reach of other immune system effectors. Destruction of infected cells destroys the microorganism or exposes it to other effector mechanisms. Cytotoxic T cells thus fight intracellular pathogens. Interestingly, cytotoxic T cells can also destroy normal, uninfected cells, such as Fas-bearing activated lymphocytes, thus in part ensuring down-regulation of immune responses. Neither the perforin- nor the Fas-based mechanisms in isolation, nor both together, seem to account fully for graft rejection.

When an effector cell approaches a target cell, it “recognizes” it through an array of diverse molecules at the surface of the effector cell (TCR/CD3/peptide, CD4 or CD8, LFA-1, etc.) and of the target cell (Class I or Class II MHC, ICAM-1, etc.). How, then, does the cytotoxic cell destroy the target cell? First indications were obtained at a phenomenological level. Engagement of the above-mentioned molecules leads to effector cell activation, including an increase in the concentration of free cytoplasmic calcium (2) within a matter of minutes, immediately followed by reorientation within the effector cell of the secretory apparatus towards an area facing the target cell (3). This suggested the possible participation of secretory phenomena in at least one mechanism of cytotoxicity. Many cytotoxic T cells indeed contain peculiar cytoplasmic granules. Their content can be released by degranulation in the extracellular fluid on target cell recognition (see Protein Secretion).

Among the phenomena then observed in the target cell is the early disintegration of nuclear DNA (4, 5) into fragments of around 180 bp, and multiples thereof, corresponding to the size of **nucleosome**-shielded DNA, which is due to the action of one or several **endonucleases** activated early in the sequence of events leading to target cell death. Other events in this sequence include an influx of calcium, condensation of the cytoplasm, fragmentation of the cytoplasm and nucleus, and only very late secondary membrane disruption. This phenomenology of cell death is very similar, if not identical, for example in developmental circumstances. In all cases, the same program seems to govern the course of events in a cell that dies, including, as we now know, a similar cascade of molecular events and the same “apoptotic” morphological traits (6). What may be different is merely the signaling of this death program. The nature of the signals produced by cytotoxic cells has been largely unraveled by studies at the molecular level.

1. The Perforin/Granzyme B Mechanism of Cytotoxicity

A first approach to identify molecules involved in cytotoxicity has been to look for effector cell molecules themselves endowed with cytotoxic activity. This approach led to the detection (7, 8), characterization, and cloning of *perforin*, a 60-kDa protein present in granules in the cytoplasm of many cytotoxic T and NK (natural killer) cells. At high concentrations, it can act on membranes as a calcium-dependent channel-former; most interestingly, it shows significant homology to the terminal components of the complement system cascade. A formal demonstration that perforin was involved in a mechanism of cytotoxicity was provided by several groups (9), all showing that cytotoxicity mediated by T cells was greatly impaired in mice made perforin-deficient through gene targeting.

Other molecules present in granules of cytotoxic T cells were identified by subtractive cloning. Prominent among molecules isolated this way were a number of serine proteinases, such as CTLA-1/CCP1/Granzyme B (10-12) and H Factor/CTLA-3/Granzyme A (10, 12, 13). Granzyme B was demonstrated through gene targeting to be required in a mechanism of cytotoxicity (14).

A current view on the cooperation between perforin and Granzyme B within the same mechanism of cytotoxicity is as follows. On recognition of the target cell, perforin- and granzyme B–containing granules in the effector cell reorient towards the target cell and are triggered to **exocytose**. Granzyme B may somehow enter the target cell and migrate into a target cell compartment where it would be innocuous, but from which it can be released by perforin at sublytic concentrations (15-17). Intracellularly released Granzyme B would then activate the standard programmed cell death cascade, through direct cleavage and therefore activation (18) of some of the ICE-family cysteine proteases called caspases. However, while target cell death mediated by Granzyme B (or at least by purified granules) may involve caspase activation for phenomena such as DNA fragmentation, it may, interestingly, use a noncaspase pathway for cell membrane disruption (19).

2. The Fas-Based Mechanism of Cytotoxicity

Through a **somatic cell** genetic approach it was found (20) that another mechanism of T cell–mediated cytotoxicity required a protein called Fas/APO-1/CD95 (21, 22) at the target cell surface. This in turn led to the cloning of the Fas ligand that is expressed at the effector cell surface (23). Fas belongs to a family of **receptors** (including Fas, TNF-R1, DR3, DR4, DR5), most or all of which are very efficient at transducing a signal interpreted as a cell death signal, while Fas ligand belongs to a family of corresponding ligands (including the Fas ligand, the TNFs, TRAIL, etc.). Involvement of Fas in cytotoxicity may be a reflection *in vitro* of the main roles of the Fas system *in vivo*, such as down-regulation of the immune response (24), protection against the immune system (25, 26), or potential major physiopathological effects (27).

Target cell Fas and effector cell Fas ligand define molecularly the Fas-based mechanism of cytotoxicity. In this mechanism, when an effector cell encounters a target cell, engagement of the T cell receptor of the effector cell by target cell major histocompatibility complex (MHC) leads to expression of the Fas ligand at the effector cell surface. Fas-ligand expression can be induced on CD8+ and on Th0 and Th1 CD4+ T cells (28-30) following specific recognition of antigen through the T cell receptor. This induction seems to involve the activation of **tyrosine kinases**, requires RNA and protein synthesis and the presence of calcium, and is inhibited by cyclosporin A (31-34). Other molecules may be involved, such as Myc and Max, 9-*cis*-**retinoic acid**, and its receptors, the **orphan receptor** for steroids, Nur77, and ALG-3.

Once expressed, effector cell Fas ligand engages target cell Fas, which leads to target cell death. In more detail, engagement of Fas leads in a matter of seconds to protein recruitment via the Fas "death domain," the cytoplasmic segment of Fas that is necessary and sufficient to transduce a death signal (35, 36). First, FADD/MORT-1 (37, 38) directly binds the death domain of Fas via its own *C*-terminal death domain. FADD/MORT-1 also includes an *N*-terminal death effector domain through which it associates with another molecule, FLICE/MACH (39, 40). FLICE/MACH includes two death effector domains at its *N* terminus and, strikingly, a caspase-homology domain at its *C* terminus (39, 40). Thus, the Fas-FADD-FLICE complex provides a remarkably direct link from a membrane signal to caspase activation, which is required for programmed cell death.

3. Concluding Remarks

The perforin-based and the Fas-based pathways account for most, and perhaps all, of T cell–mediated cytotoxicity (41-44), at least as assessed in a 4-hr assay *in vitro.* Other molecules, such as TNF-R1 or the TRAIL receptors, may play a role in longer assays. The Fas pathway is used by both $CD4^+$ (mostly Th1) and $CD8^+$ effector cells, while the latter also use the perforin/granzyme pathway. Thus, in $CD8^+$ T cells, two signals may stem from the T cell receptor/CD3 complex on antigen-specific recognition, one of them leading to granule exocytosis and the other one leading to transcription of the Fas ligand gene. Neither the exact nature of these distinct signals (45), nor whether they can be triggered simultaneously in a given cytotoxic cell is known as yet.

More generally, both mechanisms of T cell–mediated cytotoxicity seem to act by signaling the caspase activation step of the evolutionarily conserved programmed cell death cascade within the target cell. In this sense, the emergence in evolution of T cell–mediated cytotoxicity has not required the invention of new mechanisms of killing, but merely of new ways of signaling a preexisting programmed cell death cascade.

D Gene Segment

The existence of D genes encoding a short region of the third complementarity determining region (CDR3) of immunoglobulin heavy chains was first postulated when it was apparent that expressed H chains between the sequences encoded by the **variable** (V) and **J (joining)** genes contained a segment variable in length that had no counterpart in either gene. It turned out that variability of this region resulted from 2 causes: One was the existence of a set of D genes (D for Diversity); the second was due to the presence of nucleotides that were not germline encoded but added enzymatically at both the VD and the DJ junctions by terminal-deoxynucleotidyl-transferase, which is specifically expressed in lymphocytes. As the result of these combined events, heavy-chain CDR3 appeared as the most hypervariable region of Ig molecules, and therefore of prime importance as a basis for antibody specificity.

D gene segments appear to be present in all heavy-chain gene loci, from the lowest vertebrate species. In humans, about 30 D gene segments have been identified, clustered between the IgVH locus and the JH genes. The various D genes differ in length, but are always limited to a small number of potential **codons**. They are flanked on both their 5′ and 3′ ends by the conventional recombination signal sequences recognized by the RAG1 and RAG2 recombinases. The spacers are of different length on each side, so they meet with the 12/23 alternate size rule, to recombine with VH and JH gene segments. D genes make a major contribution to heavy-chain variability of CDR3, not only because of their number and sequence diversity, but also because they are used in many alternate possibilities: (a) They may be inserted in either orientation; (b) any reading frame may be used (in humans, not in the mouse; see text below), although one is more frequently encountered; (c) they may join to each other, so that examples of as many as four fused D genes have been described, thus providing a CDR3 of unusual length; and (d) they may be partially deleted at both ends before being inserted between the V and J genes. All of this clearly can generate a huge diversity potential.

In the mouse, minor differences from the above situation in D gene use and function have been reported, due to the fact that there is essentially only one reading frame used by murine D genes. There are two reasons for this. One gene rearrangement introduces a stop codon in the 3′ JC sequence. The second reason is more complicated. Some mouse D genes have a **promoter**-like region that can be activated after the first gene rearrangement making the DJ joint has been performed. In that case, a D-J-Cm protein is synthesized, which becomes exposed at the surface of the preB cell and blocks any further gene rearrangement (see B Cell), but is unable to contribute a functional immunoglobulin.

The genes for T-cell receptors (TCRs) have also D genes on the b and d chains. There are only a number of D genes, which are used in either orientation and reading frame. They have 12-bp spacers of identical length on both 5′ and 3′ flanking recombination signal sequences, corresponding to the 23-bp spacers of the V and J genes. TCR D genes also contribute to CDR3, a region that is most variable, as for immunoglobulins.

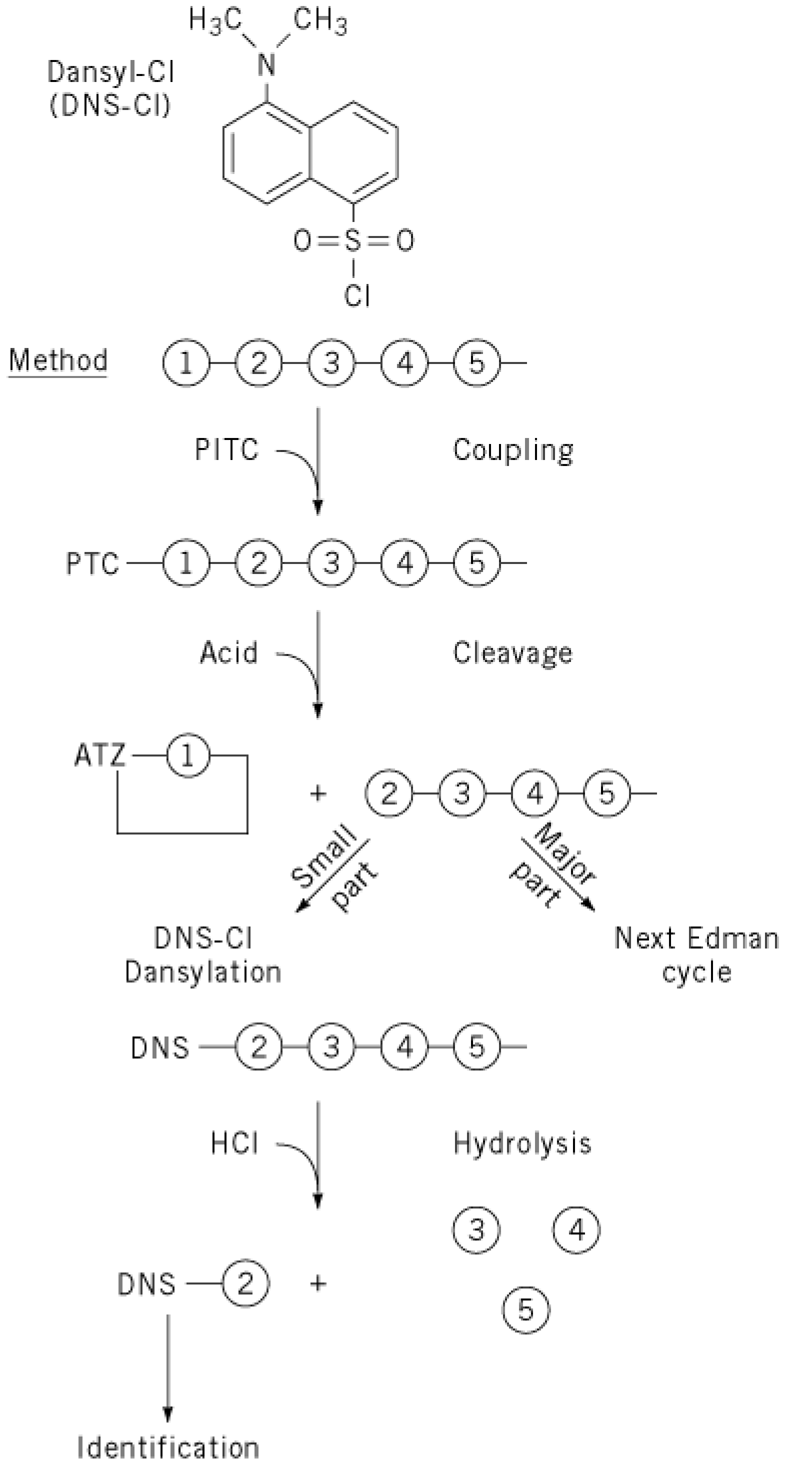
Dansyl Chloride

The repetitive nature of the Edman Degradation reaction opened the way to protein sequencing and to automation in the form of protein sequencers, but manual Edman degradations also became popular during much of the 1960s and 1970s.

One major manual method used dansyl (1-dimethylaminonaphthalene-5-sulphonyl) chloride (Fig. 1, see top of next page) to detect the new N-terminus after each Edman cycle (1). Combined with purification of peptides on paper by high-voltage electrophoresis and chromatography (see Peptide

Mapping), it made protein sequence analysis accessible to many laboratories without the need for large equipment. It also avoided the difficulties in identification of the phenylthiohydantoin (PTH)-amino acids that existed early, and replaced PTH-identification with dansyl-amino acid identification. The latter became rapid and reliable by **thin-layer chromatography** (2). Hence, many of the original protein primary structures determined used this methodology, originating from the MRC Laboratory of Molecular Biology, Cambridge, England. Together with the Sanger method of DNA sequencing later developed there, the "dansyl-Edman/paper purification" technique made this laboratory the leader in sequencing technology for a long time in the 1960s and 1970s.

Figure 1. Principle of the "dansyl-Edman" modification of the Edman degradation reaction, with N-terminal analysis of separate samples. PITC, phenylisothiocyanate; ATZ, anilinothiazolinone; PTH, phenylthiohydantoin; Dansyl, 1-dimethylaminonaphthalene-5-sulphonyl.



Dansyl chloride reacts with protein N-termini much like the original Sanger reagent, fluorodinitrobenzene (FDNB) (3), but it is easier to use, more sensitive, and fluorescent, making it easily detectable. Dansyl chloride is still used for protein labeling in many cases where fluorescence is desirable.

Databases

Molecular biology is an empirical discipline that requires observing and understanding different types of data. For example, a **gene** may imply a physical location on the chromosome, a **nucleotide sequence**, an amino acid sequence, a three-dimensional protein structure, a molecular component of cellular function, a regulatory mechanism of **gene expression**, or even a **phenotypic** difference caused by mutation. In addition to this variability, the quantity of molecular biology data is increasing rapidly, especially for gene and protein sequences and 3-D structures, due to advances in experimental technologies. Molecular biology databases are a number of resources available over the Internet that comprise a bioinformatics infrastructure for biomedical sciences. Each database contains a specific type of data that has cross-references to other databases, which can be used for integrated information retrieval. This is possible because a database is generally organized as a collection of entries, and connections can be made at the level of entries without standardizing how data items should be organized within an entry. The advent of the World Wide Web (WWW) in the early 1990s was a boon to molecular biology databases because the concept of hyperlinks is fully compatible with the practice of cross-references. The WWW also dramatically increased the accessibility of computers to biologists. The primary resources of molecular biology databases are bibliographic databases, sequence databases, and structure databases.

Although bibliographic, sequence, and structural aspects of molecular biology are relatively easy to computerize, the next step is to organize their functional aspects. There are resources in that direction, such as motif libraries that contain higher level knowledge abstracted from sets of functionally related sequences and pathway databases that contain computerized knowledge of molecular interactions and biochemical pathways. Representative examples of these resources are shown in Table 1.

Table 1. Selected List of Molecular Biology Databases

Data Type	Database	Organization
Biomedical literature	Medline	National Center for Biotechnology Information (NCBI)
Nucleotide sequence	GenBank	
	EMBL	European Bioinformatics Institute (EBI)
	DDBJ	National Institute of Genetics, Japan
Amino acid sequence	PIR	National Biomedical Research Foundation

Sequence motif	PROSITE	
3-D structure	PDB	Brookhaven National Laboratory

Biochemical pathway	KEGG	Kyoto University

Abstraction of a real problem is made through a data model. For example, data are organized in two-dimensional tables in the relational data model. The relational database based on the relational model has been widely used in a number of applications, including some of the sequence databases. Although in principle all different types of molecular biology data can be stored in a single, unified, relational database, this is impossible in practice because of the varying views of how data items should be organized and related. In the current web of molecular biology databases, different types of data are integrated by a loose coupling based on links (cross-references), rather than a tight coupling based on unified schema. This approach is extended to include other types of links, especially similarity links computed by similarity search algorithms and biological links representing molecular interactions, which can also be integrated for biological reasoning (1). The major bioinformatics servers shown in Table 2 provide link-based database retrieval systems, such as Entrez at NCBI, SRS at EBI, and DBGET/LinkDB at GenomeNet in Kyoto.

Table 2. WWW Addresses for the Major Bioinformatics Servers

Server	Address
NCBI	www.ncbi.nlm.nih.gov
EBI	www.ebi.ac.uk
ExPASy	(site currently unavailable)
GenomeNet	www.genome.ad.jp

In scientific disciplines, the merit of storing and managing information in a computer was first realized in bibliographic databases, which were designed for humans to read and understand. In the next step, factual data reported in the literature were computerized in factual databases, such as in sequence databases, which made more sophisticated retrieval available, for example, sequence similarity searches. Even in this case, however, the database is still a static resource to be retrieved, and it is up to humans to make sense out of the retrieved data. In contrast, the knowledge of links or relationships is more dynamic in nature. For example, ancestors in a family can be retrieved from a "deductive" database that contains parent–child relationships and the rules for combining them. Thus, knowledge is different from data or information, in that new knowledge can be generated dynamically from existing knowledge by logical reasoning. In the era of mass data production, molecular biology requires logical computation based on empirical knowledge rather than numerical computation based on first principles (see Bioinformatics). The web of molecular biology databases also requires a new generation of knowledge bases.

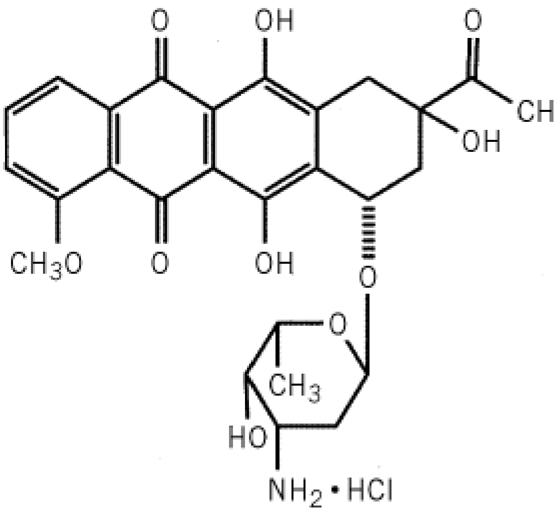
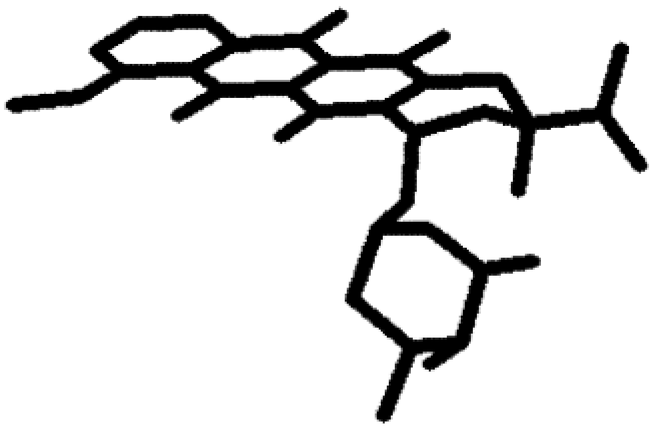
Daunomycin

Daunomycin (synonym: daunorubicin) is the prototype of the clinically important anthracycline antibiotics that are widely used in cancer chemotherapy. Daunomycin and its close relative adriamycin are natural products isolated from various *Streptomyces* species. These two anthracyclines are probably the most widely used antitumor agents worldwide (1, 2). Daunomycin is primarily used in the treatment of acute leukemias. The structure of daunomycin is shown in Figure 1; it is composed of two major parts: an anthraquinone ring system and the pendant daunosamine, an amino sugar.

Figure 1. The chemical structure (**a**) and molecular model (**b**) of the anthracycline antibiotic daunomycin.



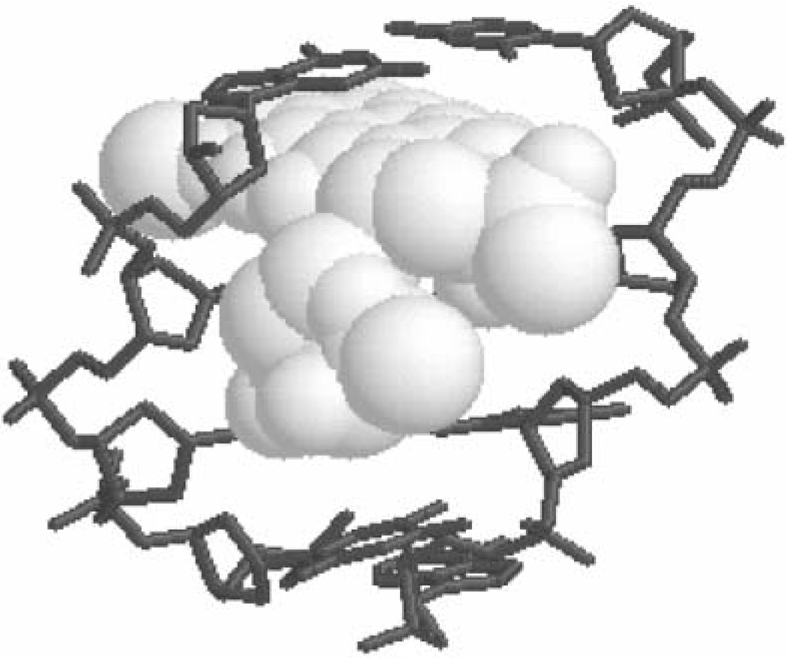
(a)



(b)

Daunomycin rapidly permeates into cells, passing through the membrane into the cytoplasm, and then accumulates in the nucleus, where it binds avidly to **DNA**. It binds to DNA by the process of intercalation, in which the anthraquinone ring inserts between adjacent DNA base pairs. The daunosamine moiety provides additional interactions that stabilize the complex by fitting into the minor groove of the DNA double helix, where it participates in van der Waals interactions. These additional interactions in the minor groove distinguish daunomycin from simple intercalators like ethidium bromide, which are stabilized only by the interactions within the intercalation site. Figure 2 shows the structure of a daunomycin–DNA complex determined by X-ray crystallography (3). Intercalation simultaneously lengthens and unwinds the DNA duplex, and it stabilizes DNA against thermal denaturation, increasing its **Tm (melting temperature)**.

Figure 2. Structure of a daunomycin–DNA complex. The anthraquinone portion of daunomycin (shown in a space-filling representation) is intercalated between the CpG step in a DNA oligonucleotide (shown in a stick representation). The daunosamine portion of daunomycin lies in the DNA minor groove. This figure was prepared from coordinates (file DDF01) deposited in the Nucleic Acid Database (Rutgers University), http://ndbserver.rutgers.edu.



Daunomycin, despite its small size (527.5 MW), exhibits several levels of **molecular recognition** (4). It is structurally specific and strongly prefers to bind to right-handed, B-form DNA over alternate helical forms. Daunomycin will **allosterically** convert left-handed Z DNA to an intercalated, righted-handed form (5). There is pronounced sequence selectivity in the binding of daunomcyin to DNA, which is revealed by DNase I footprinting experiments. Daunomycin binds preferentially to the triplet sequences 5′(A/T)GC and 5′(A/T)CG, where the notation (A/T) indicates that either A or T may occupy the sequence position (6, 7).

The mechanism by which daunomycin acts to kill cancer cells remains incompletely defined, and it may involve inhibition of several different cellular functions. Daunomycin, like most intercalators, is an effective inhibitor of DNA replication and of transcription, both *in vitro* and *in vivo*. The most likely intracellular target for daunomycin, according to recent evidence, is the enzyme topoisomerase II (see DNA Topology). Daunomycin poisons this key enzyme, by trapping an intermediate enzymatic species in which cleaved DNA strands are covalently attached to topoisomerase II, by preventing the normal resealing of the duplex DNA after strand passage (8). A comprehensive study of several anthracycline derivatives, including daunomycin, showed that intercalation is necessary, but not sufficient, for inhibition of topoisomerase II (9).

The anthraquinone moiety of daunomycin readily undergoes a number of oxidation–reduction reactions, with the production of oxygen free radicals. These free radicals can damage cells, and they may represent another important mechanism in the cytotoxicity of daunomycin. A serious, complicating side effect in the clinical use of daunomycin in cancer chemotherapy is its cardiotoxicity (1, 2). Free-radical production has been implicated as the primary cause of such cardiotoxicity.

Daunomycin was one of the first effective cancer chemotherapeutic agents identified, and it remains clinically important after over 30 years of use. It is one of the best characterized and understood intercalators and serves as an important model for understanding how small molecules bind to DNA.

DEAD and DEAH Domains

DEAD and DEAH domains contain a characteristic Asp-Glu-Ala-Asp/His sequence that is usually abbreviated DEAD or DEAH, using the amino-acid one-letter code. The **domains** belong to a large superfamily of enzymes involved in nucleic acid metabolism. Both DEAD and DEAH domains alter nucleic acid secondary structure in a nucleoside triphosphate (NTP)-dependent manner. Many function as either DNA helicases or RNA Helicases, which unwind DNA and RNA duplexes, respectively.

The general properties of DEAD/DEAH domains are summarized, and the functions of several well-characterized DEAD and DEAH domains are reviewed. Included are the DEAD domain of eukaryotic initiation factor 4a, eIF-4A, and the precursor RNA processing (PRP) DEAH domains found in the spliceosome, a multiprotein complex responsible for processing pre-messenger RNA into mRNA (see RNA Splicing). Finally, the structural basis for sequence conservation will be discussed using the **X-ray crystallographic** structures of the DExx DNA helicases from *Bacillus stearothermophilus* and *Escherichia coli* and the DExH RNA helicase from the hepatitis C virus (HCV).

1. Identification and Classification of DEAD and DEAH Domains

Helicases are enzymes that remove double-stranded regions of nucleic acid when single-stranded RNA and DNA are required. Regulated production of single-stranded nucleic acids occurs during many cellular processes, including replication, recombination, and transcription. The energy required for unwinding is derived from the hydrolysis of NTPs such as ATP.

Amino acid sequences can be used to identify and classify helicases. Helicase sequences contain seven regions or motifs of conserved residues (1). On the basis of the sequences of the individual motifs, helicases have been broadly grouped into two major superfamilies, SFI and SFII, and several smaller families [(2), Fig. 1). With the increased availability of genome information, helicases are frequently identified from their sequences alone, prior to the demonstration of helicase activity *in vitro*.

Figure 1. Representative examples of conserved sequence motifs. The seven common sequence motifs of DEAD and DI
one-letter code. Helicases from both superfamilies I and II are given. The NTP-binding sequences within motifs I and II

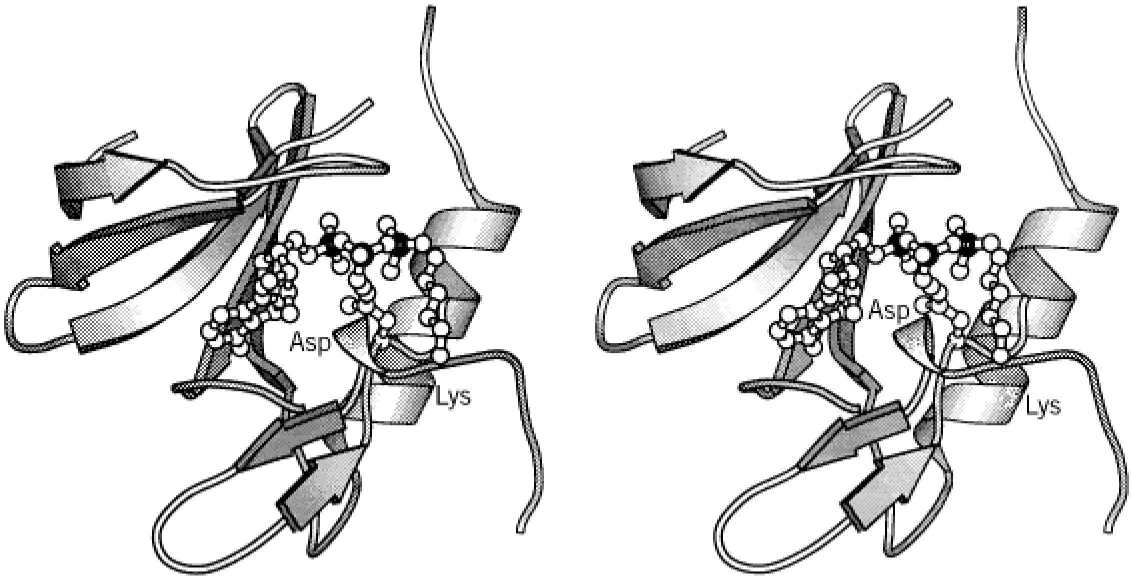
The energy for helicase-mediated unwinding of nucleic acid duplexes is derived from the hydrolysis of NTPs. Consequently, amino acid residues known to bind NTPs in other proteins are among the most conserved across the helicase families. By analogy with structures of ATP:protein complexes, the conserved lysine residue embedded in the Ala-x-x-Gly-x-Gly-Lys-Thr sequence of motif I probably interacts with the b and g phosphates of NTP (Fig. 2). Similarly, NTPases share an aspartic acid residue in motif II that ligates the magnesium of the NTP: Mg^{+2} complex (Fig. 2). In the DEAD and DEAH domains, this conserved aspartic acid occurs within the title sequences Asp-Glu-Ala-Asp/His. In 1982, Walker et al. (3) identified the functional significance of these motifs through sequence comparisons of ATP-utilizing enzymes. For this reason, motifs I and II are also referred to as Walker motifs A and B. In the literature, DEAD domains are occasionally referred to as DEAD-box proteins.

Figure 2. Stereoscopic views of an enzyme:ATP complex. Interactions made by the conserved lysine and aspartic acid residues of the protein with the ATP phosphates and Mg^{2+}, respectively, are highlighted. The protein backbone is shown as ribbons and the bound ATP in the ball-and-stick representation. Phosphate atoms are shown as solid spheres. The Mg^{2+} ion is situated between the phosphate oxygen and aspartic acid. For clarity, the complete coordination of the Mg^{2+} is not shown. Coordinates were taken from the crystal structure of the human cyclin-dependent kinase 2:ATP complex [(28), PDB entry 1HCK].



Initially, the classification of helicases by residues within motif II grouped functionally related proteins. However, as more helicase sequences became known, many exceptions to the strict conservation of motif II residues within functional families have been found. Indeed, a new DExH domain family containing helicases from positive-strand viruses has been proposed (4). For these enzymes, a variety of residues can be accommodated at the third position. Overall, amino acid sequence comparisons suggest that the DEAD and DEAH domains belong to a larger family of DExx domains, where x indicates sequence variability at the third and fourth positions of the DEAD/DEAH motif.

2. General Properties of DEAD and DEAH Domains

Isolated DEAD and DEAH domains typically exhibit NTPase activity that can be stimulated by the addition of nucleic acid polymers. The domains bind NTPs with **dissociation constants** in the micromolar range. K_m values for ATP of 80, 260, and 250 µM were measured for eIF-4A (5), PRP16 (6) and HCV helicases (7), respectively. Unlike eIF-4A, which is an obligate ATPase (8), little specificity for NTP is observed for some DEAD and DEAH domains. K_m values for ATP, CTP, GTP, and UTP ranged from 260 to 580 µM for the PRP16 DEAH domain (6) and from 250 to 1300 µM for the HCV DExH helicase (7). For the HCV helicase, the addition of poly U increases its ATPase activity approximately 10-fold (9). In the case of eIF-4A, the addition of poly U increases the ATPase activity approximately 8-fold (8).

The mechanism by which NTP hydrolysis is coupled to the modification of a nucleic acid secondary structure remains one of the most interesting questions regarding the function of DEAD and DEAH domains. As outlined below, several lines of evidence support the hypothesis that the hydrolysis reaction produces conformational changes in the domain. The changes alter the stability of the bound nucleic acid to favor the single-stranded form.

DEAD and DEAH domains typically contain ~300 residues and frequently reside within a longer sequence, or as subunits of a larger protein complex. For example, each of the seven *Saccharomyces cerevisiae* PRP splicing factors contains a DEAD/H domain. One of the larger splicing factors, PRP22, also contains an amino-terminal RNA-binding domain (6). The human DNA helicase II has two double-stranded **RNA-binding** domains, a DExH domain, and a glycine-rich domain (10). The HCV nonstructural protein 3 (NS3) is a bifunctional enzyme with an amino-terminal serine proteinase activity and a helicase activity in the carboxy-terminal DExH domain (11).

3. DEAD Domains

One of the most well-characterized DEAD domains is eukaryotic initiation factor 4A, eIF-4A. eIF-4A is one of three initiation factors required for binding of the 40S ribosomal subunit to mRNA during the initiation of translation. The ribosome-binding reaction requires ATP hydrolysis. During initiation of translation, eIF-4A may use the energy of ATP hydrolysis to disentangle structured regions in the 5′-untranslated regions of messenger RNA. When complexed with eIF-4B *in vitro*, eIF-4A unwinds duplex RNA in an ATP-dependent manner.

The biochemical characterization of eIF-4A provided the first detailed views of RNA helicase activity, which serve as a framework for comparison of newly discovered helicases. Studies of eIF-4A are reviewed in (12) and (13).

Mutational studies on eIF-4A demonstrated the functional importance of residues in motifs I and II. For example, the conversion of residues within the DEAD sequence to either NEAD or DQAD (substitution of the first conserved aspartic acid with asparagine, or the second residue with glutamine) abolished ATPase activity (12). The same result was observed when the conserved lysine residue in motif I was changed to asparagine. Similar experiments with other DExH domains have confirmed that these amino acid residues are essential.

Studies of the eIF-4A mechanism support the hypothesis that alterations in RNA structure are induced by conformational changes in the DEAD domain. By monitoring the domain's susceptibility to **proteolysis**, ADP was found to cause conformational changes in both the free eIF-4A and eIF-4A:RNA complex (14). Conformational changes were also observed on the binding of an ATP analog to the eIF-4A:RNA complex. Similarly, the observed nucleic acid-dependent differences in eIF-4A affinity for either ADP.Mg^{+2} or ATP.Mg^{+2} were also thought to reflect structural changes in eIF-4A.

4. DEAH Domains

The DEAH domains are involved in RNA processing and display many features common among helicases. Originally classified as DEAH domains, new sequence information has expanded the classification to DEAD/H domains. DEAD/H helicases are associated with the large ribonucleoprotein (RNP) complex called the spliceosome. The spliceosome processes pre-messenger RNA to remove intervening untranslated sequences called **introns**, so the resultant messenger RNA contains only expressed sequences, or exons.

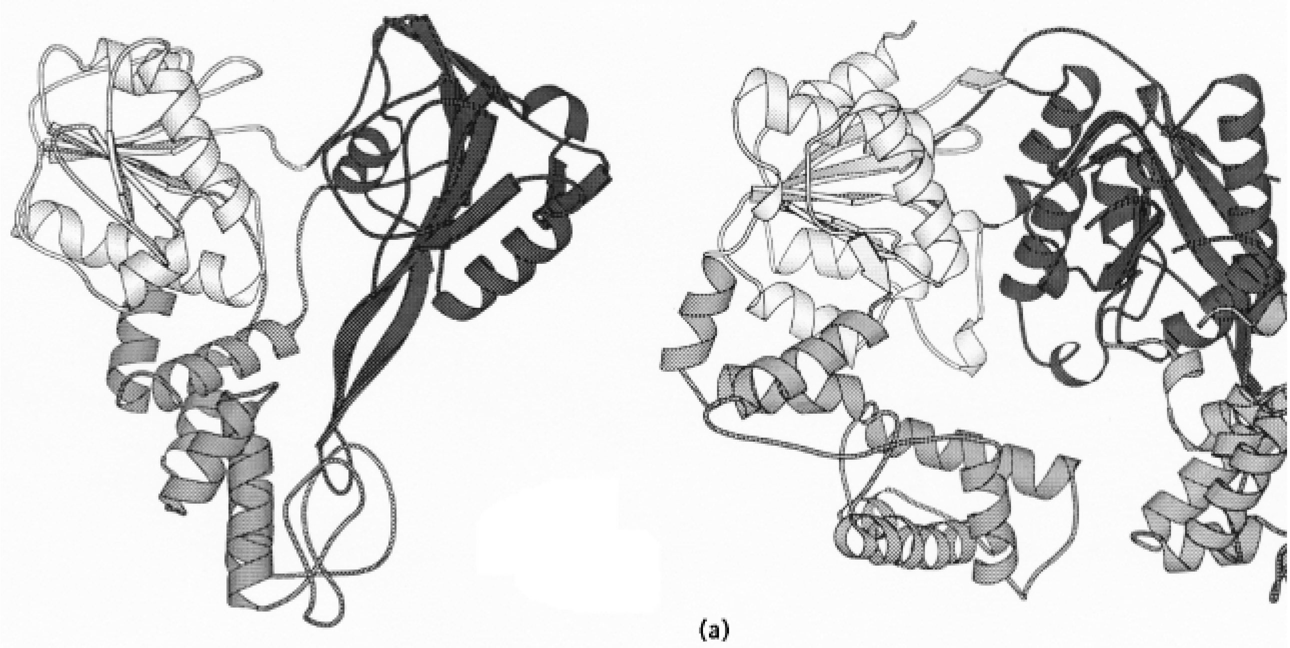
A number of precursor RNA processing (PRP) proteins associate with the spliceosome. The proteins contain either DEAD or DEAH domains and are also called splicing factors. Similar to many helicases, the isolated DEAH domain protein, PRP22, exhibits ATPase activity that is stimulated by the addition of poly(U) RNA (15). Mutagenesis studies of PRP22 variants demonstrated that the ATPase activity requires the conserved lysine residue of motif I. Although helicase activity has been demonstrated for the DEAH splicing factor PRP16 *in vitro*, the functional significance of these data is unclear (6). Most evidence suggests that the PRP splicing factors interact directly with the RNA in the spliceosome, to modulate RNA structure for efficient processing (15-17).

5. Structures of DExx and DExH Domains

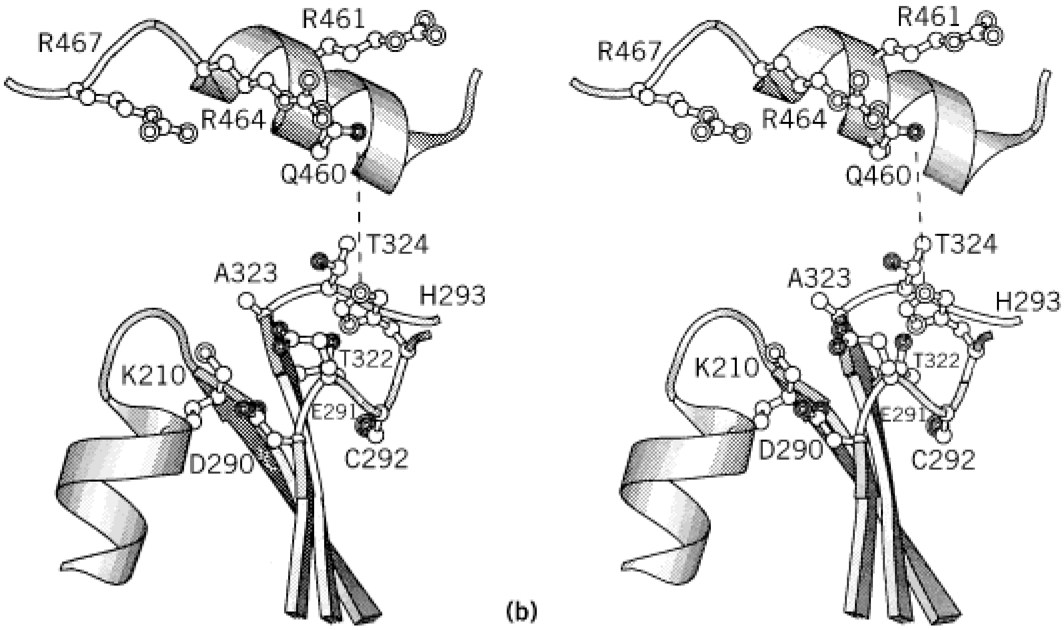
X-ray crystallographic structures of several helicases have been reported. The structures include two DExx DNA helicases belonging to SFI, *Bacillus stearothermophilus* PcrA helicase (18), and *E. coli* Rep helicase (19), and the HCV RNA DExH domain of SFII (20, 21).

The helicases are multidomain structures (Fig. 3). The DNA helicases fold into structurally similar halves, with two domains each. Each half is composed of a bab domain and an **alpha-helical** domain. A deep groove separates the two major helicase domains. The HCV RNA helicase domain contains three folded units: two bab domains and one a-helical domain. Comparison of the helicase structures revealed that the bab domains are structurally similar in both overall fold and their relative spatial orientation (22).

Figure 3. Structural features of DExx and DExH domains. The ribbons trace the polypeptide backbones of the HCV RN (left drawing, part **a**) and *E. coli* Rep DNA helicase (right drawing, part **a**). The upper left domain in each structure is the domain (shown in the lightest ribbon). The NTP-binding domain and second domain (shown in the darkest ribbon) share bab fold. Many of the conserved sequence motifs are located near the deep groove that separates the bab domains. A det motif II, III, and VI residues of the HCV RNA helicase is shown in stereoscopic representation (part **b**). Figures prepare Molscript (29).



(a)



(b)

Both helicase motifs I and II are located within one of the bab domains. The overall fold of the bab domain and spatial arrangement of residues in motifs I and II are similar to conserved features present in other NTP-utilizing enzymes. The crystallographic structure of the PcrA:ADP complex also showed nucleotide binding to this domain (18). The structural studies taken together, including comparison of the superfamily I and II proteins, have identified the NTP-binding domain.

The structural studies also revealed conformational flexibility that is potentially important in helicase function. Comparison of the independent molecules in the HCV RNA helicase crystals revealed that one of the bab domains could rotate relative to the remainder of the molecule (21). When the helicase structures are compared to those of NTP-binding proteins known to function as molecular switches, the observed structural changes in the helicase were found to involve residues at the end of a beta-strand previously shown to constitute part of the energy transducing mechanism (18, 21). These residues in the DExH domain map to motif III, which mutagenesis studies have shown is required for coupling NTP hydrolysis to unwinding (12, 23). Some indication of the extent of possible structural changes is found in the structure of the Rep DNA helicase complexed with a short oligonucleotide, where two orientations differing by a 130-deg rotation about a hinge region of the protein were observed for one of the helical subdomains (19).

6. Roles of DEAD and DEAH Residues

The mechanistic roles of the first and last residues of the DEAD and DEAH have been largely deciphered. Structural studies on the free and ADP-bound forms of DExx and DExH domains support the participation of the conserved aspartic acid in binding the NTP phosphate groups. Comparison of the structures of ATP:protein complexes suggests that the aspartic acid probably coordinates either the Mg^{+2} of the $NTP.Mg^{+2}$ complex, or it interacts with the phosphate groups via an intervening water molecule. However, the exact nature of the interaction has yet to be defined.

The last residue of the motif II tetrapeptide is involved in coupling the energy generated by NTP hydrolysis to duplex unwinding. Researchers working with eIF-4A generated a molecule in which the wild-type DEAD sequence was changed to DEAH (12). The ATPase activity of the modified eIF-4A was slightly enhanced, but the helicase activity was decreased 90% relative to the wild-type molecule. In a similar set of experiments, the DExA mutants of the DExH vaccinia virus nucleoside triphosphate phosphohydrolase II (NP-II) (5) and HCV RNA helicase exhibited NTPase activity and RNA binding comparable to the wild-type protein (24). In contrast, the RNA unwinding activity of these proteins was essentially undetectable.

Crystal structures of the DExH domains show that the histidine side chain is oriented toward the deep groove separating the two bab domains. Although a detailed structural description of the precise role played by the last residue of motif II in the helicase reaction has not been determined, the structures show that the histidine residue is close to conserved residues in motif VI. Mutagenesis experiments on eIF-4A (25) and vaccinia virus NP-II (26) demonstrated that residues in motif VI are required for helicase activity. Altered proteins exhibit decreased ATPase and helicase activities, without compromised RNA binding (27). The structural proximity of the DExH histidine and residues of motif IV offers the possibility that the residues interact directly during the helicase catalytic cycle (Fig. 3).

7. Conclusion

The well-characterized DEAD and DEAH domains play essential roles in nucleic acid metabolism. Structural and mutagenesis studies, and amino acid sequence comparisons, have revealed the functions of the first D residue and the terminal D and H residues, although the mechanistic details of their interactions have not been determined. The DEAD and DEAH sequences are required for nucleoside triphosphate hydrolysis and, along with residues of motifs Ia, III, and VI, are required for coupling hydrolysis to mechanical action.

DEAD and DEAH domains occur widely in nature and exhibit a variety of biological functions. The functional diversity of these domains constitutes a challenge for classification by sequence-based approaches. Overall, the DEAD, DEAH, and DExH domains appear to be required in processes involving large-scale conformational changes of domain and substrate. Thus, their utilization as molecular motors is emerging as a unifying theme (14).

Dead-End Inhibition

Dead-end inhibition of an enzyme occurs when a compound, usually a structural analogue of a substrate, combines at the active site of the enzyme, but does not undergo reaction. The resulting complex can only dissociate back to the components from which it was formed. Dead-end inhibitors are useful for determining kinetic reaction mechanisms because dead-end inhibition patterns can be characteristic of a particular mechanism. Rules have been formulated for the qualitative prediction of such inhibition patterns (1) and these rules can be summarized as follows:

1. A dead-end inhibitor affects the *slope* of a double-reciprocal plot (see Lineweaver–Burk Plot) when
   - the inhibitor and the variable substrate combine with the same enzyme form or
   - a reversible connection exists between the points of addition of the inhibitor and the variable substrate. Such a reversible connection exists only when the variable substrate adds after the inhibitor.
2. A dead-end inhibitor affects the *intercept* of a double-reciprocal plot when the inhibitor and variable substrate combine with different forms of enzyme and saturation with the variable substrate does not overcome the inhibition. Intercept effects will always be observed unless steps between the points of addition of the variable substrate and the inhibitor are at thermodynamic equilibrium.

The results of the application of the rules to kinetic mechanisms for Bi–Bi reaction mechanisms are given in Table 1. Further examples are given in Competitive inhibition, Noncompetitive Inhibition, Product Inhibition, Substrate Inhibition, and Uncompetitive inhibition.

Table 1. Dead-end Inhibition Patterns for Bi–Bi Reaction Mechanisms[a]

Mechanism	Inhibitor Combines with	Variable Substrate	
		A	*B*
Ordered	E	C	NC
	EA	UC	C
	EQ	UC	UC
	EA + EQ	UC	NC
Equilibrium-ordered	E	C	C
	EA	UC	C
Rapid equilibrium,	E + EB	C	NC
random	E + EA	NC	C
Ping-pong	E	C	UC
	F	UC	C
	E + F	NC	NC

[a] The mechanisms are illustrated under **Kinetic mechanisms**. C = linear competitive inhibition. NC = linear noncompetitive inhibition. UC = linear uncompetitive inhibition.

Deamidation

Deamidation is the reverse reaction of amidation (see Carboxyl Groups) and involves release of an amine from an amide. Deamidation occurs spontaneously in proteins at asparagine and glutamine residues, which causes heterogeneity, instability, and sometimes defects in the function of the proteins.

Deamidation in proteins occurs enzymatically or chemically. Enzymes that participate in deamidating of proteins are transglutaminase and peptidoglutaminase. An amide bond in an asparagine or glutamine residue is relatively labile, especially in acidic media, and is easily hydrolyzed chemically. The rate of deamidation is sensitive to the environment of the amide. Exposed amides are more readily deamidated than those buried in the interior of a protein. Thus, denatured proteins often have high potential for deamidation.

The Asn-Gly sequence is especially notorious for rapid deamidation. The reaction shown below proceeds readily in this sequence. Additional reactions such as **racemization**, transpeptidation, and cleavage of peptide bonds take place during this reaction. These reactions also occur with the Asp-Gly sequence and pivotal components of protein deterioration.

The rates of deamidation vary with different peptides. The **half-times** for deamidation of various asparagine residues under the same conditions range from 3.3 to 277 days. Deamidation causes conformational destabilization of proteins and accelerates their degradation. Thus the deamidation of Asn or Gln residues has been regarded as a timer of protein turnover (1).

Asparaginase hydrolyzes asparagine to aspartic acid (deamidation). Because asparagine in the blood is an essential nutrient for the growth of malignant white cells, the intravenous administration of asparaginase suppresses the growth of some types of animal and human leukemias.

Decapentaplegic

The *decapentaplegic* (*dpp*) gene plays a key role in patterning both embryonic and adult structures in the fruitfly *Drosophila*. The name of the **locus** underscores the multiple requirements for *dpp* activity during development and refers to the wide range of defects caused by mutations in the **gene** (*decapentaplegic* = 15 defects) (1). *dpp* is one of the few haplo-insufficient loci in *Drosophila*; consequently, even a 50% reduction in *dpp* activity leads to embryonic lethality. Less severe alleles of *dpp* are viable but result in adults that have defects in structures derived from one or more imaginal discs. The *dpp* gene encodes a protein that is **homologous** to secreted growth factors of the **transforming growth factor**-b (TGF-b) superfamily. Ligands that belong to this group of signaling molecules have been identified in animals across the phylogenetic spectrum and are involved in cellular and developmental processes ranging from regulation of the cell cycle and the extracellular matrix, to establishment of embryonic pattern and aging. Genetic and molecular studies of *dpp* and the genes involved in *dpp* signal transduction have proven to be of broad general interest, because the basic mechanisms involved in generating and receiving TGF-b signals are evolutionarily conserved.

1. Molecular Features

The *dpp* gene spans ~55 kb of DNA, the bulk of which consists of a large array of *cis*-regulatory elements (2). *dpp* messenger RNA is expressed in a complex spatial and temporal pattern that reflects the multiple roles the ligand plays during development. Three major cis-acting domains regulate transcription of the gene: an upstream *dpp*-shv region required for expression in the embryonic gut and pupal wing, a central *dpp*-Hin region that directs embryonic expression, and a downstream *dpp*-disk region that regulates transcription in imaginal discs (2). These dispersed regulatory elements contribute to the genetic complexity of the locus and mediate *dpp* transcription in response to inputs from a variety of signaling pathways. For example, *dpp* expression in the blastoderm stage embryo is regulated by **Dorsal**, a transcription factor homologous to mammalian NFkB. Later in embryogenesis, *dpp* transcription in the dorsal-most cells of the germband is controlled by genes acting in the Jun kinase signaling pathway, while expression of *dpp* in the midgut is dependent on multiple factors, including **homeobox** DNA-binding proteins, the growth factor Wingless, and Dpp itself. During imaginal disc development, localized expression of *dpp* in the wing and leg discs is regulated by the ***hedgehog*** and ***wingless*** genes.

The *dpp* locus gives rise to three major and two minor transcripts through the use of alternative **promoters** that are utilized at different stages of development (2). While the mRNAs have unique 5′-untranslated sequences, they share common second and third exons that contain an open reading frame coding for a single 588-amino-acid-residue protein (see Cell Cycle and Extracellular Matrix). Dpp is most closely related to the vertebrate bone morphogenetic proteins BMP-2 and BMP-4, and it shares ~75% identity with these proteins in the carboxy-terminal region that constitutes the mature ligand **domain**. While the vertebrate BMPs were first identified by their ability to induce ectopic bone, they are now known to have important roles in embryonic development in a number of organisms, including frogs, mice, and humans. Dpp and BMP-4 can substitute for one another functionally, because a human BMP-4 transgene can rescue patterning defects in a *Drosophila* embryo lacking Dpp (3). Conversely, the fly protein can induce the formation of ectopic bone when injected subcutaneously into rats. Like other ligands belonging to the TGF-b superfamily, Dpp is processed and secreted as a **disulfide**-linked dimer of ~30kDa.

2. Dpp Signal Transduction

Dpp acts as a secreted ligand to influence the developmental fate of cells that receive the signal. Genes involved in Dpp signal transduction have been primarily identified using two strategies. Some genes have been recovered in genetic screens to isolate enhancers of weak *dpp* **alleles**, while others have been isolated in low stringency **hybridization** screens, based on their homology to TGF-b signaling components identified in other organisms.

According to the current paradigm for BMP signaling, the ligand binds a heteromeric complex of two structurally related transmembrane **serine-threonine kinases**, called the type I and type II receptors (4, 5). Formation of the ligand–receptor complex allows the type II kinase to **phosphorylate** and activate the type I receptor. A type II receptor, Punt, as well as two type I receptors, Thick veins (Tkv) and Saxophone (Sax), have been implicated in Dpp signaling. Although the role of Punt and Tkv as receptors for Dpp is well established, it appears that Sax may primarily mediate the response to other BMP-related ligands in Drosophila. Activation of Tkv results in the direct phosphorylation of a cytoplasmic protein encoded by *mothers against dpp* (*mad*). This modification triggers **Mad** to form a complex with Medea (a structurally related protein), and it enables their translocation from the cytoplasm into the nucleus. Mad and Medea contain DNA-binding domains and are thought to regulate the expression of downstream target genes in association with other transcription factors (4, 6). The Mad family of proteins is evolutionarily conserved. The human homologue of Medea (DPC4) has been identified as a **tumor- suppressor** gene, a result that appears logical in light of the known antiproliferative effects of TGF-b.

3. Biological Role of Dpp

Dpp plays an important role in the specification of cell fate and morphogenesis in a number of tissues (1). Mutations in *dpp* that interfere with production of an active ligand affect all developmental events regulated by the gene, while mutations that disrupt specific enhancer elements affect *dpp* function in a tissue- or stage-specific manner. Among the processes that require *dpp* signaling are: oogenesis; establishment of dorsal–ventral pattern during embryogenesis;

morphogenetic movements of dorsal closure; subdivision of the mesoderm along the dorsal–ventral axis; specification of the visceral mesoderm and endoderm in the embryonic gut; development of the heart, gastric cecae, salivary glands, and the trachea; and growth and patterning of imaginal discs.

The ability of Dpp to trigger distinct responses in a single field of cells has generated a great deal of interest in understanding the mechanisms underlying *dpp* function. Dpp has been shown to specify cell fate in a concentration-dependent manner; that is cells respond to different thresholds of Dpp by following distinct pathways of differentiation. A critical issue that arises is how gradients of *dpp* activity are established, and how such gradients are interpreted. Based on recent studies, two alternative mechanisms have evolved: one is based on diffusion of Dpp from its site of synthesis to generate a protein concentration gradient, and the second involves an inhibitor that diffuses into the domain where *dpp* is expressed and interferes with Dpp signaling in a graded manner. This results in a gradient of ligand activity, rather than concentration. Both types of gradients are discussed further below.

Adult structures in the fruitfly arise from imaginal discs, small groups of epithelial cells that are set aside during embryogenesis. These discs grow and are patterned during the larval and pupal stages in response to different signals. In the wing imaginal disc, Dpp acts as a long-range morphogen to specify cell fate along the anterior–posterior axis. *dpp* is expressed in a narrow domain of cells at the anterior–posterior compartment boundary, from where it diffuses to generate a gradient of protein in the surrounding tissue. Cells up to 20 cell diameters away respond to different threshold concentrations of Dpp by activating the transcription of target genes like *spalt* and *optomotor blind* (7, 8). Expression of *spalt* occurs close to the source of *dpp* protein, while *optomotor blind* expression overlaps with, and extends further than, *spalt* expression. The nested domains of Dpp target gene expression further subdivide the wing disc into distinct regions that are specified by the combination of genes expressed.

During early development, a gradient of Dpp signaling is required to establish cell fates within the dorsal half of the embryo. Peak levels of Dpp signaling specify the dorsal-most amnioserosa tissue, while lower levels are required to specify the dorsal ectoderm (9, 10). Reduction in the level of Dpp signaling results in progressive loss of dorsal structures, while increasing concentrations of Dpp can induce dorsal cell fates. Since *dpp* mRNA is expressed uniformly in all dorsal cells, it is generally believed that Dpp activity, rather than its concentration, is graded. A number of extracellular proteins are involved in generating a gradient of Dpp signaling in the embryo. A second BMP ligand, Screw, acts synergistically with Dpp to enhance signaling in the dorsal-most cells. The activity of these ligands is antagonized by a secreted factor, Short gastrulation (Sog), that can prevent ligand binding to the receptor. The inhibitor Sog is expressed in ventral cells and diffuses dorsally to generate a ligand gradient of the opposite polarity. In addition, a metalloproteinase, Tolloid (Tld), promotes signaling in dorsal cells by cleaving Sog and releasing the ligand. Thus modulation of ligand activity at multiple levels contributes to establishment of a gradient of BMP signaling in the embryo (11-14).

Similar antagonistic interactions involving homologous proteins are involved in patterning the dorsal–ventral axis in vertebrate embryos. In *Xenopus*, BMP-4 promotes ventral development, while a homologue of Sog (Chordin) promotes dorsal cell fates. Recently an amphibian homologue of Tld (Xolloid) has been shown to cleave Chordin (12). These and other studies suggest that the dorsal–ventral axes in *Drosophila* and vertebrates are specified by a similar mechanism, although they are inverted relative to one another. The extensive parallels between TGF-b/BMP signaling in vertebrates and invertebrates allow one to extend the insights gained from studying Dpp signaling in *Drosophila* to other organisms, including humans.

Degeneracy of the Genetic Code

The genetic code for translation of the gene sequence in **protein biosynthesis** is degenerate—there is more than one triplet **codon** for most amino acids. For example, tyrosine is encoded by UAU and

UAC, and arginine is encoded by CGU, CGC, CGA, CGG, AGA, and AGG. Two codons that share the same first two nucleotides encode the same amino acid if the third nucleotide is either C or U, and they often do if the third nucleotide is A or G. Alternate synonymous codons are not used randomly. The GC content of the DNA, especially of bacteria, varies widely in different species, and there is a corresponding difference in **codon usage**. In bacteria and the **yeast** *Saccharomyces cerevisiae*, and even to some extent in *Drosophila* (except for the histone genes), the most frequently used codons are those that are decoded by abundant transfer RNA, and they are strongly preferred in genes expressed at high levels. In genes expressed at low levels, codon usage is more uniform (1-3). In bacteria with extreme DNA base composition biases (for example, the *Mycoplasma capricolum* genome is 25% G + C, whereas that of *Micrococcus luteus* is 74% G + C), not surprisingly, all genes have similar codon usage using those codons with the corresponding G + C content (4). Codon usage also varies among genes from the same genome. This is true of mammalian genomes but also, to some extent, in *S. cerevisiae*. Regions of differing G + C content were initially recognized in mammalian chromosomes and termed isochores. Overlying differences in codon usage between individual genes is the apparent higher density of genes in GC-rich isochores, and this may influence codon usage. As genome sequencing projects proceed, this relationship is expected to be clarified.

Dehydrogenases

Pyridine nucleotide-linked dehydrogenases are enzymes that catalyze oxidation–reduction reactions involving a pyridine nucleotide and the transfer of a hydride (one proton and two electrons) from or to a second substrate molecule. Most dehydrogenase reactions are readily reversible, but some are not, and the enzymes responsible for essentially irreversible reactions are referred to as *reductases*; there are exceptions, however, such as *formate dehydrogenase* . The oxidized forms of the pyridine nucleotides are **NAD** (nicotinamide adenine dinucleotide) and **NADP**. The latter nucleotide has an additional phosphoryl group attached at the 2′-position of the ribose that is part of the adenosyl moiety (Fig. 1). The general form of a dehydrogenase reaction can be illustrated by reference to the reaction catalyzed by lactate dehydrogenase (Eq. 1):

$$\text{Lactate} + NAD \rightleftharpoons \text{pyruvate} + \text{NADH} + H^+ \qquad (1)$$

Not all dehydrogenase reactions are as simple as that described by Equation 1. The oxidation reactions catalyzed by *isocitrate* and *glutamate* dehydrogenases give rise to the release of CO_2 and NH_3, respectively. NAD and NADP are written frequently as NAD^+ and $NADP^+$ even though the overall charge on the molecule is negative in the neutral pH region; the plus refers to the charge on the nitrogen atom of the nicotinamide moiety of the oxidized forms of the pyridine nucleotides.

Dehydrogenases usually show a distinct preference for one or the other of the two pyridine nucleotides; examples are given in Table 1, and a more extensive list is available (1). The binding to the enzyme of the nonpreferred nucleotide is generally weaker, and the maximum velocity is usually lower.

Figure 1. Structure of NADH / NADPH, showing the two prochiral hydrogen atoms at the 4-position of the nicotinamide moiety. R at the 2′-position of the ribose moiety represents either a hydrogen atom (NADH) or phosphoryl group (NADPH).

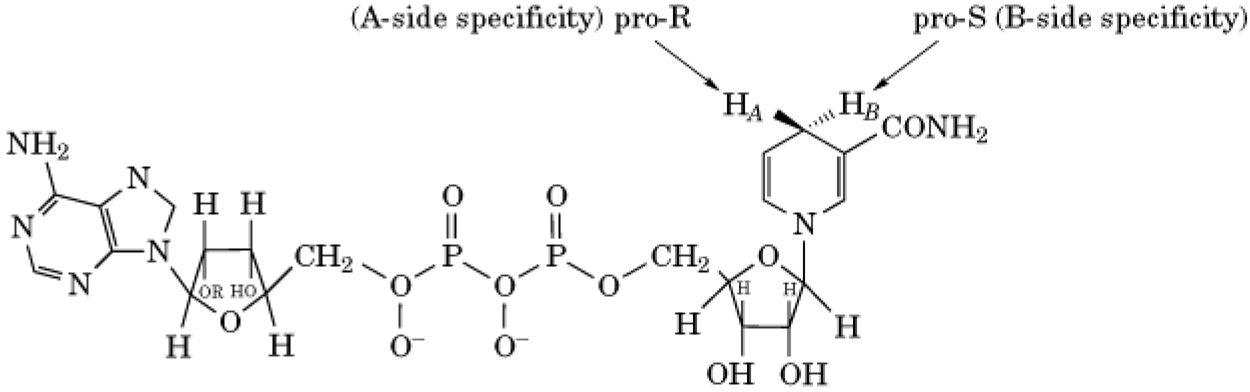

Table 1. Pyridine Nucleotide Specificity of Some Dehydrogenases

Dehydrogenase/Reductase	Pyridine Nucleotide	Stereospecificity
Alcohol	NAD	A
Glyceraldehyde-3-phosphate	NAD	B
3-Phosphoglycerate	NAD	B
Lactate	NAD	A
Glutamate	NAD/NADP	B
Glutathione	NAD/NADP	B
Dihydrofolate	NADP	A
Glucose-6-phosphate	NADP	B
Isocitrate	NADP	A

In dehydrogenase reactions (Eq. 1), the hydride is transferred to the 4-position of the nicotinamide ring of NAD or NADP (Fig. 1). The two hydrogen atoms at this position in NADH and NADPH are chemically equivalent, and the tetrahedral carbon atom is not **chiral**. However, the two hydrogen atoms at the 4-position are prochiral. The binding of reduced pyridine nucleotides to dehydrogenases is such that hydride transfer involves only one of the two hydrogen atoms. Thus, the enzymes exhibit regiospecificity, and hydride transfer occurs either from the pro-R hydrogen (A-side specificity) or from the pro-S hydrogen (B-side specificity). Examples of dehydrogenases that fall into each of these two classes are given in Table 1. Attempts have been made to explain why some dehydrogenases are A-side and others are B-side, but no convincing explanation has been forthcoming (2).

The side-specificity of dehydrogenases allows the preparation of reduced pyridine nucleotides with a deuterium (D) or tritium (T) atom replacing a hydrogen atom in either the pro-R or pro-S positions (see Hydrogen Isotopes). Extensive use has been made of deutero- and tritio-pyridine nucleotides to gain information about enzymic catalysis (3). The cleavage of a bond can be expected to be two to eight times slower than with a bond. With chemical reactions, the full isotope effect difference in rates is usually observed, because the bond-breaking step is rate-limiting. But with enzyme-catalyzed reactions, steps other than the catalytic one can be at least partly rate-limiting. This results in the observed isotope effect, with NADD or NADPD being smaller than the absolute value for the bond-breaking step. Indications as to where the rate-limiting steps lie for a particular dehydrogenase reaction come from the use of initial velocity studies to determine the apparent first-order rate constants k and the maximum velocities V with the protio- and deutero-substrates. The observed isotope effects are then calculated from the ratio of the values for $(V/K)_H$ and $(V/K)_D$, expressed as $^D(V/K)$ and the ratio of the values for V_H and V_D, expressed as ^DV. The values for these ratios usually range from 1.0 to 3.5. Low values for $^D(V/K)$ can result from the stickiness of substrates. Values for ^DV will be low whenever product release is rate-limiting (3). The tritiated forms, NADT and NADPT, can be used for determinations of $^T(V/K)$, but not from initial velocity studies, as the tritium is only a trace label. For this same reason, it is not possible to obtain values for ^TV. The value for $^T(V/K)$ will be higher than that for $^D(V/K)$ as the bond is stiffer than the bond. As $^Tk = (^Dk)^{1.442}$, the general function $[^Dk - 1]/[^Dk^{1.442} - 1]$ can be used to determine the intrinsic isotope effect for a dehydrogenase reaction (4). It is this value that gives insights into the chemical mechanism of the reaction and the nature of the transition state.

The pyridine nucleotides that function as effective substrates for most dehydrogenases have a nicotinamide–ribose linkage (Fig. 1) with a b-anomeric configuration and are referred to, for example, as b-NAD. These pyridine nucleotides also occur with an a-anomeric configuration and are found in tissue extracts, as well as commercial preparations. Both a-NADH and b-NADH undergo thermal **epimerization** reactions to produce an equilibrium mixture with 10% of the a form (5). There are no examples of a dehydrogenase that specifically uses a-NADH or a-NADPH, although alcohol dehydrogenase and lactate dehydrogenases utilize a-NADH with maximum velocities some three to four orders of magnitude lower than with b-NADH. The same side-specificity is observed with both anomers of NADH (5). By contrast, a-NADPH is a relatively good substrate for the dihydrofolate reductase that is encoded by an R-plasmid (6). The K_m value of 17 µM is comparable to the value of 4 µM for b-NADPH. The maximum velocity of the reaction with a-NADPH is 70% of that with b-NADPH. It has been proposed that those dehydrogenases which show activity with both the a- and b-anomers must have sufficient conformational freedom to permit specific orientation of the dihydronicotinamide ring for the reduction of other substrates.

Denaturants Stabilizers

The structures of globular proteins (and other biological macromolecules) are not very stable (see Protein Stability). Therefore, it is often necessary to increase the stability by addition of inert compounds in order to maintain a biochemical activity or to preserve an assembled structure, such as various **organelles** or multisubunit enzymes. The stabilizing compounds must characteristically be added at high concentration (>1 M), since their interactions with proteins are weak (see Stabilization And Destabilization By Co-Solvents). Strongly interacting molecules, although effective in particular cases, generally tend to alter some properties of the protein molecules (see Binding).

The most frequently used stabilizing agents are 1 *M* sucrose, other sugars (trehalose, glucose), 3 to 4 *M* glycerol, neutral amino acids at 1 *M* levels (glycine, proline, alanine), methyl amines (betaine, sarcosine, trimethyl amine N oxide), polyols (sorbitol, inositol, mannitol), some salts [Na_2SO_4, $(NH_4)_2SO_4$] (see Sulfate Salts) (1). All have the property of being preferentially excluded from proteins, which imparts stabilization and precludes excessive surface contacts that could alter the local protein structure (see Preferential Hydration). Most stabilizers used in the laboratory are also cryoprotectants and osmolytes, in that they are chosen by nature to maintain high osmotic pressure in, eg, amphibians, and to protect against freezing (2).

Conversely, a number of compounds are used to denature proteins when so desired. These again act at high concentration and are characterized by their preferential binding to proteins. The most common denaturants are urea, **guanidinium** chloride, sodium dodecyl sulfate (**SDS**), trichloroacetic acid, $CaCl_2$, LiBr, and other salts on the denaturant side of the Hofmeister series (3). (See Guanidinium Salts, Hofmeister Series.)

Denaturation Mapping

Denaturation of the **double-helical** structure of **DNA** is an essential first step in many of the most common methods for investigating **chromosomal** structure. The method relies on the unique order of bases in DNA and the capacity of two separate complementary strands to recognize each other through the process of **hybridization**. Denaturation mapping can be done using either sections of tissue or chromosomal preparations. The sample slide to be analyzed is heated to denature the double helix into two separate DNA strands. Rapid cooling of the preparation in the presence of formaldehyde keeps the DNA strands separated. The cloned gene or sequence of interest is prepared as a DNA probe in single-stranded form with a label attached. This label could be either a source of radioactivity, or an epitope recognized by an antibody (often using streptavidin as an antigen). A change in salt concentration and temperature facilitates hybridization between complementary DNA strands. The probe and chromosomal sequences compete with each other, but a sufficient excess of probe can be added so that some of the probe hybridizes to the specific site on a chromosome.

When initially developed by Pardue and Gall in 1970, the probe was labeled with the radioactive hydrogen isotope tritium (1). More recently the use of antibodies has become popular (2, 3). The antibodies are usually linked to an enzyme that acts on an appropriate substrate to generate a visible signal. This could either be a colored precipitate on the chromosome, that is detectable under a light microscope, or the antibody could be linked to a fluorochrome that is visualized by a **fluorescence** microscope. This latter technique is known as fluorescent in situ hybridization (FISH). Now modifications of this technique allow analysis under the electron microscope for increased resolution or in the **confocal microscope** that builds up three-dimensional images by optical sectioning.

A number of specialized methods have acquired their own acronyms. These include fluorescence in situ hybridization (FISH) as described; genomic in situ hybridization (GISH); whole chromosome painting (WCP); and primed in situ labeling (PRINS). GISH is a method for detecting species–specific chromosomes when the entire genomic DNA is labeled and hybridized to whole chromosomal spreads. It is useful in analyzing of cell fusion hybrids and in evolutionary studies. In WCP, DNA from a single chromosome is labeled and prehybridized with repetitive DNA to stop cross-reaction with other chromosomes from the same organism. WCP probes are available commercially for all 22 autosomes and the sex chromosomes in humans. In PRINS, the polymerase chain reaction (**PCR**) is used to label sequences on the actual chromosome or tissue. There are many other adaptations of these important methodologies.

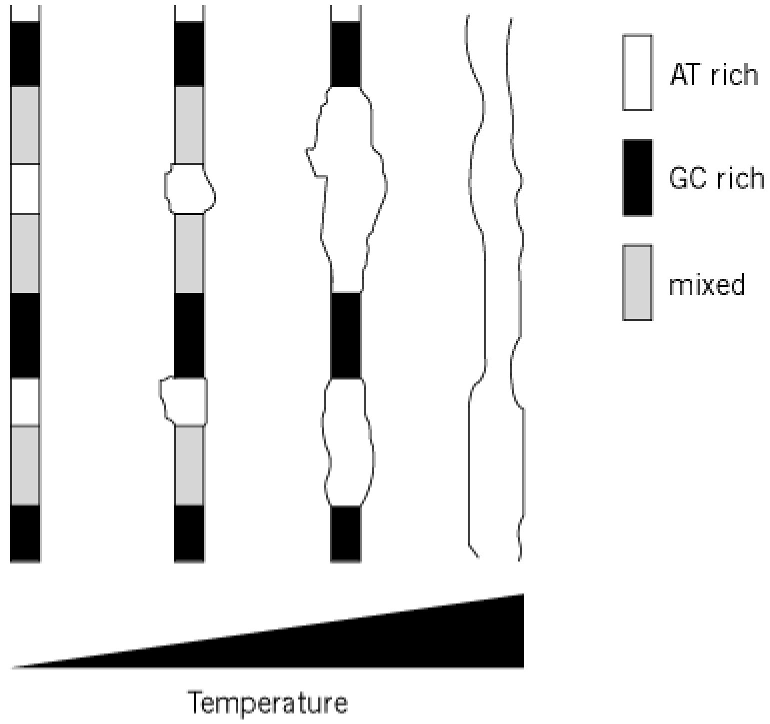
Denaturation, Nucleic Acids

Disruption of the secondary and tertiary structures of nucleic acid polymers is promoted by exposure to extreme conditions. Most commonly, nucleic acid denaturation refers to the formation of two free single-stranded nucleic acids from a duplex. Denaturation (loss of native structure) of the polymer duplex can be promoted by a variety of conditions or agents, including heat, chemical denaturants, and extremes of pH. The stability of the duplex varies by region, and the base pair composition (% GC) determines the stability of a given region (Fig. 1). Under most conditions, regions of the duplex that are composed predominantly of AT (for DNA) or AU (for RNA) base pairs are less stable than GC-rich regions. As the conditions shift toward those favoring single-stranded polymers, the path from fully base-paired duplex to fully denatured single strands passes through intermediate states, where first the AT/AU rich regions "melt," forming internal loops, then mixed sequence regions, then finally the GC-rich regions. As the last GC-rich regions "melt," the strands separate.

Figure 1. Mechanism of melting of polymeric DNA.



1. Thermal Denaturation

Because it is easy to manipulate, heat is frequently employed to denature nucleic acids. The temperature can be changed rapidly and reversibly in the small volumes typically employed in nucleic acid studies. Heating to temperatures above the T_m and rapid cooling can trap the strands of a duplex in the separated state. The melting transitions of mixed-sequence nucleic acid polymer duplexes are quite broad. To ensure strand separation, the duplex must be exposed to temperatures significantly above T_m. Failure to separate the strands results in a prenucleated duplex that can readily reanneal. This method does not work for oligonucleotide duplexes for which thermal denaturation is readily reversible.

Equilibrium thermal denaturation curves are used to study duplex (or other structure) thermodynamic properties. The extent of the thermally induced denaturation transition as a function of temperature is monitored either by some optical property, usually ultraviolet absorbance, or via heat capacity, as in differential scanning calorimetry. “Melting curves,” where the observed parameter is plotted as a function of temperature, contain quantitative information about the stability of the duplex and the thermodynamic origins of that stability (1). Optically monitored thermal denaturation curves are analyzed using the van't Hoff model and can readily provide thermodynamic (DH°, DS°, and DG°) and extrathermodynamic data (T_m). Not all melting transitions are consistent with the assumptions underlying the models used to extract thermodynamic data from equilibrium melting curves. Differential scanning calorimetry provides a direct model-independent means of generating thermodynamic data on thermally induced denaturation.

2. Chemical Denaturation

Chemical denaturants reduce the thermal stability of nucleic acid duplexes. Some denaturants, such as formaldehyde, form covalent bonds to the bases. Others act by altering the noncovalent interactions of the solvent with the nucleotide bases. A wide variety of reagents can induce denaturation of DNA (2). The isolated bases that, when attached to the backbone, comprise a nucleic acid are rather insoluble in aqueous solution. The **hydrophobic** character of the bases, coupled with the hydrophilic character of the sugar–phosphate backbone, push the single-strand–duplex equilibrium toward duplex formation. The stacked configuration of the bases in a duplex is favored over the unstacked bases of the single strand (see Base Pairs). There are conditions under which the bases in a single strand will stack, but the duplex also competes successfully against these structures. Inclusion of a **denaturant** solubilizes the bases, thereby reducing the energetic cost of losing the stacking interactions of the duplex. As a consequence, the thermal stability of the duplex is reduced.

3. pH-Dependent Denaturation

The stability of nucleic acid duplexes is rather insensitive to changes in hydrogen ion concentration in the vicinity of neutral pH. This is because none of the functional groups present in typical nucleic acids titrate in this region. If the pH is decreased to a value below 5 or increased to a value above 9, significant destabilization of the nucleic acid duplex is observed. Because pH is simple to manipulate, high pH frequently is used to denature nucleic acid duplexes. Care must be taken to avoid degradation of the polymers under high pH conditions, which can promote depurination and strand breakage, particularly at high temperature. The presence of mismatches or modified bases may alter the pH sensitivity of the duplex because often these anomalous structures exhibit protonation equilibria in the vicinity of neutral pH. Certain nonnatural backbone structures alter radically the pH dependence of duplex stability. Low pH stabilizes cytosine-containing pyrimidine-purine-pyrimidine triple helices. Therefore, when sequence requirements for **triple helix** formation are met, care must be taken to adjust pH so as to avoid unintended triple helix formation.

Denaturation, Protein

The term protein denaturation usually refers to the process during which the specific properties of a native, functionally active protein disappear under some nonphysiological conditions without chemical modification of the molecule. Because the functional properties of a protein are provided by the unique disposition of all of its functional groups, the unique, native, three-dimensional protein structure, denaturation of a protein assumes that the native structure is disrupted, and the polypeptide chain partially or completely unfolds, but without any change of the covalent bonds.

The native protein structure is maintained by a delicate balance of various types of interactions between the various protein groups and the surrounding media, which depend on the environmental conditions (see Protein Stability). *In vitro* this balance is usually optimal under conditions close to physiological. Departure from them can result in protein denaturation. Correspondingly, denaturation is usually classified in accordance with the external condition inducing it, for example, by heating (see Thermal denaturation , below), by cooling (Cold denaturation), by pressure (Pressure denaturation), by acids or alkali (pH denaturation), or by **denaturants** such as urea or guanidinium salts, for example, guanidinium chloride (GdmCl) (Denaturant denaturation).

Denaturation can be characterized (1) by the extent to which the native protein structure is disrupted, the completeness of polypeptide chain unfolding (see: Unfolded Proteins); (2) by its reversibility upon restoring conditions optimal for the native state (see Reversibility, below); and (3) by its **cooperativity**. The completeness of disruption of the protein structure depends on the environmental conditions and also on the ability of the given protein to withstand the denaturing action of the environment (see Protein Stability). Studying all these aspects of protein denaturation is important for understanding the mechanism of **protein folding** and stabilization of the native protein structure, in other words, understanding the forces maintaining this structure. It is also important for the practical purpose of designing new proteins and modifying of natural proteins (see Protein Engineering). Correspondingly, this process has been extensively studied for many years using various proteins and their mutant forms, fragments and synthetic models in various solvents and by various experimental techniques. The results of these studies are summarized in numerous reviews (see bibSect). The following discussion assumes that the protein being studied is pure and no covalently modified variants are present in substantial quantity.

1. Reversibility of Denaturation

Under the appropriate conditions, the native state of a protein is usually restored when the denaturing conditions are removed. Thus the change of conformation of a protein upon denaturation, even complete unfolding of the polypeptide chain, in principle, is a reversible process determined by the environmental conditions. The folding of a polypeptide chain into a native conformation is a **thermodynamically** driven process in accordance with the genetic information included in the sequence of amino acid residues of the polypeptide chain (see Self-Assembly. This was realized first by Anson and Mirsky (1, 2), followed by Eisenberg and Schwert (3), and formulated as one of the most fundamental principles of protein science by Anfinsen (4, 5). That is why denaturation is usually reversible, so long as the newly synthesized protein has not been chemically modified *in vivo* (processed) after it has folded (see Post-Translational Modifications). However, some of the groups of proteins that are exposed by denaturation (unfolding), such as thiol groups, are highly reactive and they become covalently modified. Others interact chaotically with each other and with the groups of other molecules to form aggregates. Furthermore, exposure of nonpolar groups upon unfolding decreases the solubility of proteins, thereby enhancing their aggregation. Consequently, the observation of complete reversibility of protein denaturation is not always straightforward, especially for large proteins that have high effective molarities of reactive and nonpolar groups in the unfolded state. Observation of reversibility often requires special conditions: (1) low concentrations of protein to decrease the probability of contacts between the protein molecules; (2) increase of electrostatic repulsions between the protein molecules by the appropriate pH and ionic strength of the solution; (3) exclusion from the solution of all other reactive molecules that might react irreversibly with protein groups (eg, oxygen, compounds containing thiol groups and disulfide bonds, etc.); and (4) the use of co-solutes that increase the solubility of the unfolded proteins (eg, urea or GdmCl). The reversibility of unfolding diminishes at higher temperatures, especially above 70°C, and with prolonged incubation because of secondary temperature-induced chemical changes of protein groups, for example, reshuffling of disulfide bonds and deamidation of Asn and Gln residues (6). Renaturation (refolding) is also delayed by cis-trans isomerization of proline peptide bonds in the unfolded state (7, 8). This is especially pronounced if there are many proline residues and if in the folded state they are in the intrinsically unfavorable *cis* conformation (9). Searching for conditions under which a protein denatures reversibly is important for studying the thermodynamics of formation of protein structure, its energetic basis (see Protein Stability).

2. Cooperativity of Unfolding

The various properties of a protein molecule, observed by different methods upon varying the external conditions, change simultaneously in some cases, but not in others. Changes of different properties of a protein reflect different changes in its structure, so denaturation of protein structure can be either a single- or multistage process. Under denaturing conditions, the protein structure can change either as a whole or in several stages. Various parts of the molecule can be disrupted by different denaturing conditions.

For small globular proteins, whose a molecular mass is less than about 20 kDa, all parameters that are sensitive to structural change usually change almost simultaneously with an increase of denaturing action (Figs. 1 and 2). Therefore, denaturation of these proteins is a single-step process in which the protein undergoes a single transition from the unique native state to the denatured state. Partly folded intermediate states probably occur during unfolding/folding, but they are highly unstable and would be present at equilibrium at only very low levels. Denaturation of such proteins is approximated rather well by a two-state transition that ignores all possible intermediate states. It is assumed that their native structure breaks down and refolds in an all-or-none manner (12, 13). Because proteins consist of many structural elements connected by covalent bonds into a polypeptide chain, this assumes that all the groups (amino acid residues) of small globular proteins change their states simultaneously, that is, cooperatively.

Figure 1. Thermal denaturation of ribonuclease A at pH 2.19 according to Ref. 10; (*f*) intrinsic viscosity, (○) optical rotation at 365 nm, and (△) absorption spectroscopy.

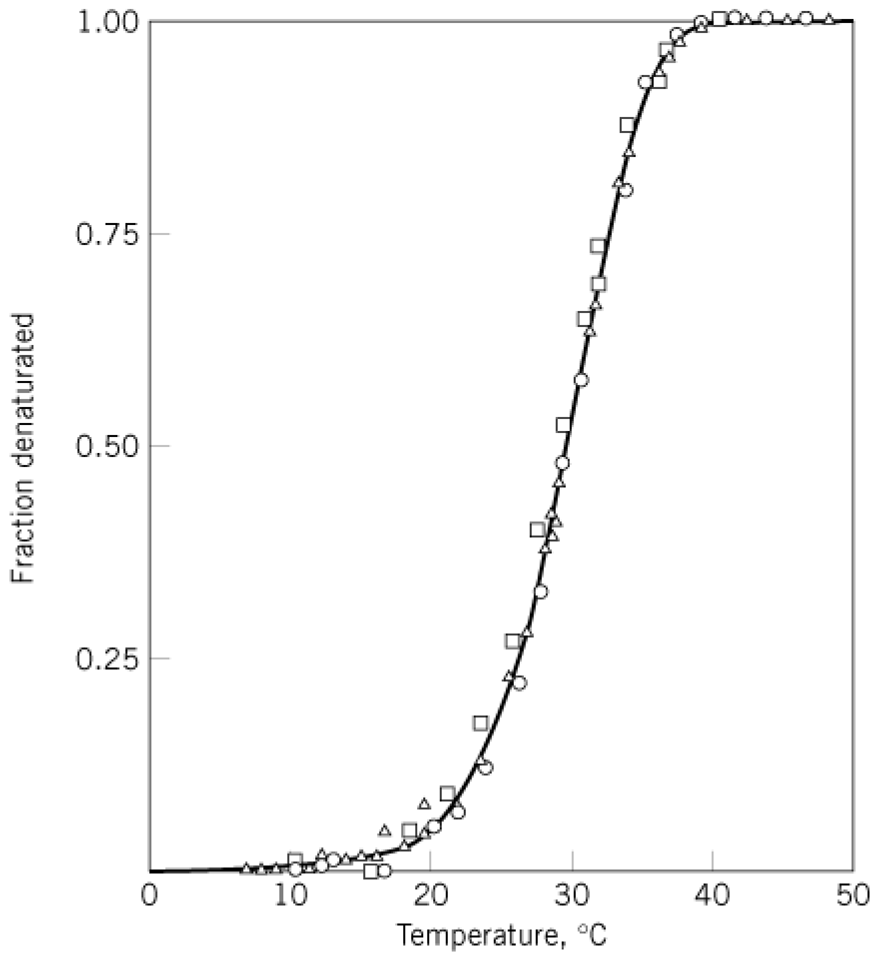

Figure 2. Urea denaturation of **ribonuclease** $\mathbf{T_1}$ according to Thomson et al. (11). (△) circular dichroism ellipticity (CD) at 238 nm; (▽) UV absorbance at 287 nm; (○) optical rotatory dispersion (ORD) at 295 nm; and (*f*) fluorescence at 320 nm.

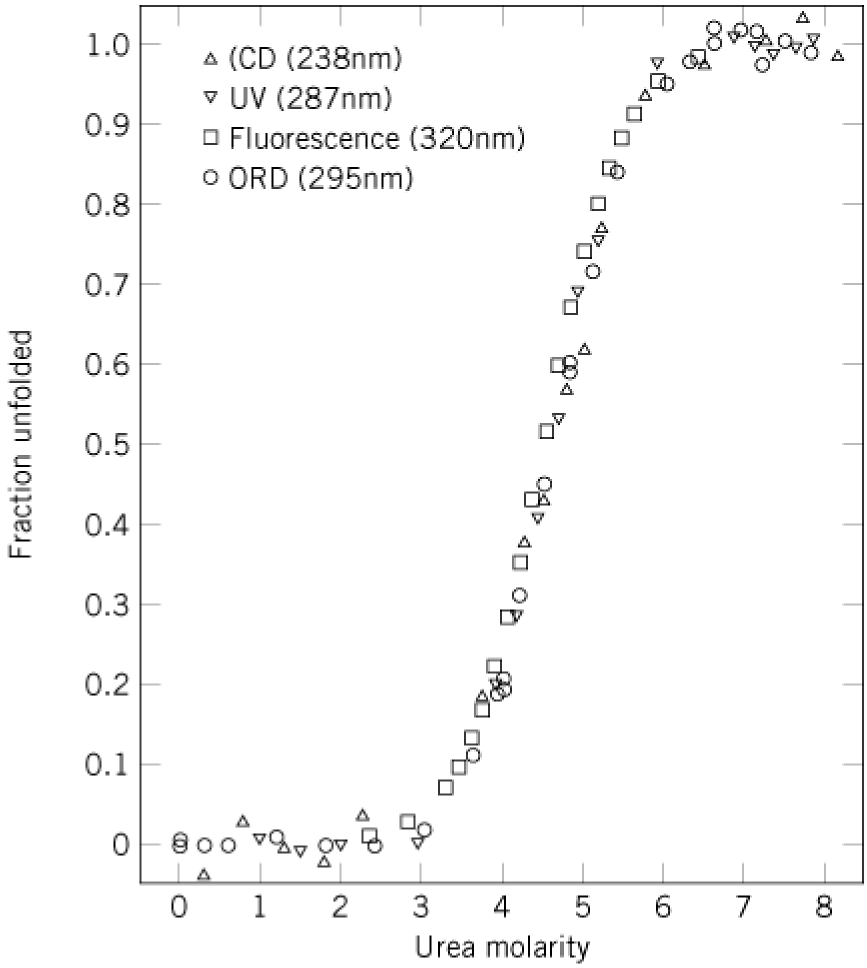
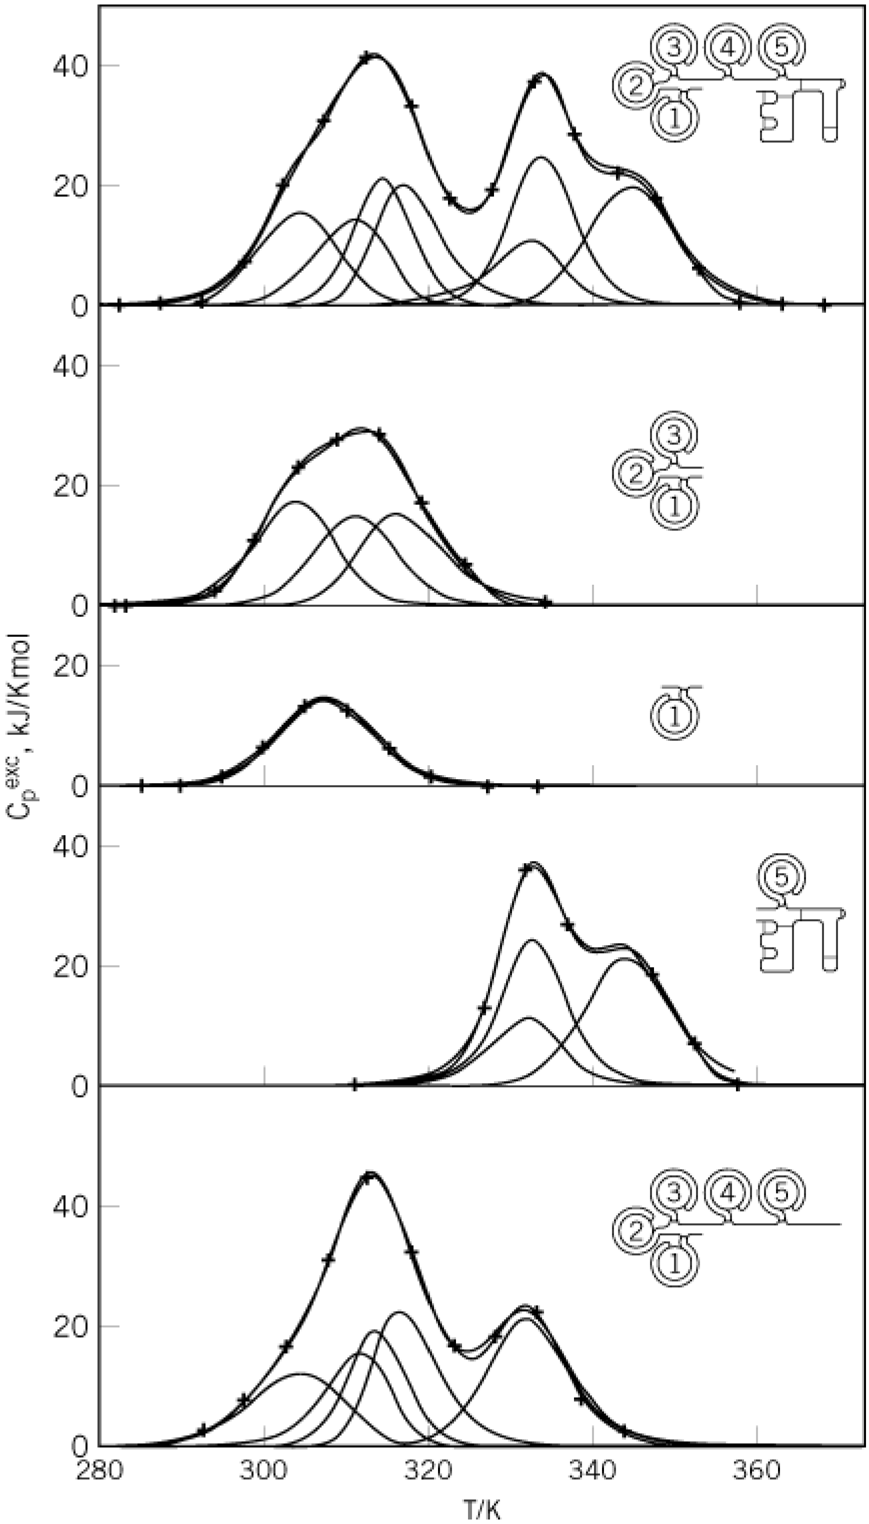


In contrast, multistage denaturation is normal for large proteins. Some smaller fragments of large proteins that separately preserve their native-like structure also denature reversibly and highly cooperatively (14-16). These observations have shown that the structures of large proteins are subdivided into cooperative units, called structural **domains**, which fold and unfold more or less independently ((17-19); for a review see Ref. 20). The stabilities of the different protein domains usually differ. So they unfold under different denaturing conditions, and the denaturation profile of such multidomain proteins is usually very complex (Fig. 3). Conversely, a complex denaturation profile usually means that the protein has a multidomain structure. It follows that the thermodynamic analysis of protein denaturation can provide information on the domain organization of large protein molecules (20-22).

Figure 3. Calorimetric characterization of the thermal unfolding of plasminogen and its proteolytically liberated domains, according to Ref. 16. The thin lines show the deconvolution of the excess heat absorption profiles into individual two-state transitions for the various domains of each of the molecules. The inserts show schematically the domain structures of the protein molecule used; complete plasminogen is at the top.



Simultaneity in changes of all properties of a protein upon denaturation is one of the tests for cooperativity of this process and, correspondingly, for the cooperativity of the protein structure. However, if the domains of the protein are similar, they denature under the same denaturing conditions, and all parameters that specify the state of the protein change simultaneously, giving the impression that the protein denatures in a single cooperative process. If such a transition is analyzed assuming that it is a two-state transition, fictitious thermodynamic parameters result that have no real meaning.

A stronger test of the cooperativity of the denaturation process consists of comparing the effective thermodynamic parameters derived from the equilibrium analysis whose real values are measured by direct experimental methods. In thermodynamic analysis of the equilibrium between two states, the effective equilibrium constant K^{eff} can be expressed as:

$$K_{eff} = \frac{Y_x - Y_n}{Y_d - Y_n} = \exp\left(-\frac{\Delta G^{eff}}{RT}\right) \tag{1}$$

where $\boldsymbol{Y}_n$ and $\boldsymbol{Y}_d$ are values of any observed parameters that characterize the pure native and the pure denatured states, respectively, $\boldsymbol{Y}_x$ represents the value of the index under the given conditions, and DG_{eff} is the effective Gibbs **free energy** difference between the two states. By following the dependence of the equilibrium constant on various fundamental intensive external parameters, such as temperature (T), pressure (P), or the activity of given ligand I (a_i), one can find the effective extensive thermodynamic parameters that specify the process, the changes in **enthalpy** DH^{eff}, **volume** DV^{eff}, and the number of bound **ligands** DN^{eff}:

$$\Delta H^{eff} = RT^2 \frac{\partial \ln K^{eff}}{\partial T} \tag{2}$$

$$\Delta V^{eff} = -RT \frac{\partial \ln K^{eff}}{\partial P} \tag{3}$$

$$\Delta N_i^{eff} = \frac{\partial \ln K^{eff}}{\partial a_i} \tag{4}$$

These effective parameters are derived assuming that the observed process represents a two-state transition, so if they correspond to the real values measured by direct experimental methods, this is a strong indication that the observed process indeed represents a two-state transition. The most efficient approach for this type of analysis is temperature-induced changes, particularly when they are observed by the associated heat effects measured by supersensitive scanning micro **calorimetry** (13). Comparing the calorimetrically measured enthalpy of the temperature-induced unfolding of a protein with the effective or van't Hoff enthalpy calculated from the sharpness of transition indicates how close the observed process is to a two-state transition.

More elaborate methods of analyzing of cooperativity, which reveal intermediate stages in the temperature-induced denaturation process consist of computer deconvolution of the calorimetrically measured excess **heat capacity** function of temperature (21, 22) or simulation of this function based on statistical mechanical modeling of the process (23, 24). Using these methods for thermodynamic analysis of the calorimetrically measured heat capacity function of a protein and of its proteolytic fragments corresponding to various domains under different solvent conditions yields quite detailed information about the domain organization of a protein. This is especially valuable for large proteins, the structures of which often cannot be studied by NMR because their large size or by X-ray crystallography methods because to their reluctance to crystallize (for a review, see Ref. 20). This approach has permitted investigating the domain organization of such large proteins as fibrinogen (15), plasminogen (16), fibronectin (25), plasminogen activator (26), recombinant factor XIII (27), and protein C (28) (see Blood Clotting).

NMR is a powerful method for analyzing the cooperativity of unfolding of small proteins and identifying any domains. Using the chemical shifts of individual proton resonances, one can follow the state of individual amino acid residues of a protein and their rate of hydrogen exchange as a function of the environmental conditions. Such analysis showed that small proteins unfold cooperatively (29), but that some of the proteins reveal indications of subdomain organization under some conditions (30-32).

The mechanism of the extreme cooperativity of unfolding/folding of single-domain proteins is still a subject of discussion. Perhaps the most important conclusion, which is most commonly accepted, is that extreme cooperativity is a specific property of heterogeneous polypeptide chains that can fold into a unique compact structure in which all groups are tightly packed that is, it represents a lock and key system. For the theoretical models of cooperativity, see (23, 33-35).

2.1. Denaturant Denaturation

Denaturants are various agents (cosolutes) that lead to denaturation of proteins when they are added to aqueous solutions (Fig. 2). The most commonly used denaturants are urea and **guanidinium** chloride (GdmCl). Most proteins denature in concentrated solutions (eg, 5 to 8 M) of these compounds. Studies of the dependence of protein conformation on the concentration of these denaturants is the simplest and therefore the most popular method for quantitatively evaluating protein stability, the more so because denaturation by denaturants is also the most reversible of the various types of denaturation. Furthermore, the very significant changes in the hydrodynamic and optical properties of proteins in concentrated solutions of these denaturants led to the conclusion that they induce the most complete unfolding of polypeptide chains (see Unfolded Proteins). The denaturant-induced denaturation of small single-domain proteins usually occurs very sharply over a small change in denaturant concentration (Fig. 2), and it usually is regarded as a cooperative, two-state transition. If so, the equilibrium studies of the influence of denaturants on a protein can provide information on the energetics of protein unfolding/folding, that is, the stability of the native protein structure. Using any parameter *Y* sensitive to the protein conformation, the equilibrium constant and the Gibbs free energy of the transition can be estimated by, Eq. (1). Usually, the value of D*G* varies linearly with denaturant concentration [D]:

$$\Delta G = \Delta G^{\circ} - m[D] \qquad (5)$$

and determines the value of D*G* at zero concentration D*G*° of denaturant (36). The parameter *m* is a measure of the dependence of D*G* on the denaturant concentration. It is believed that the value of *m* correlates very strongly with the amount of protein surface exposed to solvent upon unfolding (37).

The main difference between the effects of urea and GdmCl on protein stability is that, although urea is likely to be only a destabilizing agent, GdmCl has a dual role. At high concentrations GdmCl destabilizes the protein native state, but at low concentrations it stabilizes it (38, 39) because, in contrast to urea, GdmCl is a salt. An increase in its concentration increases its activity as a denaturant and also the ionic strength of the solution, which reduces destabilizing electrostatic interactions within proteins. If the GdmCl concentration varies and the ionic strength of the solution is kept constant by adding of neutral salts, the stability of the protein is directly proportional to the concentration of GdmCl over an extended concentration range (40). Then, the stability of the protein can be determined from Eq. (5), and it corresponds well with the estimates of D*G*° determined from calorimetric data (see Protein Stability). This equation is valid, however, only if the denaturant-induced unfolding of the protein is truly a two-state transition. Because this is not evident *a priori*, it needs to be verified.

Notwithstanding the extensive experimental data on the influence of denaturants on the state of proteins, the mechanism of this influence is yet to be understood. It is generally believed that one or both of two mechanisms are responsible for the ability of these compounds to destabilize the native state of proteins. In the first model, these solutes increase the solubility of the nonpolar side chains that form the compact cores of globular proteins (41-43). A sound argument for this hypothesis is the observation that denaturants increase the aqueous solubility of small nonpolar molecules. According to the other model, highly polar denaturants form hydrogen bonds with polar groups of proteins, particularly the peptide groups, and increase the probability of their exposure. These hydrogen bonds would have to be stronger than those formed by water (44). A strong interaction of urea with the polar groups of proteins has been concluded by studies of the influence of these cosolutes on the solubility of model compounds (45). According to calorimetric studies, urea and GdmCl interact with proteins in both the folded and unfolded states and cause a strong heat effect that is proportional to the exposed surface area and depends strongly on temperature (46, 47). It became evident that the denaturing action of urea and GdmCl is caused mainly by the enthalpic binding of these compounds. With increased temperature, the bound denaturants dissociate gradually absorbing heat that results in an apparent heat capacity increase of the protein in the presence of urea and GdmCl. This explains the observed decrease of the intrinsic **viscosity** of the unfolded polypeptide chain with increasing temperature (48). Analyzing calorimetric data by the standard model for multisite **ligand binding** was determined the number of denaturant binding sites and the binding constant (47). Timasheff (49) examined these calorimetric data in terms of preferential binding. He concluded that the weak overall thermodynamic interaction of the denaturants with proteins results from the strong favorable interactions of proteins with denaturants at the exchangeable sites that are compensated for by unfavorable interactions, almost as strong, at loci on the protein surface at which the denaturants cannot displace water. Schellman &Gassner (50) have analyzed calorimetric data for the interactions of urea and GdmCl with proteins based on the solvent-exchange model . According to this model, the free energy and preferential interactions for very weak binding and high concentrations of cosolvent do not depend on the high concentrations of cosolvent, but on its excess occupation over that of the bulk solution. The binding constant *k* and the number of binding sites *n* derived by using this model differ considerably from those derived using the standard binding model, but the values of the binding enthalpy D*H*, and of *nkDH* are rather close.

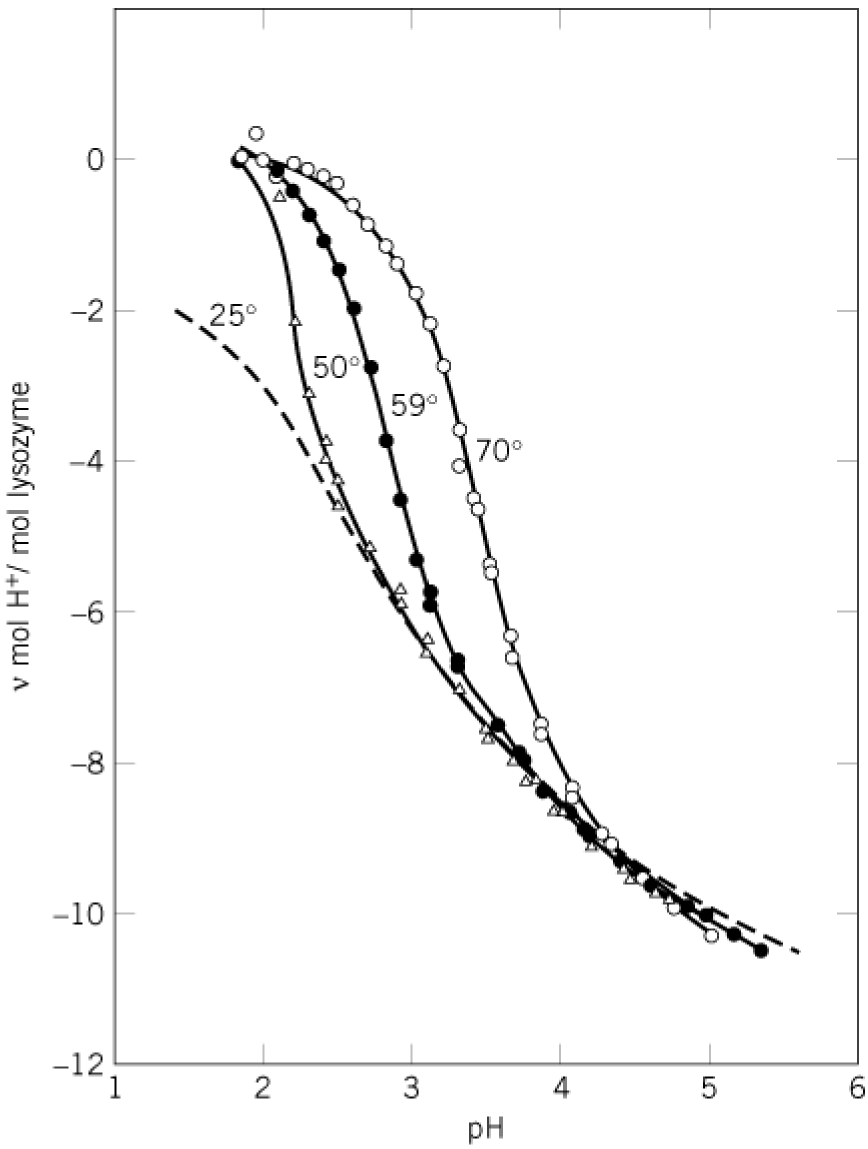
The specific interaction of urea with polar groups of proteins has been shown by X-ray crystallography using crystals of diketopiperazines (51) and proteins (52). The number of binding sites for urea and GdmCl were determined crystallographically for **ribonuclease A** and dihydrofolate reductase, and they closely correspond with the numbers estimated from calorimetric data by the standard binding model. Furthermore, binding of the denaturant significantly decreases the crystallographic B temperature factor of the protein, that is, the mobility of its native state (53). Each molecule of urea or GdmCl must interact simultaneously with several groups of the protein by forming multiple hydrogen bonds (54). If so, one might expect these denaturants to form even more extensive networks of hydrogen bonds with the groups of the unfolded polypeptide chain, increasing its rigidity and consequently its intrinsic viscosity. Then, the conformation of polypeptide chains in the presence of urea or GdmCl could not be regarded as a standard random coil because it would be a stretched random coil, at least at room temperature.

2.2. pH Denaturation

The pH of the solution is one of the most important factors that determines the state of a protein. The changes of protein structure with variation of pH are frequently complex. For of small, single-domain proteins, the intensive, denaturational changes in all parameters that characterize protein conformation usually occur over a narrow range of pH and are clearly distinguishable above a smooth background of gradual changes. In accordance with the Le Chatelier principle, pH-induced denaturation is associated with the release or uptake of protons (Fig. 4). Potentiometric titration of proteins revealed that smooth changes result from titrating of protein groups that have pK_a values not very different from those of the corresponding free amino acids, whereas the gross conformational changes associated with pH denaturation are accompanied primarily by the unmasking of buried groups (56, 57).

Figure 4. Protonation state of hen lysozyme versus pH at different temperatures, according to Ref. 55. At 25°C the protein is native at all pH values, but at higher temperatures it unfolds with decreasing pH, unmasking and

protonating the buried groups.



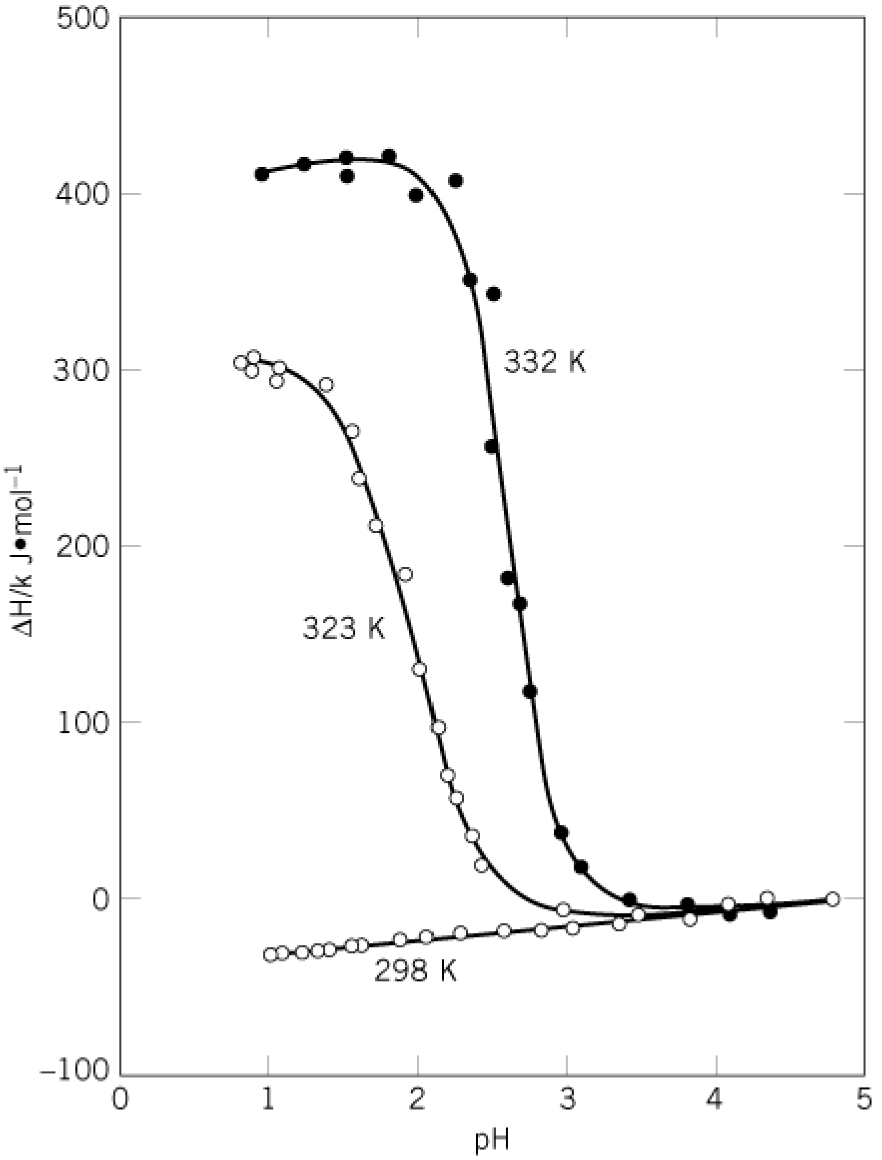
pH-induced denaturation depends on temperature and, therefore, temperature-induced denaturation depends on the pH (see Thermal denaturation). Because the temperature-induced denaturation of a small single-domain protein is a two-state transition, it was assumed that the transition induced by variation of pH at a fixed temperature is also two-state, so that the initial and the final characteristics of the protein are independent of the sequence of pH or temperature variation. Then, one can determine the Gibbs free energy difference between the native and denatured state from the potentiometrically measured pH-dependence of the protonation difference Dn(pH) between these states (55):

$$\Delta G(pH) = 2.3RT \int_{pHt}^{pH} \Delta v(pH)dpH \qquad (6)$$

where pH_t is the transition pH at which half of the molecules are in the denatured state. Comparison of Gibbs free energy values of pH- and temperature-induced denaturation showed that they indeed correspond very well, a strong argument that the pH-induced denaturation of small globular proteins can be regarded as a two-state transition (58).

Calorimetric titration studies have shown that pH denaturation of proteins creates significant heat effects that depend on temperature (Fig. 5). If corrected for the heats of protonation, the enthalpy of pH-induced protein transitions is identical to the enthalpy of the temperature-induced transition and depends similarly on temperature (55). Thus, the pH-induced denaturation of protein results in a heat capacity increase similar to that observed for temperature induced-denaturation. For the theory of acid-induced denaturation, see Refs. 56, 57, and 59 and for a review, see Ref. 44.

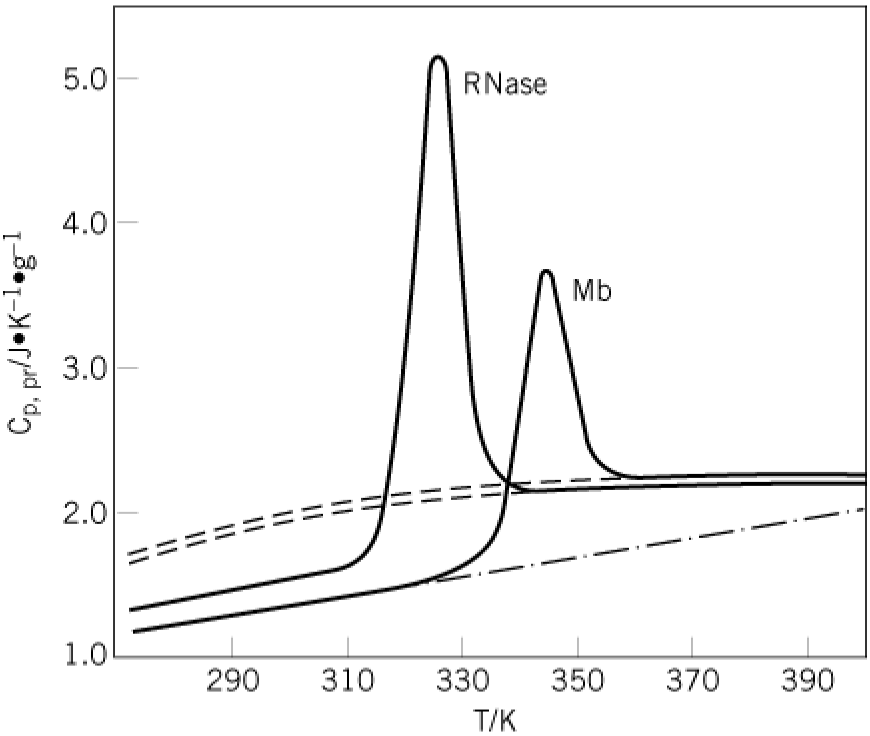
Figure 5. Heat of transfer of lysozyme from pH 4.8 to a given pH, at constant temperature, according to Ref. 55. At 298 K (25°C), the protein remains folded at all pH values, but it unfolds at low pH at the higher temperatures used.



With increased temperature increasing thermal motion induces disruption of the ordered native structure of a protein. Breakdown of the native structure of small globular proteins occurs over a relatively narrow temperature range, in which all specific characteristics of the native protein change simultaneously (Fig. 1). In that temperature range the microscopic fluctuations coalesce into a global macroscopic fluctuation, that is, the macroscopic unfolding of a protein structure (60), which results in drastic changes in the rate of hydrogen exchange of the protein's amide groups (61). Therefore, the thermal denaturation of a single-domain small protein is a highly cooperative process. Because this process is induced by increased temperature, it is obvious that it should be result in an increase in the enthalpy, which is the extensive thermodynamic parameter conjugate with temperature, that is, it should proceed with heat absorption in accordance with the Le Chatelier's principle. Assuming that this process does indeed represent a two-state transition, one can estimate the enthalpy of denaturation by using Eq. (2), which is known as the van't Hoff equation .

The heat effect of denaturation can be observed directly by scanning microcalorimetery as an intensive heat absorption peak (Fig. 6). For small single-domain proteins, the calorimetrically measured enthalpy of denaturation agrees well the van't Hoff enthalpy, showing that thermal denaturation of these proteins is well approximated by a two-state transition (13). Deviation between the calorimetric and van't Hoff enthalpies does not usually exceed 5%, which means that the population of intermediate states is rather low. This was confirmed by detailed analysis of the excess heat absorption profile (63) and has been shown subsequently for many small single-domain proteins.

Figure 6. Temperature-dependence of the partial molar heat capacity of pancreatic ribonuclease A (RNase) and of sperm whale met-myoglobin (Mb) in solution at pH 4.4. The dashed lines show the heat capacities of the unfolded states, extrapolated to lower temperatures according to Eq. 9 of the text. The other line is a linear extrapolation of the heat capacity of the native state of myoglobin. Reproduced from Ref. 62.



For a two-state transition at the mid-transition temperature T_t, where $K = 1$,

$$-RT_t \ln K = \Delta G(T_t) = \Delta H(T_t) - T_t \Delta S(T_t) = 0 \quad (7)$$

For the entropy of transition,

$$\Delta S(T_t) = \frac{\Delta H(Tt)}{T_t} \tag{8}$$

The most remarkable feature of the thermal denaturation of proteins is that the partial heat capacity of the denatured protein is always significantly higher by 25 to 50% than that of the native state (13, 64). The value of the denaturation heat capacity increment is specific for a given protein, depends on the temperature, and decreases at higher temperatures (65-67). Several explanations for the denaturation heat capacity increment can be suggested: (1) gradual melting of residual structure in the protein with continued increase in temperature; (2) increase of configurational freedom of the polypeptide chain upon disrupting of the rigid compact native structure of the protein molecule; or (3) hydration of the groups that are exposed to water by protein unfolding. The contribution of residual structure to the denaturation heat capacity increment is not significant because the heat capacity increment observed upon thermal denaturation is almost the same as in denaturation by denaturants, if the effects of denaturant solvation are taken into account properly (46), whereas it appears that proteins denatured by denaturants (urea or GdmCl) do not generally have residual structure. According to theoretical estimates (68), the contribution of the increased configurational freedom to the observed denaturation increment of the protein heat capacity cannot be large. Thus, the main reason for the higher partial heat capacity of the protein denatured state is that in this state more groups, particularly the nonpolar groups, are exposed to solvent, that is water. It is known that transfer of nonpolar groups into water increases the heat capacity (69-72). Exposure of the polar groups to water has the opposite effect. It decreases the heat capacity (66, 72-76). Detailed calorimetric study of the transfer of model compounds into water has also revealed that aromatic groups are not identical in hydration properties to nonpolar groups but are somewhere in between the nonpolar and polar groups (75). Thus, there are three main contributors to the heat capacity increment upon protein unfolding: exposure of the nonpolar, aromatic, and polar groups that were buried in the folded conformation. Each of them contributes in proportion to their water-accessible surface areas exposed upon unfolding (DA_{np}, DA_{arom}, and DA_{pol}, respectively). At 25°C the heat capacity increment of protein unfolding can be calculated as follows:

$$C_p^{hyd}(25°C = -(2.14\Delta A_{np} + 1.55\Delta A_{arom} - 1.27\Delta A_{pol}) \times JK^{-1}\ \mathrm{mol}^{-1} \tag{9}$$

The coefficients in this equation depend on temperature [for details, see (77)]. Ignoring this dependence and the usual identification of the aromatic groups with nonpolar groups is not justified in quantitatively analyzing thermodynamic properties of proteins (78). Upon protein unfolding, the surface area of the nonpolar plus aromatic groups exposed is greater than that of the polar groups, so unfolding of a protein results in an overall increase of the partial heat capacity (Fig. 6).

The important consequence of the denaturation heat capacity increment is that the enthalpy and entropy of denaturation are temperature-dependent functions. Indeed, because $\frac{\partial \Delta H}{\partial T} = \Delta C_p$ and $\frac{\partial \Delta S}{\partial T} = \frac{\Delta C_p}{T}$ for the enthalpy and entropy,

$$\Delta H(T)_{pH} = \Delta H(T_t)_{pH} + \int_{T_t}^{T} \Delta C_p(T)dT \tag{10}$$

and

$$\Delta S(T)_{\mathrm{pH}} = \frac{\Delta H(T_t)_{\mathrm{pH}}}{T_t} + \int_{T_t}^{T} + \frac{\Delta C_p(T)}{T} dT \quad (11)$$

Because DC_p is positive and decreases with increasing temperature, the enthalpy and entropy of protein denaturation increase asymptotically to some constant level (78, 83).

2.4. Cold Denaturation

Interest in the influence of low temperatures on the stability of native protein structure began with a paper published by Hopkins in 1930 (79). Studying the precipitation of ovalbumin upon denaturation by concentrated urea at various temperatures, he noticed that the rate of denaturation was greater at 0°C than at 23°C. Similar effects were observed later by others with other globular proteins, showing that in many cases the stability of a protein to urea or GdmCl denaturation is maximal around 30°C and decreases at lower temperatures. Meanwhile, evidence accumulated showing that many enzymes in aqueous solution, without urea or GdmCl, are inactivated at low temperature (about 0°C) but their activity was restored at room temperature (for a review, see Refs. 80 and 81). Most of these proteins are **oligomeric**, and it is likely that their cold inactivation resulted from their dissociation into subunits, as was found for several supermolecular structures, such as microtubules (82, 83). The quaternary structure of proteins is less stable than the tertiary, and its stability decreases with decreasing temperature.

The dual sensitivity of proteins to both high and low temperatures was formally explained when it was realized that protein unfolding results in a significant heat capacity increase and consequently that the enthalpy and entropy of unfolding are temperature-dependent and decrease with a decrease in temperature (Fig. 7). If so, according to the thermodynamic formalism, the Gibbs free energy difference between the unfolded and folded states of the protein should be a monotonic function of temperature but should have an extremum at the temperature at which the entropy difference between the two states decreases to zero (see Protein Stability). If the entropy and enthalpy functions continue to decrease below that point, with a change of sign in entropy, one might expect that the Gibbs free energy difference should become zero at some low temperature (Fig. 8). At this temperature, the protein should denature, that is unfold, but, in contrast to thermal denaturation at high temperature, it should proceed with a release of heat and a decrease of the enthalpy and entropy, that is, an increase in order. This paradoxical conclusion was confirmed by microcalorimetric measurements of the heat effects resulting from cooling aqueous solutions of proteins. It was shown that proteins do indeed denature upon cooling, release heat (Fig. 9), and change other properties (viscosity, circular dichroism NMR spectra) indicating that the polypeptide chain unfolds (84-86). Studies of various proteins under different conditions showed that cold denaturation is a very general property of globular proteins that depends on the environmental conditions and on their specific structure (81, 87). The temperature of cold denaturation is highest for proteins that change most in heat capacity upon unfolding and can be raised significantly by appropriate choice of solvent conditions (pH, ionic strength, buffer, presence of denaturants), which facilitate observation of this process.

Figure 7. Temperature-dependence of the enthalpy and entropy differences between the native and denatured states of ribonuclease A (RNase) and of sperm whale met-myoglobin (Mb) per mole of amino acid residues under solvent conditions that provide the maximum stabilities of these proteins. Reproduced from Ref. 62.

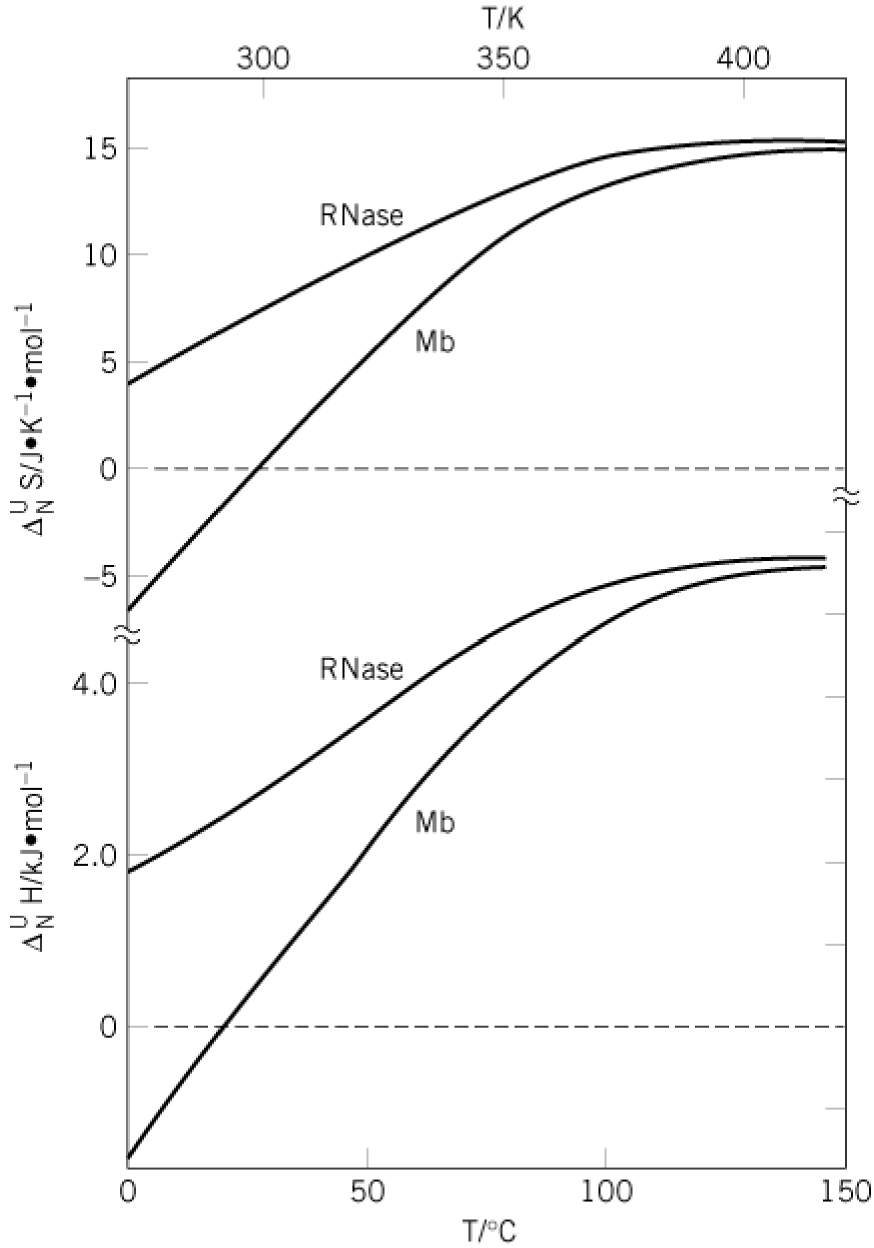


Figure 8. The Gibbs free energy difference between the denatured and native states of metmyoglobin in acetate buffer solution at the pH values indicated on the curves. Under these conditions, the protein cold denatures within the temperature range 0° to 30°C. Each curve is at a maximum when the entropy of unfolding is zero. Reproduced from Ref. 84.

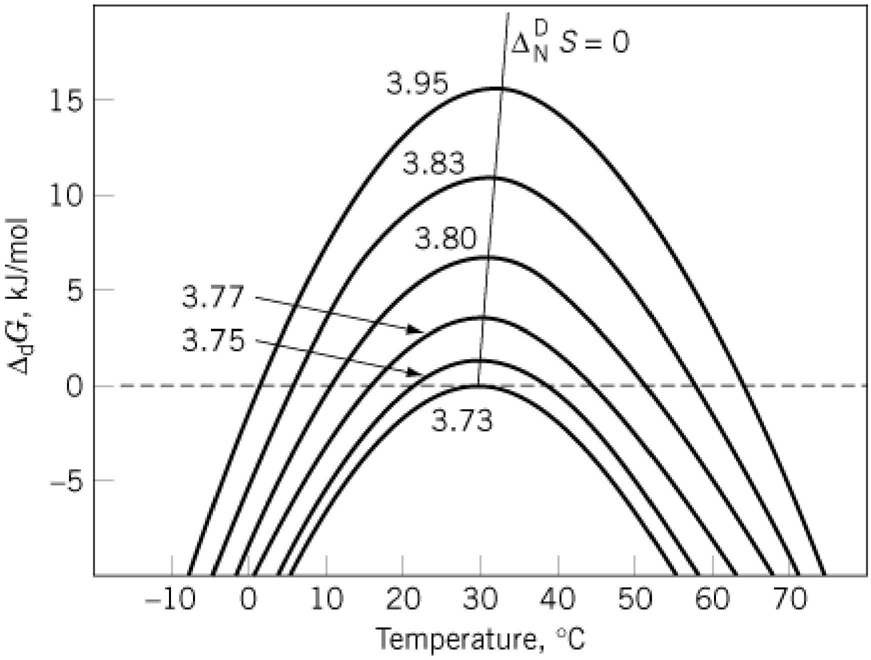
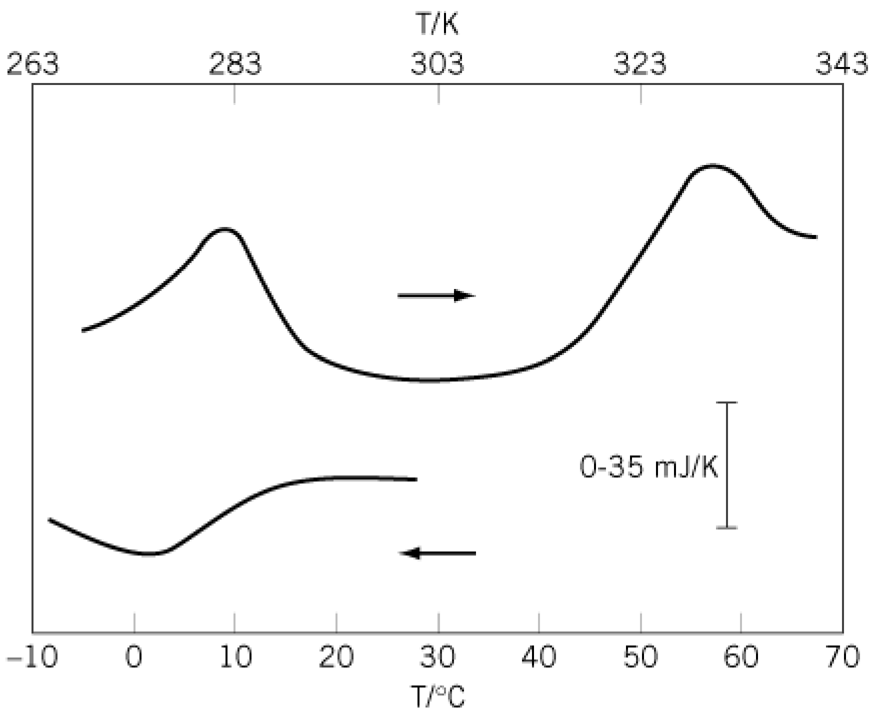


From the formal point of view, the cold denaturation of proteins is caused by the fact that the heat capacity of the unfolded protein is greater than that of the folded protein. The increased heat capacity upon protein unfolding is usually explained by the hydration of nonpolar groups (see Protein Stability), which also results in a decrease of entropy (DS^{hyd}). The latter is considered to be the main cause of the hydrophobic effect, which as an entropic force is proportional to absolute temperature (TDS^{hyd}) and should decrease upon lowering the temperature, thus destabilizing the protein. However, the real situation is not so simple. Indeed, because of the hydration heat capacity effect, the negative entropy of hydration of nonpolar groups is intrinsically temperature-dependent and increases in magnitude with decreasing temperature, thus balancing to some extent the entropic contribution of nonpolar groups to the stabilization of the folded protein's compact state. On the other hand, the unfolding of a protein results in exposing and hydrating the nonpolar groups and also polar and aromatic groups. The effects of hydrating of these groups contributes negatively to stabilizing protein structure, and the magnitude increases with decreasing temperature (77).

2.5. Pressure Denaturation
Pressure is one of the fundamental physical parameters that determine the state of any system, in particular, biological systems. Living organisms habituate at very different pressure conditions, from less than 1 bar in high mountains to thousands of bars in deep water. Therefore, it is natural that studies of pressure effects on proteins began a long time ago. In 1914, the first experiments done by Bridgmen showed that high pressure induces protein denaturation. But quantitative investigations of the effect of pressure on proteins began much later, in the middle 1960s, when it became clear that this is the only practical way to acquire information abouth the **volume** effects of protein folding (for reviews see Refs. 88-92).

Even early studies of the influence of pressure on proteins revealed that proteins are not very sensitive to pressure, and only at extremely high pressures do they exhibit changes like those observed in temperature and pH denaturation. However, according to more recent studies, particularly by high-pressure NMR spectroscopy, pressure-denatured proteins retain more residual structure than when denatured by heat, pH, or denaturants (86, 90, 93). The pressure-induced denaturation of proteins takes place over a relatively narrow pressure interval, depending on the temperature and solvent conditions, particularly the pH (Fig. 10). At the same time, the temperature and pH of denaturation also depend on pressure. Thus, these three parameters are interdependent, and variation of any one of them at fixed values of the others can lead to disruption of the native protein structure. Because denaturation of small, single domain proteins by temperature and pH is a highly cooperative process that is well approximated by a two-state transition, it was concluded that pressure-induced denaturation also represents a transition between two states, the native and denatured (94). This conclusion was confirmed by using an **electrophoretic** technique at high pressure (95), but it was challenged by later NMR studies (86, 93). In particular cases of multidomain proteins, the different domains undergo independent structural changes at specific well-defined limiting values of pressure (96). The immediate effect of pressure on oligomeric proteins is dissociation into subunits, followed by unfolding (80, 89, 90).

Figure 9. Microcalorimetric recordings of the heat effects upon cooling metmyoglobin under conditions where it cold denatures (bottom curve) and subsequent heating (top curve) that demonstrates first the refolding of the cold-denatured state and then its thermal unfolding at high temperatures. Reproduced from Ref. 84.



Assuming that pressure-induced denaturation represents a two-state transition, one can calculate the effective change of molecular volume upon unfolding, bearing in mind that according to the Le Chatelier principle, a pressure-induced shift in equilibrium should result in a decrease in volume that can be determined by Eq. (3). The great advantage of this approach to studying volume effects is that it does not require supersensitive volumetric techniques but can be realized by using any physical parameter (eg, **spectrophotometry**) that is sensitive to the conformational state of the protein and can indicate the pressure-induced change in equilibrium between the native and denatured states. This is important because proteins denature only at very high pressures, usually above 2 kbar.

It follows from the inefficiency of pressure in inducing protein denaturation that the volume change DV_d upon denaturation is very small, usually less than 0.5% of the total protein volume. For example, the volume decrease in denaturation of ribonuclease A is –(30 ± 10) ml/mol at an average pressure of about 1 kbar, and it decreases by –4 to –5 ml/mol when the temperature increases from 25° to 50°C (97-99). Zipp and Kauzmann (100) discussed the parallelism between the thermodynamic factors governing the process of reversible denaturation of proteins and the dissolution of hydrocarbon molecules in water. If the interior of a protein resembles a liquid or solid hydrocarbon and if significant numbers of nonpolar groups are exposed to water on unfolding, one would expect a significant volume decrease upon unfolding at low pressure. With increasing pressure, the volume reduction should become less negative and should change sign at 2kbar. However, this does not happen in protein denaturation. Therefore, the simple hydrophobic model that considers globular proteins as an oil drop or a solid hydrocarbon (101) does not work. In contrast to liquid or solid hydrocarbons, the native protein interior is densely packed, but it has some cavities and loose parts. Then, increasing hydrostatic pressure forces water molecules into the protein interior, gradually filling cavities and eventually breaking up the protein structure (90). This would explain why pressure-denatured proteins retain elements of structural organization to a much greater extent than proteins denatured by other means. But this also questions how closely pressure-induced unfolding is approximated by a two-state transition. In turn, this questions the reliability of the volume effects of protein folding that are determined by pressure denaturation.

Dendrotoxins

The venom of the *Dendroaspsis* mamba snakes contains several toxins, termed dendrotoxins, which bind with nanomolar affinities to voltage-dependent **potassium channels** and facilitate neurotransmitter release because they prolong membrane depolarization. Their polypeptide chains consist of 57 to 60 amino acid residues, with three disulfide bonds and folding closely similar to that of **BPTI**-type inhibitors of serine proteinases. A short amino-terminal 3_{10}-helix is followed by a two-stranded b-sheet and a short COOH-terminal a-helix (1). Dendrotoxins provide yet another example of a stable protein module that has been readapted during the course of **evolution** to perform a different biological function.

Density Gradient Centrifugation

Many centrifugation separations simply centrifuge an initially homogeneous sample and physically remove any heavy and large particles or molecules from the solution, leaving them as a pellet on the bottom of the centrifugation tube. In contrast, density gradient separations employ a gradient of varying, high concentrations of a small molecule, such as sucrose or cesium chloride, distributed along the axis of the centrifugally generated force. The lowest concentration is at the solution meniscus and the highest at the base. With sufficiently high concentrations of the small molecule, the density and viscosity of the solution also vary along the gradient. The density gradient is produced directly before centrifugation, or it is generated by the centrifugal force itself. A wide variety of materials is used to form gradients (Table 1), depending on which components are to be separated.

Table 1. Gradient Materials Used for Density Gradient Centrifugation[a]

Material and Typical Use	Maximum Aqueous Density (g/cm^3)
Cesium salts	
Acetate: Isopycnic separation of proteoglycans, DNA, RNA, and viruses	2.00 at 20°C
Bromide: Separation and fractionation of glycoproteins	1.72 at 20°C
Chloride: Most widely used density gradient material for isopycnic separations	1.91 at 20°C
Formate: DNA hydration	2.10 at 20°C
Oxalate: Isopycnic separation of proteoglycans, DNA, RNA	2.01 at 20°C
Ficoll: Isopycnic and rate-zonal separation of cells and subcellular fractions	1.17 at 20°C sucrose polymer
Glycerol: Rate-zonal separation of RNA, proteins and enzymes sensitive to sucrose	1.26 at 20°C
Percoll: Isopycnic separation of cells and large subcellular components	aqueous solution of polyvinylpyrrolidone-coated colloidal silica particles ~20 nm in diameter
Potassium salts	
Bromide: Isopycnic centrifugation of lipoproteins and density-labeled proteins	1.37 at 20°C
Iodide: Isopycnic centrifugation of DNA	1.72 at 24°C

and RNA	
Tartrate: Isopycnic centrifugation of viruses	1.49 at 20°C
Rubidium salts	
Chloride: Isopycnic banding of proteins	1.49 at 20°C
Trichloroacetate: Isopycnic DNA banding	1.90 at 20°C
Sodium salts	
Bromide: Rate-zonal and isopycnic separation of lipoproteins	1.53 at 20°C
Chloride: Rate zonal separation of DNA and lipoprotein fractionation	1.20 at 20°C
Iodide: Isopycnic centrifugation of DNA and RNA	1.90 at 20°C
Sucrose: Rate-zonal separation of DNA, RNA, subcellular fragments, proteins, and viruses; isopycnic banding of subcellular particlesand viruses	1.3 at 20°C

When a sample of molecules is subjected to centrifugation in a density gradient, they sediment toward the bottom if they have a greater buoyant density than the solution, or they will float toward the top if they have a lower density. The rates of sedimentation through the gradient of the various molecules can be measured, as in sedimentation velocity centrifugation, and depends on their buoyant densities and sedimentation coefficients **(*s*-values)**. Alternatively, the centrifugation can be continued until each molecule reaches that point in the gradient when the solution density is the same as its buoyant density. At this point the molecule neither sediments nor floats. Then different molecules are separated on the basis of differences in their buoyant densities, which can be measured in this way. The physical process of banding significantly improves the resolution of this technique.

1. Rate-Zonal Centrifugation

Separations of macromolecules or subcellular fractions with different sedimentation rates and/or sizes are accomplished by layering the sample of material as a narrow zone onto the top of a preformed gradient of the appropriate material (Table 1) and subjecting the sample to centrifugation. During centrifugation, the constituent components of the sample proceed through the gradient as individual zones, each at its specific sedimentation rate. The sedimentation process results in separating the sample components into discrete bands or zones that can be recovered from the centrifuge tube, typically by simple fraction collection (below). The shape of the gradient, that is, the change in solution density as a function of the physical length of the centrifuge tube or distance from the center of rotation, is a function of the gradient material and its concentration, the rate of centrifugation, etc. Five principal types of gradient systems used in rate-zonal separations are summarized in Table 2

Table 2. Principle Types of Gradients in Rate-Zonal Centrifugation[a]

Type	Gradient Characteristics as a Function of Distance Along Centrifuge Tube
Linear	Solution density or gradient-forming-solute concentration versus distance is linear
Isokinetic	Solution density or gradient-forming-solute concentration versus distance is usually convex but sometimes linear; all particles of the same density sediment at a constant rate at all distances from the center of rotation
Step or discontinuous	Solution densities or gradient-forming-solute concentrations versus distance form discrete zones with (relatively) large differences in density (concentration) from one to another
Shallow	Solution density or gradient-forming-solute concentration changes gradually versus distance
Sharp or steep	Solution density or gradient-forming-solute concentration changes rapidly versus distance

[a] Adapted from Spinpro Software from Beckman Instruments.

Approximate values of the sedimentation coefficients (s-values) of macromolecules and subcellular components can be obtained from rate-zonal gradient centrifugation without purifing the protein. This is accomplished in isokinetic gradients, where particles sediment at a constant rate, as in sucrose gradient centrifugation. To determine the s-value, it is necessary to include sedimentation "markers" of macromolecules with known sedimentation coefficients. It is necessary only to be able to differentiate between the various molecules, perhaps by their **spectroscopic** properties or by their biological activities.

2. Flotation in Gradient Centrifugation

This technique is a subclass or offshoot of gradient techniques. It occurs in centrifugation when the buoyant densities of the centrifuged macromolecule or subcellular components are less than that of the solution in which they are centrifuged. The rates of flotation of the individual solution components to the top of the solution are a function of their sizes, shapes and densities, just as in sedimentation to the bottom of the tube.

3. Isopycnic Gradient Centrifugation

Isopycnic procedures are used to separate macromolecules on the basis of their buoyant densities. The density gradient is chosen so as to include the densities of the species to be separated from each other. The sample to be sedimented may be prepared either by homogeneously distributing it throughout the gradient or by layering it on top of the gradient. In either case, when centrifugal force is applied to the sample, the sedimenting components move along the density gradient to where they have the same buoyant density. If they are at a lower solution density initially, they tend to sediment, whereas they tend to float when at a higher solution density. When the density gradient is maintained by the centrifugal force, and perhaps even generated by it, such as with cesium chloride (Table 1), the gradient is "self-generating." When all the molecules present are at their equilibrium positions, the centrifugal force condenses the molecules into sharp zones and maintains them. Unlike rate-zonal centrifugation, where the zones of the various molecules are constantly broadened by diffusion, but like isoelectric focusing, isopycnic density gradient centrifugation condenses the sample into a narrow zone and keeps it stable and sharp in time. This results from two opposing force fields:

diffusion, which tends to dissipate the zone, and the centrifugal field, which forces any “escaping” molecule back into its appropriate zone.

If the components to be separated have small differences in buoyant densities, the gradient used should bracket the desired density range and should also be shallow, so as to afford significant separation between components. Alternatively, if the components to be separated have large differences in buoyant densities, the gradient can be adjusted so that any undesired component either floats to the top of the gradient or sediments to the bottom, whereas the desired components are within the middle of the gradient.

4. Gradients of Viscous Materials

When viscous gradient materials, such as sucrose, Ficoll, Percoll, and glycerol, are used, the gradients are often prepared by layering steps of decreasing density in the centrifuge tube. Then the various steps are allowed to diffuse into each other (usually for 1 to 3 hours at room temperature) to form an approximately linear gradient. Alternatively, the sample is layered and centrifuged immediately through the series of discontinuous step zones; the sample often accumulates at an interface between two steps, so the steps are chosen so that different materials accumulate at different interfaces. Often a cushioning layer of high density gradient material is incorporated into the bottom of the tube to prevent the desired sample from pelleting onto the tube.

5. Salt Gradients

Cesium chloride is sufficiently heavy that it forms a substantial density gradient under the sole influence of rapid centrifugation. In this case, the starting solution can be uniform in both the cesium chloride and the sample. During centrifugation, the density gradient of cesium chloride is generated, and the molecules of the sample migrate to their isopycnic positions. The appropriate initial cesium chloride concentration must be chosen to give the desired density gradient with the centrifugal force used. It is possible to shorten the time required for attaining equilibrium by preforming the gradient, which then requires centrifugation runs of only 2 to 8 hours. Often a cushioning layer of high density gradient material is incorporated to prevent complete pelleting of the sample on the bottom of the tube.

6. Fractionating Gradients After Centrifugation

The density gradients employed aid the process of recovering the samples, minimizing the disturbance of banded zones in a centrifuge tube. Methods for recovering the banded samples depend on whether the tube in which the experiment has been performed is reusable or disposable. In the former case, the tube is held rigidly while a flat-end syringe needle of appropriate length is carefully inserted at the center of the tube down through the length of the column of gradient solution to the tube base. Then the contents are slowly pumped out. In the latter case, the bottom of the tube is punctured with a needle, and the tube contents are permitted to flow out slowly. Then they are collected in a fraction collector, perhaps after passing through a UV **absorbance**, **fluorescence**, or other detector. An alternative fractionation device for this process, a centrifuge tube slicer, is available from Beckman Instruments.

Once separated into individual fractions, the gradient samples can be analyzed for the molecules of interest, such as their enzymatic activity, spectral properties, or a **radiolabel**. The exact shape of the density gradient at the end of the centrifugation is determined by measuring the refractive index of the solution.

7. Centrifuge Rotors for Gradient Density Separations

Three types of rotor are used for density gradient centrifugation, varying in the orientation of the sample during centrifugation. In the swinging bucket rotor, the sample swings outward away from the center of rotation during centrifugation and extends at a right angle to the axis of rotation. Consequently, the force applied to the column of liquid containing the sample is always along the long axis of the liquid column, and the sedimenting sample moves along the linear axis of the applied force. Swinging bucket rotors are often used with sucrose density centrifugation. In fixed-angle rotors, the liquid column is tilted at a fixed angle relative to the axis of rotation. Thus, the centrifugal force is applied at an angle to the long axis of the tube and differentially at the cell meniscus and cell base. Fixed-angle rotors are routinely used for pelleting samples and for heavier isopycnic salt gradients, where the gradient can reorient after the centrifugation run. In vertical tube rotors, the liquid column is held parallel to the axis of rotation, and the centrifugal force is applied perpendicularly to the long axis of the tube. Because the sedimentation path is short, simply the width of the tube, these rotors permit very short run times, but with good resolution, and are useful for isopycnic separations. The advantages and disadvantages of each rotor type vary significantly with the particular application.

Suggestion for Further Reading

R. Hinton and M. Dobrota (1980) *Laboratory Techniques in Biochemistry and Molecular Biology: Density Gradient Centrifugation* (T. S. Work and E. Work, eds.), North-Holland, New York. A somewhat dated but useful compendium of techniques for preparative density gradient centrifugation.

Deoxycholate

Sodium deoxycholate, a bile acid salt, is a strongly **denaturing**, anionic detergent that is structurally close to sodium cholate. The 5-OH group of cholate is replaced with a hydrogen atom in deoxycholate (Fig. 1). This detergent has been used to solubilize many membrane-anchored proteins, such as those that are membrane-linked via a phosphatidylinositol-containing glycolipid (termed **GPI-anchored** proteins) (1, 2). Although it has rarely been shown that sodium deoxycholate solubilizes integral membrane proteins, certain insoluble, extracellular proteins, such as human lens membrane proteinase, have been efficiently solubilized by using sodium deoxycholate (3). Sodium deoxycholate has a relatively high critical micelle concentration (cmc) of ~10 mM, which makes it easy to be removed by dialysis from the solubilized proteins and lipids. Although this detergent is strongly denaturing toward integral membrane proteins, it solubilizes membrane lipids efficiently (4) and also stimultes **G-protein**-coupling to an effector, such as phospholipase C (5).

Figure 1. The structure of sodium deoxycholate.

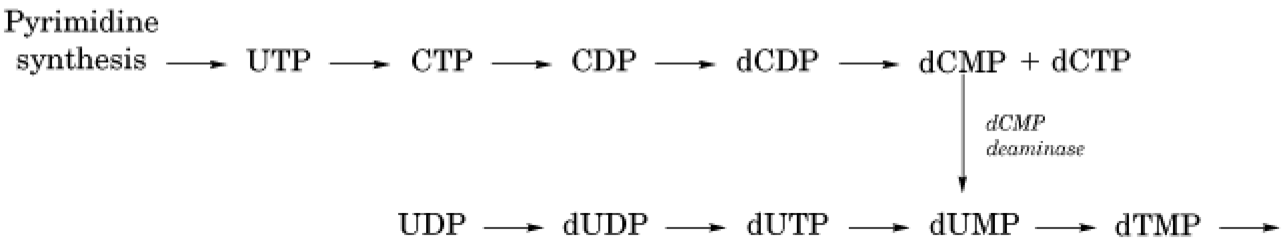
Deoxycytidylate Deaminase

Deoxycytidylate deaminase (dCMP deaminase) is one of two **allosteric** enzymes in the *de novo* biosynthetic pathways to **deoxyribonucleoside triphosphates** (dNTPs); the other allosteric enzyme is ribonucleotide reductase). Inasmuch as dCMP deaminase sits at a branch point in the synthesis of pyrimidine dNTPs, the importance of this control in maintaining balanced dNTP pools can be readily appreciated.



It is assumed, although not yet established with certainty, that dCMP, dCDP, and dCTP are in ready equilibrium with one another via the actions of dCMP kinase and nucleoside diphosphate kinase. Clearly, dCMP is a precursor of dCTP, and the accumulation of dCTP can be a signal to the cell to divert dCMP, *via* dCMP deaminase, to pools of thymidine nucleotides. At the same time, dTTP accumulation can signal the metabolic machinery to shut off its own synthesis, and dCMP deaminase makes an appropriate regulatory target.

Scheme 1 shows two distinct pathways to dUMP, one involving dCMP deaminase and the other involving the reduction of UDP by ribonucleotide reductase with subsequent action of nucleoside diphosphate kinase and deoxyuridine triphosphatase (dUTPase). Radioisotope labeling experiments in mammalian cells show that the deaminase-based pathway is far more significant than the second pathway as a source of dTMP residues in DNA (1).

1. Structure and Regulation of dCMP Deaminase

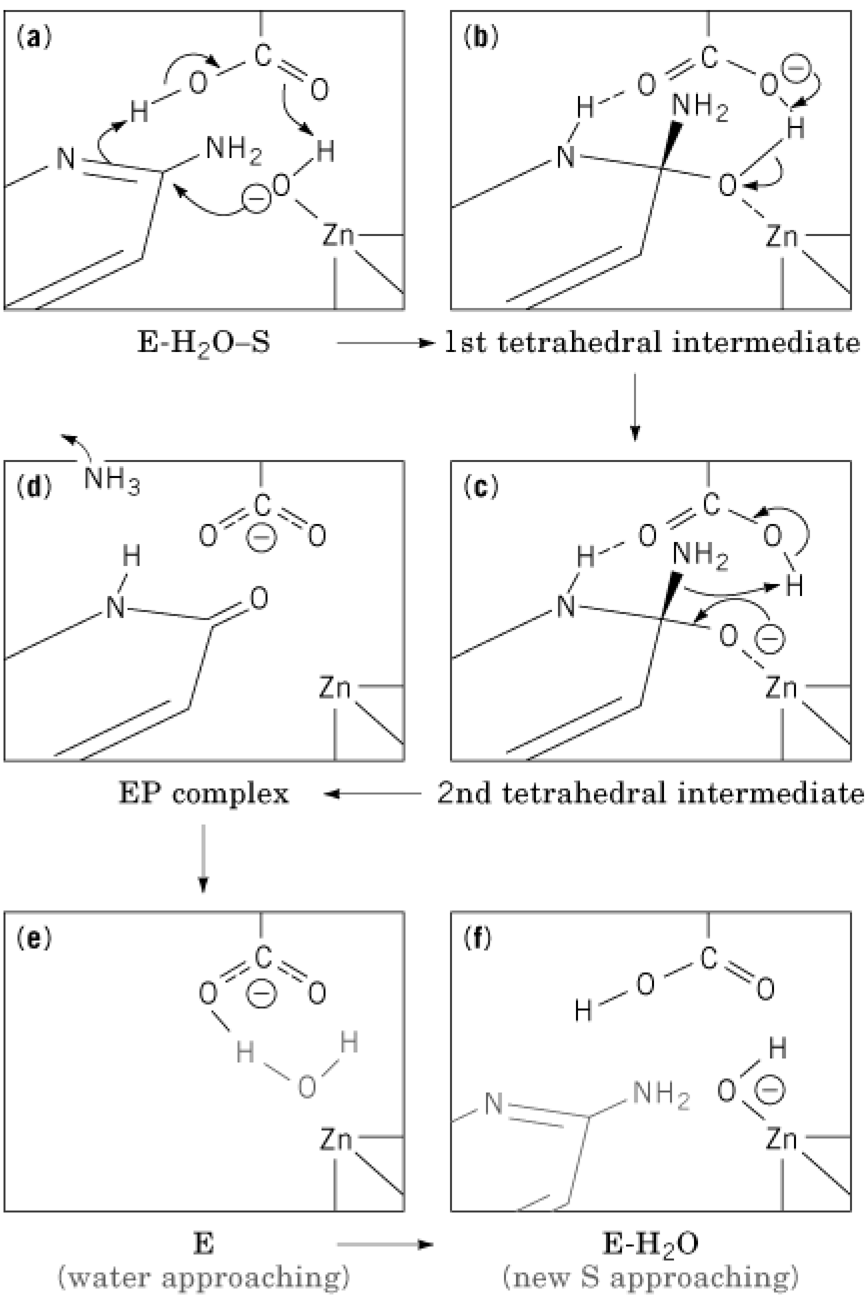
Deoxycytidylate deaminase was first described in the late 1950s and early 1960s in papers by the Maleys in the United States (2, 3) and by Scarano and colleagues in Italy (4). As shown above, the enzyme catalyzes the hydrolytic deamination of deoxycytidine monophosphate to deoxyuridine monophosphate, the immediate precursor to thymidine nucleotides via thymidylate synthase. As an enzyme involved in the synthesis of a specific DNA precursor, the activity of dCMP deaminase is closely correlated with the proliferative activity of the cell (2). In a series of papers in the 1960s, both the Maley and Scarano laboratories showed that vertebrate dCMP deaminase is inhibited by dTTP and activated by dCTP (3, 4). dCTP was found to be almost completely required for activity, whereas dTTP is a strong inhibitor, with inhibition constant (K_i) values in the micromolar range. Reversal of dTTP inhibition by dCTP was shown to vary with the dCTP concentration in a highly sigmoidal manner as did the variation of the enzyme velocity with the concentration of dCMP as substrate (see Allostery). Activation involved an apparent change in subunit structure of the enzyme, for the dCTP-activated enzyme from chick embryo was shown to have a sedimentation coefficient ($s_{20,w}$) of 6.78 S whereas the dTTP-inhibited enzyme had $s_{20,w}$ of only 3.63 S (3). Conformational changes were also involved, as shown in part by large circular dichroism changes resulting from dCTP binding.

In early work, the subunit structure of dCMP deaminase was more readily defined in studies with T-even bacteriophage-infected bacteria, a much more abundant source than vertebrate tissues (5, 6). The phage T2 enzyme was shown to be a homohexamer of about 120,000 molecular weight, and the phage T4 and T6 enzymes are similar. The effects of dCTP and dTTP were shown to be similar to those observed with the vertebrate enzyme. However, dCTP is not a physiological regulator in these systems. T-even phage DNA contains 5-hydroxymethyl-cytosine substituted for cytosine, and the dCTP pool in infected cells is completely replaced by 5-hydroxymethyl-dCTP. This latter nucleotide was shown to be equivalent to dCTP in its effect on phage dCMP deaminases, and it is undoubtedly the true *in vivo* positive regulator of the phage enzymes. Like other phage-coded enzymes of deoxyribonucleotide synthesis, T-even phage-coded dCMP deaminase functions as part of a multienzyme complex that evidently facilitates the biosynthesis of dNTPs and possibly their incorporation into DNA (see Thymidylate Synthase). Incidentally, the host organism for T-even phages, *Escherichia coli*, does not contain dCMP deaminase. Instead, the conversion of deoxycytidine to deoxyuridine nucleotides occurs at the triphosphate level (7) through the action of a structurally unrelated enzyme, as follows:

$$\mathrm{dCTP} + \mathrm{H_2}O \rightarrow \mathrm{dUTP} + \mathrm{NH_3} \tag{2}$$

With recombinant DNA approaches, large-scale isolation of dCMP deaminase has become possible, and structural studies are under way with the T4, **yeast**, and human enzymes (8, 9). The three dCMP deaminases show significant sequence homology at the C-terminus, but the yeast subunit is far larger than the T4 or human polypeptide chains. Both the T4 and human enzymes contain catalytically essential zinc (see Zinc-Binding Proteins). This fact, plus an apparent active-site homology with adenosine deaminase and cytidine deaminase, suggest a mechanism comparable to that of cytidine deaminase, whose structure has been determined (10; see Fig. 1). This mechanism is consistent with the potent inhibition of dCMP deaminase by tetrahydrodeoxyuridine monophosphate, a presumed transition state analogue.

Figure 1. A mechanism for the cytidine deaminase reaction, based on structural analysis of the *E. coli* enzyme. The mechanism for dCMP deaminase is probably similar or identical. Reprinted with permission from L. Betts, S. Xiang, S. A. Short, R. Wolfenden, and C. W. Carter Jr. (1994) *J. Mol. Biol*. **235**, 635–656.



2. dCMP Deaminase is the Product of a Mutator Gene

A mutator gene is one in which the action of a mutant allele contributes toward an increase in the spontaneous mutation rate at all loci; conversely, the action of the wild-type allele contributes toward genetic stability. A classic example is the *E. coli mutH*, *mutL*, and *mutS* genes, in any of which a mutation raises the mutation rate by compromising DNA mismatch repair.

In the same sense, the gene encoding dCMP deaminase is a mutator gene, as shown first in mouse S49 cells (11), where a subline evidently deficient in dCMP deaminase activity caused accumulation of dCTP and a deficiency of dTTP consistent with the loss of a major pathway to dTTP synthesis, and an increase in spontaneous mutation rates of at least an order of magnitude. Similar results were observed in yeast (12) and in *E. coli* infected with a dCMP deaminase deletion mutant of phage T4 (13). In these latter studies, additional information was gained about the mutational events occurring as a result of the dNTP pool imbalance. Infection by the T4 deaminase deletion led to dramatic accumulations of 5-hydroxymethyl-dCTP and specific increases in mutations that occur along an AT

→ GC transition mutation pathway, as expected if mutation results from misinsertion of the abundant 5-hydroxymethyl-dCMP opposite template A. On the other hand, most of the mutations in yeast that were stimulated by dCMP deaminase deficiency were GC → CG transversion mutations, an event that does not follow in any logical fashion from the dNTP pool imbalance demonstrated in these cells.

Clearly, understanding mutagenesis induced by DNA precursor pool imbalance involves factors other than concentration-dependent competition between nucleotides that are correctly and incorrectly base-paired to a template base. Adding to the complexity is the existence of a dCMP deaminase-defective hamster V79 cell line in which a large increase in the [dCTP]/[dTTP] pool ratio has only a negligible effect on the spontaneous mutation rate (14). Based on analysis of synchronized Chinese hamster ovary cells (15), it is possible that most of the expanded dCTP pool in these cells is located outside the nucleus, where it cannot directly influence replication fidelity. In any event, it is apparent from the several systems that have been investigated that the biochemical consequences of dCMP deaminase deficiency are clear—cells or phage survive because an additional metabolic route to dTTP is present, but the [dCTP]/[dTTP] or [hydroxymethyl-dCTP]/[dTTP] ratio increases dramatically, as expected from the loss of a quantitatively major pathway. However, the genetic consequences of these events underscore the difficulty in understanding all the biochemical factors contributing to spontaneous mutagenesis.

Deoxyribonucleotide Biosynthesis And Degradation

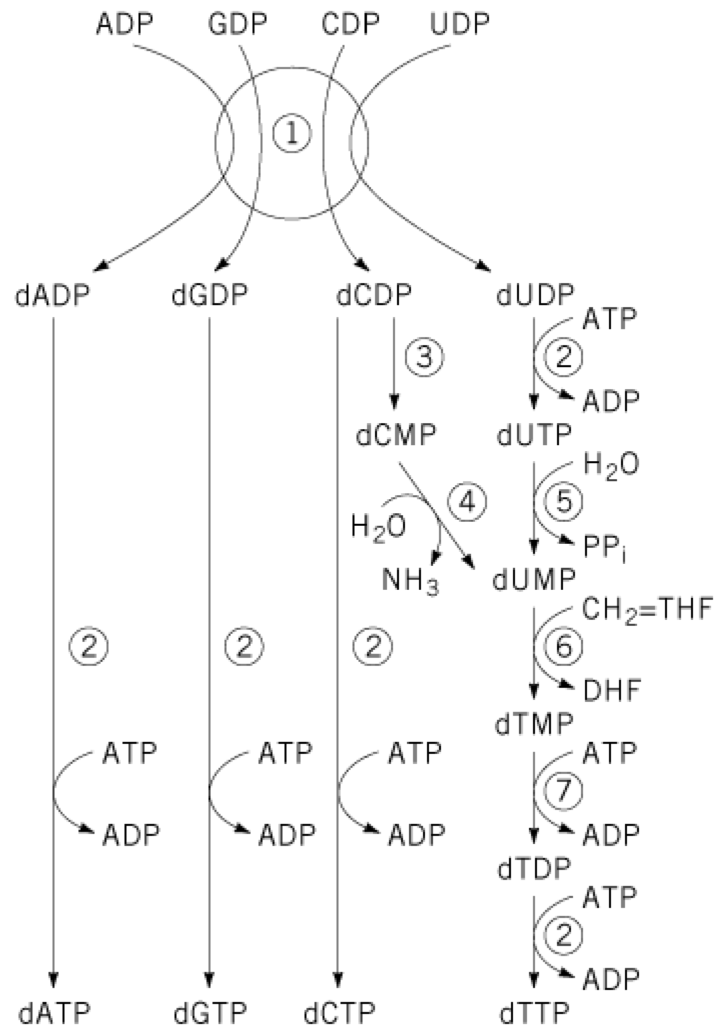
Most cells contain five to ten times as much RNA as DNA. The deoxyribonucleotide precursors to DNA use the same pathways for synthesis of purine and pyrimidine rings as do the ribonucleotides that are used for RNA synthesis and for a host of other metabolic functions (see Purine Ribonucleotide Metabolism and Pyrimidine Ribonucleotide Metabolism). Therefore, the pathways that lead from the *de novo* purine and pyrimidine synthetic pathways toward deoxyribonucleoside triphosphates (dNTPs) are quantitatively minor. They are of obvious significance, however. Not only must they be sufficiently active to supply the cell's needs for **DNA replication, recombination**, and DNA repair but they must be activated and deactivated in coordination with the timing of DNA replication during the cell cycle because dNTPs have no known metabolic roles other than their function as DNA precursors. Moreover, the pathways must be regulated so as to provide the four DNA precursors at rates corresponding to the base composition of the genome being served. dNTP pool imbalances that develop when regulatory mechanisms are perturbed have numerous biological consequences (1)—including mutagenesis, recombination, induction of latent **viruses**, and cell death—caused by stimulation of apoptosis (2).

1. Pathways to dNTPs

1.1. Chemical Differences between RNA and DNA

It is useful to begin our survey of deoxyribonucleotide biosynthesis by considering the processes through which the chemical differences between DNA nucleotides and RNA nucleotides arise. The methyl group of thymine, which distinguishes it from uracil, arises through the transfer of a single-carbon functional group to a uracil nucleotide, catalyzed by thymidylate synthase. The presence of 2-deoxyribose as the sugar in DNA nucleotides rather than the ribose found in RNA comes about through reduction of the ribose sugar on a ribonucleotide substrate (see Ribonucleotide Reductases). Some aerobic bacteria and all anaerobic microorganisms studied carry out this reduction at the ribonucleoside triphosphate (rNTP) level. In all other organisms studied, however, the substrates for ribonucleotide reductase are the ribonucleoside 5′-diphosphates (rNDPs). Whether a particular reductase acts on rNDPs or rNTPs, a single enzyme reduces all four ribonucleotide substrates. Accordingly, the enzyme interacts with **allosteric** modifiers to ensure that the four DNA precursors are produced at rates commensurate with the base composition of the organism's genome. In this article, we will describe the predominant pathways to dNTPs that begin with reduction of rNDPs to deoxyribonucleoside diphosphates (dNDPs). These pathways are summarized in Figure 1.

Figure 1. Pathways of dNTP biosynthesis *de novo*. Although these pathways are widespread, they are not universal, as indicated in the text. Enzyme 1, ribonucleoside diphosphate reductase; 2, nucleoside diphosphate kinase; 3, dCMP kinase (probably); 4, dCMP deaminase; 5, dUTPase; 6, thymidylate synthase; 7, thymidylate kinase. CH_2 = THF is 5,10-methylenetetrahydrofolate, and DHF is dihydrofolate.



1.2. The Role of Nucleoside Diphosphate Kinase

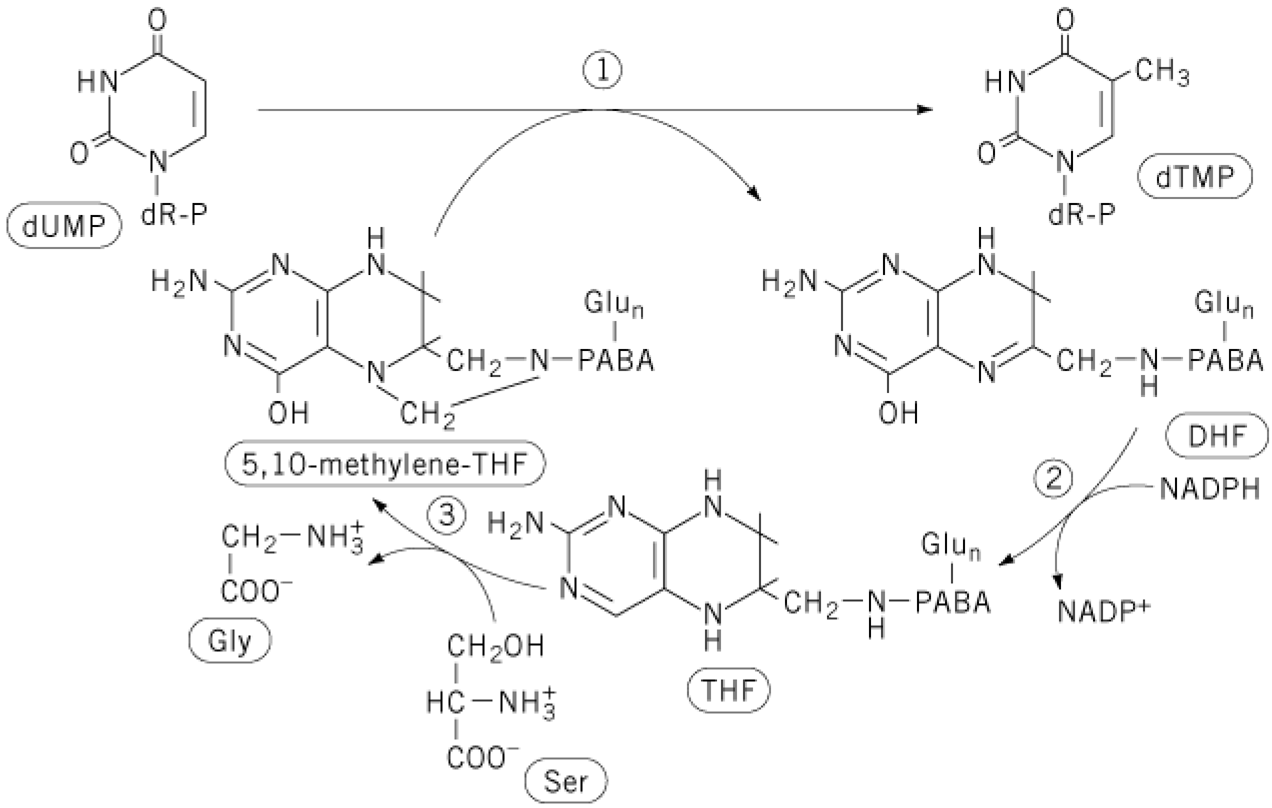
For three of the four nucleotides—ADP, CDP, and GDP—the conversion to the dNTP involves simply a phosphorylation of the rNDP reductase product, catalyzed by nucleoside diphosphate kinase. In most cells, this enzyme is very active, and all known forms of the enzyme have very low specificity. Thus, the enzyme catalyzes the reversible transfer of the g-phosphate of any common rNTP or dNTP to the phosphate at the b-position of any common rNDP or dNDP. The equilibrium constant for each reaction catalyzed is close to unity. Thus, the direction in which a nucleoside diphosphate kinase-catalyzed reaction occurs *in vivo* depends on the concentrations of substrates and products. Because ATP is almost always the most abundant intracellular nucleoside triphosphate, most such reactions involve the ATP-dependent conversion of a ribo- or deoxyribonucleoside diphosphate to the corresponding triphosphate.

1.3. Thymine Nucleotide Biosynthesis

The biosynthesis of thymidine triphosphate is obviously more complex than that of any other dNTP given that thymine nucleotides are derived from uracil nucleotides and a methyl group must be created. In most cells, the dUDP produced by rNDP reductase action on UDP is phosphorylated to dUTP by nucleoside diphosphate kinase. dUTP is cleaved by an active pyrophosphatase, deoxyuridine triphosphatase, or dUTPase. This enzyme plays a dual role: (1) Because dUTP is a good substrate for DNA polymerase, dUTPase minimizes the steady-state pool size of dUTP and, hence, helps to exclude dUMP from DNA. (2) The dUTPase reaction is a significant biosynthetic route to dUMP, the substrate for thymidylate synthase.

Thymidylate synthase catalyzes the transfer of a single-carbon functional group from 5,10-methylenetetrahydrofolate to position 5 of the pyrimidine ring in deoxyuridine monophosphate, yielding thymidine monophosphate (Fig. 2). dTMP is phosphorylated to dTDP by , and conversion to dTTP involves nucleoside diphosphate kinase.

Figure 2. The thymidylate synthesis cycle. Enzyme 1, thymidylate synthase; 2, dihydrofolate reductase; 3, serine transhydroxymethylase. dR-P is deoxyribose 5′-phosphate; PABA is *p*-aminobenzoate; Glu_n refers to the multiple glutamate residues on naturally occurring folate coenzymes.



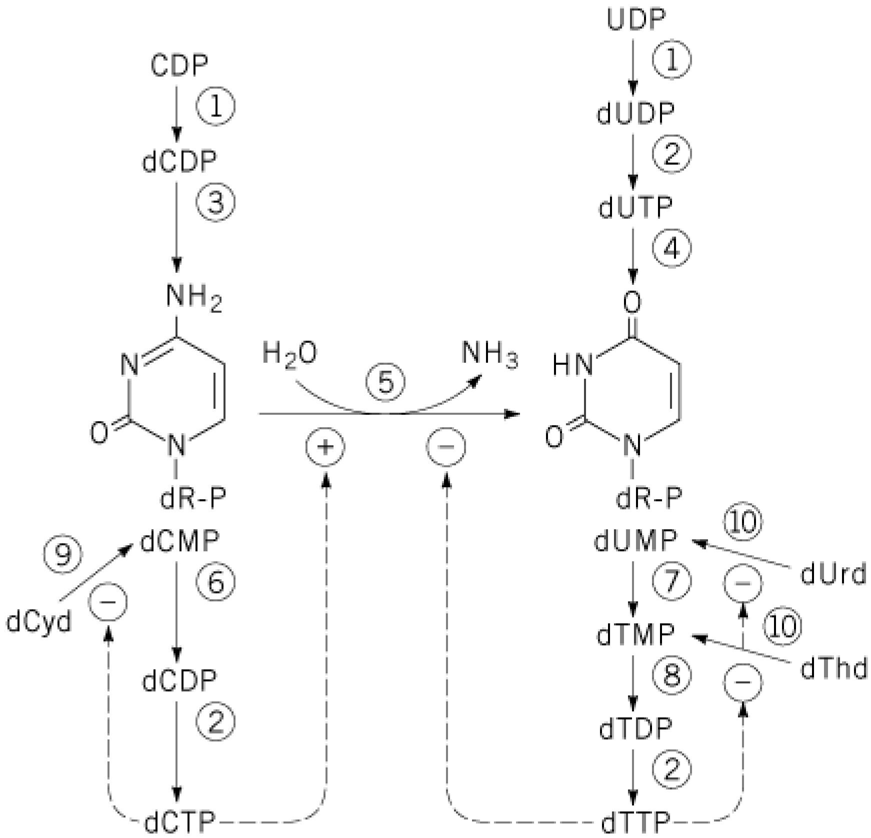
In the thymidylate synthase reaction, the transferred methylene group must be reduced to the methyl level, and the electron pair that brings this reduction about comes from the reduced pteridine ring of 5,10-methylenetetrahydrofolate. The coenzyme, therefore, loses both its methylene group and an electron pair, leading to dihydrofolate. Transformation of the coenzyme for reuse involves, first, its reduction to tetrahydrofolate by dihydrofolate reductase and, next, transfer of a single-carbon group to the pteridine ring, usually catalyzed by serine transhydroxymethylase. The stoichiometric requirement for the folate cofactor in the thymidylate synthase reaction probably explains the selective toxicity of dihydrofolate reductase inhibitors toward proliferating cells (3). Such inhibitors include Methotrexate, widely used in cancer chemotherapy, and Trimethoprim, an antibacterial agent that specifically inhibits dihydrofolate reductases of prokaryotic origin(see **Aminopterin**). Proliferating cells have a continuous requirement for dTTP synthesis, to sustain DNA replication. The greater the flux rate through thymidylate synthase *in vivo*, the more rapidly tetrahydrofolate pools will be depleted after administration of a dihydrofolate reductase inhibitor and, hence, the greater will be the sensitivity of those cells toward the growth-inhibiting or lethal effects of blockage of dihydrofolate reductase.

1.4. Biosynthetic Routes to dUMP

As noted earlier, the cleavage of deoxyuridine triphosphate to the corresponding monophosphate, catalyzed by dUTPase, provides a significant source of dUMP for the synthesis of thymine nucleotides. In most cells, however, an additional route, involving deamination of deoxycytidine nucleotides, is more important in a quantitative sense. As shown in Figure 3, the hydrolytic deamination in most organisms involves conversion of dCMP to dUMP, catalyzed by **dCMP deaminase**. In a few bacteria, including *Escherichia coli*, the deamination occurs at the triphosphate level, with conversion of dCTP to dUTP, catalyzed by dCTP deaminase. In such organisms, the conversion of CDP to dUMP occurs by the following pathway:

$$\text{CDP} \rightarrow \text{dCDP} \rightarrow \text{dCTP} \rightarrow \text{dUTP} \rightarrow \text{dUMP}$$

Figure 3. dCMP deaminase as a branch point between dCTP and dTTP synthesis. Allosteric modifiers of dCMP deaminase are shown, as is the regulation of salvage synthetic pathways. Enzyme 1, ribonucleoside diphosphate reductase; 2, nucleoside diphosphate kinase; 3, dCMP kinase (possibly); 4, dUTPase; 5, dCMP deaminase; 6, dCMP kinase; 7, thymidylate synthase; 8, thymidylate kinase; 9, deoxycytidine kinase; 10, thymidine kinase.



The most widespread pathway, shown in Figure 3, involves deamination at the monophosphate level. In many vertebrate cell lines, this is the predominant, often exclusive, pathway leading to dUMP (4). It is not clear why the *in vivo* flux rate from UDP to dUDP is so low, particularly when the activities of ribonucleotide reductase on CDP and UDP are regulated virtually identically as shown by assays of the purified enzyme *in vitro* (5). Whatever the reason, dCMP deaminase is an important metabolic branch point between routes to dTTP and dCTP. Allosteric regulation of this enzyme—activation by dCTP and inhibition by dTTP—ensures that these two dNTPs are produced at relative rates commensurate with their need for DNA synthesis. dCMP deaminase is not essential for cell viability, at least as determined in cell culture systems. However, mutant cells lacking dCMP deaminase have abnormally high dCTP pools (1, 6), and the resultant increase in the [dCTP]/[dTTP] pool ratio often brings about a **mutator** phenotype, in which the dCTP pool expansion stimulates its incorporation opposite template nucleotides other than dGMP (1).

2. Deoxyuridine Nucleotide Metabolism

As noted earlier, dUTPase plays a role in providing dUMP for the thymidylate synthase reaction. Of equal or greater importance is its role in minimizing the incorporation of dUMP into DNA in place of dTMP (see Deoxyuridine Triphosphatase). Cells possess two independent mechanisms to minimize the amount of dUMP in DNA: (1) dUTPase acts to deplete the dUTP pool, and hence to minimize dUMP incorporation by DNA polymerase, usually opposite dAMP in template DNA. (2) The second mechanism is a base excision repair process, starting with . This enzyme scans DNA, and when it contacts a dUMP residue, it cleaves the glycosidic bond, probably by a base-flipping mechanism (7). This reaction creates an abasic site, which initiates a repair process that results in insertion of the correct nucleotide at that site (8).

Because the base-pairing properties of uracil and thymine are essentially identical, it seems likely that the mechanisms for uracil exclusion from DNA are not designed primarily to replace dUMP with dTMP, when that dUMP is base-paired with dAMP in the template DNA. Instead, the probable target for DNA uracil exclusion is dUMP residues incorrectly paired with dGMP, but DNA-uracil *N*-glycosylase simply recognizes every dUMP residue in DNA, no matter what its partner. G · U DNA base pairs would arise most frequently by deamination of a dCMP residue paired in duplex DNA with dGMP. Cytosine undergoes spontaneous deamination at appreciable rates whether as a free nucleic acid precursor or as a residue in DNA or RNA. If C in a G · C base pair underwent deamination, the resultant G · C base pair would generate a G · C and an A · U base pair in the next round of replication and, ultimately, the deamination would lead to a G · C → A · T transition mutation. Thus, the DNA-uracil exclusion systems probably act to maintain stability of the genome.

3. Salvage Routes to dNTPs

As noted in Salvage pathways to nucleotide biosynthesis, deoxyribonucleotide salvage pathways involving uptake of extracellular precursors primarily use deoxyribonucleoside kinases. Human cells contain four such enzymes of varying specificities, two located in the cytosol and two in mitochondria, whereas other organisms, such as *E. coli*, contain thymidine kinase as the only deoxyribonucleoside kinase. Thymidine kinase has received particularly intensive study, partly because of the mechanism of its cell cycle regulation (9) but largely because the enzyme is so useful as a means for incorporating radiolabel into DNA. For reasons still not clear, thymidine competes extremely effectively with the *de novo* synthetic pathway to dTTP such that, in many animal cell systems, radiolabeled thymidine is incorporated into DNA at full specific activity, often bypassing substantial endogenous pools generated by *de novo* synthesis (10). One popular experimental organism for which this does not work is **yeast**; fungi lack thymidine kinase. Investigators have circumvented this difficulty, however, by designing yeast strains that are permeable to dTMP, strains for which exogenous dTMP can be used as a labeled DNA precursor.

For salvage of deoxyribonucleoside monophosphates released by intracellular DNA degradation, the deoxyribonucleoside monophosphate kinases play the key roles. Animal cells contain four such enzymes, each specific for one deoxyribonucleotide, ie, dAMP kinase, dCMP kinase, dGMP kinase, and dTMP kinase . The enzyme phosphorylating dAMP acts also on AMP and is the well-known adenylate kinase, or myokinase. dCMP kinase acts also on UMP, and dTMP kinase acts also on dUMP. dTMP kinase is involved also in *de novo* dTTP synthesis, as shown in Figure 1. dCMP kinase may also play a role in *de novo* dNTP synthesis. The enzyme converting dCDP (produced by ribonucleotide reductase) to dCMP, en route to dUMP and dTMP, has still not been identified. Since nucleotide kinases all have equilibrium constants close to 1, it is quite possible that the role of dCMP kinase is to carry out the synthesis of dCMP:

$$\mathrm{dCDP} + \mathrm{ADP} \rightleftharpoons \mathrm{dCMP} + \mathrm{ATP}$$

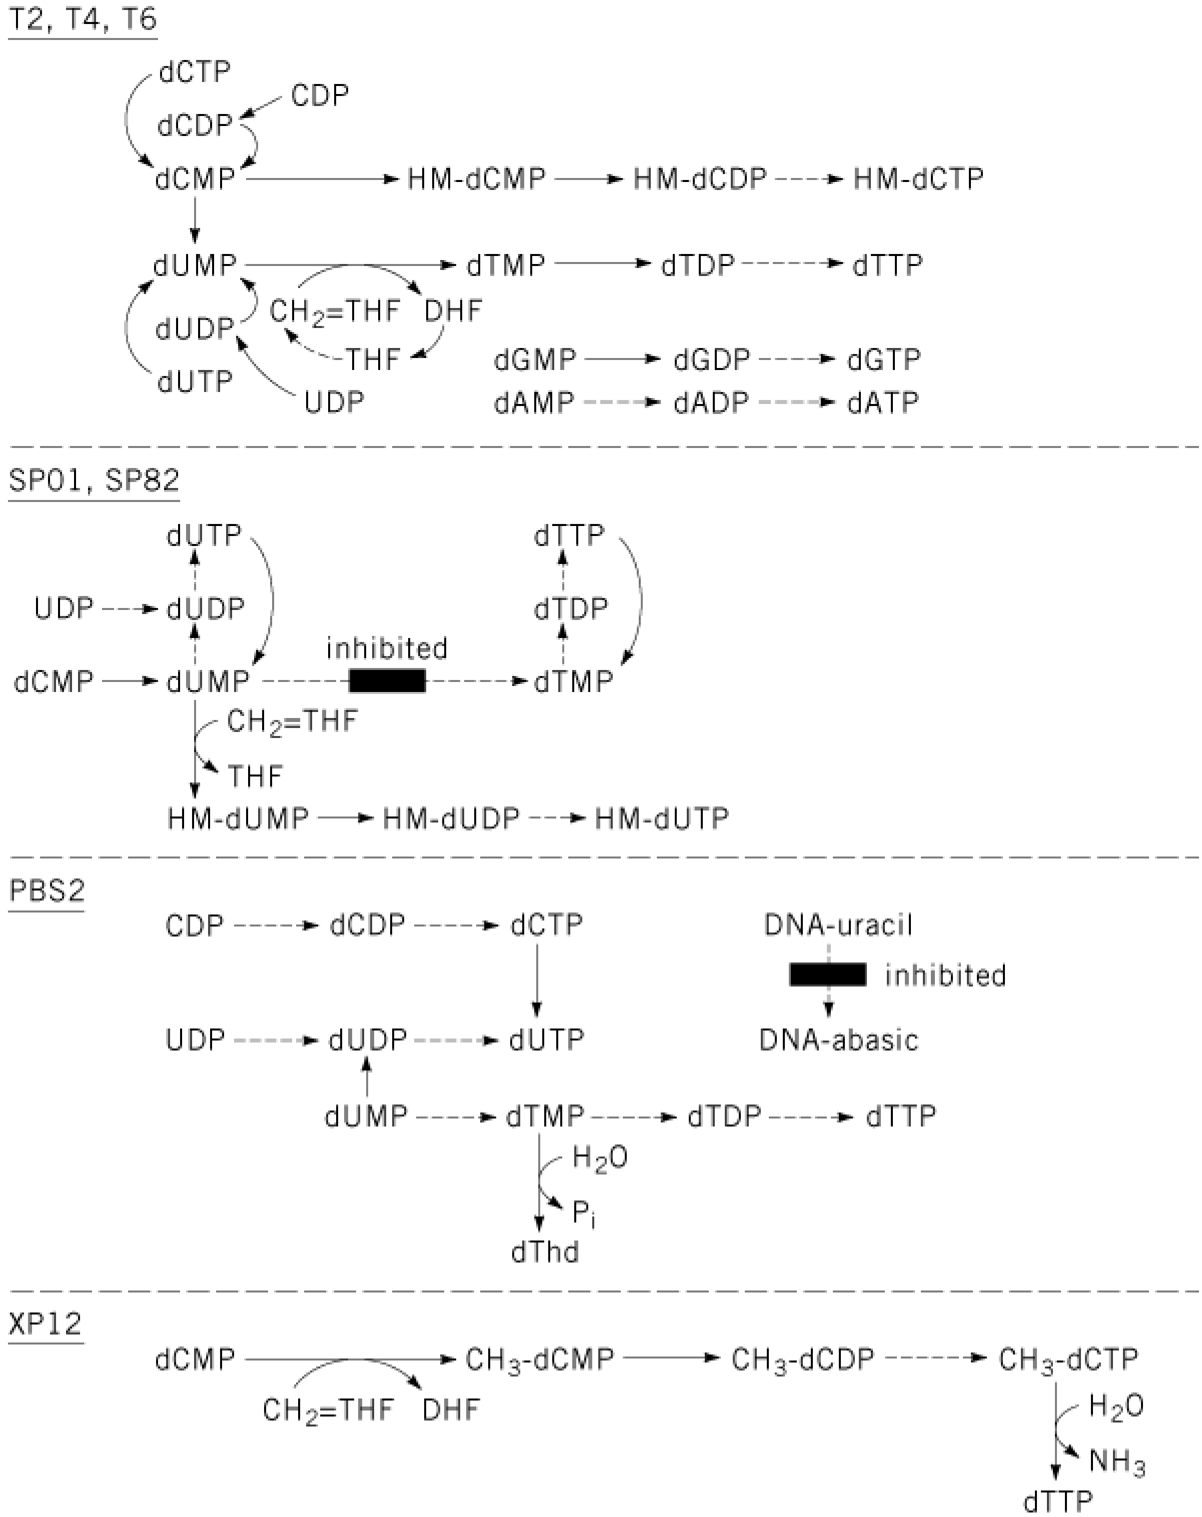
By contrast, dAMP and dGMP kinases play roles only in nucleotide salvage reactions because the *de novo* pathways lead directly from ribonucleoside diphosphate to deoxyribonucleoside diphosphate to deoxyribonucleoside triphosphate.

The action of nucleoside phosphorylases provides another route to salvage dNTP synthesis, eg, deoxyadenosine + $P_i \rightarrow$ adenine + deoxyribose-1-phosphate. Now the deoxyribose-1-phosphate can react with another base in a nucleoside phosphorylase-catalyzed reaction proceeding in the reverse direction, eg, dR-1-P + Thy $\rightarrow$ dThd + P_i. Thymidine can then become a nucleotide via the thymidine kinase reaction leading to dTMP. Although this process can significantly change relative dNTP pool sizes, it does not involve net deoxyribonucleotide synthesis; rather, it involves redistribution of the deoxyribosyl units linked to purine and pyrimidine bases.

4. Biosynthesis of Novel Nucleotides in Bacteriophage Infection

Much of what is known about pathways of dNTP synthesis in bacterial and animal cells came from investigations of the biosynthesis of unusual modified nucleotides in infection by certain bacteriophage (11). T-even bacteriophages of *E. coli* contain 5-hydroxymethylcytosine completely substituted for cytosine; many hydroxymethyldeoxycytidylate (HM-dCMP) residues in phage DNA are further modified by glycosidic links through the hydroxymethyl group to one or two glucose residues. These modifications occur through the action of phage-encoded enzymes that catalyze reactions comparable to those in cellular metabolism (Fig. 4). For example, the hydroxymethylation reaction is carried out by an enzyme, dCMP hydroxymethylase, that transfers a single-carbon group from methylenetetrahydrofolate to C-5 of dCMP, much as thymidylate synthase modifies C-5 of the pyrimidine dUMP (12); in fact, T-even phages encode a thymidylate synthase that displays significant amino acid sequence homology with dCMP hydroxymethylase. Not shown in Figure 4 is the involvement of glucosylation in the transfer of glucose to hydroxymethyl groups of HM-dCMP residues after their incorporation into DNA.

Figure 4. Metabolic pathways induced in bacteriophage infection. Solid arrows identify reactions known to be catalyzed by phage-coded enzymes; dashed arrows identify reactions catalyzed only by enzymes encoded by the host cell genome.



Other modifications are carried out by bacteriophage SP01 and SP82 of *Bacillus subtilis*, in which 5-hydroxymethyluracil substitutes for thymine and two other *B. subtilis* phages, PBS1 and PBS2, which replace thymine with uracil. The relevant pathways are also shown in Figure 4. Finally, the figure shows pathways induced in *Xanthomonas oryzae* by XP12, a bacteriophage in which cytosine is completely replaced by 5-methylcytosine. These base modifications help the virus to parasitize the host bacterium, overrunning pathways used by the host cell to produce its own DNA. Perhaps it should not be surprising that these are all virulent phages.

5. Deoxyribonucleoside Catabolism

5.1. Substrate Cycles and dNTP Pool Regulation

Nucleotide kinase-catalyzed reactions are readily reversible. Whereas these enzymes have long been considered to participate primarily in dNTP synthesis, there is now good evidence that nucleotide kinases function in both directions *in vivo* and that they can participate in dNTP degradation (13). For example, when DNA replication was blocked in mammalian cells with aphidicolin, intracellular dNTPs were degraded, and deoxyribonucleosides were excreted into the medium in significant amounts (13, 14), with little change in the steady-state pool size of the four dNTPs. The implication of these findings is that dNTP pool sizes are controlled not only at the level of synthesis but are also regulated by catabolism.

Under conditions that do not interfere with DNA synthesis in cultured cells, pulse-chase experiments show that the rate of utilization of a particular dNTP for DNA synthesis is equivalent to the rate at which the pool of that dNTP turns over (15, 16). These observations argue against the compartmentation of dNTP pools in animal cells; with one known exception, all the dNTP molecules in these cells are accessible to the replication machinery. The one exception is dCTP labeled by deoxycytidine (13); much of this pool is used for synthesis of the deoxycytidine counterparts to cytidine diphosphate-containing **lipid precursors**, such as CDP-choline. It is not yet clear whether these dCDP-containing “liponucleotides” play a metabolic role distinct from those of the more abundant cytidine-containing lipids.

For cells that don't excrete deoxyribonucleosides but instead degrade them further, that further degradation usually involves attack by nucleoside phosphorylases to yield deoxyribose-1-phosphate plus the free base. Further degradation of the purine and pyrimidine bases proceeds by pathways outlined in Purine ribonucleotide metabolism and Pyrimidine ribonucleotide metabolism.

5.2. Enzymatic Degradation of dGTP

A widely distributed enzyme is a dGTP pyrophosphatase , which catalyzes the hydrolytic cleavage of dGTP to dGMP and pyrophosphate. The metabolic role of this enzyme was obscure until it was found in *E. coli* that the enzyme is encoded by the *mutT* gene (17). The *mutT* gene product acts to prevent transversion mutations that proceed by G · C → T · A and A · T → C · G pathways. Mutant alleles of *mutT* cause spontaneous rates of these transversion mutations at other loci to increase by 100- to 10,000-fold. Mutations of these types are caused by oxidizing agents, such as hydrogen peroxide, which act in large part by oxidizing guanine residues in DNA to 8-oxoguanine. This oxidized purine readily base-pairs with adenine, setting in motion the events leading to mutagenesis. These realizations led to the discovery that the MutT protein is far more active in cleaving 8-oxo-dGTP than dGTP. Thus, it seems clear that the mutagenic effects of oxidizing agents include oxidation of guanine, not as a DNA residue but as a DNA precursor that is incorporated into DNA and then stimulates a transversion pathway by pairing with adenine. The MutT nucleotidase prevents this by degrading the mutagenic DNA substrate, 8-oxo-dGTP, before it has a chance to be incorporated into DNA.

E. coli contains a second dGTPase, which is distinctive in that it hydrolyzes dGTP to deoxyguanosine plus tripolyphosphate. Unlike the MutT dGTPase, which is widely distributed in organisms, this other dGTPase is found only in enteric bacteria (18). Its metabolic role is still obscure.

Suggestion for Further Reading

19. The best single reference in this area is Chapter "2", “"Biosynthesis of DNA Precursors",” in A. Kornberg and T. Baker (1992) *DNA Replication*, 2nd Ed., W. H. Freeman and Co., New York, pp. 53–100.

Deoxyuridine Triphosphatase

Living cells contain two enzyme systems whose primary role is evidently to assure the exclusion of uracil from DNA where thymine occurs instead. Deoxyuridine triphosphatase (dUTPase) catalyzes the hydrolysis of dUTP to deoxyuridine monophosphate and pyrophosphate, thereby removing from the nucleotide pool a precursor, dUTP, that is recognized by **DNA polymerases** as readily as is thymidine triphosphate for incorporation into DNA opposite template adenine residues. The other system involves a DNA base excision repair process that begins with the action of DNA-uracil *N*-glycosylase. This enzyme cleaves the glycosidic bond linking uracil to deoxyribose, and an oligonucleotide patch that contains the abasic site is removed and replaced.

Current interest in dUTPase focuses on its very high substrate specificity, its significance as a possible chemotherapeutic target, the evolution and functions of virus-coded forms of dUTPase, and the generation and regulation of organelle-specific isoforms in eukaryotic cells.

1. Biological Functions of dUTPase

Although dUTPase was discovered in the early 1960s (1, 2), the enzyme was not characterized as a highly purified protein until 1978 (3). Much of the interest in the 1970s related to the role of uracil metabolism in creating short DNA fragments that had been identified as intermediates in DNA replication. After Okazaki proposed that DNA replication involves the discontinuous synthesis of short DNA fragments—which became known as Okazaki Fragments—several laboratories reported that nascent DNA chains are complementary to both template DNA strands, suggesting that both daughter DNA strands grow discontinuously. However, Tye et al. (4) showed that many of the short fragments arose not as intermediates in replication but through the action of the uracil exclusion systems. Incorporation of dUMP into DNA, followed by the action of uracil *N*-glycosylase and base excision repair, caused DNA strand breakage that converted nascent high-molecular-weight DNA into small fragments. When corrections were made for this factor, it was found that **leading-strand** DNA replication occurs continuously, with short fragments of DNA arising as replication intermediates only in synthesis of the lagging strand.

Why uracil should be excluded from DNA was not immediately apparent because uracil is identical to thymine in its base pairing with adenine, and so its substitution for thymine was not expected to affect DNA function or genetic specificity significantly. Indeed, the existence of bacteriophages, such as the *Bacillus subtilis* phage PBS2, whose DNA contains uracil but no thymine (5), indicates that substituting U for T is *biologically* acceptable. However, it was recognized that uracil can arise in DNA either through incorporation of dUMP opposite dAMP or through deamination of dCMP in a G · C base pair. This latter event is potentially **mutagenic** because the resultant G · U base pair would be converted to an A · T base pair in subsequent rounds of replication. Because dUTPase has no direct involvement in these events, it was thought that dUTPase should be a dispensable function in most organisms. However, El-Hajj et al. (6) were unable to isolate a null mutant of dUTPase in *Escherichia coli*, leading them to speculate that the protein plays an additional, essential metabolic role; similar results were reported for yeast (7). In a later study, however, El-Hajj et al. (8) analyzed a **conditional lethal** dUTPase (*dut*) mutation of *E. coli* and found that it could be suppressed by a mutation in *dcd*, the structural gene for dCTP deaminase, the enzyme that synthesizes dUTP in enteric bacteria (see Deoxyribonucleotide Biosynthesis And Degradation). This finding, plus the construction of a multiple mutant bacterium that survived extensive substitution of uracil for thymine in its DNA (8), indicated that the primary role of dUTPase is indeed to keep the dUTP pool small and facilitate the exclusion of uracil from DNA. The lethality of dUTPase null mutants is ascribed, then, to excessive accumulation of dUMP in DNA, leading to double-strand breaks that result when repair of single-strand breaks occurs at nearby sites on opposite DNA strands.

2. Structure of Deoxyuridine Triphosphatase

The dUTPase molecule must be constructed to exacting design specifications in order to cleave efficiently one deoxyribonucleoside triphosphate while having little or no effect on structurally similar dNTPs needed for DNA synthesis, in particular, dUTP and dTTP. Accordingly, kinetic analysis of *E. coli* dUTPase (9) showed the ratio k_{cat}/K_m (see Enzymes) to be, remarkably, more than 10^5-fold lower for dCTP than for dUTP. The nucleotides dTTP and UTP were even poorer substrates as no action of dUTPase on these nucleotides was detectable. The effects of pH on the K_m for dUTP suggested important contributions of **hydrogen bonding** involving N3 and the carbonyl oxygen on C4 in establishing the specificity of dUTP binding to dUTPase, which is consistent with structural studies (10, 11). Crystallographic analysis of both the *E. coli* and human enzymes reveals a homotrimeric structure, with each of three substrate-binding sites made up from residues in two adjacent polypeptide chains. The bacterial enzyme was crystallized in the presence of a **competitive inhibitor**, dUDP, which identified the active site and provided a structural explanation of the kinetic observations.

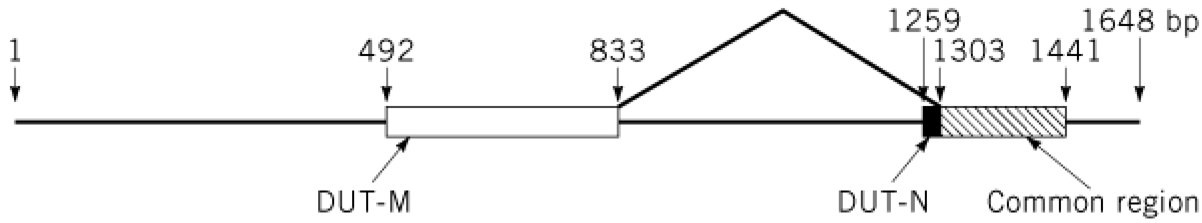
3. dUTPase as a Chemotherapeutic Target

Thymidylate metabolism has long been recognized as a target for drugs that would act to inhibit DNA replication in either cancer or infectious diseases (see Thymidylate Synthase; Fluorodeoxyuridine; Dihydrofolate Reductase (DHFR)). Beginning in the early 1980s, it was recognized that a significant contributor to the lethality of inhibitors of dihydrofolate reductase or thymidylate synthase is the accumulation of dUTP and its resultant incorporation into DNA (12). Inhibition of thymidylate synthase flux either directly, by 5-fluorodeoxyuridylate, or indirectly, by inhibition of dihydrofolate reductase, was seen to cause accumulation of dUMP which, in turn, would be converted to dUTP faster than it could be cleaved by dUTPase. Hence, the resultant accumulation of dUMP in DNA was seen to cause double-strand DNA breaks by the process discussed above. The existence of a class of fluorodeoxyuridine-resistant cell mutants with elevated levels of dUTPase (13) is consistent with this interpretation. Now that X-ray crystallography structures for dUTPase are available, this enzyme has been recognized as a suitable target for structure-assisted drug design. In principle, dUTPase inhibitors could be used, either alone or in conjunction with inhibitors of dihydrofolate reductase or thymidylate synthase, to kill proliferating cells selectively by stimulating the incorporation of dUMP into their DNA.

4. dUTPase Isoforms in Eukaryotic Cells

One of the most intriguing recent developments concerning dUTPase (14) relates to the discovery of two different **isoforms** in mammalian cells, one located predominantly in the nucleus and the other localized to mitochondria (although an earlier study (15) had localized human dUTPase to the cytosol). Presumably, the mitochondrial isoform plays the same role in mitochondrial DNA synthesis as the nuclear enzyme plays for nuclear DNA replication. Of great interest is the recent finding of Ladner and Caradonna (16) that both isoforms are encoded by the same nuclear gene, with alternative splicing at the 5′ end of the dUTPase gene (Fig. 1). The use of different 5′ exons for the two isoforms (see Introns, Exons) gives a subunit size of 22 kDa for the cytosolic enzyme and 23 kDa for the mitochondrial isoform. This may be the first reported instance of alternative splicing of the same transcript to generate isoforms of the same enzyme localized in different cell compartments.

Figure 1. Alternative splicing at the 5′ end of the human dUTPase gene as a means to generate nuclear and mitochondrial isoforms of dUTPase. Exons are boxed, and open reading frames of the mitochondrial, nuclear, and common sequences are shown by different shading. Intron/exon boundaries are indicated and numbered with respect to an arbitrary start point for the 5′ end of the gene. The amino-terminal splice junction is indicated by joined lines. Reprinted with permission from R. D. Ladner and S. Caradonna (1997) *J. Biol. Chem*. **272**, 19072–19080.



Cell-cycle analysis of protein and messenger RNA levels shows that the mitochondrial enzyme is expressed constitutively throughout the cell cycle (as is mitochondrial DNA replication), whereas the expression of the nuclear form is closely linked to nuclear DNA replication status. The nuclear isoform undergoes **protein degradation** as cells exit the cycle. Whether this differential regulation is related to **phosphorylation** of the enzyme is an intriguing unanswered question. Ladner et al. (14) showed that the cytosolic dUTPase is phosphorylated at Ser11, in a **cyclin**-dependent protein kinase phosphorylation site, whereas the same site remains unphosphorylated in the mitochondrial isoform. The functional significance of this difference has not yet been defined.

5. Virus-Encoded dUTPases

Numerous **virus**-specific forms of dUTPase have been described, including those encoded by the RNA genomes of retroviruses. The first viral dUTPase to be described (17) was shown to be an activity of dCTPase, an enzyme induced after T-even bacteriophage infection, which is responsible for exclusion of cytosine from phage DNA. This activity is essential to the observed complete replacement of cytosine by 5-hydroxymethylcytosine in the phage genome. Purification of dCTPase revealed an associated dUTPase activity (18), and both activities were shown to be intrinsic to the same protein. Also, unlike the unrelated bacterial and eukaryotic dUTPases, the phage enzyme is equally active on the respective deoxyribonucleoside diphosphates, cleaving dCDP and dUDP to dCMP and dUMP, respectively, plus inorganic phosphate. In T4, this multifunctional enzyme is encoded by gene 56. Mutants defective in this gene are lethal because they incorporate dCMP into phage DNA, and the viral genome encodes **nucleases** that specifically recognize and degrade cytosine-containing DNA.

dUTPase is encoded by the genomes of herpes viruses, pox viruses, several nonprimate lentiviruses, and type B and D retroviruses. A sequence in the *gag-pro* gene region of retrovirus genomes, originally identified as the evolutionary result of the duplication of a proteinase gene, was found, as these sequences began to accumulate in the data banks, to be homologous to dUTPase genes (19). Cloning and expression of these "pseudoproteinase" genes showed that they did indeed express functional dUTPases (20, 21). It is of particular interest that the human immunodeficiency virus (HIV) genome does not encode a dUTPase, although such a gene is expressed by the closely related feline immunodeficiency virus (FIV), which is being studied as a model for HIV infection. Lerner et al (22) infected cats with wild-type FIV and with a dUTPase-negative FIV mutant. After nine months of infection, sequence analysis of viral genomes isolated from both groups of infected animals showed a fivefold increase in mutations in the dUTPase-negative infections, most of them involving G → A transitions. These could have arisen from the formation of rG · dU base pairs during **reverse transcription** in the presence of expanded dUTP pools. Of great interest is the possibility that the extreme genetic variability of HIV is related to the lack of a dUTPase gene in the wild-type HIV genome, giving HIV the same mutator **phenotype** as observed in dUTPase-deficient FIV mutants.

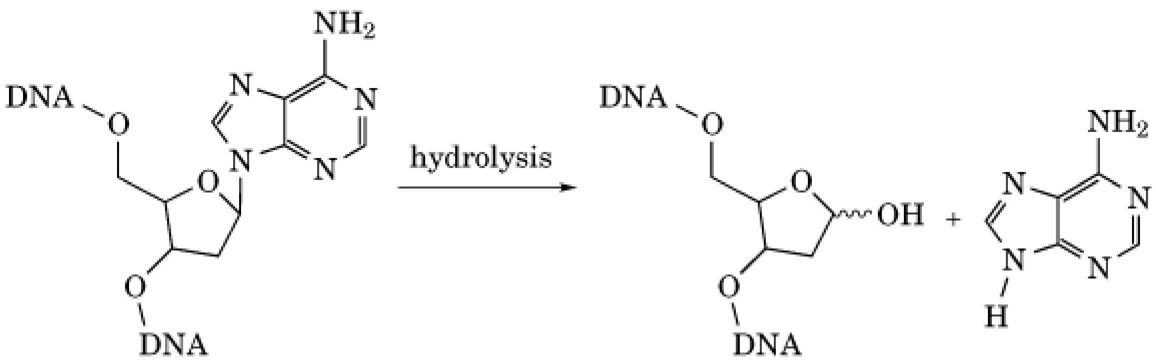
Depurination

An abasic site one lacking a nucleotide base, is created at a site in DNA when the glycosidic bond connecting a **purine** base to the deoxyribose sugar is cleaved, leaving the phosphodiester backbone of the DNA intact (Fig. 1). Depurination occurs at an estimated rate of 10^4 depurinations per mammalian cell per day (1), often through spontaneous hydrolysis. Other processes in the cell that lead to depurination are enzymatic removal of altered bases by specific glycosylases or through chemical modifications of purine bases (primarily alkylation at N7) that labilize the glycosidic bond. There is good evidence that depurination plays a major role in spontaneous **mutagenic** events (2). Although apurinic sites inhibit chain elongation by **DNA polymerases**, bypass must occur because there is enhanced incorporation of nucleotides that are noncomplementary to the template bases. The rate of misincorporation varies with different polynucleotide complexes, but the frequency of misincorporation is directly proportional to the extent of depurination (2).

Figure 1. Formation of an abasic site in DNA depurination.



Weymouth and Loeb (3) and Kunkel et al. (4) studied the fidelity of DNA polymerases in copying natural DNA templates and the mutagenic implications of the misincorporation events. They measured revertants generated by misincorporation in *am*3 bacteriophage fX174, a mutant containing a single base-pair substitution mutation. These studies confirmed that the copying of depurinated *am*3 fX174 DNA templates by purified DNA polymerases is mutagenic, and that the frequency of revertants correlates positively with the ability of different polymerases to copy past apurinic sites. Eukaryotic DNA polymerases are error-prone and read past apurinic sites at a high frequency.

Although direct mutagenicity is readily envisaged following error-prone read through of an apurinic site, it also appears that many mutations resulting from depurination in prokaryotes are **SOS-response-dependent** (5). Miller and Low (6) examined more than 600 independent spontaneous mutations in the lacI gene of SOS-induced *E. coli*. Most were specifically G.C → T.A, and to a lesser extent A.T → T.A, transversions and occurred primarily at certain sites. These transversion mutations are thought to have arisen from the insertion of dAMP opposite purines or apurinic sites, possibly through the SOS-induction process altering the specificity of the DNA replication complex to favor misincorporation of dAMP opposite purines. Miller and Low suggested that many spontaneous mutations may result from replication past cryptic apurinic sites. There are also several lines of evidence that apurinic sites are intermediates in mutagenesis by chemicals that form bulky DNA adducts (2).

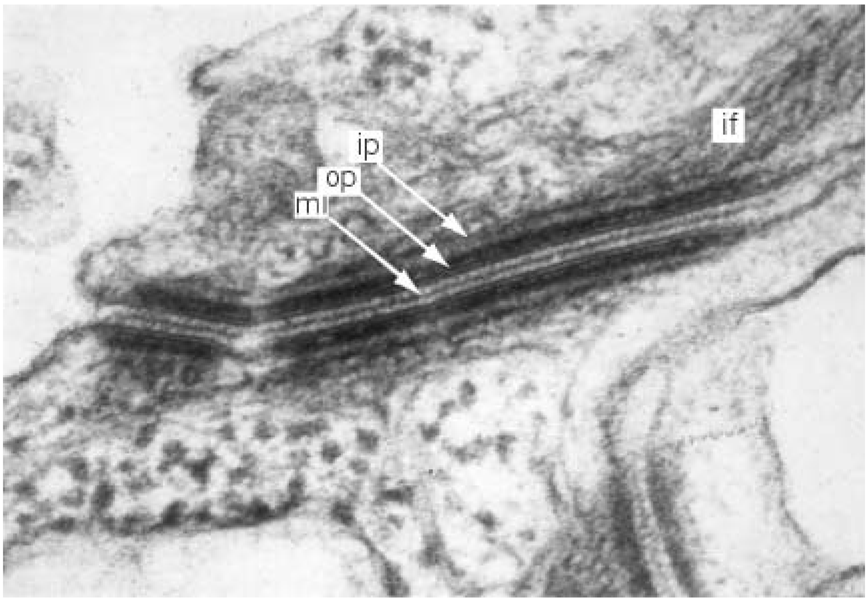
Desmosomes, Desmocollin, Desmoglein, and Desmoplakin

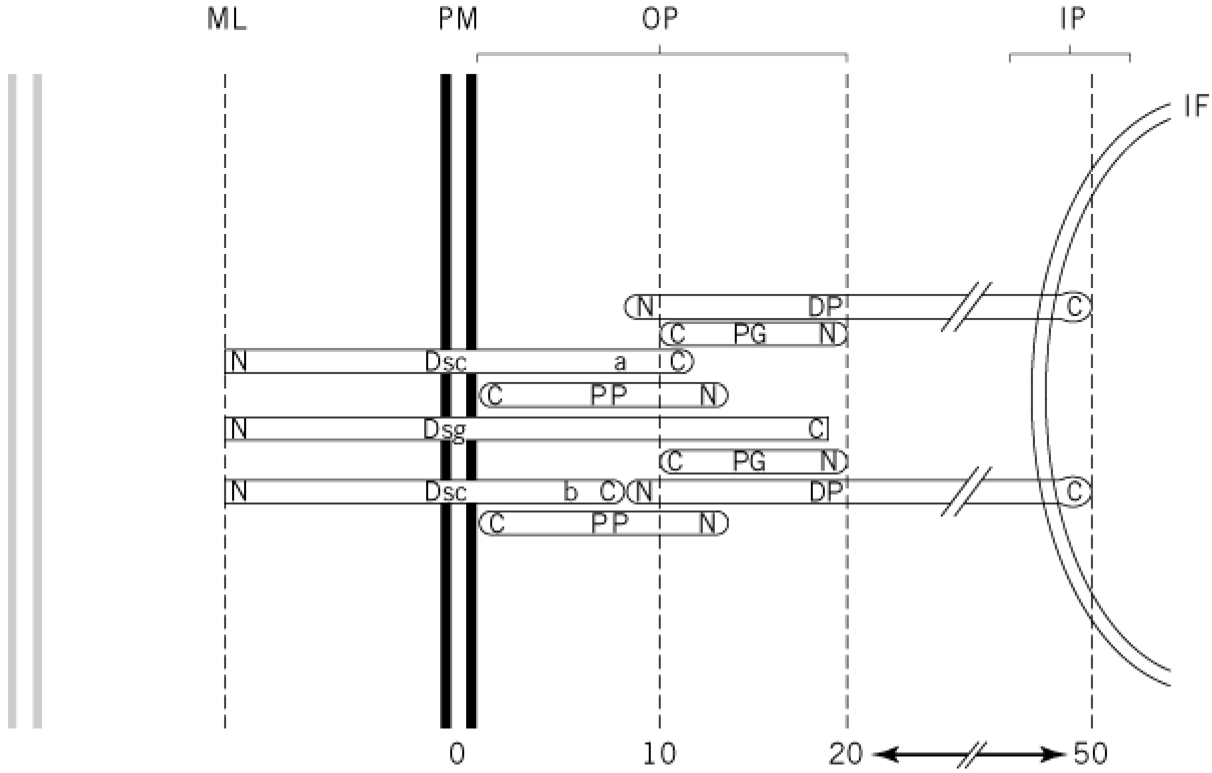
Desmosomes are punctate, adhesive intercellular cell junctions that bind cells together and provide membrane anchoring points for the intermediate-filament cytoskeleton (Fig. 1). They are circular membrane domains of up to 0.5 µm in diameter. The intercellular material, or desmoglea, has a highly organized ultrastructure consisting of an electron-dense midline that is bridged to the plasma membranes of the adhering cells across a distance of ~30 nm. Close to the cytoplasmic faces of the plasma membranes are dense outer plaques, the most consistent and easily recognizable feature of these junctions, approximately 20 nm in thickness. At about 50 nm from the plasma membranes are less dense inner plaques that appear to associate with the intermediate filaments. Thus the total thickness of a desmosome from one inner plaque to the other is approximately 130 nm. The desmosomes may be thought of as the "scaffold couplings" that link the intermediate filament cytoskeleton throughout a tissue. Widely distributed, desmosomes are especially abundant in stratified epithelia, where strong intercellular adhesion is required to resist external friction. They are present in almost all epithelia, but also in cardiac muscle, the arachnoid and pia of the meninges, and the follicular dendritic cells of the lymphoid system.

Figure 1. An electron micrograph of a desmosome from mouse tongue epithelium, showing the midline (ml), the outer and inner plaques (op and ip), and the intermediate filament (if) or tonofilament.



Desmosomes are macromolecular complexes consisting of at least six interacting proteins (Fig. 2). Their adhesion molecules are the desmocollins and desmogleins, members of the cadherin family of calcium-dependent cell **adhesion molecules** (1, 2). These transmembrane proteins have their extracellular domains in the desmoglea and their cytoplasmic domains in the dense outer plaques. The outer plaque contains two proteins that are members of the armadillo family named after the *Drosophila* segment polarity signaling gene. These are plakoglobin (3), also known as g-catenin and present in other intercellular junctions, and plakophilin (4). The outer and inner plaques are bridged by the plakin family member desmoplakin (5), which mediates interaction between the adhesive domain and the intermediate filaments. The most recently discovered desmosomal components are the two plakin family members, envoplakin (6) and periplakin (7), which although not exclusively epidermal, appear to be involved in cornified envelope formation.

Figure 2. Diagram showing the major principle molecular components of the desmosome and their location within its structure. The diagram shows one-half of a demosome from the midline (ml) in the intercellular space, through the plasma membrane (pm) and the outer plaque (op), to the inner plaque (ip) and the intermediate filaments. The numbers at the bottom represent distances in nanometers from the plasma membrane. The amino-terminus (n) and the carboxy-terminus (c) of each component is indicated. The positions of these have been mapped by immuno-gold labeling with domain-specific antibodies and electron microscopy (unpublished observations). The components are: DP, desmoplakin; Dsc a, desmocollin “a” form; Dsc b, desmocollin “b” form; Dsg, desmoglein; PG, plakoglobin; PP, plakophilin.



1. Desmosomal Glycoproteins

There is direct evidence that the desmocollins (Dsc) and desmogleins (Dsg) mediate desmosomal adhesion, probably by a heterophilic interaction (8). Adhesive interaction probably involves tripeptide sequences known as "cell adhesion recognition sites" near the amino termini of the glycoproteins (9). These molecules represent two subfamilies of the cadherin superfamily, each occurring as three different isoforms and the products of different genes. The molecules resemble classical cadherins in their extracellular domains, but show unique features cytoplasmically. Desmocollins have **alternatively spliced** cytoplasmic **domains** [the longer "a" form and a shorter "b" form (10)], and the desmogleins have long cytoplasmic domains containing unique 29-amino-acid-residue repeats (11). The extracellular domains of these glycoproteins form an ordered array, giving rise to the highly structured desmosomal midline region or desmoglea. Their cytoplasmic domains contribute to the structure of the cytoplasmic plaque. The precise roles of the different cytoplasmic domains are unclear. That of the desmocollin "a" form can support plaque assembly and intermediate filament attachment (12), but the functions of desmoglein and desmocollin "b" in plaque assembly have not been resolved. Both desmocollin and desmoglein have been shown to bind plakoglobin and plakophilin, and desmocollin "a" can also bind desmoplakin. Three isoforms of desmocollin and desmoglein show tissue-specific expression (13, 14). Dsc2 and Dsg2 are ubiquitous in all desmosome-bearing tissues, but Dsc1, Dsg1, Dsc3, and Dsg3 are largely restricted to stratified epithelia. Desmosomal glycoprotein genes are closely linked on chromosome 18q12, and this is of possible significance for regulation of the expression.

2. Plakoglobin

Plakoglobin is a member of the *armadillo* family of proteins. It is not exclusively desmosomal but also occurs in adherens or intermediate junctions, even in non-desmosome-bearing tissues such as endothelia. It is, like b-catenin and armadillo itself, both a junctional protein and a member of the **wingless** Wnt signaling pathway (15). In its junctional role, it combines both with desmocollin and desmoglein, or with E-cadherin, where it is mutually exclusive with that of b-catenin. Null mutations of desmoplakin in mice result in severe disruption of desmosomes in cardiac muscle and epidermis. In its signaling role, it has been shown to produce axis duplication when overexpressed in *Xenopus* embryos and combined with the adenomatous polyposis coli (APC) protein that regulates its cytoplasmic level. The cytoplasmic plakoglobin can bind to the LEF-1 transcription factor to enter the nucleus and regulate gene activity (16).

3. Plakophilin

This is an armadillo family protein that has important junctional properties and possibly a signaling function. It exists as two isoforms that show differential tissue specific expression, PP1 being predominantly expressed in stratified tissues (17) and PP2 ubiquitously (18). The first human genetic disease resulting from a desmosomal mutation was an epidermal dysplasia/skin fragility syndrome, effectively a PP1 null mutation (19). This defect resulted in loss of adhesion between epidermal keratinocytes and detachment of intermediate filaments from the cell periphery, indicating an important role for plakophilin in linking between the desmosomal adhesion molecules and the cytoskeleton. Plakophilin has been shown to bind to both desmosomal glycoproteins, desmoplakin and cytokeratin (20). Its potential signaling role is inferred from its armadillo-type structure and because it has been detected in cell nuclei.

4. Desmoplakin

This is a plakin family member, together with plectin, bullous pemphigoid antigen 1 (BAPG1), envoplakin, and periplakin (6, 7). Except for BAPG1 all have been reported to be associated with desmosomes. Desmoplakin (DP) is a ubiquitous desmosomal component. DP1 is a coiled-coil dimer with globular end **domains**. The isolated molecule has an overall length of 130 nm. DP2 lacks the central coiled rod domain and is unable to dimerize. Its length is 43 nm. Expression studies, supported by immunogold labeling and electron microscopy (see Immunoelectron Microscopy), show that the amino-terminal globular domain associates with the desmosomal plaque and the carboxy-terminal domain with the intermediate filaments (21, 22). Thus desmoplakin plays an important role in linking between the desmosomal plaque and the cytoskeleton. Although not restricted to epidermis, envoplakin and periplakin were only identified as components of the cornified envelopes of suprabasal keratinocytes (6, 7). They are essentially similar in structure to desmoplakin, and their precise role has yet to be defined. The role of plectin is more problematic, because null mutations have no apparent effect on desmosome structure and function.

Desmosomal glycoproteins are target antigens in the **autoimmune** blistering disease of pemphigus (23). Desmosomes appear at the 32- to 64-cell stage of embryonic development, where they are trophectoderm specific (24).

Detergents

1. Detergents as Amphiphilic Molecules

Gene expression studies in both **eukaryotes** and **prokaryotes** eventually require detecting and enriching the expression product, usually a protein. When this gene product is a water-soluble, **cytosolic** protein, detecting and enriching it can begin by simply homogenizing the cells, followed by **centrifugally** separating the supernatant from the membrane-bound proteins that remain in the pellet. When the **gene** product is a plasma membrane protein, however, the task is complicated because the protein has to be detached from the membrane at some stage. Although some loosely attached proteins are released by treatment with salt solutions, integral membrane proteins are released only upon treatment with amphiphilic reagents, also termed detergents .

By definition, amphiphiles harbor both hydrophilic and **hydrophobic** moieties. In a water-oil or water-lipid mixture, detergent molecules accumulate at the interface. The hydrophobic arm is inserted into oil or lipid, and the hydrophilic (polar) end is introduced into water, thus justifying the adjective "*amphi*philic" used to describe this class of compounds. Depending on the degree of polarity, the hydrophilic end (the polar head group) of a detergent is either ionic or nonionic. Regardless of the difference in polar head groups, all detergents dissolve in water. The physicochemical properties of detergents dissolved in water have been the focus of vigorous biochemical research.

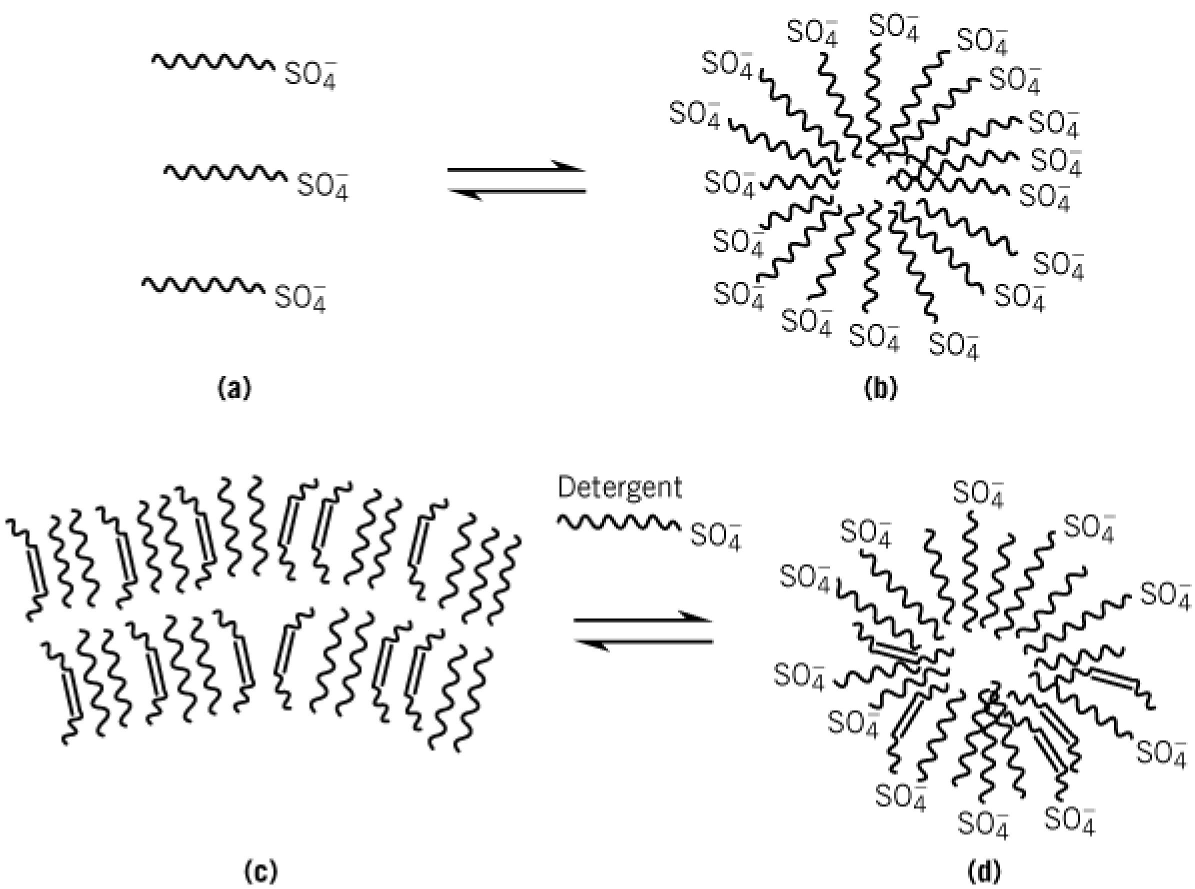
1.1. Physiological Importance of Detergents

Amphiphilic substances or detergents are central to our existence as living organisms. About 80% of the lipids in the alveolar lining is dipalmitoyl phosphatidylcholine that acts as a detergent to confer the crucial nonatelectic property to the lungs. This unusual proportion of a particular phospholipid is important because lower levels of this lipid in the alveolus lead to atelectasis (collapsed alveolus) in infants. Similarly, bile acids are crucial detergent molecules in the intestines. Bile acids emulsify water-insoluble fat molecules and thus help the intestinal lining to absorb them. The powerful detergents, lysophospholipids, produced in the intestine by phospholipase A_2-mediated cleavage of the C_2 fatty acid chains of phospholipids, also aid in lipid digestion. In fact both bile acids and lysophospholipids aid in lipid absorption and also help in absorbing and removing the metabolic products of fats and lipids.

2. General Strategy for Obtaining Solubilized and Reconstituted Membrane Proteins

Solubilization of a membrane protein is a procedure in which the proteins and lipids, originally cradled in the membrane, are dissociated appropriately in a buffered detergent solution. This controlled dissociation of the membrane results in the forming small protein and lipid clusters that remain dissolved in the aqueous solution. Next the solubilized material is separated from any insoluble substance (aggregated proteins and lipids that are dissociated by the detergent) by centrifugation. Then, the detergent is removed from the solubilized material because only after removing the detergent do the solubilized proteins and lipids reaggregate appropriately so that the activity of a functional protein is restored. Many of the functional membrane proteins retain their activity only when they are allowed to associate with other specific membrane proteins and lipids. Such reaggregation is inhibited in the presence of the dissociation-promoting detergent. Typical methods to remove detergents include (1) extensive dialysis of the detergent-solubilized fractions, whereby the detergent monomers are released from the dialysis bag; (2) **gel filtration**, which helps to retain the detergent monomers on the column while the high molecular weight, solubilized proteins flow through; or (3) hydrophobic chromatography, whereby the hydrophobic detergent molecules are removed by absorption into a hydrophobic matrix. The success of each procedure depends on the physicochemical properties of the detergent, which determine the formation of detergent aggregates, termed micelles (Fig. 1). Therefore, it is important to identify and define some of the factors that regulate aggregation of detergent molecules. The critical micelle concentration (cmc) is the maximum concentration at which the detergent molecules remain as monomers. Removal of detergents by dialysis or gel filtration occurs through the monomer and is difficult when the cmc is very low.

Figure 1. Structures of detergents and micelles. At the critical micelle concentration (cmc), monomeric molecules (**a**), which are stable below cmc and removable by dialysis, aggregate to form a spherical or cylindrical macromolecular micelle (**b**), which is stable above the cmc and cannot be removed by dialysis. In a micelle, the hydrophobic ends of the detergent molecules are pointed inward and away from water whereas the polar ends (head groups) are pointed outward into the aqueous phase. In the presence of a plasma membrane bilayer containing saturated and unsaturated fatty acid containing phospholipids (**c**), mixed micelles (**d**) that contain detergent molecules and plasma membrane lipids and proteins are formed.



2.1. Different Classes of Detergents and Their Applicability in Solubilizing Membrane Proteins

As shown in Fig. 2, the various detergents can be structurally classified as follows:

1. Negatively charged, strongly ionic detergents: (a) a detergent with a long, flexible aliphatic chain: sodium dodecylsulfate (**SDS**) (cmc ~0.23% (*w*/*v*) or 8 mM); (b) a detergent with a rigid structure: sodium cholate (cmc ~0.43% or 10 mM). Sodium cholate (1%) has been used to solubilize the adenylate cyclase-G-protein complex (1), the dopamine D1 **receptor** (2) and many other receptors.
2. Detergents that form hydrogen bonds: (a) detergents with flexible long-chain structures: octanoyl- *N*-methylglucamide (MEGA-8) (cmc ~1.9% or 60 mM), and a long chain polyoxyether, Thesit (cmc ~0.005% or 0.09 mM), which is structurally similar to Lubrol. Although 0.5% MEGA-8 has been used to solubilize intrinsic membrane proteins (3), a Thesit concentration of 1.2% has been used with membrane proteins, such as adenylate cyclase (4). (b) more polar but non-ionic detergents with sugar rings, *n*-dodecyl-ß-maltoside (cmc ~0.009% or 0.18 mM) and n-octyl-ß-glucoside (cmc ~0.7% or 23.2 mM), which have been used to solubilize the nicotinic acetylcholine receptor [1% *n*-octyl-ß-D-glucoside, (5)], opioid receptors [0.3% *n*-octyl-ß-D-glucoside, (6)], **GABA**$_A$ receptors [1% *n*-octyl-ß-D-glucoside, (7)], photoreceptor guanylate cyclase [1% *n*-dodecyl-ß-D-maltoside, (8)], and others.
3. Hydrophobic detergents with long polyoxyether chains and aromatic rings: **Triton X-100** (cmc ~0.013% or 0.2 mM) and Triton X-114 (cmc ~0.011% or 0.21 mM), which are used to solubilize the receptors for GABA [2% Tr X-100, (9)], prostacyclin (10), prolactin [1% Tr X-100, (11)], transferrin [1% Tr X-100, (12)], insulin [2% Tr X-100, (13)] and a neuronal growth cone protein, GAP-43 [1% Tr X-114, (14)].
4. **Zwitterionic** detergents: (a) a detergent with a flexible, long-chain structure: *N*-dodecyl-*N,N*-dimethyl-3-ammonio-1-propanesulfonate (in short, propanesulfonate) (cmc ~0.12% or 3.6 mM); (b) detergents with a rigid structure: CHAPS (cmc ~0.46% or 7.4 mM) and CHAPSO (cmc

~0.5%, 8 mM), commonly used to solubilize receptors, such as those for colony-stimulating factor [0.5% CHAPS, (15)], opiates [0.6% CHAPS, (16)], neurotensin [0.6% CHAPS, (17)], **somatostatin** [0.6% CHAPS, (18)], adenosine A_1 [2.5% CHAPS, (19)] and human prostatic sex-hormone-binding globulin receptor [6.0% CHAPS, (20)].

5. Positively charged, strongly ionic detergents, for example, cetylpyridinium chloride.
6. Nonionic surfactants that form inclusion complexes, for example, cyclodextrin.
7. Specific detergents, such as digitonin, used to solubilize opioid receptors [2% digitonin, (21)], neurotensin receptors [2% digitonin, (22)], ß-adrenoreceptors (23), dihydropyridine Ca^{2+} channels [1% digitonin, (24)], and many others.

Figure 2. Classification of detergents based on structural features.

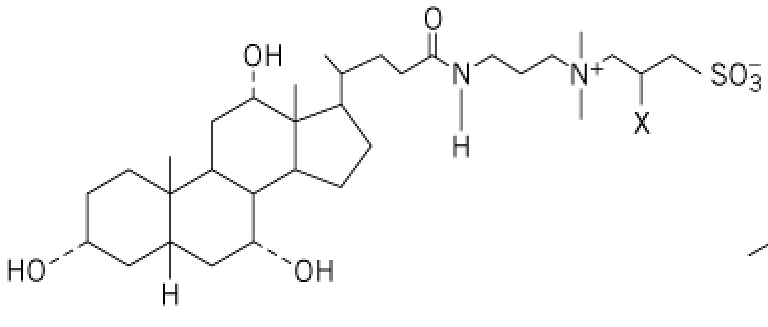
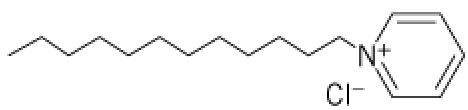
N-Dodecyl-N, N-dimethyl-3-ammonio-1-propanesulfonate (Propansulfon)



3-[(3-Cholamidopropyl)dimethylammonio]-1-propanesulfonate(CHAPS) (X=H)
3-[(3-Cholamidopropyl)dimethylammonio]-2-hydroxy-1-propanesulfonate(CHAPSO) (X=OH)



Cetylpyridiniumchloride (CPC)

Thus, the detergent concentrations used for solubilizing most biologically active receptor proteins are typically in the range of 0.5 to 2.0% (w/v), suggesting that for practical purposes the cmc is not the deciding factor for choosing detergent concentration. Instead, it is obtained empirically by optimizing protein-solubilization conditions.

The other key factor in solubilizing biologically active membrane proteins is the ratio of detergent to protein maintained during solubilization. The commonly used ratios are 1:1 (16, 19) and 2 to 3:1 (4, 7, 8). Higher ratios, such as 10:1 (20) are used less often. Optimization experiments observed that the coextracted lipids are essential for reconstituting the solubilized, sheep brain serotonin 5-HT$_{1A}$ receptor (25), and the highest yield of the active 5-HT $_{1A}$ sites was obtained with 2% CHAPS at a detergent to protein ratio of 2:1 (26). This topic is discussed in more detail later.

2.2. Other Uses of Detergents

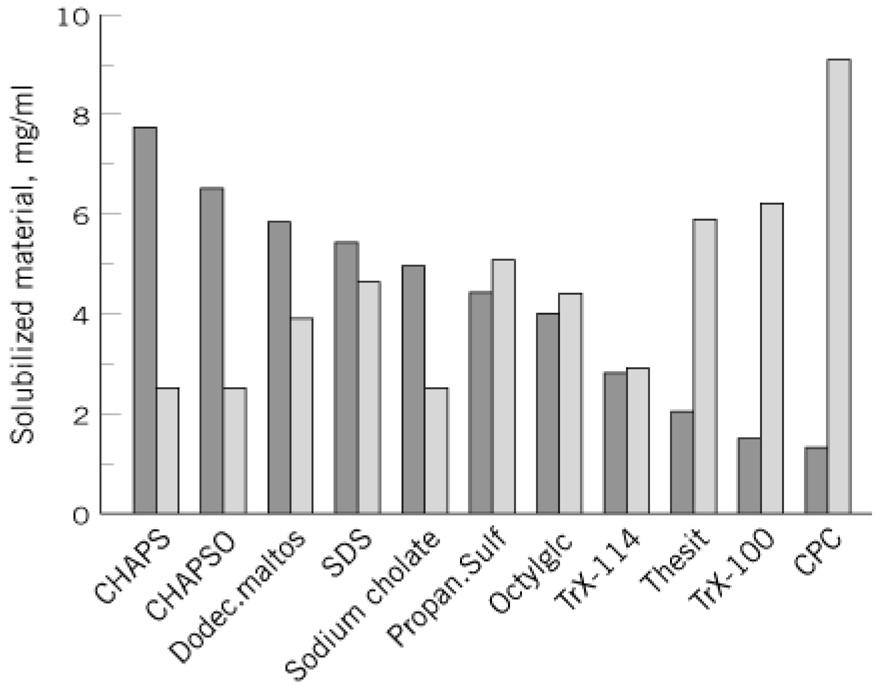
Detergents are also used in purifying **DNA** and **RNA** molecules. For example, SDS is used to denature polynucleotide molecules during the preparation of DNA, and a structurally related detergent, sodium salt of *N*-laurylsarcosine (Sarkosyl), is used in preparing RNA (27, 28). In either case, the detergent is used to denature the biopolymers and also to inhibit certain enzymes, such as **deoxyribonucleases** and **ribonucleases**, which degrade these molecules. Thus detergents are inseparable from scientific activity whether it is to solubilize lipids and proteins or to purify DNA and RNA.

2.3. Detergent Solubilization of Membrane Lipids

A survey of the literature (1-26) indicates that there is no general agreement on the choice of detergent for a single membrane protein, and the use of five or more different classes of detergents for a given receptor solubilization, usually at a concentration 1 to 2%, irrespective of the cmc, is quite common. This could account for the variable recovery of biological activity in different preparations, but it does not explain the differential efficacy of the different detergents in solubilizing active receptor proteins.

To resolve this question, the protein- and lipid-extracting abilities of each detergent in Fig. 2 were determined. Sufficient variability was observed to explain much of the bewildering variability in the recovery of biological activity reported in the literature (26). The receptor molecule used as a marker in this study was the sheep brain serotonin 5-HT $_{1A}$ receptor, which is a member of the receptor family with seven transmembrane regions, and may couple either to adenylate cyclase or phospholipase C, depending on the type of cell in which it is expressed (26). Solubilized, high-affinity serotonin 5-HT$_{1A}$ receptor sites are reconstituted only by coextracted lipids, and adding separately isolated, pure or mixed lipids during or after solubilization is completely ineffective in reactivating an inactive preparation (25). Instead, adding lipids or lipid vesicles to already solubilized, reconstituted (in coextracted lipids) and active 5-HT$_{1A}$-R preparations inhibits the **ligand-binding** activity of the receptor. Such findings indicated that coextraction of plasma membrane lipids is important in order to maintain the functionally active conformation of lipid-sensitive membrane proteins, such as the serotonin 1A receptor. So the efficiency of many detergents in solubilizing membrane lipids was studied. Considering the total amount of lipid solubilized by each detergent, detergents with long aliphatic chains that terminate in a negative charge (SDS), a zwitterionic sequence (CHAPS or CHAPSO), or a multihydroxylic-group-containing disaccharide (*n*-dodecyl-b-D-maltoside) (DDM) clearly has greater ability to solubilize lipids, irrespective of the cmc of the detergent (Fig. 3). In contrast to detergents, such as sodium cholate or sodium deoxycholate, which are also efficient in solubilizing membrane lipids, CHAPS, CHAPSO and DDM solubilized active 5-HT$_{1A}$ receptors. These results indicate that CHAPS, CHAPSO, and DDM, which are relatively milder and nondenaturing, allow the 5-HT$_{1A}$-R-membrane lipid complex to remain undisturbed during solubilization, thus allowing recovery of the active 5-HT$_{1A}$-R following removal of these detergents (25, 26).

Figure 3. Concentration of proteins and lipids (mg/mL) in the detergent-solubilized and reconstituted vesicles, compared to the solubilization of high-affinity 5-HT_{1A} binding sites.



Sodium cholate has a high cmc of approximately 8 mM (or 0.5%) and is easily dialyzed like CHAPS or CHAPSO (both of which have a cmc of ~0.5%). However, although it forms vesicles (because it coextracts sufficient lipid to give a similar lipid to protein ratio of ~2:1) (Table 1 and Fig. 3), the 5-HT_{1A} receptors obtained in the reconstituted preparations are inactive. Possible explanations include nonextraction or denaturation of the protein because of the strongly ionic nature of sodium cholate. Octylglucoside presents a different picture. As a mild, nonionic, dialyzable (cmc ~0.7%) and very mildly denaturing detergent, it is often used to extract biologically active proteins (5-7). However, its inability to coextract sufficient lipid (a lipid to protein ratio of 1:1.1) probably accounts for the low amount of solubilized 5-HT_{1A} receptor activity, which contains less than 15% of the lipids in comparable DDM supernatants.

Table 1. Distribution of Lipids, Protein, and Serotonin $5HT_{1A}$ Receptor Binding Activity in the Vesicles Obtained after Detergent Removal Followed by Dialysis and Ultracentrifugation

Detergents	Lipid, mg/mL	Protein, mg/mL	PE, %	PC, %	PS, %	PI, %	SM, %	GalCers, %	C, %	$5HT_{1A}$ Receptor Binding
CHAPS	7.7	2.5	40.0	17.6	21.0	10.3	0.0	2.8	7.7	5500.0
CHAPSO	6.5	2.5	27.9	16.2	34.0	10.0	0.7	2.7	8.5	5300.0
Dodecylmaltoside	5.8	3.9	18.3	14.8	31.3	5.3	5.9	6.5	17.7	3200.0
SDS	5.4	4.6	22.0	28.7	13.0	6.8	5.0	11.2	14.0	0.0

Sodium cholate	4.9	2.5	18.2	17.0	27.9	6.0	8.5	13.4	8.5	360.0
Propanesulfonate	4.4	5.1	22.8	29.8	19.2	17.2	5.1	8.2	10.6	60.0
Octylglucoside	4.0	4.4	25.0	20.0	24.4	6.5	1.6	8.7	13.6	600.0
Triton X-114	2.8	2.9	32.5	24.2	14.3	7.6	1.5	3.8	15.9	90.0
Thesit	2.0	5.9	14.8	37.0	13.3	5.2	3.0	12.6	14.1	155.0
Triton X-100	1.5	6.2	20.5	27.7	11.6	9.8	2.7	9.8	17.9	80.0
CPC	1.3	9.1	25.0	21.0	22.6	5.7	5.7	9.6	10.7	0.0

The detergents that extract large amounts of protein but are at the lower end of the lipid extraction scale (such as Thesit, Triton X-114, Triton X-100, and CPC) cannot solubilize enough lipid to produce vesicles and do not solubilize active 5-HT_{1A} sites. Therefore, such G-protein-associated receptors require an environment containing particular lipids (enriched in PE, PS and PI) to express their biological properties fully.

The relative amounts of individual groups of lipids solubilized by the different classes of detergents are surprisingly diverse (Table 1). The inverse profiles of PC and PS are intriguing in view of earlier work showing that PC [and GalCer, sulfated GalCer (Su) and SM] are enriched in the outer membrane domain, whereas PS (and PE and PI) are enriched in the inner membrane domain (29-31). From the profile for SM it also appears that this lipid is probably localized in the PC-containing domains. This is agrees well with the idea that choline phospholipids are concentrated in the outer leaflet of the membrane bilayer. It is hard to explain this asymmetrical extraction of lipids in terms other than specific detergent binding by the protein. Thus for eight of the twelve detergents tested, it was found that the solubilization-enrichment profile of PI is similar to that of PE, indicating a similar, inner membrane localization of PE, PI, and PS. PS binds to protein kinase C on the cytosolic face of the plasma membrane and results in activating this enzyme (31). This is consistent with the idea that the PI family is the source of internally released second messengers (32). The serotonin 5-HT_{1A} receptor polypeptide has seven transmembrane **alpha-helices** and three cytosolic loops (26), which could be more strongly associated with inner membrane lipids. Differences in protein folding could explain why a strongly denaturing detergent, such as sodium cholate, is useful in solubilizing and reconstituting the dopamine D1 receptor [which can be reconstituted by adding separately isolated lipids (2)] but is ineffective in solubilizing and reconstituting the 5-HT_{1A} receptors.

3. Summary

The importance of detergents in the normal functions of a living body is irrefutable. In scientific research, detergents provide a powerful means of undertaking subcellular fractionation of macromolecules, such as proteins, RNA, and DNA. Although gene expression studies do not directly begin with protein purification, the expressed protein is finally purified or detected through biochemical methods, such as column chromatography, **Western blotting** analysis, or enzyme assays. If the expressed protein is **lysosomal** or **cytosolic**, simply homogenizing the cells in a hypotonic buffer, followed by separation of the soluble proteins by centrifugation, yields a supernatant that contains the required protein. However, if the expressed protein is, for example, a **mitochondrial** membrane protein, detergent solubilization of this protein is required before its assay. Although in earlier studies such choices of detergents were made empirically, the data presented here provide a stronger foundation for judicious analysis of the efficacy and applicability of many of the commonly used detergents. Thus, for immunoblot analysis, one might use Triton X-100 or Nonidet P-40. To solubilize proteins that do not require membrane lipids for acquiring functional activity, one might use either the Triton family of detergents, the bile acid detergents (eg, sodium cholate), or octylglucoside. On the other hand, if the protein is heavily lipid-dependent, one should test CHAPS, CHAPSO, or DDM before using other detergents. Therefore, this practical overview of the structural classification of detergents with appropriate reference to their applicability to protein and lipid solubilization and to reconstitution of functional activity could be helpful in scientific research involving expression of specific genes.

Development

Development is the process of change in an organism with time. Such change can be either morphological (such as changes in shape or structure), biochemical (such as the synthesis of specialized proteins), or both. Development usually includes all of the changes that occur during the life of an organism. These include fertilization, embryogenesis, maturation, and gametogenesis.

Embryogenesis begins with fertilization of the **gametes** to form the diploid zygote. The zygote undergoes cleavage divisions to form the blastoderm embryo. Changes in cell shape and cell movements at **gastrulation** lead to the formation of the three germ layers: the ectoderm, endoderm, and mesoderm. The process of organogenesis forms the embryonic organs.

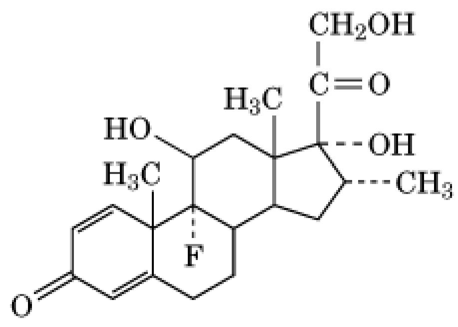
Dexamethasone

Dexamethasone (9a-fluoro-16a-methylprednisolone) (Fig. 1) is a semisynthetic glucocorticoid hormone demonstrating a greater binding affinity for the glucocorticoid **receptors**, a greater potency of action, and a longer half-life, than the natural glucocorticoids. The hormone is used as a drug and in research. Its molecular mode of action is the same as that of the natural glucocorticoids—that is, by binding to the glucocorticoid receptor and activating gene transcription.

Figure 1. Structure of dexamethasone



Dg-Dc Tailing

This procedure is used for cloning cDNA (complementary DNA) prepared from messenger RNA (1). Single-stranded cDNA prepared by **reverse transcriptase** is incubated with the enzyme terminal deoxyribonucleotide transferase and dCTP, which adds 5 to 10 C residues to the 3′ ends of the DNA molecules (C-tail). The second strands are synthesized with reverse transcriptase and oligo-dT as the primer, using the poly A tails of mRNA, and the double-stranded cDNA molecules are tailed with dC as before. The resulting molecules are cloned into **vector** molecules that have been tailed with poly G (about 10 bases per end) to create complementary ends to which the dC tails on the inserts hybridize. A recent modification is to use CTP instead of dCTP, which gives more uniform tails (2).

Diafiltration

Ultrafiltration and microfiltration are able to prepare reasonably concentrated samples of macromolecules, but they permit only a limited separation of the retained solutes from the smaller or more permeable components present in the solution needing to be filtered. In order to remove such smaller components more efficiently from the retained species, the feed solution can be washed in a process known as *diafiltration*. In this process, water or an appropriate buffer solution is added to the retentate during filtration, with the membrane-permeating species being removed as the excess fluid or buffer is filtered. Such a process may be undertaken in two different modes: continuous, in which the wash fluid is added throughout filtration, or discontinuous, in which the feed solution is first concentrated by a predetermined amount using standard ultrafiltration techniques, the wash fluid is then added, and the process repeated any number of times until the final solute concentration is achieved. When using continuous diafiltration, the amount of solute remaining in the retentate may be determined from a mass balance and expressed as

$$\frac{C_R}{C_0}\exp(-N_D S) \tag{1}$$

where C_R is the concentration of the retentate, C_0 the initial concentration, N_D is the number of diavolumes, defined as the total volume of the wash fluid divided by the initial volume of the solution, and S is the solute sieving coefficient.

For discontinuous diafiltration, it is given by

$$\frac{C_R}{C_0} = \left(\frac{V}{V_0}\right) - (n+1)S \tag{2}$$

where n corresponds to the number of discontinuous diafiltration procedures.

Diagonal Methods

It is often desirable to purify selectively those peptides from a protein that contain a particular amino acid, such as all the peptides containing **cysteine residues**. This is accomplished most elegantly by so-called "diagonal" techniques (1), which rely on a change in the properties of peptides caused by the selective modification of the amino acid residues of interest. If a mixture of peptides, generated by **proteolysis** of a protein for peptide mapping, is separated in one dimension and then subjected to the same procedure a second time, but at right angles to the first, all the peptides will lie on a diagonal because they had the same mobilities in both directions. The separation can be by electrophoresis or chromatography, but it should be carried out on a two-dimensional medium, such as paper or thin-layer plates. To detect certain peptides, and to cause them to have a different mobility in the second dimension, the entire mixture of peptides is treated after the first separation so as to modify all the residues of a particular type and to change their separation properties. After the second dimension separation, the peptides containing these residues consequently lie off the diagonal of all the other peptides and are readily identified and isolated.

1. Isolating Peptides Containing Certain Amino Acids

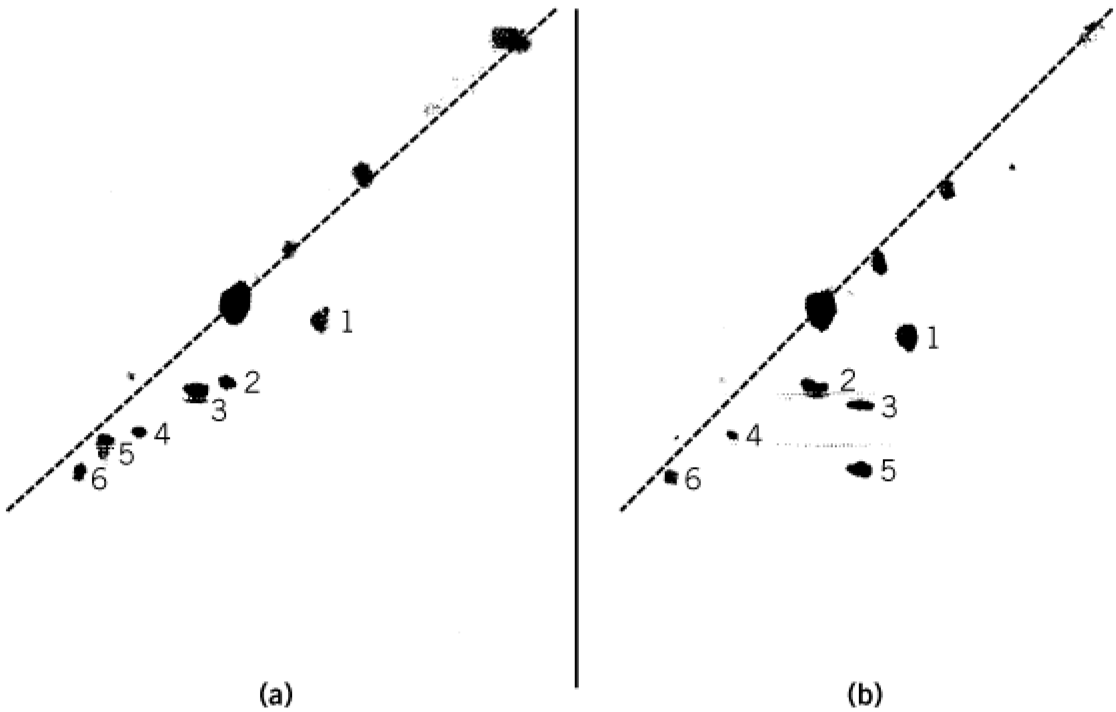
For example, peptides containing Cys residues can be purified by blocking their thiol groups by reaction with **iodoacetic acid** (Fig. 1a) (2). A two-dimensional diagonal peptide map is prepared by electrophoresis at pH 3.5, exposing the peptides to performic acid between the two separations. This oxidizes the sulfur atom of the modified Cys residues to the sulfone:

$$-CH_2-S-CH_2-CO_2^- \xrightarrow{[O]} -CH_2-\overset{O}{\overset{\|}{\underset{\underset{O}{\|}}{S}}}-CH_2-CO_2^- \quad (1)$$

carboxymethyl-Cys

which lowers the pK_a value of the carboxyl group, so that peptides containing Cys residues are somewhat more acidic in the second dimension; they then lie to one side of the diagonal. Alternatively, the thiol groups can be reacted initially with *N*-ethylmaleimide (see Thiol Groups); the *N*-ethylsuccinimide group introduced can then be hydrolyzed to the succinamic acid by treatment with ammonia after the first separation (3).

Figure 1. Isolation and identification of cysteine residues linked by disulfide bonds or modified by reaction with iodoacetate (2). The proteins were digested with trypsin, followed by chymotrypsin, and the resulting peptides were separated by paper electrophoresis at pH 3.5 in the horizontal direction (anode at the left). After exposure to performic acid vapor, the electrophoresis was repeated in the vertical direction (anode at bottom). The peptides were visualized by staining with ninhydrin. The diagonal indicated by the dashed line is defined by peptides that were not altered by the performic acid and consequently had the same mobility in both dimensions; many of these peptides have migrated off the paper. (**a**) Reduced BPTI (bovine pancreatic trypsin inhibitor) in which the six Cys residues have been blocked by reaction with iodoacetate. The six peptides containing these residues define a second diagonal, below the first, because they were slightly more acidic in the second dimension due to their oxidation to the sulfone. These peptides are identified by the numbers of the Cys residues they contain. The amino acid residues they contain are, starting from lower left to upper right, 54 to 58 (Cys55), 27 to 33 (Cys30), 5 to 15 (Cys5 and 14), 47 to 53 (Cys51), 1 to 15 (Cys5 and 14), and 36 to 39 (Cys38). (**b**) The major one-disulfide intermediate in the BPTI disulfide folding pathway (see Protein Folding In Vitro) that had been trapped by reacting all the four free Cys thiol groups with iodoacetate. The two peptides containing Cys30 and Cys51 are absent from the second diagonal of modified Cys residues and had the same mobility in the first dimension, indicating that they were originally linked by an intramolecular disulfide bond between these two Cys residues.



Analogous techniques have been developed for a few other residues, using appropriate chemical modifications specific for these residues. The amino groups of **Lys**-containing peptides are initially blocked with trifluroacetyl or maleyl groups, by treatment with the corresponding anhydride; these groups alter the charge and are easily removed after the first electrophoresis by acidification. **Met** residues are first alkylated with **iodoacetamide** to produce the charged sulfonium derivative. After the first electrophoresis, heating causes this derivative to cleave the polypeptide chain by a reaction analogous to that occurring in cleavage by cyanogen bromide. **His** residues are first blocked by dinitrophenylation of the side chain and then regenerated after the first electrophoresis by exposure of the peptides to a thiol-containing reagent. **Arg** residues are first blocked by reaction with cyclohexanedione and then regenerated at alkaline pH. **Trp** residues are modified by *o*-nitrophenylsulfenyl chloride after the first separation (4).

2. Characterizing Disulfide Bonds

Diagonal techniques were initially introduced by Brown and Hartley (1) for the determination of which pairs of Cys residues in a protein were linked by disulfide bonds. The protein is prepared for peptide mapping and the peptides are separated in the first dimension, under conditions where the disulfide bonds are stable and cannot rearrange or be reduced; the pairs of peptides linked by disulfide bonds consequently migrate together (Fig. 1b). The disulfide bonds are then cleaved by exposure to performic acid, which converts each such Cys residue to cysteic acid:

$$-\mathrm{Cys}-\mathrm{S}-\mathrm{S}-\mathrm{Cys}- \rightarrow 2-\mathrm{Cys}-\mathrm{SO}_3^- \tag{2}$$

The peptides originally linked by the disulfide bond are now independent and more acidic. During separation in the second dimension, they migrate differently and lie off the diagonal, but they can be related by their common mobility in the second dimension.

Diagonal techniques are best suited to two-dimensional separations, such as paper electrophoresis and chromatography, which were used extensively in the past but have now been supplanted by more modern techniques that require less material, but operate in a single dimension, such as **HPLC**. The same basic technique can be used, but the fractions from the first separation must be separated again individually.

Dialysis

Dialysis is the transport of a solute through a membrane under the influence of a difference in the concentrations (or activities) of the solute in the solutions separated by the membrane. The separation of solutes is induced by differences in their transport by diffusion through the membrane matrix. A diffusable low-molecular-weight solute can thus be separated from a solution containing nondiffusable large macromolecules. The rate of dialysis is directly proportional to the membrane area and inversely proportional to the membrane thickness. Since the 1960s, the principal clinical use of this technique has been the treatment of patients with kidney disease.

Nonclinical applications of dialysis techniques for the separation of solutes with molecular weights ranging from 100 to 100,00 Da may be on a small laboratory scale or with larger-scale commercial units for the recovery of alkai or in food processing applications. Dialysis is also important in biotechnology, as it provides a technique whereby products can be separated from fragile shear-sensitive or heat-sensitive solutions. A number of variants of the technique exist. These may be divided into batch and continuous processes. The simplest batch process is one in which a semipermeable membrane tubing made from cellulose and sealed at one or both ends contains the solution of interest. The tubing is suspended in a buffer solution or water. Small molecules contained within the solution bounded by the membrane diffuse into the surrounding buffer solution. The transfer of the substance across the membrane obeys Fick's law, if we assume that chemical equilibrium is established between the membrane and solution. If no water transfer occurs, and the mass transfer coefficient is constant along the diffusion path, the amount of substance transferred through the membrane W may be expressed as

$$W = DA\Delta C \quad (1)$$

where D is the overall dialysis coefficient of the substance, A the membrane area, and DC the logarithmic mean bulk concentration difference across the membrane based on the initial and final values.

A variation of equilibrium dialysis is *reverse dialysis*, in which the fluid contained in the semipermeable membrane tube is placed into a water-soluble polymer, such as polyethylene glycol. This causes the water to diffuse out of the membrane tube and concentrates the macromolecule within the tube.

For batch dialysis, where mass transfer is not at steady state, the transfer rate is given by

$$kt = -m \log_e \left(\frac{C_0 - C}{C_0} \right) \quad (2)$$

where k is the dialysis rate constant, t the time, m the volume of the feed ratio to diffusate, C_0 the concentration of the feed, and C the concentration of the dialysate.

Equilibration of the low-molecular-weight solutes or electrolytes by this technique can be speeded up by ensuring that the area of membrane contact is large relative to the volume of solution being dialysed. Since any molecule from the solution held within the membrane has to pass through the stagnant fluid film or boundary layer on either side of the membrane, as well as across the membrane itself, the overall dialysis rate may be enhanced by the minimization of the stagnant layers. This can be achieved by the introduction of a stirrer into the system, or by frequent changes of the dialysis fluid.

The transfer rate is also dependent on temperature. Biological materials such as proteins usually need to be dialyzed in the cold to minimize bacterial growth or protein **denaturation**. Under such conditions, the transfer of molecules will be reduced compared with that at room temperature.

If the solution requiring to be dialyzed is available in a sufficiently large quantity, continuous methods that use a *countercurrent flow* configuration to maintain a large difference in the solute concentration across the membrane may be used. For such systems, which are similar to those used in the treatment of renal failure, the amount of solute transferred across the module, if we assume that the membrane is the primary barrier to diffusion, may be expressed as

$$Q(C_{\text{in}} - C_{\text{out}}) = kA\Delta C \quad (3)$$

where Q is the flow rate of the solute undergoing dialysis, C_{in} and C_{out} are the concentrations at the inlet and outlet, k and A are as previously defined, and DC is the log mean concentration difference between the dialysis fluid and the fluid being dialyzed.

Many substances **bind** to proteins or plasma. The solute transfer referred to above relates to an unbound solute. However, a bound solute will be in equilibrium with the unbound solute, the extent of the binding being governed by the solute **association constant**. The effect of this will be that there will be an overestimate of the concentration driving force present. As free solute is removed, there will be unbinding of the solute with the effect of understating the concentration driving force.

In a single-pass situation, ie, where the dialyzing fluid flows to waste and the solute undergoing dialysis is recirculated, the solute exchange rate within the module used for dialysis is expressed in terms of dialysance D, defined as

$$D = \frac{\text{Change in concentration of the incoming solute}}{\text{Concentration driving force}} \tag{4}$$

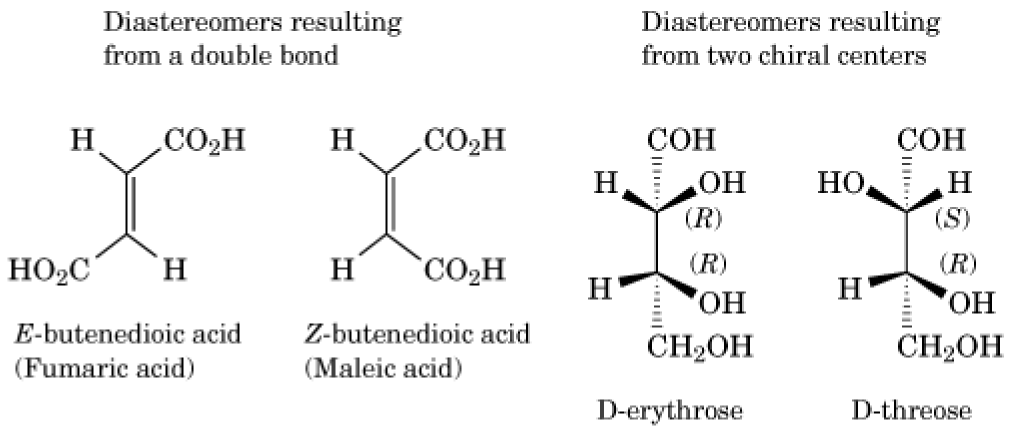
The generalized concentration driving force will be determined by the Donnan factor a, defined as the ratio of the ionic concentrations in the dialysis fluid and in the solute undergoing dialysis at equilibrium. If the solute is noncharged, a = 1, and the measurement of the transport rates may occur by the use of a single pass flow configuration on the dialyzate side, while the fluid being dialyzed is recirculated. In such a flow configuration, provided that the volume being dialyzed V is unchanged, the concentration at time t, C_t, may be expressed in terms of the removal rate k and the initial concentration C_0 by

$$C_t = C_0 \exp - \left(\frac{kt}{V}\right) \tag{5}$$

Diastereomer

Diastereomers are stereoisomers, molecules that differ only in their spatial arrangement of atoms, that are not enantiomers (1). Diastereomers have different chemical properties. There are several common types of diastereomers. Molecules containing carbon–carbon and carbon–nitrogen double bonds will exist as two different geometric diastereomers, if both of the double-bonded atoms have two different substituents. These diastereomers are differentiated with the designation **cis** and **trans** and more formally as Z and E (from the German zusammen for together and entgegen for opposite). The Z isomer describes the orientation when the two substituents with the higher priority are on the same side of the double bond. In potentially ambiguous cases, the priority of the substituents of each double-bonded atom is determined by the Cahn, Ingold, and Prelog rules (2) (see Configuration). The other common form of diastereomers occurs when a molecule contains more than one **chiral** center. If two stereoisomers contain at least one corresponding chiral center with the same configuration and one corresponding chiral center with the opposite configuration, the molecules will be diastereomers. These two forms of diastereomers are shown in Figure 1.

Figure 1. The two common types of diastereomers are depicted, *cis*/*trans* geometric isomers and molecules containing more than a single chiral center.



Two atoms are referred to as *diastereotopic* if, on substitution with a different isotope, they would generate different diastereomers (1, 3) (see Prochiral). Diastereotopic atoms are chemically different and, importantly, can be distinguished by NMR.

Dicentric Chromosome

Dicentric chromosomes have two centromeres. Such chromosomes are products of chromosomal damage, breakage, and fusion. Dicentric chromosomes normally break at **anaphase**, when the centromeres have separate attachments to the spindle and are subject to forces pulling them apart.

The definition of a chromosome breakage-fusion-bridge cycle in **maize** by McClintock in 1951 was an important step in defining chromosomal dynamics (1). The origin of chromosomal breakage in this case in maize is the transposable element Dissociation (*Ds*), which causes chromosomal instability in the presence of another element called Activator (*As*). *Ds* is present at specific sites in the chromosome and transposes to a different site only in the presence of *As*. Events such as these led to the discovery of transposable elements. Two forms of this cycle have been described resulting in the appearance of either dicentric chromosomes or chromatids.

One type of cycle is shown in Figure 1. Several convenient markers are present on chromosome 9 of maize, which include colored (C1), shrunken (sh1), bronze (bz1), and waxy (wx1). Each of the two chromosomes has a *Ds* element located at the site indicated (*Ds*). When the *Ds* element is activated, chromosome breakage may occur. The acentric fragment without a centromere is lost. The ends of the two sister chromatids fuse to form a bridge, so the resulting single DNA molecule contains two centromeres. At the anaphase, the dicentric fused chromosomal arms break, so that segments of the chromosome are either duplicated or deficient in daughter cells. This cycle occurs either at **meiosis** or **mitosis**.

Figure 1. Chromosome breakage-fusion-bridge cycle in maize. (**a**) A break in maize chromosome 9 at the site of the transposable element *Ds* is indicated. (**b**) At the end of the S-phase and in G2, two sister chromatids are formed that have a break at this site (sticky ends). (**c**) The sticky ends of the two chromatids fuse to form a chromosome containing two centromeres—a dicentric chromosome. (**d**) At the anaphase, the two centromeres may be forced to move in opposite directions, leading to chromosomal breakage and forming two chromosomes, one containing a short duplication and the other a deficiency.

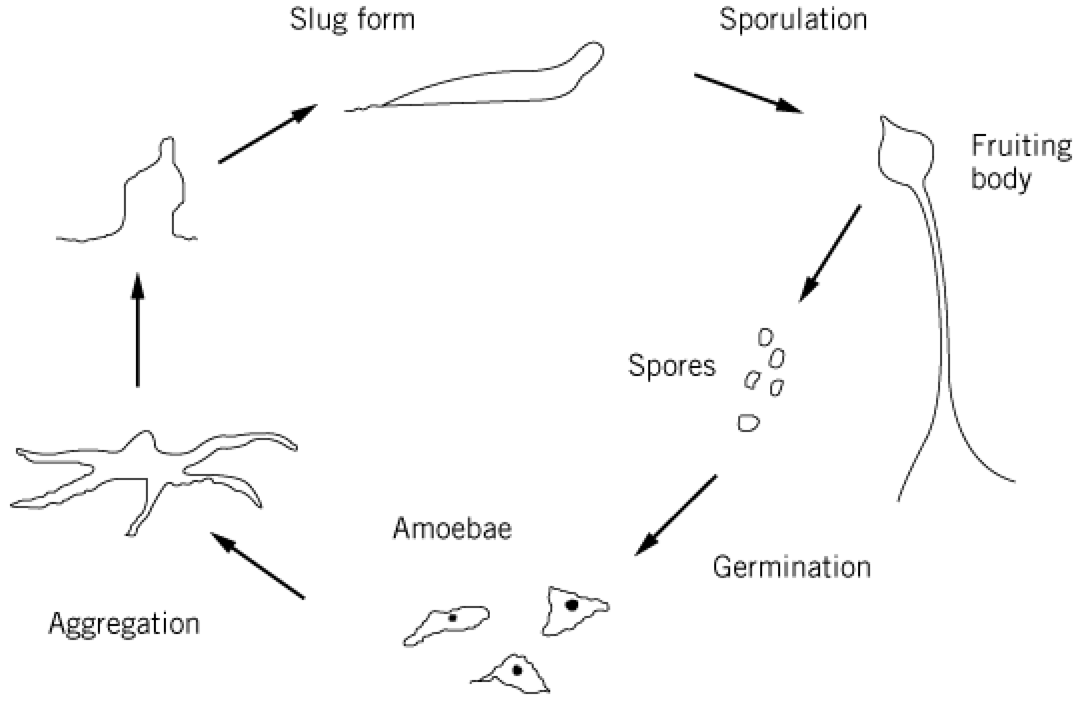
Dictyostelium

The cellular slime mold *Dictyostelium discoideum* has been studied in the laboratory extensively as a model eukaryotic organism. This soil amoeba has provided extraordinary opportunities for molecular biologists and biochemists to examine a wide variety of fundamental cellular functions. Developmental biologists have characterized at the molecular level *Dictyostelium's* unique **developmental** pathway. Single free-living cells can respond to a number of chemical signals, aggregate, and then differentiate into a complex multicellular organism.

A powerful library of techniques has been developed for manipulating this organism in the laboratory. Large numbers of cells can be grown, and proteins can be purified for biochemical characterization and, in some cases, structural characterization. The recent utilization of peptide proteinase inhibitors have made this increasingly easy. Genetic techniques have been developed for making mutations, and sophisticated methods have been applied for analyzing them. Genetic selection can be carried out with a variety of metabolic and drug resistance markers. **Plasmids** that either integrate into the chromosome or replicate extrachromosomally have been constructed from fragments of naturally occurring ones, and a variety of **promoters** are available for obtaining heterologous gene expression. Cell biological techniques are also well developed, yielding information on expression and localization in fixed and live cells.

A simplified schematic of the *Dictyostelium discoideum* developmental pathway is shown in Figure 1. The free-living amoebae feed on bacteria, and they can be found outside the laboratory in forest soils and detritus. In the laboratory, they can be grown in liquid media in shaking flasks or in petri plates, either in liquid media or on agar surfaces. Strains of *Dictyostelium* have been developed that can grow in synthetic and fully characterized media. On surfaces, the amoebae are motile and can use a variety of chemotaxis signals to find food and to optimize growth conditions (1).

Figure 1. A schematic diagram of the *Dictyostelium* developmental cycle.



Under certain conditions, such as the onset of starvation, a population of amoebae can suspend their cell cycle and begin a highly regulated set of gene inductions, which initiates the developmental pathway. In the laboratory, this can be done synchronously. Early in this process, a series of **new enzymes** are synthesized that are responsible for the synthesis, detection, and degradation of cyclic AMP (cAMP). These enzymes are used to regulate the chemotactic response of the cells in such a way that the cells aggregate. A founder cell initiates the aggregation process by secreting pulses of cAMP. Surrounding cells, if they are competent to respond, do so in two ways. First, they migrate toward the cAMP source. Second, they secrete a cAMP pulse themselves, which serves to amplify the signal and to increase the area over which it can travel. An extracellular phosphodiesterase degrades the cAMP between the waves.

As the cells migrate, they form cell–cell contacts that serve to establish polarity signals, which are used as the aggregate forms a mound and the cells differentiate into different types and sort into different locations. The tip of the mound becomes an organizing center which, based on environmental factors, decides whether to proceed in development to a fruiting body or to search for more favorable conditions by becoming a slug. If the organism becomes a slug, the mound tips over on the surface, and the outside cells secrete an extracellular matrix, commonly known as slime, which is left behind on the surface after the organism has passed. The tip of the slug controls its migration direction chemotactically, as well as by detecting gradients of temperature and light. Migration rates can exceed 1 cm/h.

When the mound or slug is ready to proceed to form a fruiting body, the cells have differentiated, through a pattern of differential gene expression, into either of two distinct cell types: pre-stalk or pre-spore. As the pre-stalk cells migrate to the bottom of the forming structure, they differentiate terminally into a plant-like cell with a rigid cell wall. A clorinated alkyl phenone, DIF-1, is released to induce stalk cell differentiation. Pre-spore cells differentiate into small environmentally resistant spores, which are carried up by the forming stalk. The spore sac is quite sticky, which facilitates its use of insect legs as transport in the wild. When conditions are optimal, the spores can germinate and begin dividing once again as amoebae.

The haploid genome of *Dictyostelium* is about 54×10^6 base pairs in six chromosomes, and a detailed map has been assembled (2). The DNA has an unusually high content of A and T nucleotides. Complete characterization of the genome is underway. A wide variety of genetic tools have be developed for manipulation of *Dictyostelium*. Mutations can be created, and the resulting **phenotypes** can be analyzed in many ways. Naturally occurring extrachromosomal plasmids have been isolated and reconstructed into a family of vectors useful in stable or transient expression of heterologous genes. Multiple selectable markers are available, allowing the construction of strains in which complementation can be used to analyze protein–protein interactions. Homologous recombination has been shown to occur, allowing gene knockouts and gene replacements to be made.

Dictyostelium has been particularly useful in the characterization of the fundamental aspects of transmembrane signaling and cell–cell communication in the regulation of motility (3). The organism has the ability to detect and respond to a whole series of environmental factors, such as light, temperature, and moisture. It also can detect a wide variety of chemical signals, from sugars to hormones. *Dictyostelium* uses a variety of mechanisms of intracellular signaling mechanisms, including proton gradients and electrochemical gradients, as well as Ca^{2+} waves (see Calcium Signaling). Analysis of a variety of protein kinases and phosphatases and their target have illuminated a number of regulatory pathways. The dynamic cytoskeleton of *Dictyostelium* has been extensively studied, particularly actin, actin-binding proteins, and the myosins, as well as tubulin, tubulin-binding proteins, and microtubule-based motor proteins. Major rearrangements of the cytoskeleton are required during cytokinesis and cell motility. Analysis of genetic knockouts of individual genes and combinations of those for cytoskeletal proteins have been particularly useful in attempting to determine their cellular roles. Targeted gene disruptions have also been used to characterize the pathways of endocytosis and exocytosis. *Dictyostelium* feeds on bacteria using phagocytosis that is highly regulated and specific (4).

The highly regulated developmental pathway of *Dictyostelium* has been extremely valuable in terms of understanding gene induction and regulation. The appearance and disappearance of specific messenger RNAs have been mapped to specific time points during development, and many of the gene products have been characterized and their function determined. The appearance of different cell types in the aggregate, along with their sorting to yield the final fruiting body, has given insights into positional information and the cell cycle in morphogenesis.

Study of the cellular slime mold *Dictyostelium discoideum*, as a model eukaryotic organism, has produced many insights into basic cellular function. It will continue to make contributions as its many features are probed in more detail.

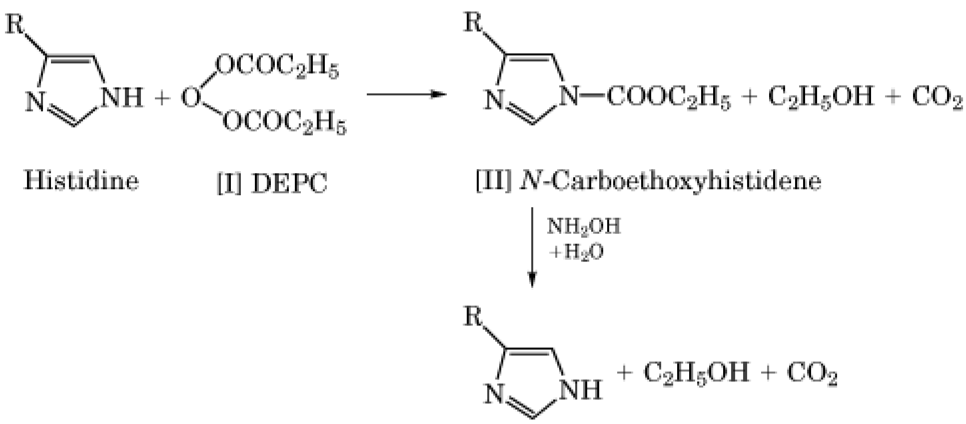
Diethylpyrocarbonate

Diethylpyrocarbonate (DEPC) [I] is an anhydride of ethoxyformic acid and is also called ethoxyformic anhydride (EFA), diethyl dicarbonate, or diethyl oxydiformate. DEPC is a liquid (density = 1.29 g/ml) with molecular weight of 162.14. It is not stable in water and hydrolyzes to two molecules of ethanol and carbon dioxide. DEPC is a good reagent for chemical modification of histidine residues. Because DEPC inhibits **ribonuclease A**, which has histidine residues at its active site, DEPC is widely employed to protect **RNA** from enzymatic attack. DEPC is a suspected carcinogen, and therefore, it should be handled carefully.

Within the pH range 6 to 8, DEPC reacts with histidine residues to give *N*-carboethoxyhistidine [II], ethanol, and carbon dioxide (Scheme 1):

Diethylpyrocarbonate



The product, *N*-carboethoxyhistidine, absorbs UV at 240 nm, and the reaction can be followed spectroscopically (De$_{240}$ = 3,200 M^{-1} cm^{-1}) (1). The product is not very stable. The **half-life** of its decay is 55 h at pH 7 and much shorter at acidic or alkaline pH values. The product is regenerated to histidine by NH_2OH (**hydroxylamine**). DEPC sometimes also reacts with amino groups and with the side chains of cysteine, tyrosine, arginine, and tryptophan residues.

To prevent the action of ribonuclease, 0.2 ml DEPC is added to 100 ml of the solution that is being treated for use with RNA. To inactivate the remaining DEPC, the solution is autoclaved (2).

Difference Fourier

The difference Fourier is an extremely useful electron density map in protein X-ray crystallography. The location of reagents such as inhibitors or water molecules, attached to or removed from the native structure (see **Ligand binding**) is easily determined if the native crystal structure is known. It is not necessary to perform a completely new structure determination for the derivative, so long as the new crystal is isomorphous with the old one, as in isomorphous replacement. Only the intensities of the reflections in the diffraction pattern of the derivative need be collected. A normal electron density map is calculated by the equation:

$$\rho(xyz) = \frac{1}{V}\sum_h \sum_k \sum_\ell |F(hk\ell)| \times \exp[-2\pi i(hx + ky + \ell z) + i\alpha(hk\ell)]$$

If the $|F(hk\ell|$'s in this equation are replaced by D $|F(hk\ell)| = |F(hk\ell)|_{PH} - |F(hk\ell)|_P$, where P stands for the native protein and PH for the derivative, then the resulting difference electron density map shows the difference in electron density between native and the derivative. The density is positive for attachment and negative for removal of atoms (1):

$$\rho(xyz) = \frac{1}{V}\sum_h \sum_k \sum_\ell \Delta|F(hk\ell)| \times \exp[-2\pi i(hx + ky + \ell z) + i\alpha_P(hk\ell)]$$

In calculating this difference Fourier, the phase angles are those of the native protein a_P $(hk\ell)$.

Because of approximations, the heights of the peaks in a difference Fourier are only half of what they would be in a normal Fourier. Nevertheless, it is a powerful method, and the attachment or removal of a few electrons can easily be detected. It also plays a useful role in locating of heavy atoms in the isomorphous replacement method. For example, after the main heavy atom site has been found from a difference Patterson map, additional weakly occupied sites can be detected with a difference Fourier.

Difference Spectroscopy

The absorbance of a chromophore depends on its molecular environment (see Absorption Spectroscopy). It is sensitive to changes in the solvent around an exposed chromophore (see Solvent Perturbation Spectroscopy) or in the exposure of a chromophore as a consequence of conformational transitions, such as the unfolding of a protein or the melting of double-helical DNA (see **DNA melting**). These changes in absorbance are sometimes small, so it is of advantage to measure directly the difference in absorbance between two samples in which the only difference is that the macromolecule is in different environments. This can be done in a double-beam spectrophotometer, where the two samples are placed in the sample and the reference cuvette. This is called difference spectroscopy.

For the measurement of difference spectra, it is of advantage to use an instrument with a high sensitivity, so that small differences between the two samples in the different environments can be monitored reliably and with good accuracy. The development of microprocessor-controlled instruments has greatly facilitated the measurement of difference spectra. The measured data can be stored and manipulated later, eg, by changing the wavelength and absorbance scales, smoothing the data, addition and subtraction of spectra, and the calculation of derivative spectra. Also, difference spectra can be compared with other data already in the computer memory. Changes in spectra during a reaction (kinetic difference spectra) can be measured very well by using a diode array spectrophotometer, because spectra can be recorded at a very short interval.

Differentiation

Differentiation is the expression of specialized functions by a cell (1). Differentiation may be reversible. For example, bacteria express sets of enzymes to facilitate the use of the nutrients that they sense in their surroundings. When the bacteria sense a change in their surroundings, such as a change in the nutrients in their culture medium, they inactivate the set of enzymes appropriate for the first medium and express a different set of enzymes to facilitate use of the new nutrients. As their surroundings change, the bacteria can change back and forth between different sets of enzymes indefinitely.

In most cases, however, differentiation is not reversible. Once a cell begins expressing specialized functions, its future choices become limited. For example, human cells that begin expressing heart-specific proteins no longer have the potential to form skin. As cells become more specialized, they find their potential fates more restricted. The restriction of fates is called *determination*, and it was often shown to occur long before differentiation of any specialized functions. As our molecular tools have become more sophisticated, the distinction between determination and differentiation has become more blurred. Looking for the first detectable signs of differentiation, more sensitive techniques allow us to find molecular differences at earlier stages. When pushed to the limits, molecular techniques have increasingly shown that the basis of determination is the expression of a specialized gene product or function, that is, merely the first step in differentiation.

Diffusion

Diffusion is the movement of molecules within a liquid driven by thermal fluctuations. It is important for most biological processes; indeed, the diffusion together of two reactants can be the limiting factor for many processes, when the reaction is said to be **diffusion-controlled**.

There are two types of diffusional motion: (*1*) *translational diffusion*, where a molecule moves its relative position within a three-dimensional system; and (*2*) *rotational diffusion*, where a molecule spins or rotates about one or more of its axes. The rates at which molecules undergo both types of diffusion are measured by their respective diffusion coefficients, D_t and D_r. The SI unit for D_t is the "Fick," or m^2/s, but for historical and other reasons, biologists tend to use the cgs (Centigrade–gram–second) system unit of cm^2/s. These measurements can give important information about the sizes, structures, and physical properties of the molecules. At room temperature and in dilute solution, a small protein of molecular weight approximately 20,000 will have D_t of about 10^{-6} cm^2/s; a large virus between 10^{-7} to 10^{-8} cm^2/s; a bacterial spore about 10^{-9} cm^2/s. Some representative values are given in Table 1.

Table 1. Translational Diffusion Coefficients and Derived Parameters of Some Molecules, Macromolecules and Biomolecular Assemblies

Substance	Molecular Weight	$10^7 \times D^{j0}_{20,w}$, cm^2/s	r_H, Å	$10^8 \times f$, g/s

Water	18	230	—	—
Sucrose	342	46.0	4.7	0.88
Ribonuclease	13,700	11.1	19.3	3.64
Ovalbumin	45,000	7.8	27.5	5.18
Fibrinogen	330,000	2.0	107	20.2
Dynein[a]	2.5×10^6	1.1*	195	36.7
Turnip yellow mosaic virus	5.7×10^6	1.4	152	28.9

[a] Although the molecular weight of dynein is smaller than that of turnip yellow mosaic virus, its diffusion coefficient is smaller because it is more asymmetric. Values of $D^{0}_{20,w}$ and molecular weight M_r for dynein are also strongly dependent on salt concentration.

1. Translational Diffusion

The translational diffusion coefficient, D_t, describes the tendency of a molecule to move (translational motion) under the influence of either (*1*) a concentration gradient or (*2*) Brownian motion.

The movement of molecules in a gradient in which their concentration varies, *dc/dx*, where *c* is the concentration (in grams per milliliter) at each point *x*, is given by Fick's first law:

$$J = -D_t(dc/dx) \tag{1}$$

where *J* is the mass of particles crossing a 1-cm^2 cross section per second.

The same D_t characterizes the Brownian diffusion of the molecule:

$$\langle x^2 \rangle = 2D_t t \tag{2}$$

where *t* is the time and $\langle x^2 \rangle$ is the average of the square of the distance the particle has moved.

The value of D_t depends not only on the intrinsic size and shape of the molecule but also on the viscosity and temperature of the medium in which it is suspended. The value of D_t must therefore be normalized to standard conditions; the standard conditions normally used are those of water at 20.0° C. The D_t corresponding to these conditions is normally designated $D_{20,w}$. It can be calculated from the value actually measured at absolute temperature T and in buffer "b," $D_{T,b}$, with the equation

$$D_{20,w} = \left(\frac{293.15}{T}\right)\left(\frac{\eta_{T,b}}{0.01}\right) D_{T,b} \tag{3}$$

where $h_{T,b}$ is the viscosity (in cgs units) of the buffer at temperature *T* and 0.01 is the viscosity of water at 20.0°C.

The value of $D_{20,w}$ can also depend on the concentration of the molecule in the solution, due to thermodynamic nonideality resulting primarily from the finite size of the molecule and its electric charge. This nonideality is represented (1) by the parameter k_d (in units of milliliters per gram) in the equation

$$D_{20,w} = D^{\circ}_{20,w}(1 + k_d c) \tag{4}$$

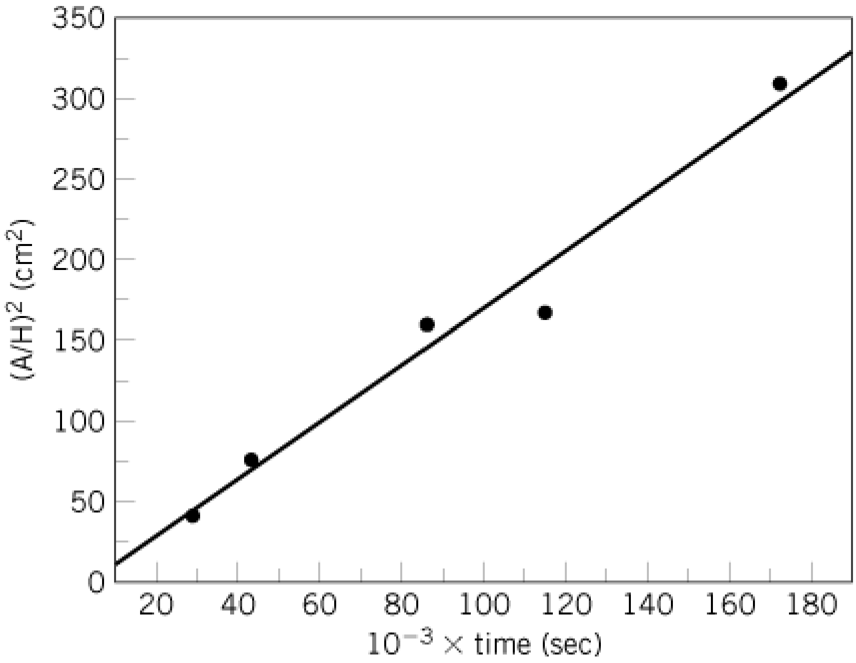
$D^{j0}_{20,w}$ is the value of $D_{20,w}$ at zero concentration of the molecule; its value can be estimated with equation 4 by measuring $D_{20,w}$ at several different concentrations. For diffusion measurements, the non-ideality term is often negligible and can be neglected.

The value of D_t can be measured either by following the rate of disappearance of a concentration gradient or by dynamic light scattering. The former is the traditional method of measuring D_t (2, 3). The principle is to determine how the concentration changes with time at the boundary between two solutions, one containing the molecule of interest and the other, just the buffer or dialyzate. A special diffusion cell can be used with an appropriate optical system for recording either the concentration, c, or the concentration gradient, dc/dx, as a function of distance, x, from the center of the boundary. Alternatively, the optical system of an analytical **ultracentrifuge** can be used to measure the boundary spreading in a synthetic boundary cell. A speed is chosen to be sufficiently small that sedimentation of the molecule is negligible. The Schlieren optical system is very useful, as it gives the value of dc/dx as a function of x. The value of D_t can be determined by measuring the variation in the height of the boundary, specifically, the maximum value of dc/dx, with time, t:

$$\left(\frac{A}{H}\right)^2 = 4\pi D_t t \tag{5}$$

where A is the area under the curve of dc/dx versus x. A plot of $(A/H)^2$ versus time will yield D_t from the slope; an example is given in Figure 1.

Figure 1. Measurement of the translational diffusion coefficient, D_t, for ovalbumin by the boundary spreading technique (4). As in Equation (5) of the text, the square of the ratio of area (A) to the height (H) of the boundary is plotted as a function of time.



Equation 5 assumes that there is no loss of material from the boundary, that is, that the area A remains constant. This assumption is reasonable for homogeneous protein preparations but may not be valid for polydisperse materials such as mucus **glycoproteins** and polysaccharides.

These methods have also generally been superseded by dynamic light scattering. Nevertheless, the classical measurements are preferable with nonglobular macromolecules, with asymmetric shapes.

2. Interpretation of the Translational Diffusion Coefficient

The value of $D_{20,w}$ or $D^{\circ}_{20,w}$obtained by either dynamic light scattering or boundary spreading can be used to provide a number of useful characteristics about a macromolecule.

2.1. Hydrodynamic Radius

The simplest deduction that can be made from the $D^{\circ}_{20,w}$is the size of the molecule as represented by its equivalent hydrodynamic radius, r_H, which is also known as the *Stokes radius*. The r_H is the radius of the equivalent sphere that would have the same $D^{\circ}_{20,w}$. The two parameters are related by the *Stokes–Einstein equation*:

$$r_H = \frac{k_B T}{6\pi\eta_{20,w} D^{\circ}_{20,w}} \tag{6}$$

where k_B is the Boltzmann constant (1.379×10^{-16} erg/K), T is the temperature (293.15 K at 20.0°C), and $h_{20,w}$ is the viscosity of water (0.01 P at 20.0°C). If the value of D_t is not corrected to standard conditions, the appropriate values for T and h must be used. Table 1 gives the values of r_H for several macromolecules.

2.2. Frictional Coefficient, f

The **frictional coefficient** is inversely related to the diffusion coefficient, giving a measure of the resistance to movement due to both its size and shape. It can be calculated directly from $D^{\circ}_{20,w}$:

$$f = \frac{RT}{N_A D^{\circ}_{20,w}} = \frac{k_B T}{D^{\circ}_{20,w}} \tag{7}$$

where R is the gas constant (8.314×10^{-7} erg mol^{-1} K^{-1}) and N_A is Avogadro's number (6.02×10^{23}). Values of f calculated from $D^{\circ}_{20,w}$ are given in Table 1.

It is often more informative to use the **frictional ratio**, f/f_o, which is the dimensionless ratio of the observed frictional coefficient to that of an equivalent spherical molecule of the same anhydrous mass and density.

2.3. Molecular Weight (M_r)

The molecular weight of a molecule can be calculated from the combination of its diffusion coefficient and its **sedimentation coefficient**, $S^{\circ}_{20,w}$ when corrected to standard conditions. The equation analogous to (7) for the sedimentation coefficient is

$$f = \frac{M_r(1 - \bar{v}\rho_{20,w})}{N_A s^{\circ}_{20,w}} \tag{8}$$

where v is the **partial specific volume** of the macromolecule and r $_{20,w}$ is the density of the standard solvent, water at 20°C. Elimination of f between equations 7 and 8 yields the well-known Svedberg equation:

$$M_r = \frac{s^{\circ}_{20,w}}{D^{\circ}_{20,w}} \frac{RT}{(1 - \bar{v}\rho_{20,w})} \tag{9}$$

Equation 9, of course, makes it possible to calculate $D^{\circ}_{20,w}$ if both $S^{\circ}_{20,w}$ and M_r are known.

It is possible, in principle, to measure both $D^{\circ}_{20,w}$ and $S^{\circ}_{20,w}$ simultaneously from analysis of the shape of the boundary in **sedimentation velocity** analytical ultracentrifugation, although in practice this requires data of high quality and a totally homogeneous sample.

If the general shape of the macromolecule is known to a first approximation, it is possible to estimate its molecular weight from only its diffusion coefficient, just as in the case of the **sedimentation coefficient**. The power-law relation between M_r and D_t is also known as a *Mark–Houwink–Kuhn–Sakurada relation*:

$$D_t = K M_r^{-\epsilon} \tag{10}$$

where e = 0.333 for a sphere, 0.85 for a rod, and 0.5–0.6 for random coil polymers. The appropriate value of the constant K is obtained from a collection of standard molecules of known D_t and M_r (5). Of course, the shape of the macromolecule will normally be known only approximately, so any molecular weight calculated in this way must be considered only an estimate.

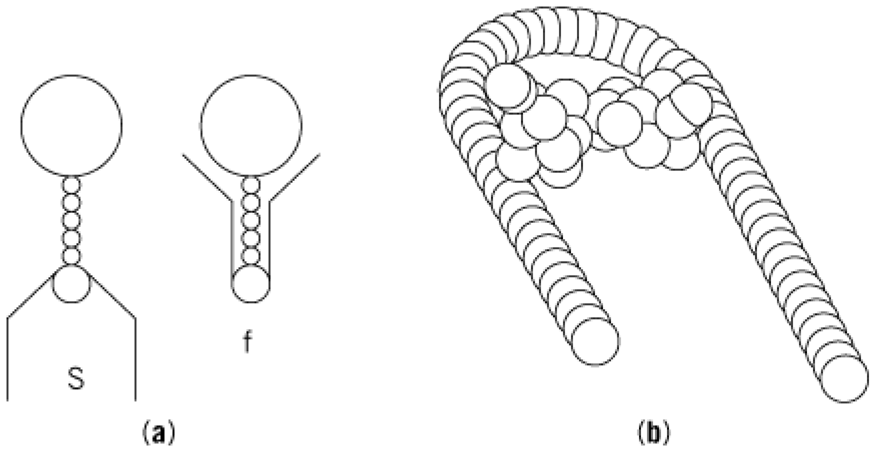
2.4. Shape

The translational frictional coefficient, f, or the frictional ratio, f/f_0, can be used directly to provide information about the shape of the molecule. The function defining the shape and flexibility of a macromolecule is the *Perrin translational frictional function*, P:

$$P = \frac{f}{f_0}\left(\frac{\bar{v}}{\bar{v} + (\delta/\rho_0)}\right)^{1/3} \tag{11}$$

where d is the amount of bound solvent, relative to the mass of the molecule, and r_o is the density of the bound solvent. For a molecule that is fairly rigid over a time-averaged period, the gross shape can be specified using *P* in terms of the axial ratio of the equivalent hydrodynamic ellipsoid or in terms of an arrangement of spheres, in hydrodynamic bead models (Figure 2). Computer programs are available for both types of modeling (6, 7). Especially with the latter approach, the diffusion coefficient should be used in conjunction with other hydrodynamic measurements, such as $s_{20,w}$, to obtain a unique solution to the modeling.

Figure 2. Use of diffusion measurements to represent the shapes of biomolecular assemblies using the hydrodynamic bead model approach: (**a**) from translational diffusion measurements: bead models of the slow "s" (tails out) and fast "f" (tails retracted) forms of a T-even **bacteriophage** (19); (**b**) from rotational (electric dichroism) relaxation measurements: bead models of the complex formed from a DNA fragment of 203 bp with two specific sites and two catabolite activator protein dimers (12).



3. Rotational Diffusion

Rotational diffusion coefficients, which result from the tumbling motion of a macromolecule about an axis or axes, are very sensitive functions of the shape of the molecule and permit the inference of some parameters of the overall shape. Unfortunately, this sensitivity comes at a severe price: measurement of rotational diffusion is usually considerably more difficult than translational diffusion.

There are two principal methods for measuring rotational diffusion. One is based on fluorescence measurements and is called *fluorescence anisotropy* decay. The other is based on electrooptical measurements and is termed *electric birefringence* (or the related *electric dichroism*) decay.

3.1. Fluorescence Anisotropy Decay

Tryptophan residues provide intrinsic fluorescent chromophores in many proteins (ie, the ability to reradiate electromagnetic energy at a wavelength longer than that absorbed). If the incident monochromatic light is plane-polarized, the reradiated radiation will not only be at a longer wavelength but will also be wholly or partially depolarized depending (among other factors) on the extent of rotational Brownian motion of the macromolecule. If the macromolecule is not a protein and does not have an intrinsic fluorescent chromophore, or is a protein-containing insufficient tryptophan residues, a chromophore can be attached synthetically.

The emitted polarization is measured by two detectors, one normal to, and the other perpendicular to, the plane of polarization; the extent or "anisotropy" of polarization, $r(t)$, is recorded as a function of time, t:

$$r(t) = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + 2I_{\perp}} \tag{12}$$

where $I_{\parallel}$ is the emitted intensity in a plane parallel to the polarization of the incident light and $I_{\perp}$ is in a plane perpendicular. In time-resolved fluorescence depolarization anisotropy, this rapid decay in anisotropy of polarization in response to a pulse of incident radiation is recorded and averaged over many pulses (in some ways, the situation is analogous to the measurement of translational diffusion using dynamic light scattering). Allowance has to be made for the decay in intensity of the chromophore itself, specifically, the decay of the intrinsic fluorescence intensity has to be deconvoluted from the anisotropy decay function. The decay in $r(t)$ with time can then be analyzed in terms of the rotational relaxation times of the molecule. There will be one relaxation time for a spherical particle, three for a particle with an axis of symmetry. For a general asymmetric molecule, there will be five relaxation times that need resolving:

$$\begin{aligned} r(t) = {} & c_1 \exp(-t/\tau_1) + c_2 \exp(-t/\tau_2) + c_3 \exp(-t/\tau_3) \\ & + c_4 \exp(-t/\tau_4) + c_5 \exp(-t/\tau_5) \end{aligned} \tag{13}$$

or, more simply $r(t) = \sum_{i=1}^{5} c_i \exp(-t/\tau_i)$where i = 15. In practice, at least two pairs of relaxation times are similar; hence the problem is one of resolving three decay constants (this will be particularly true for macromolecules with an axis of symmetry). Once resolved, these can be related to macromolecular shape and hydration (6, 7) using relations similar to Equation (11). However, extraction of decay constants from a "multiexponential decay"—of which equation (13) is an example—is what the mathematicians call "an ill-conditioned problem" and is not easy, especially if the relaxation times are relatively similar. A further problem is that the chromophore most not relative to the rest of the macromolecule.

A much simpler procedure is to measure fluorescence depolarization or anisotropy decay in the steady state, where the light source is continuous rather than pulsed (8). It can be used to obtain the harmonic mean rotational relaxation time, t_h. t_h and $1/t_{1–5}$ can all be related to the shape and hydration of the macromolecule (7, 9). A study of fibrinogen provides a good example of the application of both time-resolved and steady-state fluorescence measurements (10, 11).

3.2. Electric Birefringence Decay

Solutions of macromolecules oriented in an electric field will be *birefringent*, having different refractive indices for light polarized parallel to and perpendicular to the electric field. This is known as *electric birefringence*. A related phenomenon, for macromolecules with absorbing chromophore, is *electric dichroism*, where a solution of macromolecules oriented in an electric field exhibits different extinction coefficients parallel to and perpendicular to the electric field.

When the electric field is switched off, the birefringence (or difference in refractive indices) D*n* will decay because of rotational motions of the macromolecule:

$$\Delta n(t) = \sum_{i=1}^{5} c_i \exp(-t/\tau_i) \tag{14}$$

where i = 1–5. However, there will be just two relaxation times for molecules that can be approximated by homogeneous ellipsoidal shapes, and just one for a homogeneous ellipsoid with an axis of symmetry. An electrically homogenous spherical particle exhibits no birefringence.

Like fluorescence anisotropy decay measurements, the relaxation times t_i can be related to molecular shape and hydration (Fig. 2) (12), but there are also practical problems to be overcome. The main problem has been that of local overheating in the solution caused by the large orienting electric fields. This has meant in the past that experiments have been limited to solutions of low ionic strength. With significant advances in charge shielding in modern instrumentation, however, physiological ionic strengths are now a reality (13).

3.3. Diffusion of Small Molecules through Biomolecular Systems

Although most attention is given to diffusion phenomena in macromolecules, the importance of the diffusion through biopolymer matrices of small molecules and ions, even water molecules themselves, cannot be ignored; indeed, many physiological processes involve passive or active transport of water and other low-molecular-weight species through cellular and other matrices. As a direct comparison with macromolecular diffusion, Table 1also gives the self-diffusion coefficient at 20.0°C of water (2.3×10^{-5} cm^2/s) and a small sugar molecule, sucrose ($\sim 4.6 \times 10^{-6}$ cm^2/s); the diffusion rates are orders of magnitude greater than those for more bulky macromolecules.

Arguably the best method for measuring diffusion of water and other small molecules is *pulsed field gradient spin echo* NMR (14). Spinning charged particles, such as atomic nuclei, will have an associated magnetic dipole moment, which generates a magnetic energy when placed within a magnetic field. Quantum-mechanical considerations restrict the energies to a limited number of discrete values. Transitions between levels—whose spacing depends on the external magnetic field—correspond to radiofrequency (RF) radiation, so the nucleus will interact or "resonate" with certain radiofrequencies if the external magnetic field is varied; this is known as nuclear magnetic resonance. These frequencies, and the strength and breadth of the resonances, depend on the particular atomic nuclei that are being examined and on the environment in which they find themselves. It is therefore possible to "home in" on a particular nuclear species; for example, such nuclei could be the hydrogen atoms in a water molecule.

With the pulsed field gradient technique, an excitation pulse of RF radiation is applied across a sample—in this case a biomolecular matrix—causing alignment of spins and the generation of an NMR signal; this signal subsequently decays as a result of diffusion. If a second RF pulse is applied after an interval t, the decay processes are reversed and a refocused "echo" signal is obtained at a time 2t after application of the first pulse. This recovery process can be interrupted as follows. A pair of matched magnetic field gradient pulses that vary linearly across the sample are also applied; the first is applied between the RF pulses and the second, after the second RF pulse. The echo only has no net effect if there has been no diffusive movement of the molecules; any movement will result in an attenuation of the echo. Analysis of this attenuation can be used to determine the diffusion coefficient.

Diffusion-Controlled Reactions

Any catalytic or chemical process can be dissected, at least theoretically, into both physical and chemical steps. For a chemical reaction to occur, the reactants must come into physical contact in the correct proximity and orientation. Then whether they simply dissociate or undergo a reaction depends on a number of factors, especially the probability that the reaction will occur. With very facile reactions, every encounter results in a reaction, and the rate-limiting step for the overall reaction is the physical encounter of the two reactants, which is governed primarily by diffusion.

The second-order rate constant for a diffusional encounter of two molecules is $10^{10}s^{-1}$ M^{-1} for macromolecules and 10^8 to 10^9s^{-1} M^{-1} for small molecules. These numbers can, however, be altered by factors of up to 10^2 by attractive or repulsive interactions, especially electrostatic, between the reactants.

DIFP (Diisopropylfluorophosphate)

Diisopropylfluorophosphate, also known as diisopropylphosphofluoridate, DIPF, and sometimes abbreviated DFP, was developed as a nerve gas during the World War II. It is an irreversible inhibitor of **acetylcholinesterase** and, more generally, an inhibitor of serine proteinases (1). In **chymotrypsin**, a typical serine proteinase, the active site Ser195 is phosphorylated by DIFP in a reaction that mimics the catalytic mechanism (Fig. 1). None of the other 27 serine residues of chymotrypsin is affected. The resultant diisopropylphosphoryl serine is stable to subsequent hydrolysis, and the phosphorylated enzyme is totally inactive. The reagent is a liquid at room temperature and is usually diluted into isopropanol before use (2). It is volatile and highly toxic: LD_{50} in mice is 3.7 mg/kg when administered orally. A more convenient reagent for inactivating serine proteinases is phenylmethane sulfonyl fluoride (PMSF) (3).

Figure 1. Reaction of the hydroxyl group of the active site serine residue of a serine proteinase with diisopropyl fluorophosphate. The product is catalytically inactive.

Dihedral Angle

A dihedral angle is the angle between two planes (1). This is determined as the angle formed by normal lines to each plane, as shown in Figure 1. When the rotation about a single bond in a molecule is being measured, **eg**, the rotation about the peptide NCa bond, it is preferred nomenclature to use the conventions described for torsion angles . Unlike torsion angles, it is possible to determine the dihedral angle between the planes defined by any two groups of three atoms, whether they are bonded together or not. If any four atoms are specified in order: atom-1, atom-2, atom-3, atom-4, the dihedral angle is measured between the plane containing atom-1, atom-2, and atom-3 and the plane containing atom-2, atom-3, and atom-4. If the four atoms are not sequentially bonded, this dihedral angle may be referred to as an “improper dihedral” or “improper torsion” (2).

Figure 1. The dihedral angle F is the angle between the two planes defined by atoms 1, 2, and 3 and atoms 2, 3, and 4, respectively. The angle is determined as the angle between lines perpendicular to each plane.

Dihydrofolate Reductase (DHFR)

Dihydrofolate reductase (DHFR) catalyzes the **NADPH**-dependent reduction of 7,8-dihydrofolate to 5,6,7,8-tetrahydrofolate (E.C. 1.5.1.3). Tetrahydrofolate, in its variously modified forms, serves as a **cofactor** in the transfer of one-carbon fragments in the biosynthesis of thymidylate and **purine** nucleotides (see **Nucleosides**, **nucleotides**), as well as other metabolic functions. DHFR is universally present in every kind of living cell—**prokaryotes**, **eukaryotes** and **archaebacteria**—where it is essential for the biosynthesis of **DNA**. Thus if DHFR activity is inhibited, cellular replication cannot take place, a phenomenon that forms the basis for the action of a number of anticancer and antimicrobial pharmaceuticals (eg, **methotrexate** and **trimethoprim**) collectively known as *antifolates* . These compounds are simply inhibitors of DHFR with varying degrees of species selectivity. Though required for continuous DNA replication, the role of DHFR is a rather indirect one—that is, maintenance of the intracellular pool of tetrahydrofolate in its fully reduced state. This is necessary because during the final step of thymidylate synthesis, wherein dUMP is methylated at the 5-position to yield dTMP in a reaction catalyzed by thymidylate synthase, the reduced pteridine ring of the one-carbon donating cofactor N^5,N^{10}-methylenetetrahydrofolate is concomitantly oxidized to produce 7,8-dihydrofolate.

This article focuses solely on the molecular properties of DHFR, which, because of its biomedical importance, its conveniently small size, and its ready availability through cloning and protein engineering, has been intensively studied by essentially every enzymological and physicochemical technique available. Omitted, however, is any discussion of the several studies of **protein folding** that have been carried out with DHFR (1, 2). Nor does this article discuss what is known about how the intracellular level of DHFR is regulated during transcription (3) and translation (4) and by gene amplification (5). Also passed over without further comment is the fact that the DHFR gene has been widely employed as a selectable genetic marker (see Reporter Genes).

1. The Molecule

The polypeptide chain composing DHFR from most species is relatively short, in the range of 159 amino acids for ***Escherichia*** *coli* to 229 for *Cryptococcus neoformans* . Exceptions, however, occur in both protozoa and at least some **plants**, where the genes for DHFR and thymidylate synthase are fused and thus encode a bifunctional enzyme molecule. The degree of sequence identity among all DHFR across the biological spectrum is about 25%, with the pattern of residue conservation leaving little doubt that all are **homologous** and folded into quite similar three-dimensional structures (see Protein Structure). That structure is well established; it has been determined by X-ray crystallography for the proteins from *E. coli*, *Lactobacillus casei*, chicken, mouse, human, the protozoon *Leishmania major*, and the fungus *Pneumocystis carinii* . In all cases, these structures contain one or more bound ligands, such as the cofactor, folate, or a variety of inhibitors, so the mode of substrate binding is known in detail. A hypothetical “movie” of the *E. coli* DHFR molecule as it proceeds through its catalytic cycle has been assembled on the basis of 47 distinct crystal structures in 12 different crystal packings (6).

The molecular architecture of DHFR is typical of a basic folding plan that is seen in the case of many other enzymes, notably **NAD(P)** or **flavin** nucleotide-dependent oxidoreductases, as well as numerous enzymes that bind AMP or ATP. This kind of fold is often called an open a/b-sheet structure, because it is composed of a central twisted b-sheet flanked on both sides by a number of **a-helices**. However, this structure is quite variable in the numbers of a-helices and b-strands, their direction relative to one another, the order in which they are connected (ie, their topology), and the size and geometry of the connecting loops.

The central b-sheet of all DHFR contains eight b-strands, with the first seven strands, A–G, all parallel; the lone antiparallel strand, H, comprises the C-terminal portion of the polypeptide chain. Four a-helices flank the central b-sheet, two on each side. In vertebrate DHFR, which are slightly larger than bacterial DHFR, an extra seven-residue loop is inserted in the middle of the outermost strand G of the central b-sheet; vertebrate DHFR contain, in addition, an extra two-turn a-helix and two turns of a left-handed **polyproline**-like helix.

Both the substrate and cofactor are bound in more or less extended conformations, at approximately right angles to one another, with the pteridine ring of the substrate and the nicotinamide ring of the cofactor occupying a pocket between the carboxyl ends of strands bA and bE. They are in close contact in such a way that hydride transfer can take place between the A side (*pro-R* or *re*) of the nicotinamide ring at C4 and C6 or C7 of the pteridine ring.

2. Enzyme Kinetics

The kinetic pathway of DHFR is complicated by the participation of nine possible ligation states, each distinguished by whether the cofactor binding site and/or the substrate binding site is (i) unoccupied, (ii) occupied by the oxidized ligand, or (iii) occupied by the reduced ligand. Rate constants for the interconversion between these ligation states have been measured and assembled into complete kinetic schemes for DHFR from *E. coli* (7), *L. casei* (8), human (9), mouse (10), and *Pneumocystis carinii* (11). These schemes accurately predict **steady-state** kinetic behavior in computer simulations. Although the predominant pathways vary somewhat, in neither bacterial nor vertebrate DHFR is the chemical step (ie, proton donation to N5 and hydride transfer to C6 of dihydrofolate) **rate-limiting**. Instead, the rate-limiting steps are either substrate binding or product release. These DHFR also show evidence of a conformational isomerization prior to the chemical step, possibly involved in proton donation to N5 of dihydrofolate (12). Among the few kinetic differences between bacterial and vertebrate DHFR, most prominent is the much greater efficiency of vertebrate DHFR at catalyzing the reduction of folate.

3. Mutagenesis Studies

A plethora of mutants of DHFR (primarily from *E. coli* and human) have been engineered by site-directed mutagenesis to probe the catalytic role of evolutionarily conserved side chains. Only a handful of these mutants have been characterized both structurally and kinetically, but interpretation of the results is not straightforward for even the most thoroughly studied. For example, mutation of conserved $\mathrm{Asp27} \rightarrow \mathrm{Asn}$ of *E. coli* DHFR, or the equivalent $\mathrm{Glu30} \rightarrow \mathrm{Gln}$ in human DHFR, results in a strong pH-dependence of k_{cat}, suggesting a role for the carboxylic acid in protonation of N5 of the substrate. However, the equivalent mutation, $\mathrm{Asp26} \rightarrow \mathrm{Asn}$, in *L. casei* DHFR yields only a modest pH effect (13). Structural perturbations are minimal in these and most other such site-directed mutants, but the rate of the chemical step decreases significantly, suggesting that the entire enzyme molecule influences hydride transfer and proton donation. Further mutagenesis studies involve modification of whole a-helices (14) and loops (15) or circular permutations of the polypeptide chain (16) in an effort to understand the functional role of larger structural elements in catalysis.

4. The Transition State

At the center of the effort to understand any enzyme lies a fundamental question: How does it catalyze the reaction? In the most general terms, elementary catalysis theory dictates that the enzyme molecule must bind the transition state of the reaction many orders of magnitude more strongly than the reactants. But to progress beyond this level of understanding for any particular enzymic reaction requires that one begin with a picture of the transition state; and this is no easy matter, because the transition state is by definition an unstable, transitory molecular species. Thus one must rely on theory, and even speculation, to suggest what the transition state might look like.

In the case of DHFR, there is at least one very clear indication from the crystal structures that the enzyme molecule is indeed “designed” to bind the transition state. Certainly the transition state must involve a close approach of the two carbon atoms between which hydride ion transfer takes place, C4 of the nicotinamide and C6 of the pteridine ring. Theoretical calculations (17) predict a C4–C6 distance of 2.6 Å in the transition state, about 1 Å shorter than **van der Waals** contact distance. Happily this is just what is seen when the separate structures of the binary complexes, DHFR · folate and DHFR · NADPH, are carefully superposed on one another in the case of both the vertebrate (18) and the *E. coli* (19) enzymes. Evidence that DHFR is trying to push the C4 and C6 atoms together is seen even in ternary complexes in which both the cofactor and the pteridine are bound simultaneously; the approach distance is 0.3 to 0.5 Å shorter than the expected van der Waals distance of 3.6 Å.

Dimethyl Sulfate (DMS)

This is a mutagen that is a monofunctional alkylating agent of structure CH_3–O–SO_2–O–CH_3, which reacts with nucleophilic sites primarily by an S_N2 mechanism. This mechanism involves a concerted process with the substrate, resulting in selective methylation of only the most nucleophilic sites. Thus DMS predominantly methylates nitrogen atoms on **nucleic acids**, only rarely oxygen or phosphorus. By far the most abundant lesion produced is N7-methylguanine, with minor amounts of N_1-, N_3-, and N_7-methyladenine and N_3-methyl cytosine, and trace amounts of O_6-methylguanine (1). 7-Methylguanine has base-pairing properties very similar to guanine itself, so this modification is probably not the most important cause of mutagenesis by DMS. Both 3-methyladenine and 3-methylcytosine can cause base mispairing, which may lead directly to mutagenesis by DMS (1, 2). Although probably not primarily involved in mutagenesis, methylation at the *N*7 of guanine significantly weakens the N9-glycosidic bond, leading to enhanced formation of apurinic sites (3-5). Depurination may also occur at 3-methylated adenines (6, 7), and this itself has mutagenic consequences.

DMS is both **carcinogenic** and **mutagenic** in a wide variety of organisms, producing point mutations, chromosomal aberrations, and recombinational events (reviewed by Hoffman (8)). In many mutagenesis studies, DMS is reported to be a base-pair substitution mutagen, but it also causes frameshift mutations and deletions. It has been suggested that much of the data can be explained in terms of effects of DMS on DNA **repair** processes (8, 9). Lawley and Warren (2) found that *Escherichia coli* repair processes effectively remove 3-methylguanine and 3-methyladenine, but not 7-methylguanine, residues from DNA. These authors suggested that N-3 purine alkylations may block DNA replication and stimulate enzymatic repair processes. Inaccuracies in these may lead to many of the observed mutations in bacterial systems. 7-Methylguanine is removed from the DNA of mammalian cells, although it does not interfere with DNA synthesis (10).

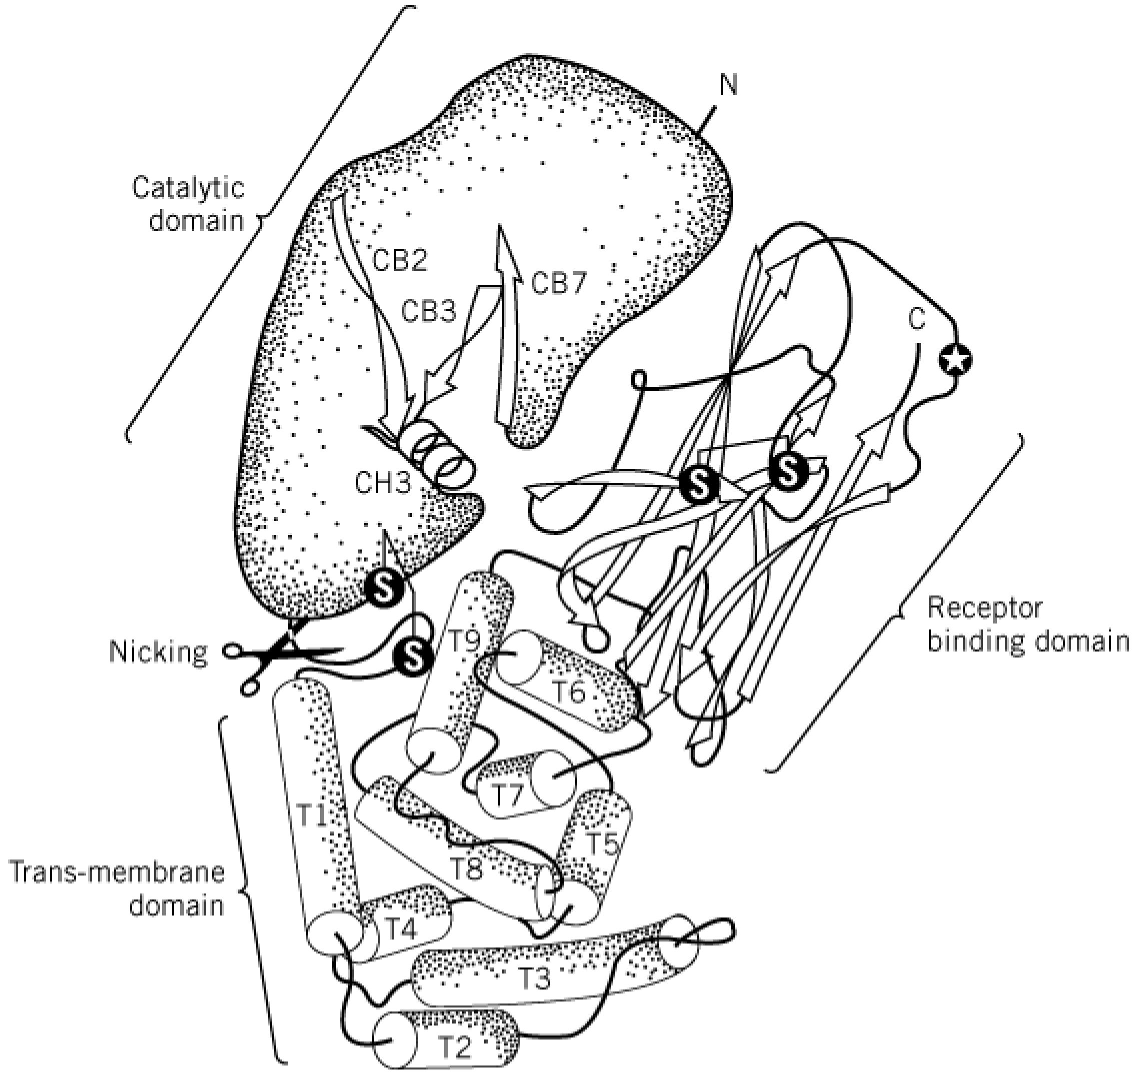
Diphtheria Toxin

Diphtheria was the first infectious disease shown to be caused solely by a toxin (1). Diphtheria toxin (DT) is encoded by a gene carried by temperate **bacteriophages**, such as the *o*-corynephage, that lysogenize *Corynebacterium diphtheriae* and make it toxigenic. The toxin gene is activated by the release of an iron-binding repressor protein, which binds to DNA in its holo form and in iron-depleted media is released as the apo form (1). The DT gene includes a 25-residue long amino-terminal **leader sequence** responsible for the export of DT from the cell (2, 3). After proteolytic removal of the leader sequence, DT is released by *C. diphtheriae* as a single polypeptide chain of 535 amino acid residues. This chain is rapidly cleaved *in vivo* by furin (4) and *in vitro* by different proteinases, within a loop containing three Arg residues that connects the first and second domains (Fig. 1). After such proteolytic nicking, DT is composed of two-chains: A (193 residues), responsible for the intracellular catalytic activity, and B (342 residues), responsible for binding and membrane translocation. A and B are linked by noncovalent forces and a single interchain disulfide bond. Figure 1 shows the three-domain structural organization of DT (5). The amino terminal domain (residues 1 to 193) corresponds to the A subunit, which is an **ADP-ribosyltransferase** with a cleft-shaped **NAD**-binding cavity harboring the Glu148, His21, Trp50, and Tyr65 residues that are essential for activity (5). NAD binds in such a way that its nicotinamide moiety overlaps the phenolic ring of Tyr65, and its adenine group lies over the indole ring of Trp50.

Figure 1. **Structure of diphtheria toxin**. Diphtheria toxin consists of three domains, characterized by different secondary structure elements and different biological properties. The cleft in the catalytic domain is the NAD binding site. The circled star indicates Ser-508 involved in receptor binding. The toxin is activated by selective proteolysis of a furin-sensitive loop between the A domain and T domain, which is responsible for membrane translocation.



In the nicked toxin, the A domain is disulfide-linked to the T domain (residues 194 to 385), which is involved in the membrane insertion and translocation of DT. The T domain is almost entirely composed of **alpha-helices**, a type of **secondary structure** found in the membrane-embedded sector of many integral membrane proteins. The third domain R (residues 386 to 535) is a flattened ß-barrel and responsible for DT binding to its specific **receptor**, which is a protein that binds heparinlike growth factors (6). The role of this receptor in cell physiology is not known, but it was shown that CD9 enhances the sensitivity of cells to DT (7). The number of DT receptors in different cell lines correlates with their DT sensitivity. Binding is followed by internalization inside clathrin -coated **vesicles**, which uncoat and merge into early endosomes, a process that requires less than 5 min in Vero cells at 37°C (8). The acidic pH of the endosomal lumen induces a conformational change of DT, with insertion of helices of the T domain into the lipid bilayer (9, 10), to create a transmembrane channel, open laterally to lipids, that mediates the translocation of the A chain into the cytosol (11). It is not known if domain A has to unfold completely in order to pass through the B channel, but it is noteworthy that A can be boiled in **SDS** and, upon detergent removal, refolds into its active conformation. The translocation and release of A are linked to the reduction of the interchain disulfide bond, which is carried out by yet unidentified reductases. Such reduction is the rate-limiting step of the entire intoxication process (8). Only about a third of the internalized DT molecules are reduced and release their A chain into the cytosol. The remaining, unreduced two-thirds, as well as the B subunits left over on the membrane after A release, are conveyed to the **lysosomes** and degraded (8).

The A chain of DT **ADP-ribosylates**, specifically elongation factor 2 (EF-2), which becomes unable to transfer the tRNA-bound amino acid to the growing polypeptide chain, and cell **protein biosynthesis** are blocked (12). DT-A is active only on the EF-2 of **eukaryotes** and **archaebacteria** because they contain diphthamide, a **post-translationally modified** His residue, which is the unique substrate of DT and of the related exotoxin A released by *Pseudomonas aeruginosa* (12). The physiological role of diphthamide *in vivo* is unknown, particularly because cell lines mutated at this His residue, or in one of the enzymes involved in its transformation into diphthamide, appear to grow normally (12). One single molecule of DT is able to kill a cell rather rapidly (13) because it can catalyze the ADP-ribosylation of about 2000 EF-2 per hour, whereas cells in culture produce only about 1500 new EF-2 per hour, and EF-2 synthesis decreases as toxin action progresses. As a result, the lethal dose of DT in sensitive animal species (those possessing DT receptors) is below 0.1 µg DT/kg.

Direct Methods

Before an electron density map can be calculated in a crystal structure determination using X-ray crystallography, the phase angles of the reflections must be found (see Phase Problem). In principle, they can be derived from the values of the amplitudes $|F(hk\ell)|$, and these are (apart from correction factors) proportional to the square root of the observed reflection intensities $I(hk\ell)$. The relationship between phases and structure factor amplitudes is due to two properties of the electron density map:

1. It is nowhere negative.
2. It is a summation of atomic electron densities.

Several types of direct methods have been derived to determine the phase angles from the structure factor amplitudes alone, and they are routinely used in structurally determining small compounds. With an increasing number of atoms, however, the power of the method becomes weaker. The maximum number of non-hydrogen atoms in the asymmetric unit is around 300. Classical direct methods are not practical for proteins unless the protein molecule is small and gives an extremely high-resolution X-ray diffraction pattern. It also helps if the protein contains one or more heavy atoms, for example, sulfur or iron (1). Although generally not practical for a complete protein structure determination, classical direct methods are suitable for locating heavy atoms from isomorphous replacement data.

A nonclassical approach to direct phase angle determination for macromolecules has been pioneered by Bricogne (2) and is still under development. It applies the maximum entropy principle. Although not yet applicable for a *de novo* structure determination, it can already be applied if combined with available information.

Direct Repeats

A repeat, or repeating, **nucleotide sequence** is any of two or more identical segments of a longer sequence or identical segments of a double-stranded **DNA**. Any DNA fragment can be inserted into a long, double-stranded molecule in either of different polarities: “head on” (taking one of the ends of the duplex as a head), or “tail on.” In the long sequence, it then appears as either one strand of the fragment or the other, complementary strand. If two identical fragments are both oriented “head on,” the repeat is called a direct repeat—that is, all identical sequences encountered in a longer sequence are direct repeats. They are normally noncontiguous and separate. Contiguous direct repeats are called tandem repeats. Various types of repeats are outlined schematically in the Figure for Tandem Repeats.

One important example are the direct repeats at the ends of some transposable elements (1). Integrated retroviral genomes and retrotransposons are flanked by the long terminal repeats (LTR) of 200–500 bp. For example, the yeast transposon Ty has 330-bp LTRs at its ends. The repeats are involved in the recombination events during integration or excision of the mobile elements. The presence of the direct repeats in a sequence may actually serve as an indication of possible transposition events. When integrated in the same polarity, the transposons themselves are an example of direct repeats.

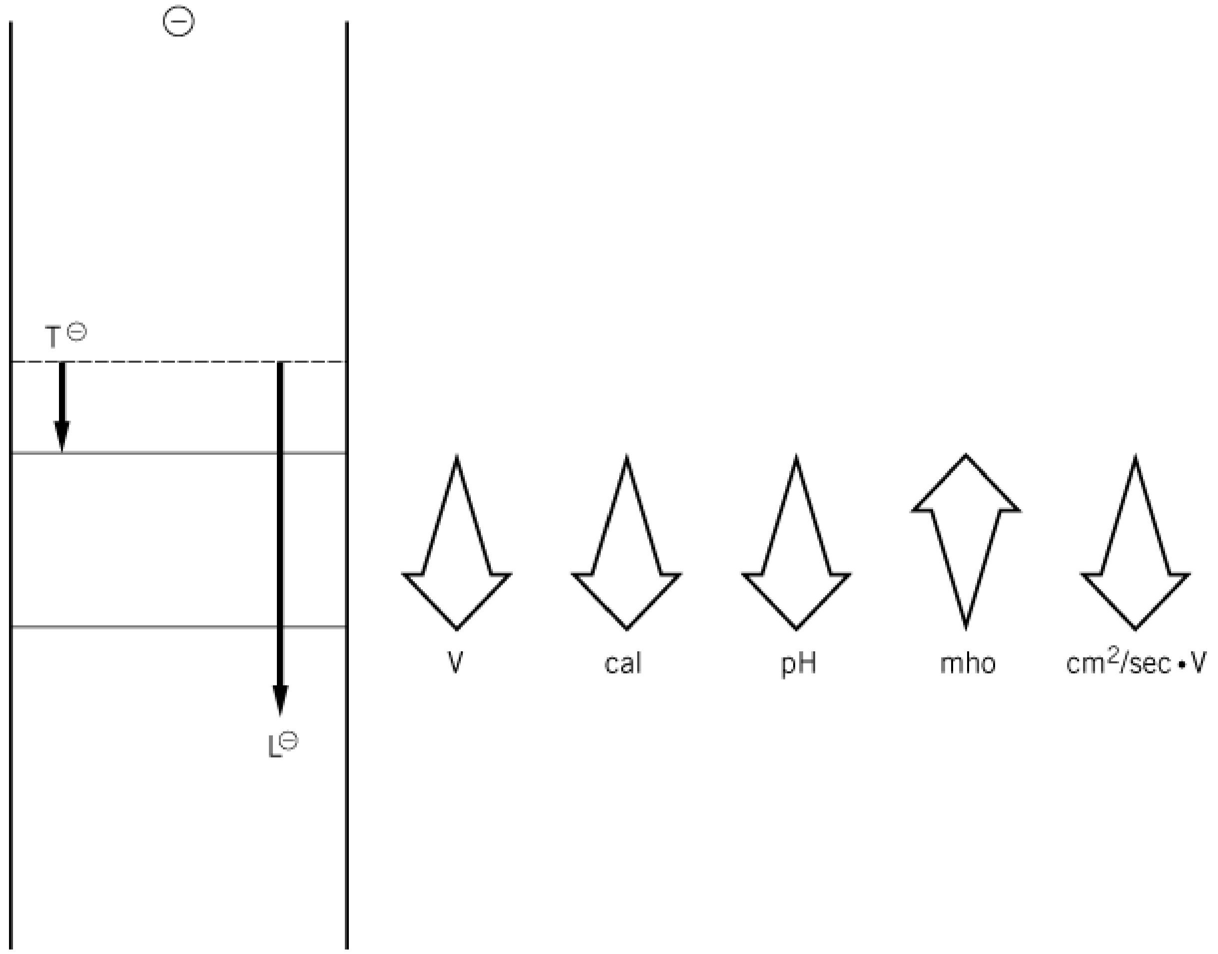
Disc Electrophoresis

Gel electrophoresis in *discontinuous* buffer systems is known as “disc electrophoresis” (1). Its main advantage is the provision of a highly concentrated starting zone even when the sample is dilute. It employs at least two electrophoresis buffers, i.e., a buffer discontinuity. They differ in either a cation or anion, whereas the counterion is the same. One of the differing ions, known as the “trailing ion,” has an electrophoretic mobility less than the species of interest to be separated; the other, the “leading ion,” has a greater mobility. Embedded within such a system, the species of interest will, at steady-state, migrate within a moving boundary between the leading and trailing ions, at a field strength (conductance) and concentration that is fixed (“regulated”) by the mobilities and concentrations of the leading, trailing, and common buffer ions constituting the boundary. This “regulation” imposes a “regulated” mobility on all trailing species with net mobilities equal to, or greater than, the trailing ion; hence, the system is designated as “equal-mobility-electrophoretic” or isotachophoretic (see Isotachophoresis). A number of species migrating isotachophoretically in order of their net mobilities is called a “stack.” The regulation of mobilities and concentrations behind the leading ion, resulting from the requirement for electroneutrality and the conservation of mass, gives rise to an increased field strength behind the fastest migrating (leading) ion in the electric field (Fig. 1). The gradient in field strength developing behind the leading ion causes equally oriented Joule heat and pH gradients, a gradient in mobility accelerating the trailing ions until at equilibrium they have attained the net mobility of the leading ion, and a gradient of specific conductance oriented inversely to the field strength gradient (Fig. 1). The key benefit of regulation of the trailing buffer phase by the leading ion is that a macromolecular ion present in that phase will migrate within the stack at a very high concentration, estimated to be on the order of 100 mg/mL for a 100-kDa protein, independent of the degree of dilution of the macromolecule in the original sample. Therefore, very dilute samples can produce very condensed zones of sample within the gel.

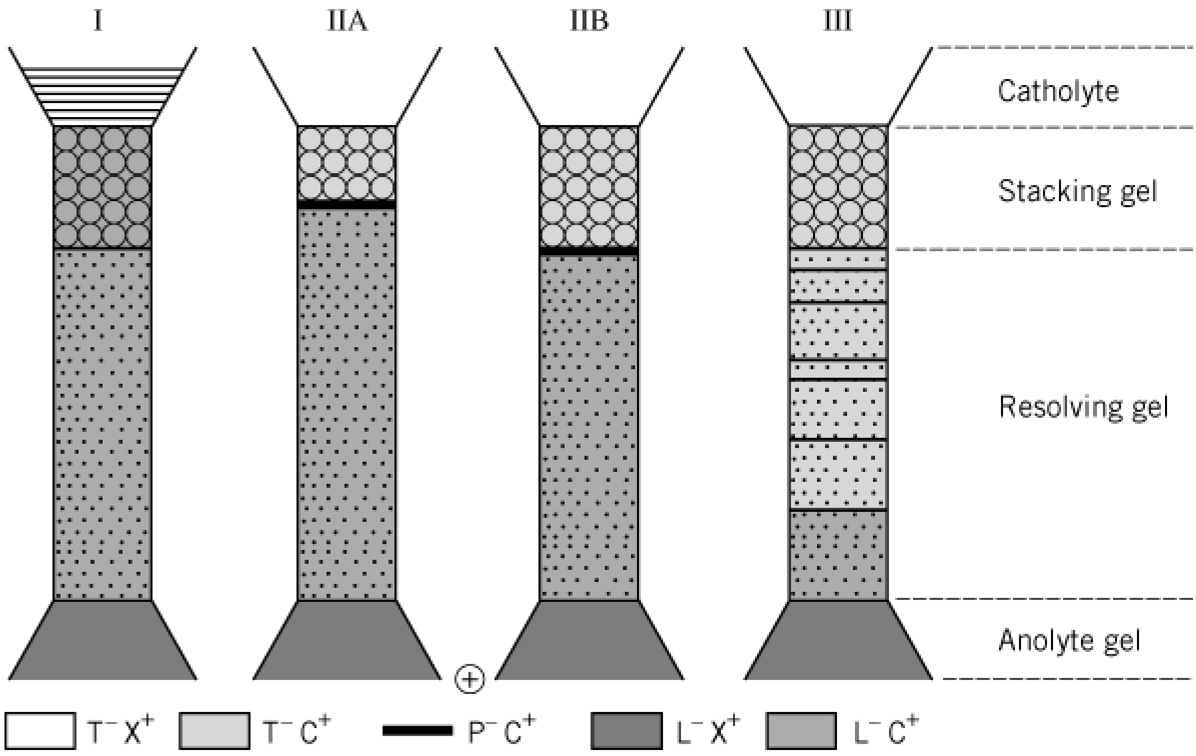
Figure 1. Operation of discontinuous buffer systems. Prior to electrophoresis, a stationary boundary (dotted line) separates the trailing ion T in the cathode buffer from the leading ion L in the gel buffer. As T and L electrophorese out of the starting zone, the greater instantaneous velocity of L would tend to create behind it an “ion vacuum.” This, however, would be in violation of the laws of conservation of mass and of the maintenance of electroneutrality. Operation of these two laws gives rise to a “regulation” in the zone behind L, which leads to an increase in field strength, Joule heat, and pH, and a decrease in conductance. These, in turn, produce an increased mobility of all species migrating between T and L until they attain the net mobility of L.



In disc electrophoresis, the concentrating (stacking) buffer phase is embedded in a gel that does not sieve but is present only to prevent convection; this gel is contiguous with a sieving gel, the "resolving gel." As the stack of moving boundaries containing the concentrated sample enters the resolving gel, the buffer boundaries are unaffected by the elevated gel concentration and changed pH, whereas macromolecules are altered in their migration by both. The retardation due to the increased gel concentration causes the macromolecules to migrate at a mobility less than that of the trailing ion. Therefore, they "unstack" and separate according to their mobilities; in contrast, the stack of buffer ions remains (Fig. 2), forming a moving boundary "front" that can be marked by an appropriate tracking dye. The ratio of macromolecular mobilities relative to the stacked tracking dye (in terms of relative mobility, R_f) characterizes an electrophoretic band and can be used, when measured at several different gel concentrations, to specify the size and net charge of the macromolecule (see Ferguson Plot).

Figure 2. Operation of gel electrophoresis in a discontinuous buffer system. (*I*) A gel electrophoresis system of four phases is set up: A cathode buffer containing the trailing ion T as a salt with any counterion X plus a tracking dye; a stacking gel of large pore size, "nonrestrictive" to the migration of macromolecular particles P and containing the leading ion L as a salt with counterion C (which is common to both stacking and resolving gels) at a pH lower than that of the resolving gel; a resolving gel at a gel concentration that lowers ("restricts") the mobility of particle P and at a pH higher than that of the stacking gel; and an anode buffer containing the common counterion C as a salt of any other ion. P is loaded on top of the stacking gel. (*II*) Upon initiating electrophoresis, a stack of L, P, and T forms by regulation (Fig. 1) in the stacking gel. (*III*) Upon arrival at the resolving gel, L and T and the tracking dye proceed as a stack at a velocity undiminished by the presence of the gel and augmented by the increased pH. In contrast, the velocity of P is lowered in the gel through "molecular sieving," so that the mobility of P now is less than that of T. That decrease in mobility is termed "unstacking" and results in the migration of all species of P in decreasing order of

their net mobility, ie, in their separation.



Most important, disc electrophoresis is an analytical or preparative separation method that is largely independent of the volume of the original sample; this precludes the necessity for a concentration step prior to electrophoresis. This fact is important for those applications—and they are in the majority—in which the sample is available only in dilute solution. Furthermore, the stacking gel can also assist separation by excluding from the concentrated band (the stack) species of low or high mobility relative to the displacement rate of the moving boundaries associated in the stack ("selective stacking").

Discontinuous buffer systems are available from a computer program (2) for electrophoresis across the entire pH scale, at either 0 or 25°C, and for both negatively and positively charged analytes.

Discontinuous DNA Replication

Elongation of the DNA chain on the lagging strand during DNA replication is discontinuous: Short segments of DNA, called Okazaki Fragments, are repeatedly synthesized in the reverse direction of movement of the replication fork (1). This occurs because the two chains of double-helical DNA are antiparallel, and **DNA polymerase** can extend a DNA chain only in the 5′ → 3′ direction. On the leading strand, which runs 5′ → 3′ in the reverse direction to fork movement, the replicative enzyme carries out chain elongation continuously in a highly processive manner. On the other parent strand, the lagging strand, which runs 3′ → 5′ in the direction of fork movement, DNA polymerase catalyzes chain elongation only in the reverse direction of fork movement. Thus, as the replication fork proceeds, the unreplicated segment is expanded on the lagging strand. When one act of chain elongation on the lagging strand is accomplished, the next round of chain elongation must be started from a newly expanded segment on the lagging strand. To achieve completion of DNA replication on an entire region of the lagging strand, numerous enzymes cooperate at the replication fork. They are participating in primer synthesis (the initiation of Okazaki fragments), chain elongation (the extension of Okazaki fragments), and a process that connects Okazaki fragments.

In *Escherichia coli*, more than 20 different proteins participate in DNA replication (2). These were identified by screening mutants defective in DNA replication and by purifying enzymes required for *in vitro* DNA synthesis (see ***dna* genes**). From their biochemical roles at different stages of chromosomal DNA replication, it appears that at least eight proteins are involved in the discontinuous replication in *E. coli*. Those are (1) primosome proteins, including DNA helicases and primase: PriA, PriB, PriC, DnaT, DnaB, DnaC, and DnaG (primase); (2) proteins required for chain elongation: DNA polymerase III (Pol III) holoenzyme and single-stranded DNA binding protein (SSB); and (3) proteins required for connecting Okazaki fragments: DNA polymerase I (Pol I), RNaseH, and DNA Ligase. Among these proteins, the DnaB helicase, primase (DnaG), and Pol III holoenzyme are the basic components acting on the discontinuous DNA synthesis at the replication fork, probably forming a multiprotein complex called a *replisome*.

DNA polymerase cannot replicate duplex DNA without assistance. This enzyme requires single-stranded DNA as a template and an RNA or DNA primer annealed to the template. Two other enzymes enable polymerase to work on duplex DNA. One is a DNA helicase that opens up the duplex at the replication fork to provide a single-stranded template. The other is a primase that synthesizes a short RNA to prime DNA chain elongation. Several DNA helicases have been identified from *E. coli* and its phage, including DnaB, T7 gp4, and T4 gp41 (3-5). The biochemical characterization of these activities in *in vitro* DNA replication systems suggests that the primary replicative helicase binds to and moves on the lagging-strand template in the 5′ → 3′ direction, unwinding the DNA double helix as it goes. Another common property of the replicative helicases is an intimate association with a primase. The bacteriophage T7 gp4 has both primase and helicase activity within the same polypeptide chain (4). Bacteriophage T4 gp41 greatly enhances the primase activity of T4 gp61 (6). A similar functional interaction has been observed between DnaB protein and *E. coli* primase, DnaG protein (7). On most templates, DnaG exhibits a very feeble priming activity that can be greatly enhanced if DnaB first binds that DNA. This stimulation of primase activity is further increased when the DnaB helicase is activated to its processive form at the replication fork.

In *E. coli*, there are two pathways by which the DnaB helicase is loaded onto the lagging-strand template DNA: One is primosome formation directed by the PriA protein, and the other is DnaA protein-directed DnaB loading (8, 9). The former process was discovered first in the replication of bacteriophage fX174 DNA and **plasmid** ColE1 DNA, and it later appeared to be involved in the resumption of chromosomal DNA replication after replication of the *E. coli* genome has been interrupted or halted. On the other hand, the latter process was found in *oriC* plasmid DNA replication *in vitro* and is thought to form a priming complex with DnaG primase at the replication fork in *E. coli* chromosomal DNA replication.

The chain elongation of Okazaki fragments in *E. coli* is catalyzed by DNA polymerase III holoenzyme (10). This enzyme possesses a capacity to synthesize DNA with a very high processivity, sufficient for completion of about 2 kb of Okazaki fragment. In addition, the Pol III holoenzyme dissociates from the nascent Okazaki fragment and restarts the next round of Okazaki fragment synthesis from an RNA primer newly settled near the replication fork (11). Enzymes to remove primer RNA and fill the gap, such as ribonuclease H and DNA polymerase I of *E. coli*, are essential for the sealing of Okazaki fragments by DNA ligase (12). Mutants defective in either DNA polymerase I or DNA ligase show a massive accumulation of short Okazaki fragments under restrictive conditions.

Although the basic biochemical processes that occur at eukaryotic and prokaryotic replication forks are similar, there are many differences in detail (13). For example, primer synthesis in eukaryotic cells is catalyzed by DNA polymerase a, which synthesizes 2 to 12 nucleotides of RNA (initiator RNA) and further adds about 20 nucleotides of DNA to the initiator RNA. The size of Okazaki fragments (40 to 300 nucleotides) in eukaryotes is significantly shorter than those observed in prokaryotes.

Disease Resistance Genes, Plant

Plants are the ultimate food source for many nonphotosynthetic organisms. In natural ecosystems, plant populations are usually too fragmented for major epidemics of bacteria, fungi, **viruses**, nematodes, or other animals to threaten the survival of a plant species, although such pathogens are still likely to select for variants with enhanced resistance. In the monocultures imposed by human cultivation, disease can be severe.

Plant pathogens are classified into necrotrophs and biotrophs (1). Necrotrophs overwhelm plant defenses with toxins and hydrolytic enzymes and then feed on the dead plant material. Biotrophs need a living plant to complete their life cycle and are better thought of as parasites; they can reduce plant yields substantially, without killing their hosts. Hemibiotrophs, such as *Phytophthora infestans* which causes potato late blight, have an initial biotrophic phase that rapidly switches to necrotrophy.

The interaction between plant and pathogen is said to be compatible if disease occurs, and incompatible if it does not. Most plants are resistant to most plant pathogens; the flax rust fungus does not cause disease on wheat, and vice versa. In this example of “nonhost” resistance, incompatibility can be due to a lack of “basic compatibility”; biotrophic parasites must specialize to grow on their specific hosts.

One of the most interesting and widely studied forms of disease resistance appears to involve recognition of pathogens by plants, followed by activation of defense responses that usually culminate in the death of plant cells near where the pathogen attempts ingress. This localized cell death is often referred to as the *hypersensitive response*, or HR. It should be noted that plants, unlike mammals, lack circulating defender cells, and every plant cell must be able to mount a defense response. The HR is correlated with the production of antimicrobial proteins and reactive oxygen species (2, 3).

Soon after the rediscovery of Mendel's work, breeders noted that resistance in wheat to rusts was inherited as a single dominant Mendelian trait. In the 1940s, H. H. Flor, studying the flax/flax rust interaction, carried out genetic analysis with both the rust fungus and its plant host. **Genes** in flax for rust resistance were dominant, as in wheat. Flor also showed that virulence in the pathogen segregated as a recessive trait. From this he inferred that each pathogen must carry dominant **alleles** of genes which permitted the plant to detect that pathogen race, and he termed these *avirulence* genes. Genetic interactions such as these are often referred to as “gene-for-gene.”

Flor's work underpins the current view that resistance (*R*) genes encode receptors which recognize pathogen-derived, avirulence (*Avr*) gene-encoded ligands. Pathogens evade recognition by mutations in *Avr* genes. Why would pathogens make *Avr* gene products that permit plants which carry the corresponding *R* gene to detect them? It is believed that pathogens generate a battery of pathogenicity factors (also known as compatibility factors) which are individually dispensable. Pathogens (and plant breeders) select for variant *R* genes that can detect one of these factors. This interpretation appears to be valid for interactions of plants with bacteria, viruses, fungi, and nematodes (4).

1. Four Classes of “Gene-for-Gene” *R* Gene Products

The first gene-for-gene *R* gene to be isolated was *Pto* from tomato (5). *Pto* confers resistance to races of *Pseudomonas syringae* that carry the corresponding *AvrPto* gene, and encodes a **serine-threonine protein kinase** of the Raf family, with strongest homology to the *Drosophila* gene *Pelle*, which is involved in signal transduction between the ***Toll*** receptor and **Dorsal** transcription factor, and it may also be involved in *Drosophila* innate immunity (6, 7). Pto also carries a putative N terminal myristoylation site. It was surprising to discover that a gene putatively involved in recognition showed homology to genes involved in signal transduction rather than to known receptors. Remarkably, recent work shows that there is probably a direct interaction between the *Pto* and *AvrPto* gene products (8, 9). How could AvrPto physically interact with Pto? Many phytopathogenic *Pseudomonas* and *Xanthomonas* species encode a type III secretion pathway that actively delivers compatibility factors to the plant cell (10, 11). The same secretion pathway is involved in delivering proteins into mammalian cells attacked by *Shigella, Yersinia, Salmonella*, or pathogenic *Escherichia coli*. Mutations in the so-called *hrp* genes specifying this apparatus in *Pseudomonas* and

Xanthomonas leave the bacterium defective in both Hypersensitive Response elicitation and Pathogenicity. The *hrp* system is believed to deliver several pathogenicity factors from bacteria to plant cells, some of which (such as AvrPto) the plant evolves the capacity to recognize. The *Pto* gene is a member of a linked **gene family** of five to seven members spread over probably less than 100 kbp, one member of which, *Fen*, confers an apparent HR when treated with Fenthion insecticide. Experiments swapping **domains** between *Fen* and *Pto* have precisely localized the region involved in *AvrPto* recognition (8, 9).

The other three classes of *R* genes carry the leucine-rich repeat (LRR) motif. LRRs have been implicated in various examples of protein–protein interactions and protein–peptide interactions (12), This repeating motif creates a parallel beta-sheet that provides a recognition surface in the interaction of porcine **ribonuclease inhibitor** (PRI) with ribonuclease. Thus, the presence of LRRs is consistent with a role for *R* gene products as receptors for pathogen-specified ligands. Based on the PRI structure, a model has been proposed for the structure of various LRR proteins, including plant *R* gene products (13).

The *Cf-2*, *Cf-4*, *Cf-5* and *Cf-9* genes of tomato confer resistance to specific races of the fungal pathogen *Cladosporium fulvum* (14-16). This biotrophic fungus proliferates in the intercellular spaces of infected leaves prior to conidiation. It secretes small cysteine-rich peptides into these spaces, presumed to be compatibility factors, some of which are *Avr* gene products (17). Avr9, recognized by *Cf-9*, is a 28 amino-acid residue peptide; after secretion, Avr4 has 105 residues. The *Cf-* genes all encode **glycoproteins** that are **membrane-anchored** at the C-terminus (probably to the plasma membrane) with 25 to 38 LRRs. Binding studies showed that Avr9 binds a protein that is present even in stocks that lack *Cf-9* (18). Conceivably, this protein undergoes a conformational change upon binding Avr9, and this change is recognized by Cf-9. No evidence for direct interaction between purified Cf-9 and Avr9 has yet been obtained.

Analysis of the *Cf*-gene family has revealed interesting insights into *R* gene evolution (19). At the *Cf-9* locus, there are five homologues of *Cf-9* (including *Cf-9*). At the homologous *Cf-4* locus, there are also five members, including *Cf-4*. Comparison of these sequences has revealed a pattern of evolution by sequence exchange, presumably by either **unequal crossing over** or **gene conversion**. This is consistent with the analysis of the maize *Rp1* locus, which provides genetic evidence that novel alleles arise correlated with meiotic recombination events (20). Analysis of the ratio of synonymous to nonsynonymous codon substitutions (Ks/Ka) suggests diversifying changes in the solvent-exposed amino-acid residues of the LRR parallel beta-sheet. Consistent with this, several other members of the *Cf*-gene family confer resistance through recognition of as-yet-uncharacterized avirulence genes. A complementary study provides evidence that several of the secreted peptides of *C. fulvum* have the potential to act as *Avr* gene products (21). The picture emerging from this system reveals a battery of secreted peptides that presumably confer a pathogenicity function for *C. fulvum*, with the plant evolving the capacity to recognize and react to them through creating a recognition specificity in a *Cf*-gene homologue. How the recognition actually occurs, and what happens next, is an area of active research.

No other *R* genes have been shown to be members of this C-terminally anchored LRR class, although several Arabidopsis homologues have been identified, where in some instances they exist as linked multigene families. The nematode resistance gene $Hc1^{pro}$ is reported to be of this class (22), although the LRR sequences vary from the canonical LRR motif.

The rice *Xa21* gene confers resistance to *Xanthomonas campestris pv oryzae*, the causal agent of bacterial blight. Interestingly, it encodes a transmembrane LRR protein kinase, combining features of Pto and Cf-9 in one protein (23). This would suggest that the *AvrXa21* gene encodes a secreted bacterial protein, but thus far the *AvrXa21* gene has not been cloned, because little genetic variation has been detected within *Xanthomonas* at this locus. Again, *Xa21* is a member of a linked multigene family (24).

The largest class of *R* genes encode cytoplasmic (but probably membrane-associated) proteins that carry a canonical **nucleotide-binding** (NB) site and C-terminal stretch of LRRs. The NB carries the *kin1a* (P loop), *kin2*, and *kin3a* sites of protein kinases (25). In addition, recent comparisons have revealed a more extended homology with a domain of the *Caenorhabditis elegans Ced4* and the human *Apaf1* gene products, which led some authors (26) to christen this extended region the NB-ARC domain (standing for Nucleotide Binding, *Apaf*, R gene, and Ced4). *Apaf1* and *Ced4* encode proteins that are effectors of apoptosis. The parallel between apoptosis and the HR has been the subject of considerable interest (27, 28), and the homologies are intriguing, but no biochemical evidence is yet available to substantiate it.

These NB-LRR genes fall into two main classes:

1. *Rps2* and *Rpm1*, *Arabidopsis* genes for resistance to *Pseudomonas* strains carrying *AvrRpt2* and *AvrRpm1*, respectively, encode a putative leucine zipper (LZ) N-terminal to the NB region (29, 30). Unusually, *Rpm1* recognizes both *AvrB* and *AvrRpm1*.
2. In contrast, the tobacco *N* gene for tobacco mosaic virus (TMV) resistance, the flax *L6* gene for rust resistance, and the *Arabidopsis RPP5* gene for downy mildew resistance carry a region at the N-terminus with homology to the cytoplasmic domain of the *Toll* receptor and *interleukin* 1 receptor (31, 33). This region has recently been proposed to adopt a structure resembling the *E. coli CheY* **chemotaxis**-response element (34), and in plants it has been dubbed the TIR domain (standing for T*oll*, the interleukin 1 receptor, and resistance gene) (4). It is striking that *R* genes from different plants conferring resistance to such distinct pathogens are so similar. The *L6* gene product carries an N-terminal putative signal anchor, which could attach it to the plasma membrane.

Additional NB-LRR subclasses may exist. The tomato *I2* gene that confers *Fusarium* wilt resistance carries a putative leucine zipper between the LRRs and the NB [35]. The tomato *Prf* gene was identified by mutagenesis as required for both *Pto* and *Fen* function; it encodes an extremely long region N-terminal to the NB but is clearly of the NB-LRR class. (36).

Paradoxically, even though LRR domains are more correlated with protein-protein interactions than protein kinase domains, no direct interaction has been detected between any of these NB-LRR *R* gene products and their genetically defined candidate ligands using yeast two-hybrid systems. Nevertheless, transient expression experiments showed that *Rps2*(37) and *Rpm1* (38) must recognize *AvrRpt2* and *AvrB* within the plant cell. *AvrBs3*, recognized by the as-yet-uncharacterized *Bs3 R* gene product of pepper, is also recognized within the plant cell (39).

It is widely believed that the *R* gene products form part of a complex with other proteins to create a functional recognition and signal transduction machine. The nature of this complex is currently under vigorous investigation. Many other questions also remain unanswered. What are the bacterial *Avr* products doing in the compatible interaction? Are fungal resistance genes of the NB-LRR type recognizing fungal proteins that are delivered into the plant cell? A combination of genetic and biochemical approaches are being used to understand *R* gene product-dependent recognition and signal transduction events. *NDR1*, identified by mutagenesis as required for *Rps2* function, encodes a novel protein with two membrane-spanning domains (40). *EDS1*, required for *RPP5* function but not *Rps2* function (41), shows homology to lipases (J Parker, personal communication). Yeast two-hybrid analysis has led to the discovery of genes whose products interact with *Pto*; some are protein kinases and some are transcription factors (42, 43).

2. Resistance to Pathogen Toxins

Some pathogens produce toxins, and resistance is conferred by a dominant gene that encodes a detoxifying enzyme. The maize *Hm1* gene encodes an NADPH oxidoreductase that inactivates the

Cochliobolus carbonum HC toxin (44). *Hm1* was the first *R* gene to be isolated, but it does not conform to gene-for-gene genetics in that recessive mutations in the pathogen to overcome Hm1 have never been recovered. In the 1970s, many maize varieties carried the T cytoplasm, whose mitochondria are sensitive to T toxin from *Cochliobolus heterostrophus*, the causative agent of Southern Corn leaf blight. Resistant varieties that use a different cytoplasmic male sterility genotype were then deployed, which controlled the disease.

3. *Mlo* Recessive Resistance Genes

There are several recessive resistance genes, of which the best characterized is barley *mlo*. *Mlo* mutants have a disease lesion-mimic phenotype and enhanced resistance to all races of the powdery mildew pathogen, *Erysiphe graminis*. The *Mlo* gene encodes a protein with seven transmembrane domains that presumably regulate negatively the defense response (45). It is also the pioneer of a new family of plant genes; analysis of the *Arabidopsis* genome sequence suggests that it will contain at least 60 genes in this class, with as yet unknown biochemical function.

4. Summary

Different classes of *R* genes in plants encode either recognition and response systems, or toxin detoxification or tolerance mechanisms, or they derepress plant defense mechanisms. Many *R* genes have now been isolated; the challenge is now to find out how their gene products work.

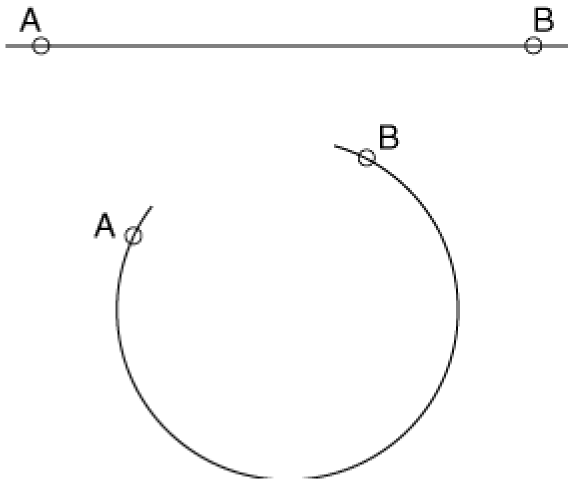
Distance Geometry

Many physical methods used to examine a biological macromolecule in solution produce information about the distance that separates two parts of the molecule. These methods include fluorescence **energy transfer**, chemical cross-linking**,** light scattering, and several kinds of nuclear magnetic resonance (NMR) observations. Any information about distances between different parts of a molecule limits the number of conformations that are possible for that molecule. Distance geometry is a mathematical approach that can be used to help define the conformations of a molecule that are consistent with experimental distance information (1-6).

With X-ray crystallography methods, the tertiary structure of the molecule of interest is defined by analysis of a set of diffraction data. A relation exists between every feature of the diffraction pattern exhibited by the crystal and the positions of the atoms of molecules within the crystal. When this connection is elucidated, the three-dimensional (3D) structure of the molecule is revealed. A different approach is used to find 3D structures using distance information. Consider a polymeric molecule in an extended conformation, represented by the line below.



If free rotation exists about some or all of the bonds along the molecular backbone, a huge number of conformations are possible for the molecule. If, however, an experimental observation indicates, for example, that the atoms at the position labeled A must be within 0.3 nm of the atoms at the position labeled B, then the number of possible conformations for the molecule is greatly reduced—the only conformations that need further consideration are those that are consistent with the constraint that atoms at A and B must be close to each other. Other experimentally defined distances would further reduce the number of possible 3D structures. If enough such constraints exist, only one or a small family of structures is likely that is consistent with all of them. Generally, the more constraints that can be established by experiment, the better known will be the tertiary structure. NMR methods, particularly those that measure nuclear Overhauser effects (NOEs), can produce a large number of distance constraints on possible conformations of a macromolecule. An advantage in using NMR observations in this way is that the molecule of interest does not have to be in the solid (crystalline) state for successful structure determination.

An N×N matrix of distances can be defined for a molecule made up of N atoms; N (N–1)/2 unique interatomic distances exist in this matrix. If all of the distances are accurately known, mathematical methods are available to define the Cartesian coordinates of the atoms from the known distances (4). Many of the distances in the distance matrix are essentially independent of conformation and are reliably known *a priori*. Such data would include the distance between two hydrogen atoms attached to an aromatic ring. Other distances can be estimated experimentally. Information about dihedral angles and other bond angles can be used to define other distances. For some distances, however, little or no accurate distance information will be available. Thus, the distance matrix will typically be incomplete, and a unique solution for Cartesian coordinates cannot be obtained. A variety of algorithms have been developed to deal with the missing or incomplete distance information. Regardless of the approach used, distance geometry calculations typically do not produce a single conformation but an ensemble of conformations, all of which are consistent with the available distance constraints. These conformations are used as starting points for additional refinement by conformational energy minimization and simulated annealing procedures. (See also Nuclear Overhauser Effect (NOE), Simulated Annealing).

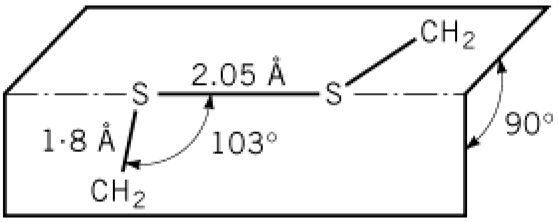
Disulfide Bonds

The disulfide bond occurs in many biological molecules, most frequently in **secretory proteins**, in the form of a covalent linkage between the thiol groups of pairs of cysteine residues (Fig. 1). Formation of a disulfide bond from two thiol groups requires an oxidant as two electrons or hydrogen atoms are released:

$$2\text{–SH} \rightarrow \text{–S–S–} + 2H^{+} + 2e^{-} \qquad (1)$$

The oxidant can be oxygen, but air oxidation of thiol compounds is a complex reaction involving many steps and intermediates, being catalyzed by metal ions, and releasing by-products such as peroxides.

Figure 1. Optimal stereochemistry of a disulfide bond between two cysteine residues. The two possible CH_2—S—S—CH_2 torsion angles about the disulfide bond of +90 and –90 are equally favorable.

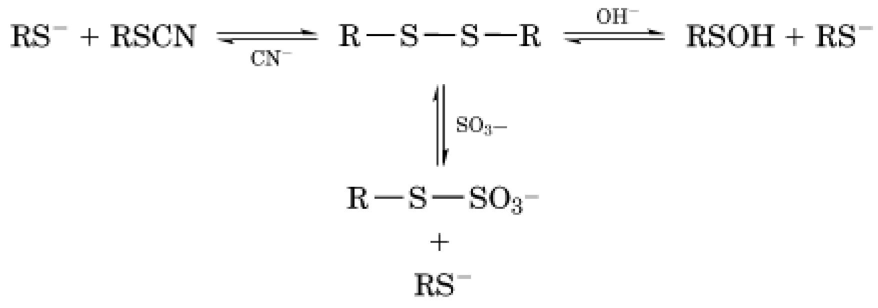


The disulfide bond is a stable covalent bond, and it would require some 60 kcal/mol (270 kJ/mol) to pull the two sulfur atoms apart. Yet this stable bond can be broken readily by a thiol group, which can react rapidly with a disulfide bond in the thiol–disulfide exchange reaction. With this reaction, disulfide bonds can be reduced by reacting them with an excess of a thiol reagent, RSH, such as b-mercaptoethanol or **dithiothreitol**:

$$P^{S}_{S} + 2RSH \leftrightarrow P^{SSR}_{SH} + RSH \leftrightarrow P^{SH}_{SH} + RSSR \qquad (2)$$

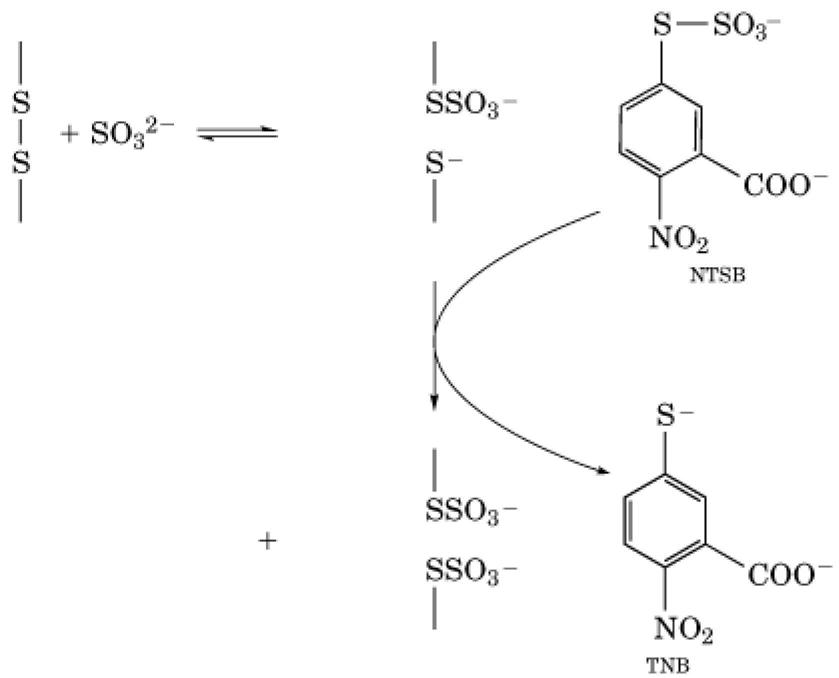
Many other reagents are available for chemically reducing disulfide bonds, such as borohydride, tributylphosphine, and tris-[2-carboxyethyl]-phosphine. The phosphines have the advantage that they function at acidic pH, where the original disulfide bond and the resulting thiol groups tend not to undergo further reactions. Furthermore, the phosphines do not react with many of the reagents that modify thiol groups, so reduction of the disulfide bond and alkylation of the thiol groups produced can be carried out simultaneously (1).

Disulfide bonds can also be cleaved by nucleophiles such as cyanide, sulfite, or hydroxide ion:



(3)

The equilibria for these reactions are such that it is difficult to drive the reactions to completion simply by adding reagent. Complete reaction can be accomplished, however, by adding a second reagent that reacts with the thiol generated. When this reagent is nitrothiosulfobenzoate (NTSB),



(4)

the reaction can go to completion, and one mole of the colored TNB product is generated for each mole of disulfide bond originally present. This is the most convenient assay for protein disulfide bonds so long as thiol groups are not also present.

The intrinsic free energy of a disulfide bond depends upon its angle of rotation (Fig. 1). It is most stable with a C-S-S-C torsion angle of ±90°, and an angle of 0° or 180° is believed to increase the free energy by about 28 kJ/mol. This corresponds to the free energy barrier to full rotation about the disulfide bond. Cyclic 5-membered rings, such as that of lipoic acid, have a torsion angle of only ±30° and are strained by about 15 kJ/mol. Cyclic 6-membered rings, such as that in the disulfide form of **dithiothreitol**, have torsion angles of about ±60°.

1. Disulfide Bonds in Proteins

Disulfide bonds are found most frequently in molecular biology within proteins, especially in proteins that are secreted. Most of the disulfide bonds observed in the X-ray crystallography structures of proteins have favorable stereochemistry and show little evidence of conformational strain, with close to the optimal torsion angles of ±90°. Only a few examples of hyperreactive disulfide bonds are known, such as that between the most distant cysteine residues in alpha-lactalbumin and hen lysozyme (2, 3).

As the disulfide bond is a covalent bond that is stable under appropriate conditions, which cysteine residues in a protein are paired in disulfide bonds can be determined chemically. The classical method is to fragment the protein into peptide fragments, under conditions where the disulfide bonds are kept intact. The peptide fragments are analyzed to determine which are linked by disulfide bonds. A newer technique is to reduce the disulfide bonds individually, using phosphines at acidic pH, where the disulfide bonds do not rearrange readily, and to identify the pairs of cysteine thiol groups generated (1, 4). A more elegant approach, but one not suited to modern separation techniques, is to use diagonal methods (5).

Disulfide bonds are well known to stabilize the folded conformations of proteins in which they occur, and conversely the folded conformations stabilize the disulfide bond. Many proteins that have disulfide bonds unfold when the disulfides are reduced. In considering disulfide bonds and protein stability, it is important to distinguish between the stability of the folded conformation relative to the unfolded protein, U, (i) when the disulfide bonds are kept intact:

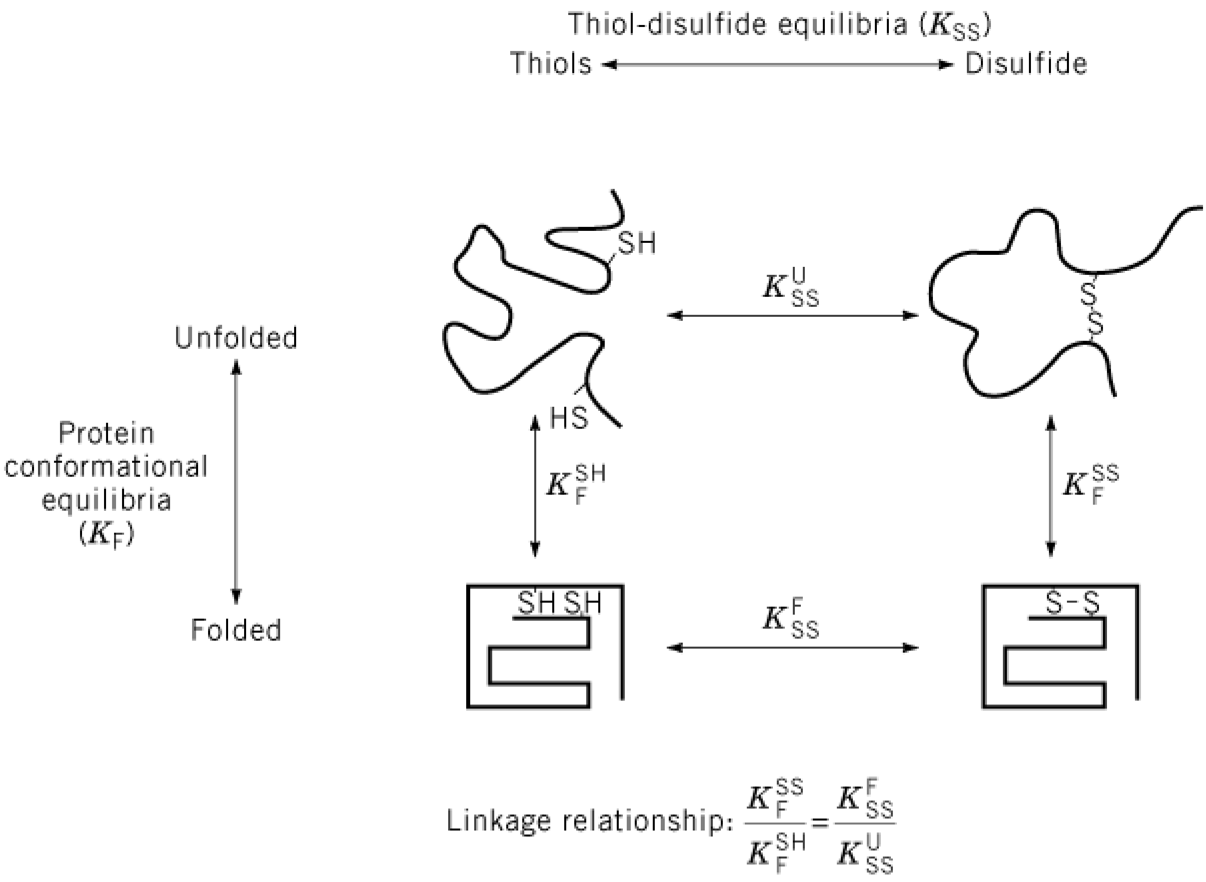
$$\mathbf{N}_{\mathbf{S}}^{\mathbf{S}} \leftrightarrow \mathbf{U}_{\mathbf{S}}^{\mathbf{S}} \tag{5}$$

and (ii) when the disulfide bonds are reduced upon unfolding and reformed when the protein folds:

$$\mathbf{N}_{\mathbf{S}}^{\mathbf{S}} + \mathbf{2RSH} \leftrightarrow \mathbf{U}_{\mathbf{SH}}^{\mathbf{SH}} + \mathbf{RSSR} \tag{6}$$

The stability of a protein disulfide bond, relative to the reduced form of the protein, with cysteine thiol groups (Eq. 6), depends upon the degree to which the protein conformation stabilizes the disulfide bond and upon the redox potential of the environment. A protein conformation that stabilizes a disulfide bond is stabilized to the same extent by the presence of that disulfide bond (Fig. 2). The greater the stability of the protein disulfide bond, the greater its contribution to stability of the folded conformation that stabilizes it.

Figure 2. Linkage between the stability of a particular folded conformation that favors a certain disulfide bond and the stability of that disulfide bond. A protein with two cysteine residues that can form a disulfide bond (right) is illustrated in either the unfolded (top) or folded (bottom) conformations. The indicated equilibrium constants represent the stabilities of the disulfide bonds, K_{SS}, and of the folded conformation, K_F. The equilibrium constants for disulfide stability, K_{SS}, must involve another reagent, as in Eq. 7 and 8, but this is omitted for simplicity. The linkage relationship states that whatever effect the folded conformation has on the stability of the disulfide bond, the presence of the disulfide bond must have the same quantitative effect on the stability of the folded conformation. Comparable linkage relationships pertain to all interactions within the folded conformation, not just disulfide bonds.



One way in which disulfide bonds stabilize the folded conformation, relative to the unfolded form with the disulfide bonds intact (Eq. 5), is by decreasing the conformational flexibility, or entropy, of the unfolded protein. The magnitude of this effect increases with increasing distance between the cysteine residues in the primary structure. It is often assumed that this is the only way that disulfide bonds stabilize the folded conformation, and equations are frequently given to predict the magnitude of the stabilization. Experimental observations indicate, however, that there are many other effects of a disulfide bond on the folded conformation, both stabilizing and destabilizing (6); the same energetically favorable disulfide bond can stabilize one folded conformation and destabilize another (7).

The redox potential determines the stability of any disulfide bond and is determined by the relative concentrations of thiol and disulfide reagents. In biological systems, this is primarily determined by the relative concentrations of the thiol and disulfide forms of glutathione, GSH and GSSG, respectively:

$$P^{SH}_{SH} + GSSG \overset{K_{eq}}{\leftrightarrow} P^{S}_{S} + 2GSH \qquad (7)$$

$$\frac{[P^{S}_{S}]}{[P^{SH}_{SH}]} = K_{eq}\frac{[GSSG]}{[GSH]^2} \qquad (8)$$

Within the cell cytosol, the concentration of GSH is generally 100-fold greater than that of GSSG, which is a moderately reducing environment, and a disulfide bond does not impart much stability. Within the endoplasmic reticulum, however, where secreted proteins fold and form disulfide bonds, the concentrations of GSH and GSSG are almost comparable (8), so any protein disulfide bond will be present about 100 times more frequently. These conditions are more oxidizing, but only stable protein disulfide bonds are generally formed and present under these conditions. Once the proteins are secreted from the cell, where the environment is usually much more oxidizing, the disulfide bonds contribute much more stability to the folded conformation.

Disulfide bonds are inserted into proteins naturally only when the protein conformation favors them. When the reduced protein, without disulfides, is unfolded, folding accompanies disulfide bond formation and can be used to determine the folding pathway (see Protein Folding In Vivo). Such pathways have demonstrated how only a slight tendency for an unfolded protein to stabilize a specific disulfide bond is consequently stabilized further by the presence of that disulfide bond, which can then lead to the formation of further disulfide bonds and the adoption of additional, and more stable, folded conformation.

Disulfide bonds are often stated to determine the folded conformations of the protein in which they occur. This cannot be the case, however, for such disulfide bonds would never be generated in a natural protein if the conformation did not favor them. In some cases, proteins have been shown to adopt exactly the same folded conformation in the absence of each of the disulfide bonds (9). Clearly, the disulfide bonds only stabilize the folded conformation and do not determine it.

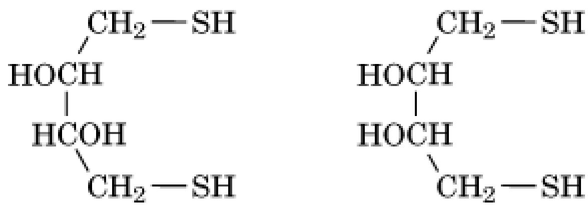
Dithiothreitol, Dithioerythritol

Dithiothreitol (DTT, or DTT^{SH}_{SH}) and dithioerythritol (DTE) have closely related structures, each with two thiol groups:



DTT^{SH}_{SH} DTE^{SH}_{SH}

(1)

They have the very useful property of forming a stable, cyclic, intramolecular disulfide bond, abbreviated here as $DTT^{S}_{S}$and DTT^{S}_{S}. Consequently, they are potent reductants of disulfide bonds, eg, RSSR:

$$DTT^{S}_{S} + RSSR \leftrightarrow DTT^{S}_{S} + 2RSH \quad (2)$$

For a typical model disulfide bond, like that of glutathione or **mercaptoethanol**, the equilibrium constant for this reaction,

$$K_{eq} = \frac{[DTT^{S}_{S}][RSH]^2}{[DTT^{SH}_{SH}][RSSR]} \quad (3)$$

has the value 200 M to 2800 M at high and low pH values, respectively (1). The dependence over the pH range of about 8 to 11 arises because of the difference in p K_a values of the thiol groups involved. The first thiol group of $DTT^{SH}_{SH}$to ionize has an apparent pK_a of about 9.2, while that of the second is about 10.2. Even with identical microscopic pK_a values, the first and second apparent pK_a values would be expected to differ by 0.6 pH units for statistical reasons, so there is little electrostatic interaction between the two thiol groups, ionization of one increasing the p K_a of the other by at most 0.4 pH units. The equilibrium constant has the unit of concentration because the disulfide bond of DTT is intramolecular, whereas that of RSSR can be considered to be intermolecular because its reduction generates two RSH molecules. The equilibrium constant can therefore be interpreted in terms of the effective molarity of the two thiol groups of DTT^{SH}_{SH}relative to each other. It has a large value of approximately 120 M because the two thiol groups are kept in reasonable proximity and are able to form a disulfide bond in a favorable 6-membered ring structure (2), even though the disulfide bond of DTT^{S}_{S}appears to be somewhat strained; it has a CSSC dihedral angle of only about 60°, rather than the most favorable 90° (3). Nevertheless, there is only a small change in enthalpy of 0.5 kcal/mol when DTT^{SH}_{SH}reduces model linear disulfide bonds, as in Eq. 2 (4). The thiol and disulfide forms may be distinguished readily by the UV **absorbance** of the disulfide form at 280 nm (5).

These reagents were introduced by Cleland (5) to overcome the limited potency of thiol reagents such as mercaptoethanol, and they are often called "Cleland's reagent." Although he appears to have overestimated their efficacy, measuring an equilibrium constant for Eq. 3 of 10^4 M, they are still some of the most effective disulfide reductants readily available.

Divergent Evolution

Divergence is defined as an evolutionary event in which two morphological or molecular traits arose from a common ancestor, and were initially identical, but became dissimilar during evolution. Divergence is, of course, extremely common and the basis for most evolution; without divergence, all lineages would remain the same.

Divergent evolution is usually apparent at the molecular level from significant similarities between the amino acid sequences of proteins and the **nucleotide sequences** of DNA or RNA. There are so many such sequences possible that it seems most improbable that two sequences could become similar by chance. Similar sequences are said to be **homologous**, and the differences between them are assumed to be related to the time since they diverged from their last common ancestor. The molecular mechanisms of evolutionary divergence of the genetic material include nucleotide substitution and deletion/insertion; chromosomal recombination, transposition, and **inversion;** gene duplication, and **gene conversion;** exon shuffling, and **domain** shuffling; and horizontal gene transfer. The number of nucleotide substitutions is a simple and useful measure of the degree of divergence between two sequences. In fact, there are a dozen methods available for estimating the number of nucleotide substitutions, using one to six parameters (1-5). Once the number of nucleotide substitutions has been estimated, a phylogenetic tree can be constructed by using those numbers, to display the pathway that the divergence has followed during evolution (6).

Divergence is contrasted with convergent evolution, which is much more rare. Convergence is an evolutionary event in which two morphological or molecular traits become similar during evolution, even though the ancestor is totally different. In the case of divergence, there must be a certain degree of similarity between two traits to suggest that they had a common ancestor. For convergence, on the other hand, a certain degree of dissimilarity must exist if the two traits originated from independent ancestors. Therefore, the distinction between divergence and convergence can be difficult to judge unless additional evolutionary information is available to indicate whether the similarities or the differences are the more significant. In the case of nucleotide or amino acid sequences, any similarities greater than expected from random are usually taken to indicate divergence. For example, the divergence of nucleotide sequences between human and chicken is shown in Figure 1, where the asterisk (*) indicates a site where nucleotide differences exist, and where 20 nucleotide sites are different and the remaining sites are the same. The probability that this similarity occurred by mere chance is extremely small. Therefore, it can be reasonably concluded that the difference in nucleotide sequences between these two species is due to divergence. Thus, it follows that divergence from the common ancestor has taken place as a result of the accumulation of nucleotide substitutions.

Figure 1. Divergence of nucleotide sequences between humans and chickens.

Human	Gly	Ile	Val	Glu	Gln	Cys	Cys	Thr	Ser	Ile	Cys	Ser	Leu	Tyr	Gln
	GGC	ATT	GTG	GAA	CAA	TGC	TGT	ACC	AGC	ATC	TGC	TCC	CTC	TAC	CAG
	*		*	*			*	***	*	**	*				*
Chicken	GGG	ATT	GTT	GAG	CAA	TGC	TGC	CAT	AAC	ACG	TGT	TCC	CTC	TAC	CAA
	Gly	Ile	Val	Glu	Gln	Cys	Cys	His	Asn	Thr	Cys	Ser	Leu	Tyr	Gln

Human	Leu	Glu	Asn	Tyr	Cys	Asn
	CTG	GAG	AAC	TAC	TGC	AAC
Chicken	CTG	GAG	ACC	TAC	TGC	AAC
	Leu	Glu	Asn	Tyr	Cys	Asn

During the process of molecular evolution, the number of nucleotide differences increases but probably never decreases. Therefore, in most cases, the evolutionary event can be explained by divergence only. Considering the tertiary structures of proteins, however, in some cases the structures are quite similar, even though their amino acid sequences, as well as their biological function, are very different. For these cases, convergence is a possibility, although it could also be simply a case of extreme divergence masking their original sequence and functional identity.

DNA Chips

The start of the Human Genome Project in the late 1980s refocused scientists' attention on new, high-throughput technologies for handling and analyzing DNA. Several technologies developed by physicists were evaluated for their potential use in the study of biomolecules. For example, mass spectrometry techniques and the scanning tunneling microscope are now used for analyzing and sequencing DNA. Another technology developed by physicists and applied to biology is the microchip. The semiconductor industry manufactured silicon chips with smaller and smaller features, which allows for greater numbers of operations with a chip of a standardized size. This benefit of miniaturization was applied to the biological sciences in the form of multiparallel arrays of DNA fragments on a small chip. Arraying of DNA or RNA samples onto nitrocellulose or nylon membranes for hybridization studies is a very common analytical procedure in a molecular biology lab (1) (see Blotting). DNA chips or microarrays are, in principle, miniaturized versions of these standard dot-blot techniques. With great precision, thousands of DNA fragments, often amplified by **PCR**, or DNA oligonucleotides are spotted/printed onto glass microscope slides. In the case of oligonucleotides, they can also be synthesized directly on coated silicon chips (see DNA Synthesis). These DNA chips are then used to probe fluorescent-labeled DNA or RNA samples for the presence of specific complementary sequences. DNA chip technology is currently being applied in the areas of monitoring gene expression, polymorphism analysis, gene mutation analysis, and DNA sequencing.

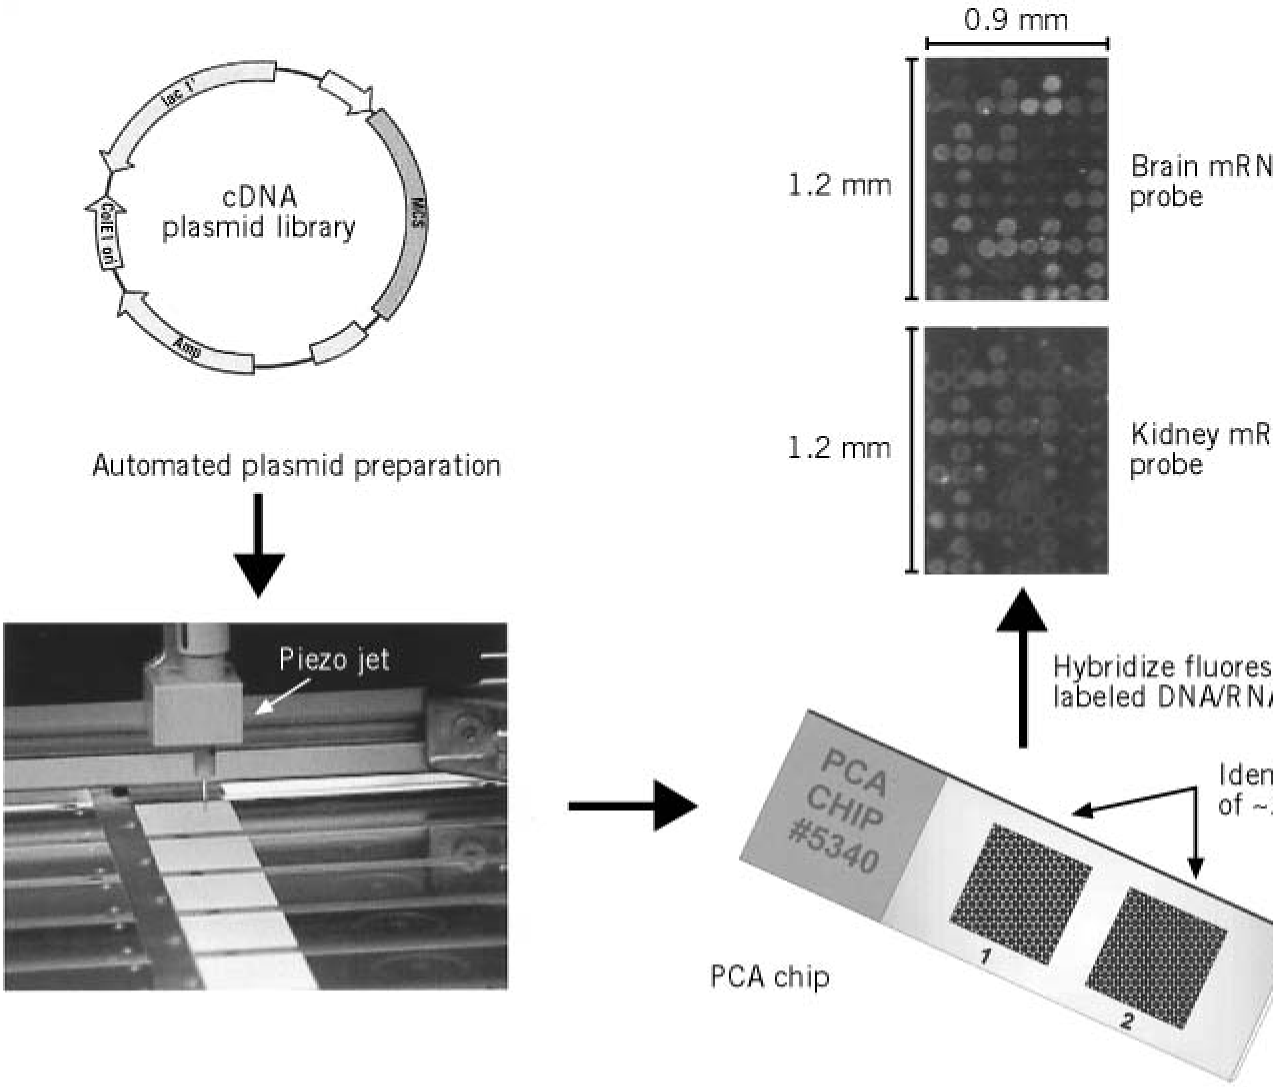
1. Putting Genes on a Chip

The fabrication of high-density arrays on chips for parallel analysis of up to several thousand cDNA clones or PCR fragments on a surface area of approximately 1 cm^2 can be achieved by two techniques: microprinting or piezojet dispensing. The high-density arrays are deposited on the flat solid support, usually a glass slide. The key function of the printing or dispensing process is the extraction of a small volume of sample from a reservoir (eg, a microtiter plate) and the deposition of the same amount of sample fluid in each spot, at equivalent locations on each chip. The center-to-center separation of individual spots in high-density arrays is typically 150 to 500 µm. The deposited sample volume ranges form 50 to 400 pl per spot.

Microprinting devices use an array of pins with either hollow steel capillaries or flat tips. The amount of sample deposited at each spot is defined by the capillary forces acting on the droplet, which adheres to the pin after immersion into the sample reservoir. The droplets at the tips are then transferred to the spots in the array by moving the pins close to the chip surface. After each sample, the tip is cleaned by rinsing. The amount of liquid deposited depends on the size of the tip.

The piezojet is a contactless dispensing technique for subnanoliter droplets. It is based on a cylindrical piezo ceramic that compresses a glass capillary with an inner diameter of ~1 mm on application of an electric pulse. A small droplet is then expelled through the funnel-shaped orifice of the capillary. The outlet diameter of the orifice is ~50 µm. Very uniform droplets can be prepared by this method (see Fig. 1).

Figure 1. The principle of preparing and applying plasmid chip arrays (PCA), as developed by U. Certa and R. Hochstra Hoffmann–La Roche Ltd, Basel, Switzerland).



The piezojet-dispensing process consists of three steps: (1) Aspiration of an aliquot of sample through the capillary, (2) dispensing of one subnanoliter droplet of sample to equivalent spots on each chip, and (3) discharge of remaining sample volume and cleaning of the piezojet. In order to use the sample material effectively, the aspiration volume of the piezojet should be in the microliter range.

The deposited DNA has to be immobilized on the surface in order to enable the subsequent processing steps. The most commonly used attachment method is to coat the glass slides with polylysine, which holds the negatively charged DNA backbone by electrostatic interactions. Alternative methods, like **streptavidin**-coated slides to bind **biotin**-labeled DNA, and various chemical approaches to bind DNA covalently to pretreated glass, are under development.

The most elegant way to attach DNA fragments covalently onto the glass chips has been developed by Fodor and colleagues at Affymetrix (2-4). This method allows light-directed synthesis of thousands of DNA fragments (oligonucleotides) in precise locations on the microchip. To begin the process, linkers modified with a photochemically removable protecting group are attached to the solid substrate. Light is directed through a photolithographic mask, illuminating specific grid squares on the chip and causing photodeprotection, or the removal of the blocking group, in those squares. The chip is then incubated with a nucleotide harboring a photolabile protecting group at the 5′ end. The cycle continues: the chip is exposed to light through the next mask, which activates new grid sites for reaction with the subsequent photoprotected nucleotide. Using the proper set of masks and chemical steps, it is possible to construct a defined collection of oligonucleotides, generally 20 to 25 bases long, each in a predefined position on the array. A standard 1.28-cm^2 chip can currently be packaged with about 400,000 individual, well-defined oligonucleotides representing many thousand genes.

2. Monitoring Gene Expression

A bacterial genome, such as that of *Escherichia coli*, encodes 4288 different genes, the yeast *Saccharomyces cerevisiae* genome about 6000 genes; *Caenorhabditis elegans* has about two times more genes, and the human genome may contain approximately 100,000 unique genes. At least partial sequence information for all these genes will be available soon. Sequence information alone, however, is insufficient for a full understanding of gene function and the control of gene expression. Only a subset of all encoded genes is expressed in any given cell; in higher eukaryotes, this subset is smaller than in bacteria or yeast cells. The levels and the timing of gene expression determine the fate of the cells, their reproduction, differentiation, function, communication, and physiology. Methods such as **Northern blots**, nuclease protection, and RT (reverse transcriptase)- **PCR** are frequently used to measure gene transcripts, but they have the inherent disadvantage of being serial, analyzing a single messenger RNA at a time. Most comparative techniques, like subtractive hybridization, differential display (5) of amplified mRNA's on gels, and the SAGE (serial analysis of gene expression) method of Velculescu et al. (6), are laborious, often nonreproducible, and not particularly sensitive. Arrays of several thousand genes, the DNA chips, for the first time make it possible to obtain gene expression information on complete genomes (7) quickly, accurately, and efficiently. These gene arrays are in principle reverse Northern blots, where the DNA probes have been immobilized to identify and measure large numbers of mRNA species in parallel. Two prototype DNA microarrays for gene expression monitoring can be described:

2.1. cDNA Microarrays

Brown and his colleagues developed a high-capacity system to monitor the expression of many genes in parallel (8, 9). In short, the complementary DNA of expressed mRNAs from cells is collected, and individual cDNA molecules are isolated and amplified. A microsample of each cDNA from the library is then deposited by high-speed robotic printing on a polylysine-coated glass surface in an array format. Each gene has a unique location in the microarray, which may represent several thousands of genes on a few square centimeter. To compare expression of these genes between two tissues or two cell types, the $poly(A)^+$–mRNA in the two samples is copied into cDNA and labeled with two differently colored fluorescent molecules. Both probe samples are applied to a single microarray and allowed to react with the DNA on the microarray. After the appropriate washing steps, each element of the microarray is scanned for fluorescence intensity from the two colors by a laser fluorescence scanner. The observed fluorescence intensity at each array element is proportional to the number of fluorescent cDNA molecules bound to it, and the ratio of the two colors is an accurate measurement of the relative expression level of the genes in the two tissue or cell samples. Twofold changes in expression can be detected (10). As an illustration, Figure 1 shows a similar DNA microarray, the plasmid chip array (PCA), made by piezojet dispensing in the labs of R. Hochstrasser and U. Certa (F. Hoffmann-La Roche Ltd., Basel, Switzerland).

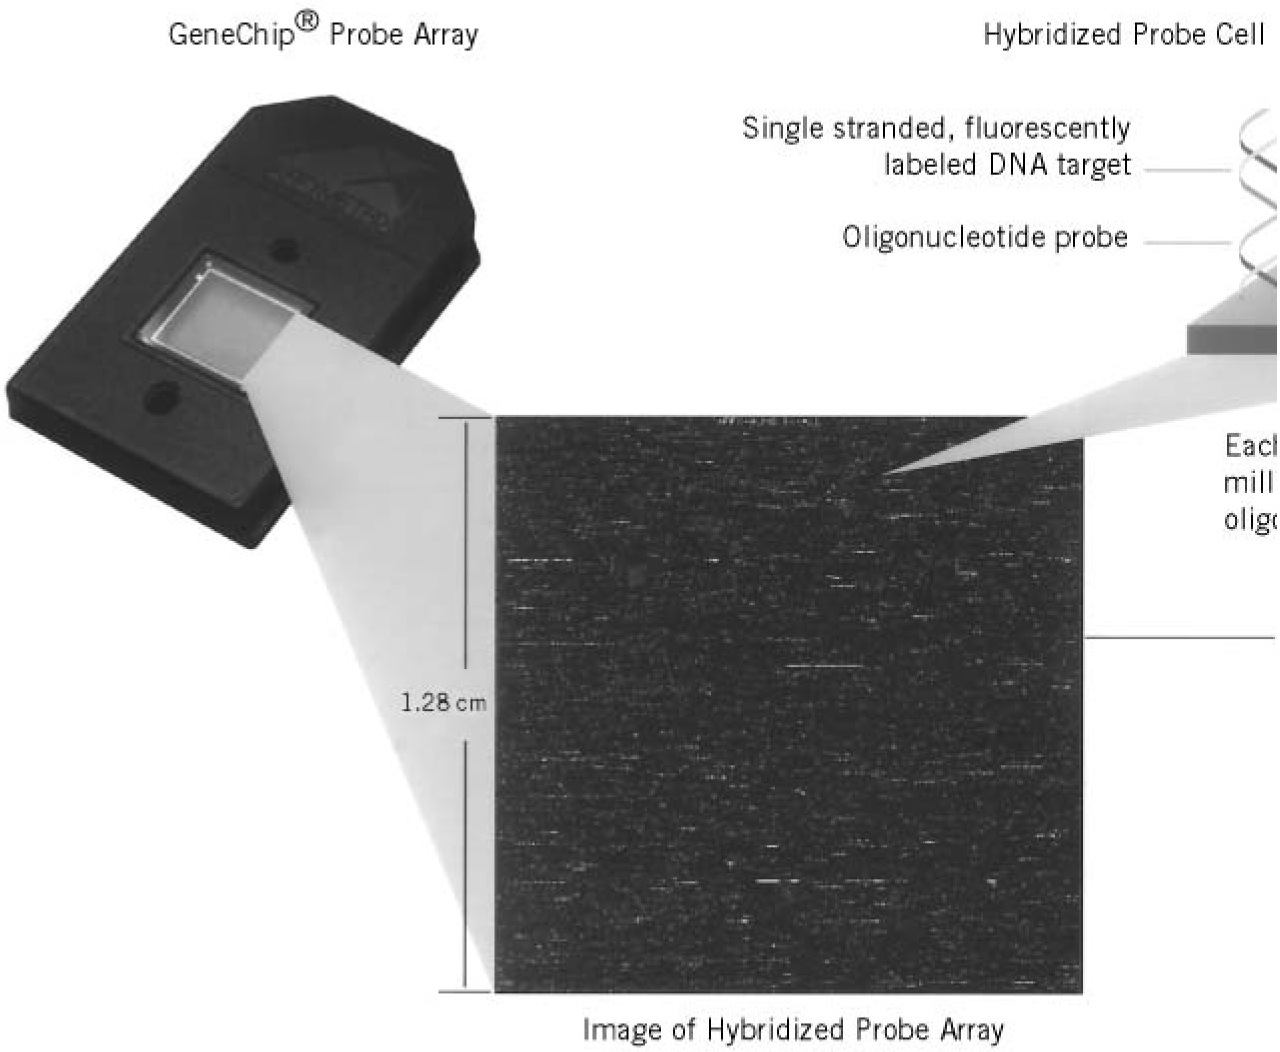
2.2. Oligonucleotide Microarrays

High-density arrays of oligonucleotide probes represent the other prototype method for mRNA expression monitoring. Sequence information about the expressed genes is used directly to select oligonucleotides and to design the photolithographic masks for combinatorial synthesis of the probes directly on derivatized glass, as described previously. The arrays are intentionally redundant, as they contain collections of pairs of probes for each of the RNAs being monitored. Each probe pair consists of a 20- to 25-mer oligonucleotide that is perfectly complementary to a subsequence of a particular message and a mismatch oligo that is identical except for a single base difference in a central position, which serves as an internal control for hybridization specificity. For array hybridization experiments, target RNA is prepared from cellular mRNA by incorporating labeled ribonucleotides in an *in vitro* transcription reaction (11), or by direct chemical attachment (12). After hybridization and washing, fluorescence imaging of the arrays is accomplished with a scanning **confocal microscope**. Because oligonucleotide probes for each gene are specifically chosen and synthesized in known locations on the arrays, the hybridization patterns and intensities can be interpreted in terms of gene identity and the relative amount of each transcript. This technology has been successfully applied for monitoring gene expression in mammalian cells (11), yeast (7), and bacteria (12), measuring expression levels of less than one copy of mRNA to several hundred copies per cell in one hybridization experiment.

3. Accessing Genetic Diversity

High-density oligonucleotide probe arrays (Fig. 2) can also be applied to a broad range of nucleic acid sequence analysis problems, including pathogen identification, polymorphism detection and sequence checking. The significant instability of internal probe–target mismatches relative to perfect matches (4, 13) is used to design arrays of probes capable of detecting differences between nucleic acid targets. To interrogate the identity of a nucleotide as position X of a known DNA sequence, four oligonucleotides can be offered with the four different choices A, G, T, C in the middle of 15 or so flanking nucleotides that perfectly match the reference sequence. The probe with the highest intensity after hybridization would indicate the identity of the unknown base. This concept can be extended to detect polymorphisms/mutations relative to a characterized **consensus sequence**. Thus, to screen 1000 nucleotides for polymorphisms/mutations would require 4000 probes. Current applications of this technique include the survey of drug-resistance mutations in **HIV**-1 reverse transcriptase and proteinase genes, a p53 mutations screen, and a cytochrome P450 allelic variants screen.

Figure 2. The basic principle of oligonucleotide microarrays (courtesy of Affymetrix, Santa Clara, CA).



4. Sequencing by Hybridization

Hybridization can also be used to determine the sequence of unknown DNA, ie, *de novo* DNA sequencing. Sequencing by hybridization is based on the use of oligonucleotide hybridization to determine the set of constituent subsequences in a DNA fragment. This concept which was spearheaded by Crkvenjakov (14, 15) uses a microarray of all possible *n*-nucleotide oligomers, eg, 65,635 possible octamers, to identify all the *n*-mers present in an unknown DNA sequence. Powerful computational approaches are then used to assemble the complete sequence from the measured hybridization patterns. High-density oligonucleotide probe array technology shows significant promise in enabling *de novo* sequencing in a fast and reliable manner.

DNA Damage, Inducible Responses To

Agents that damage **DNA**, like other external stimuli, elicit a complex series of cellular responses in both prokaryotes and eukaryotes. The molecular mechanisms and the consequences of induction of these genotoxic responses in prokaryotes are well-understood. In eukaryotes, in contrast, the mechanisms and the effects of the multiple response reactions remain ill-defined. In *Escherichia coli* there are genotoxic response reactions that are induced mainly, but not exclusively, by bulky DNA lesions (SOS response), by alkylating agents (adaptation), and by oxidative stress (adaptive response to oxidative stress). These response reactions result in **transcriptional** activation of genes that inactivate the noxious agent, repair the damage caused by the agent (see DNA Repair), or help the cell survive the DNA damage.

1. SOS Response

The SOS response is a coordinated cellular response in *E. coli* and aids in the survival of the organism by affecting the expression of proteins that are involved in cellular division, **replication**, recombination, and excision repair (1) (see SOS Response). About 30 genes are involved. The basic mechanism of regulation is relatively simple (2, 3). Under normal conditions, the LexA repressor binds to the SOS box, with the sequence 5′-CTG-N $_{10}$-CAG-3′, to maintain repression of the SOS regulon. Directly or indirectly, DNA damage or other replication blocks generate single-stranded regions that lead to the formation of single-stranded DNA, on which the RecA protein polymerizes (4, 5). The RecA-single-stranded DNA filament binds to LexA and stimulates its autoproteolysis activity (6). Cleavage of LexA inactivates its repressor activity (2-5), allowing transcription of the SOS genes, including *lexA* and *recA* themselves. Cell division stops, excision (7, 8) and recombination (2, 3) activities increase, and the capacity of replicase to bypass the damage increases (9, 10). All of these enable the cell either to eliminate the DNA damage or to survive with damaged DNA. Upon recovery, the inducing signal disappears, and LexA accumulates and represses the cognate genes. The excision repair genes *uvrA*, *uvrB*, and *uvr*D (7, 8) are under the control of the

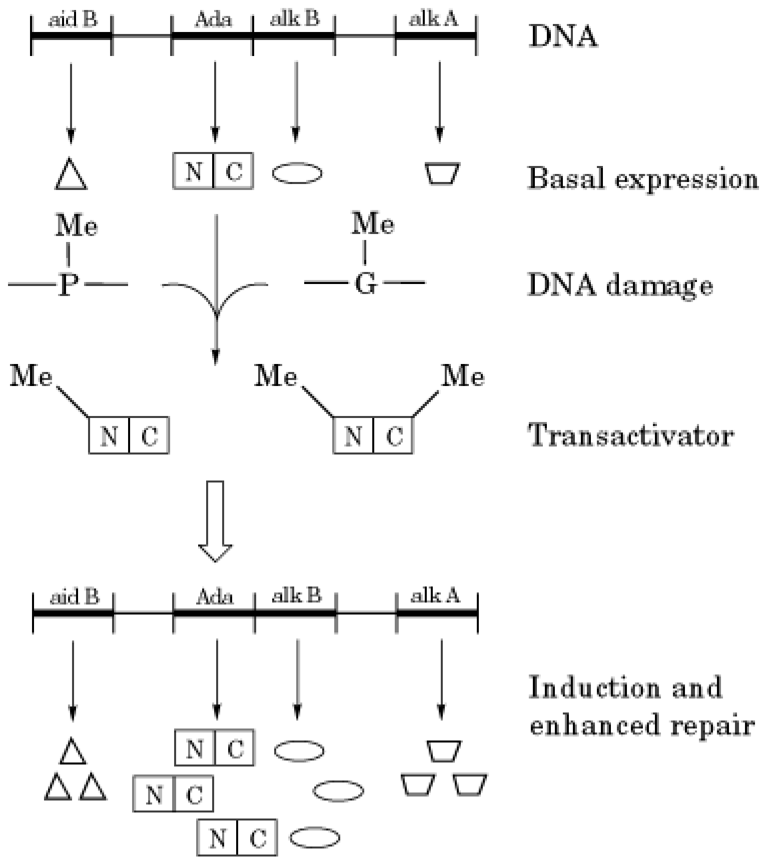
LexA protein; consequently, the cellular excision repair activity increases transiently as part of the SOS response reaction and then drops down to preinduction levels after repair.

2. Adaptive Response

The adaptive response is the phenomenon of increased resistance of cells to killing and mutation by alkylating agents that results from prior exposure to lower doses of the same agent (11). The phenomenon was originally discovered in *E. coli* and was later found in other prokaryotes. There is no evidence for an adaptive response in eukaryotes or archaebacteria, although alkylating agents elicit a general stress response reaction in eukaryotes.

The molecular mechanism of the adaptive response in *E. coli* is relatively simple and known in considerable detail (12, 13) (Fig. 1). Treatment of cells with alkylating agents such as *N*-methyl-*N*′-nitro- *N*-nitrosoguanidine (MNNG) methylates multiple sites on DNA, including the backbone phosphate groups. The methylphosphotriesters that are formed by such treatments are mostly nonmutagenic and nonlethal. In contrast, the product O^6-methylguanine is a miscoding base that induces G to A transition mutations, and 3-methyladenine is a lethal lesion. However, it is the methylphosphotriesters that constitute the signal substrate for the repair of the mutagenic and lethal alkylation products.

Figure 1. Adaptive response in *E. coli*. The Ada protein transfers the methyl group from methylphosphotriesters to Cys69 of the protein. This covalent modification activates Ada as a transcription factor, which induces its own gene for repair of O^6-methylguanine, *alkA* for repair of 3-methyladenine, and *aidB* and *alkB* for protecting DNA.



The adaptive response is a positive regulatory response reaction. The central regulator in this response reaction is the 39-kDa Ada protein (O6-methylguanine DNA methyltransferase). The structure of the Ada B protein in *E. coli* exhibits a **helix–turn–helix** variant **DNA-binding** motif, but this motif is separate from its active site (14). Ada acts both as a transcription factor and as a methyltransferase. Upon formation of methylphosphotriesters, the Ada protein transfers the methyl group from the phosphate to a cysteine residue (Cys69) in the amino-terminal domain of the molecule. This reaction induces a conformational change in the protein, which increases its affinity for the Ada box, with the sequence A_3 –N_3–A $_3$–GCGCA (12, 13), upstream of cognate **promoters**. Binding of Ada to these promoters activates transcription of target genes that are involved in preventing and repairing the damage caused by alkylating agents. The following genes are induced by Ada: the *ada* gene itself, *alkA*, *alkB* and *aidB*. The roles of these genes in cellular defense against alkylation killing and mutagenesis are summarized below.

2.1. Ada

The Ada protein performs three functions. It transfers the methyl group from O^6-methyl-guanine (or O^4-methylthymine) to Cys321 of Ada (15), it transfers the methyl group from the methylphosphotriester to Cys69, and it binds upstream of the promoters of cognate genes and acts as a positive transcriptional regulator. The order of the methyl transfer reactions is random, and they are independent of one another. In contrast, binding of Ada to promoter regions is strongly influenced by methylation of residue Cys69. Even though unmethylated Ada binds to certain promoters (such as the *ada* promoter) with low affinity, the binding is strongly stimulated by methylation of Cys69, and the binding to other promoters is completely dependent on the methylation of Cys-69. The methylation status of Cys321 has no effect on the regulatory activity of the protein. In addition to Ada, *E. coli* and some other prokaryotes contain a second alkyl transferase with no regulatory function (16).

2.2. AlkA

The AlkA protein removes 3-methyladenine and other alkylated purines by a DNA glycosylase activity. There are two 3-methyladenine DNA glycosylases (Tag). One is encoded by the *tag* gene (TagI), which is not regulated by Ada and has narrow substrate specificity. The other, which is regulated by Ada and encoded by *alkA* (TagII), removes 3-methyladenine and other methylated purines, as well as O^4-methyl thymine, and thus has a wide substrate range.

2.3. AlkB

The AlkB protein is a 27-kDa monomer that enables cells to survive DNA damage induced by SN2 alkylating agents, but not by SN1. Although it is known that the protein acts at the level of DNA, the precise mechanism of the repair reaction is not known.

2.4. AidB

The AidB protein is a 60-kDa monomer with a high degree of homology to several mammalian acetyl coenzyme A dehydrogenases, and it exhibits isovaleryl coenzyme A dehydrogenase activity. Metabolic activation by glutathione or other nonprotein thiol groups is necessary for the toxic effect of MNNG. It is possible that AidB confers resistance by affecting the intracellular thiol pool, or by acting directly on MNNG and detoxifying it. The situation is somewhat similar to the induction of *zwf* as part of the oxidative stress response reaction. This gene encodes glucose-6-phosphate dehydrogenase; upon induction of the SoxRS regulon by superoxides, the level of the dehydrogenase increases, and the enzyme in turn increases the cellular NADPH pool, which detoxifies reactive oxygen species.

2.5. Mechanism of the Adaptive Response

The homeostasis of the adaptive response is maintained as follows. Upon DNA damage by MNNG, the Ada protein, which is present at about 100 copies per cell, reacts with methylphosphotriesters and transfers the methyl group to Cys69. As a result, Ada becomes a potent transcription factor, binds upstream of the *ada-alkB*, *aidB* and *alkA* operons, and turns on these genes. Upon completion of DNA repair and elimination of the alkylating agent, the methylphosphotriester inducing signal disappears. The accumulated Ada is no longer methylated; because of its high concentration, it binds to but cannot induce the cognate genes, interfering with binding of alkylated Ada. Eventually, the alkylated Ada is degraded or diluted out by cell growth and division, and the adaptation reaction is turned off.

Human O^6-methylguanine DNA methyltransferase has been characterized in some detail (17). It has no regulatory function, but it has an unusual relation to cellular transformation. Resistance to alkylating agents has been observed in some tumor cell lines that lack O^6-methyltransferase. The resistance appears to be due to simultaneous defects in O^6-methyltransferase and in mismatch repair. An accumulation of unrepaired O^6-methylguanine lesions should lead to cell death, because of a phenomenon called futile cycling, where mismatch repair systems attempt, but fail, to repair the lesion, halting replication and finally inducing apoptosis. Therefore, in tumor cell lines that already lack O^6-methyltransferase, an additional defect in mismatch repair results in the loss of futile cycling and allows the cells to survive treatment with alkylating agents.

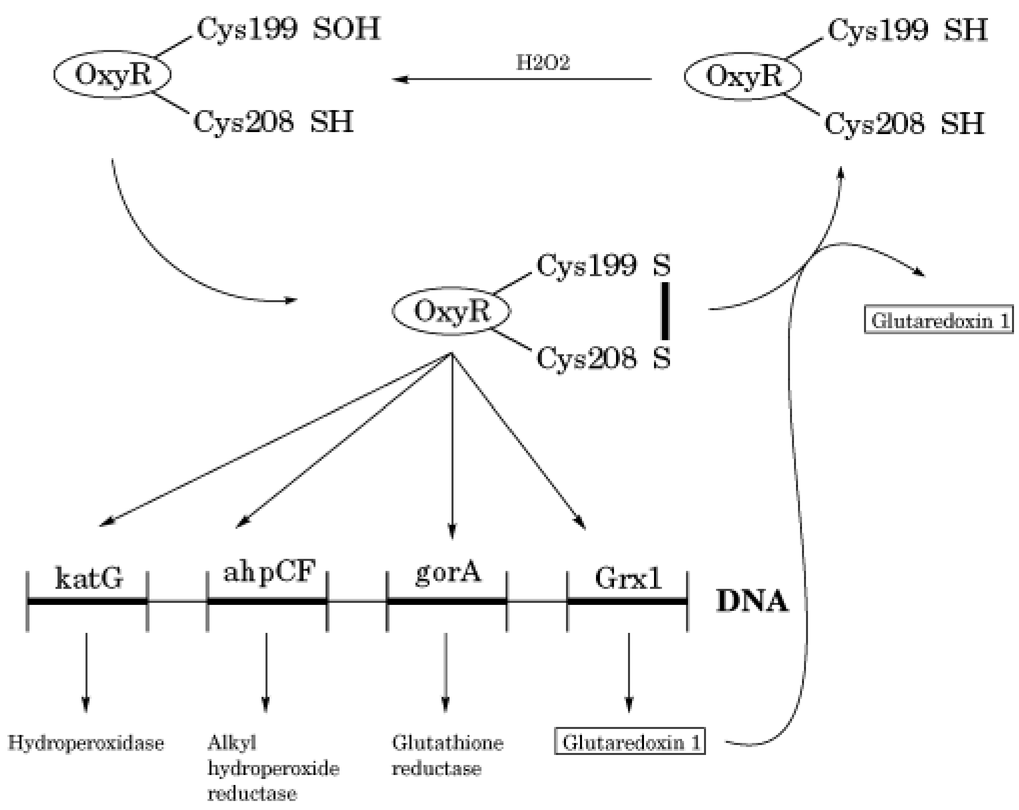
3. Adaptive Response to Oxidative Damage

Oxidative stress in the form of reactive oxygen species (ROS: OH, H_2O_2, $O_2^{-\cdot}$) induces the transcription of a variety of genes in both prokaryotes and eukaryotes. The molecular mechanisms of induction and the significance of the induction reaction for cellular survival have been elucidated in *E. coli*. In this organism there are two regulatory pathways. One is induced by H_2O_2 and is referred to as the OxyR regulon. The other is induced by superoxides and is referred to as the SoxRS regulon.

3.1. OxyR Regulon

The OxyR system belongs to the LysR family of single-component bacterial regulators, in which the same protein functions both as a sensor and as a signal transducer-regulator (18-20). The OxyR protein acts as both a sensor and transducer of the oxidative stress signal (Fig. 2). The activity of OxyR is regulated by the oxidation status of two cysteine residues, Cys199 and Cys208. Peroxides lead to formation of a disulfide bridge between the two cysteine residues (21). Both disulfide and dithiol forms of OxyR bind to the *oxyR* promoter, but only the disulfide form binds to the *katG* (hydroperoxidase) and *ahpC* (hydroperoxide reductase) promoters. Binding of reduced OxyR to its own promoter represses its gene, whereas the disulfide form turns on this gene, as it does to the *katG*, *ahpC*, *gorA*, and *grx1* genes. The members of this regulon are involved solely in antioxidant defense and not DNA repair.

Figure 2. Adaptive response to peroxides. Peroxides convert two cysteine thiol groups on OxyR to a disulfide bond. This activates OxyR as a transcription factor, which turns on genes whose products combat peroxides. In the absence of peroxides, glutaredoxin reduces OxyR and converts it to the inactive form.

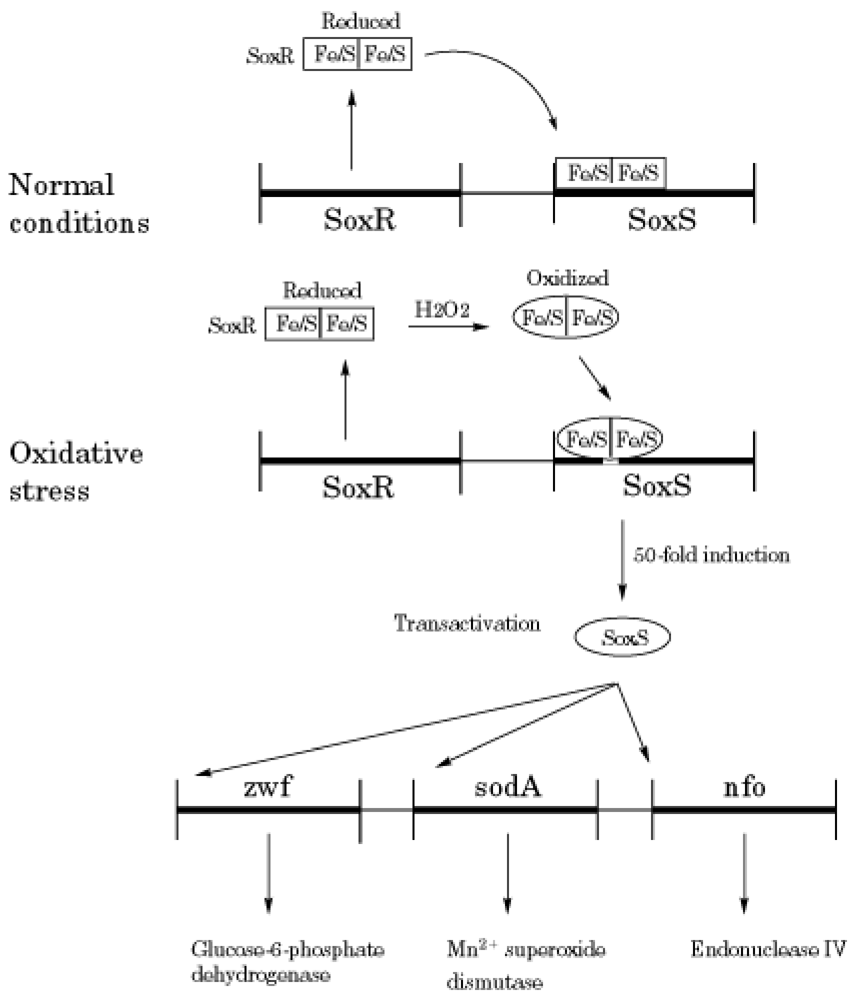


An extremely important fact regarding OxyR-mediated antioxidant response is the finding in *Mycobacterium tuberculosis* that the *oxyR* gene contains deletions and point mutations, resulting in frameshifts that make OxyR nonfunctional (22). This explains the unusual sensitivity of *M. tuberculosis* to the antituberculosis drug isoniazide. As a result of this mutation, alkylhydroperoxide reductase (encoded by *ahpC*) is not induced upon oxidative stress. Isoniazide is activated by KatG catalase-peroxidase; the reactive oxygen species that are side products of this reaction attack DNA and membrane lipids, leading to cell death. These reactive oxygen species are inactivated by alkylhydroperoxide reductase—hence the inability of *M. tuberculosis* to turn on *ahpC* in response to the oxidative burst caused by metabolizing isoniazide leads to its death by oxidative stress (22).

3.2. SoxRS Regulon

The SoxRS regulon is a two-component regulatory system that responds to superoxide stress (Fig. 3). SoxR is an iron–sulfur protein that is sensitive to superoxides, and when oxidized it becomes a transcriptional activator for SoxS. SoxS is a positive regulator of genes encoding superoxide-detoxifying and DNA–repair enzymes. The ferredoxin-like protein SoxR is a 34-kDa homodimer containing one essential [2Fe–2 S] cluster per polypeptide chain (23, 24). Both the reduced and oxidized forms of SoxR bind to the SoxS promoter, with comparable affinities, although binding of the reduced form does not induce transcription. Increased superoxides in the cell convert OxyR to the oxidized form and activate it as a transcription factor. Thus, the activation occurs not by increasing the affinity of SoxR for DNA, but by causing a conformational change in the protein that facilitates the binding of RNA polymerase to the *soxS* promoter and initiation of *soxS* transcription. While the *soxS* promoter is bound by the reduced form of SoxR, the distance between the two signature sequences is shorter than optimal for **RNA polymerase** binding. The conformational change induced in SoxR by oxidation results in overwinding of the promoter, which aligns the –35 and –10 sequences in register for optimal binding by RNA polymerase. The net result is about a 50-fold increase of *soxS* transcription. The SoxS protein then activates transcription of other genes that detoxify superoxides or repair DNA damage caused by superoxides. The following enzymes/proteins are up-regulated by SoxS: SodA Mn^{2+}-superoxide dismutase), Nfo (endonuclease IV, which is a type-II AP endonuclease), MicI (which inhibits the synthesis of a porin, thereby blocking the uptake of $O_2^{-\cdot}$) generators), aconitase, O_2-insensitive fumarase (which replaces $O_2^{-\cdot}$) damaged enzymes), flavodoxin, $NADP^+$ oxidoreductase (Fpr, which reactivates damaged Fe-S centers), and Zwf (glucose-6-phosphate dehydrogenase) which generates the NADPH that is used by Fpr and also perhaps directly reacts with superoxides and eliminates the offending agents).

Figure 3. Adaptive response to superoxides. The SoxR protein has a [2Fe–2 S] active center. The protein binds to the *soxS* promoter in reduced form, but does not turn it on. Upon oxidation by superoxides, it overwinds the promoter of *soxS*, making it a high-affinity site for RNA polymerase. Increased transcription of *soxS* leads to increased SoxS protein, which is a transcriptional activator that turns on genes involved in inactivating superoxides (*zwf*, *sodA*) or repairing DNA (*nfo*).



Induction of the members of this regulon enables the cell to reduce the uptake of superoxide generators, inactivates the superoxides, and repairs the DNA damage caused by oxidative stress. Upon disappearance of the inducing signal, the reduced state of the intracellular milieu is restored, which leads to conversion of the Sox from the oxidized to the reduced forms and the turning off of the oxidant stress response reaction.

In mammalian cells, oxidative stress induces many genes and regulates several transcription factors, including AP1 (25) and p53 (26, 27). However, the physiological relevance of these effects is not clear at present.

DNA Degradation *In Vivo*

Low levels of DNA degradation occur continuously in all cells, from bacteria to humans, in conjunction with various DNA repair processes. Probably 90% of this degradation can be attributed to excision repair, during which only a few **nucleotides** are released from each damaged site by the actions of repair **endo** and **exonucleases** and recycled in the overall process. Within a population of cells, high levels of DNA degradation occur in individual cells that need elimination from the population. This need occurs either because their DNA has become too heavily damaged to be successfully repaired, because the cells have been infected with bacteriophages or **viruses** or, during development and tissue remodeling in multicellular organisms, because these cells have received signals instructing them to commit suicide. In higher **eukaryotes**, this cell suicide is known as apoptosis. In this case, the chromatinDNA is fragmented and packaged with other cellular materials into apoptotic bodies that are engulfed by adjacent healthy cells in the tissue and digested in their **lysosomes**. The digestion products are recycled in these cells.

Most chromatin DNA fragmentation in eukaryotic cells follows an ordered path that yields first 300-kbp double-strand (ds) fragments, then 50-kbp ds fragments and lastly a range of small ds fragments that are multiples of nucleosome -sized DNA, 180–200 bp (1). This fragmentation pattern reflects the different levels of packing of the DNA in the chromatin. Six 50-kbp loops form 300-kbp rosettes that are stacked together. Cleavage between rosettes releases the 300-kbp fragments, and cleavage at the bases of the loops releases 50-kbp linear ds DNA that is readily cleaved between nucleosomes to small fragments that have 3′-OH and 5′-P termini. When separated by gel electrophoresis in agarose, the latter appear as a characteristic “ladder” of DNA. All stages of the fragmentation are Mg^{2+}-dependent, but the subsequent cleavage to small fragments is also activated by Ca^{2+}. This may indicate that there is more than one **nuclease** involved in chromatin DNA cleavage. In a few cases, the earlier stages of fragmentation are sufficient for apoptosis to proceed to completion. Random DNA degradation occurs during cell necrosis as a result of very heavy damage to the cell or tissue injury and is accompanied by lysosome disruption and cytolysis.

Except for a small body of work on *Escherichia coli*, little is known about cell suicide in bacteria. When DNA bacteriophages that have not adapted to growth in *E. coli* are cleaved by host restriction enzyme nucleases, the resulting ds DNA fragments are degraded to small oligonucleotides by a nuclease with Mg^{2+}- and ATP-dependent endo- and exonuclease activities encoded by the recB, recC, and recD genes, the recBCD nuclease. This nuclease normally acts in recombination and in recombinational ds break repair, a minor DNA repair pathway. Some bacteriophages that have adapted to *E. coli* contain genes that encode specific inhibitors of the recBCD nuclease. This nuclease is also responsible for degrading genomic DNA damaged beyond repair by UV light or ionizing radiation (2), but the details of the process are not known. The enzyme has **homologues** in many other species of bacteria.

The identity of the nucleases that are responsible for chromatin DNA degradation during apoptosis in higher eukaryotes remains uncertain. Two difficulties encountered are that **nuclei** contain very low levels of active nucleases and that they are readily contaminated during isolation by nucleases from other **organelles** . The potent **mitochondrial** nuclease has been shown to contaminate nuclei isolated from calf thymus (3), a tissue that exhibits a high rate of apoptosis, although this nuclease is not known to act in chromatin DNA degradation. DNase II, an acid **deoxyribonuclease** (DNase) normally found in the lysosomes, generates a ladder of ds DNA fragments when incubated with isolated nuclei at acidic pH. A small decrease in intracellular pH (0.3 pH units) occurs during apoptosis (4), but this would not be enough to result in appreciable activation of DNase II, even if it had a bona fide nuclear location. DNase II is not metal ion–dependent and makes ds breaks with 3′-P and 5′-OH groups, termini not found on the apoptotic ds DNA fragments. However, the corresponding acid DNase of the flatworm, Caenorhabditis *elegans*, does play a role in apoptosis, namely, in digesting the apoptotic bodies when engulfed by healthy cells. A loss of function of the nuclease caused by mutation of the *nuc1* gene led to accumulation of the apoptotic bodies in the lysosomes (5).

Considerable attention has been paid to **DNase I** as a possible candidate for chromatin DNA fragmentation (6). It is Mg^{2+}-dependent and Ca^{2+}-activated and makes the appropriate ds breaks in DNA. Where expressed, DNase I occurs in an inactive complex with actinthat is activated *in vitro* by proteolysis. However, the activity is not expressed in many cell types that undergo apoptosis and, when DNase I is added to isolated nuclei, a smear of randomly cleaved DNA results, rather than a ladder of DNA fragments. Overexpression of the bovine DNase I gene in monkey COS cells induced chromatin DNA ladder formation. However, expression of any nuclease activity in the nuclei may “damage” (nick or cleave) DNA sufficiently to trigger activation of the endogenous apoptotic program.

A bewildering array of other Ca^{2+}, Mg^{2+}-endonucleases, which vary in size from 18 to 97 kDa and generate ladders of DNA in isolated nuclei, have also been proposed to act in chromatin DNA degradation (7). These have been isolated from nuclei of apoptotic cells, but none have been fully characterized, no inactive forms have been reported, and little is known about their possible relationships. The smallest of these is NUC-18 (18 kDa), which has been identified as a cyclophilin (8). Cyclophilins have peptidyl prolyl cis–trans isomerase activity and play a role in **protein folding**. Since the specific nuclease activity associated with purified cyclophilins is very low, this activity may be associated with a contaminant. The largest (97 kDa) species cross-reacts with antibody raised against purified endo-exonuclease from *Neurospora crassa* (7), a Mg^{2+}-dependent enzyme with homologues in other **fungi**and **yeast** that has been shown to act in recombination and in recombinational ds break repair (3). It may be the eukaryotic counterpart of the bacterial recBCD nuclease. It occurs in both active and inactive forms and has endonuclease activity with both DNA and RNA and exonuclease activity with DNA. A mammalian endo-exonuclease, synergistically activated by Ca^{2+}, has been isolated from monkey CV-1 cells (9). It is the major degradative nuclease in nuclei of human leukemia cells, present entirely in inactive form. Proteolysis of endo-exonuclease has been detected by immunoblotting in response to different apoptotic agents and yielded polypeptides identical in sizes to the various Ca^{2+}, Mg^{2+}-endonucleases isolated from apoptotic cells by others. Proteolysis, an essential feature of apoptosis, may result in the activation and turnover of endo-exonuclease. Direct activation of endo-exonuclease, circumventing the apoptotic signaling pathways, could lead to new therapies in eliminating unwanted cells.

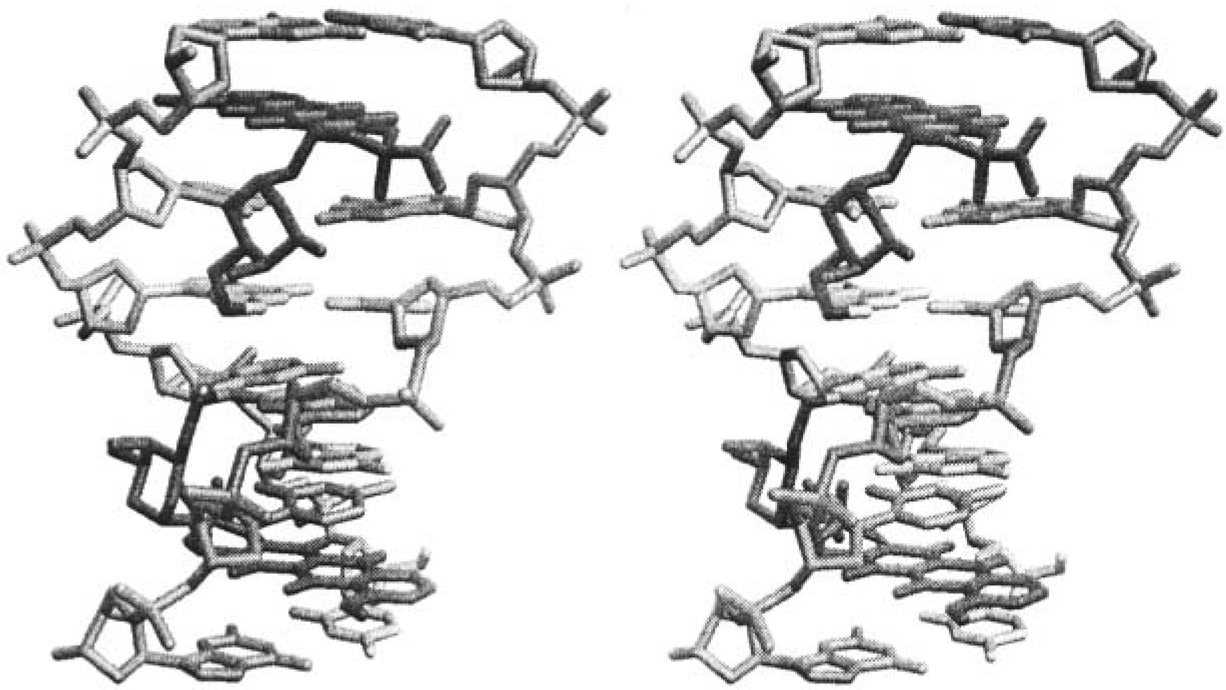
DNA Dynamics

DNA possesses many properties associated with a linear polymer, including various mechanical (rigidity) and motional properties. The normal B-DNA is considerably more flexible than both A-DNA and Z-DNA. DNA structure in solution has two classes of motional properties: large-scale and local motions. The large scale tumbling motion of a DNA duplex of the size in the range of 10–100 base pairs has a correlation time of nanoseconds to microseconds. It is related to rigidity of the duplex (of varying composition and sequence) as measured by the persistence length. This global flexibility of DNA can be used to understand the behavior of DNA in solution and in gels. There are also local motions that are important in the biological functions of DNA. The dynamic properties of DNA allow it to stretch, bend, twist, and so on. The binding of many intercalators to DNA requires that adjacent DNA base pairs be separated to 6.8 Å in order to accommodate the aromatic intercalator. This is a large conformational change (including sugar pucker rearrangements), involving many torsion angles. Since the binding of intercalators is a reversible process, DNA must be in constant motions, so that the on-off binding process can happen at any time. Figure 1 shows the high resolution structure of the complex between the anticancer drug daunorubicin and CGCGCG **crosslinked** by formaldehyde (1). Finally, the motion of DNA or drug–DNA complexes may be analyzed by high resolution X-ray crystallography structure refinement that incorporates refinement of anisotropic temperature factors. This demonstrates that various parts of the complex have different motional properties, as is evident in their thermal ellipsoids.

Figure 1. The three-dimensional structure of the daunorubicin–CGCGCG complex (Protein Database DDF023).



Some dinucleotide steps, such as CpG, TpA, or TpG (= CpA), appear to be more flexible (see Base Pairs). In fact, those steps are the preferred binding sites for intercalator binding. They are also the preferred kinked sites induced by binding of proteins. The local dynamic property associated with the CpG site (and other sites) has been probed by high resolution and solid-state nuclear magnetic resonance (NMR) spectroscopy (2). The line shape analysis of the ^{2}H-NMR spectra of the dodecamer CGCGAATTCGCG, with the ^{2}H probe incorporated at different sites of the DNA, suggested that the deoxyribose of the C9 residue has a greater motional amplitude than do the other nucleotides. The atypical motional property of the CpG step has been attributed to be correlated with the cleavage at this site by the restriction enzyme EcoRI. Therefore, the local dynamics of DNA clearly play important roles in DNA bending induced by proteins, in binding of intercalators, in restriction enzyme action, and undoubtedly in other biological functions.

Dna Genes

Mutations in certain **genes** can adversely affect DNA replication and, as such, these genes have been designated as "*dna* genes." Each *dna* gene falls within one of two groups distinguished by how the kinetics of DNA synthesis are influenced when cells harboring a conditional mutation in that gene are shifted from permissive to nonpermissive conditions: (*1*) Mutations of genes whose products are involved in initiation of replication exhibit a slow-stop **phenotype**; DNA synthesis is sustained until ongoing rounds of replication are completed. Proteins encoded by these genes include initiator proteins, **heat-shock** proteins, and a protein involved in **primosome** assembly. (*2*) Mutations of genes whose products participate in DNA elongation exhibit an immediate or fast-stop phenotype. Genes encoding **helicases**, primases, and subunits of **DNA polymerases** fall within this category.

1. Initiation Genes

Among the first temperature-sensitive DNA replication mutants to be isolated from *Escherichia coli* were those mutated in the *dnaA* gene. These mutants exhibited a slow-stop phenotype, implicating the gene product in initiation of replication (1). It is now known that the 52.5-kDa DnaA protein initiates replication by recognizing the **origin of replication**, melting the double-stranded DNA, and recruiting replication machinery to this site. The *dnaA* gene, found at 83.6 minutes on the *E. coli* chromosomal map (2), is one of the mostly highly conserved of the *dna* genes in **prokaryotes** . **Homologues** have been identified in at least 16 species of evolutionarily distinct **gram-negative** and gram-positive bacteria (3). Two regions within the gene are conserved: a short amino terminal and a long *C*-terminal encoding segment are highly homologous among species (3).

In *E. coli*, the *dnaA* gene is the first gene in an **operon** also containing *dnaN* (a gene encoding the b subunit of DNA polymerase III holoenzyme) and *recF* (involved in recombination). The gene *gyrB* follows these three genes but probably is not part of the transcription unit (4). Regulation of the *dnaA* gene occurs via two **promoters** found 240 and 160 nucleotides upstream of the start site, denoted dnaA1p and dnaA2p,and a DnaA binding site, called a “DnaA box,” that is found between these two promoters. In *E.coli* and *Bacillus subtilis*, DnaA protein regulates its own expression by binding to the DnaA box and inhibiting transcription of the gene (4). Other mechanisms of regulation include sequestration of the hemimethylated form of the gene and ppGpp signaling (4).

The arrangement of the operon in which dnaA is found is highly conserved, with the *dnaA* gene linked to the *dnaN* gene in most bacterial species. The gene arrangement, *dnaA-dnaN-recF-gyrB*, has been identified in numerous bacterial species, including *E. coli* (3), *Caulobacter crescentus* (5), *Proteus mirabilis* (6), *Staphylococcus aureus* (7), and *Mycobacterium tuberculosis* (8). *Borrelia burgdorferi* has a unique gene arrangement, *rpmH-dnaN-dnaA-gyrB*, which is most likely the result of a genetic rearrangement during evolution (9). In addition to its proximity to the *dnaN* gene, *dnaA* is found closely linked to oriC in most bacterial species. An exception is *E. coli*, where the *dnaA* gene is found almost 42 kbp counterclockwise of oriC (4).

Numerous extragenic **suppressors** of *dnaA* mutations in *E. coli* suggest that there is a complicated interaction of DnaA with numerous other proteins. For example, specific mutations in the genes encoding the b subunit of RNA polymerase (*rpoB*), topoisomerase I (*topA*), thioredoxin (*trx*), and the chaperonins GroES (*groES*) and GroEL (*groEL*) are able to suppress temperature-sensitive *dnaA* mutants (3).

In addition to mutations of the *dnaA* gene, mutant forms of the *E. coli dnaC* gene (99 minutes) (2) hinder initiation of replication. The 27.9-kDa DnaC protein delivers DnaB helicase to the DnaA protein–oriC complex. *E. coli dnaC* is found within an operon that also contains *dnaT* (involved in primosome assembly) and an unknown gene, *p18*. These genes are cotranscribed from a promoter located approximately 104 base pairs upstream of *dnaT* (10). Conservation of the *dnaC* gene among bacterial species is not well documented, but DnaC from *Salmonella typhimurium* can substitute for *E. coli* DnaC in an *in vitro* replication assay (11). While most temperature-sensitive *dnaC* mutants exhibit a slow-stop phenotype, two temperature-sensitive *dnaC* mutants, *dnaC1* and *dnaC7*, cause a fast stop in DNA synthesis, suggesting that DnaC protein also plays a role in elongation (12). In *B. subtilis*, mutations in the *dnaB*, *dnaC*, and *dnaD* genes render cells defective for initiation. The *dnaB* gene is found at 250 degrees on the chromosomal map (13), encodes a 472-residue protein, and bears no homology to any known *dna* genes (14). The *dnaB* gene product is required for the binding of the chromosomal origin to the membrane and is necessary for the initiation of replication (15). *DnaB* is cotranscribed with the *dnaI* gene, whose product is required for an unknown step of chromosomal replication (16). The *dnaC* gene product of *B. subtilis* has been suggested to be a DNA helicase and has been shown to bear 42% homology to the *E.coli* helicase, DnaB (17). *B. subtilis dnaD* mutants are also defective in initiation, as a result of an unknown mechanism. This gene has been mapped to 200 degrees on the *B. subtilis* chromosome and encodes a 232-residue protein with no known homologue in *E. coli* (18).

Temperature-sensitive mutants of the *dnaR* gene of *E.coli* are also defective in initiation of chromosomal replication. This gene is found at 26.3 minutes on the chromosomal map (19) and encodes phosphoribosyl pyrophosphate (PRPP) synthetase; PRPP is a precursor for the synthesis of nucleotides and the amino acids histidine and tryptophan (20). Mutants are capable of producing enough PRPP for replication, implicating another role for PRPP in replication besides as a nucleotide precursor. Interestingly, wild-type *dnaR* is required for DnaA-dependent, but not for DnaA-independent, chromosomal replication (21). In addition, functional DnaA protein is required for mutations in the gene encoding ribulosephosphate epimerase (rpe) to suppress the temperature sensitivity of *dnaR* mutants. Some *dnaR* mutations are also suppressed by mutations in the gene for **RNA polymerase**, *rpoB*. It is hypothesized that the dnaR gene product interacts with the products of the *dnaA* and *rpe* genes during initiation of DNA replication, possibly in a transcriptional event (22).

2. Heat Shock Genes

The products of the *dnaJ* and *dnaK* genes are involved primarily in the heat shock response, where their expression is induced by increased temperatures or other environmental stresses. These proteins act as **molecular chaperones** that use nucleoside triphosphate hydrolysis to disrupt **hydrophobic** interactions and thus facilitate proper folding of proteins (12, 23) (see Protein Folding In Vitro). In addition to their role in the heat shock response, the *E. coli* proteins encoded by *dnaJ* and *dnaK* are required for initiation of replication at the lambda phage origin (24), which led to their designation as *dna* genes. For the most part, mutations in these genes do not affect *E. coli* chromosomal replication, but instead affect processes such as chromosome segregation, **plasmid** maintenance, and normal cell growth, division, and survival (12, 25). An exception is the *dnaK*111 mutant, which is defective for initiating DNA replication at nonpermissive temperatures (26).

The *dnaJ* and *dnaK* genes are the most highly conserved of all the *dna* genes. Homologues of *E. coli dnaJ*, a member of the Hsp40 protein family, have been identified in bacterial species such as *Mycobacterium tuberculosis* (27), *B. subtilis* (27), *Clostridium acetobutylicum* (27), *B. burgdorferi* (28), *C. crescentus* (29), *S. aureus* (30), and *Lactococcus lactis* (27); in the **archaeon** *Methanosarcina mazei* (31); and in **eukaryotes** such as *Saccharomyces cerevisiae* (32), *Schizosaccharomyces pombe* (33), and *Homo sapien* (34). Homologues of *E. coli dnaK*, a member of the Hsp70 protein family, have been identified in bacterial species such as *B. subtilis* (28), *B. burgdorferi* (28), *C. crescentus* (35), *Zymomonas mobilis* (36), *Clostridium acetobutylicum* (31), *Chlamydia trachomatis* (37); in the archaeon *M. mazei* (31); as well as in eukaryotes such as *S. cerevisiae* (38), *Drosophila melanogaster* (38), and *H. sapien* (12). In *E. coli*, a single operon (39) of *dnaK-dnaJ* is found at 0.3 minutes (2). The gene arrangement *grpE-dnaK-dnaJ* has been identified in *E. coli* (28), *B. burgdorferi* (28), *B. subtilis* (40), *Chlamydia acetobutylicum* (28), *Clostridium acetobutylicum* (41), *Bacillus stearothermophilus* (42), and *S. aureus* (30). In contrast, the *dnaK* operons of *C. trachomatis* and *Lactococcus lactis subsp. lactis* are unique in that the *dnaJ* gene is absent from this region (43). In *E. coli*, *dnaJ* and *dnaK* are transcribed from a promoter located at the head of the *dnaK* cistron (44). *In B. subtilis*, two primary transcripts are synthesized by the *dnaK* operon. One is the entire *dnaK* operon, resulting in both *dnaK* and *dnaJ* transcripts, and the other is the result of transcription starting from an internal vegetative promoter immediately upstream of *dnaJ*. This promoter sequence is found in numerous gram-positive organisms (27, 42). Another common feature of organisms containing the *dnaK* operon is a nine-base-pair inverted repeat upstream of the promoter region. This region, called CIRCE (controlling inverted repeat of chaperone expression), acts as a negative *cis* element of the *dnaK* operon (45) and has been found in at least 27 eubacterial species (37). The *dnaK* operon in *C. crescentus* is regulated by two promoters; P1 is heat shock inducible, while P2, a sigma 70-like promoter, is under temporal control (29).

3. Primosome Assembly Genes

The *dnaT* gene of *E. coli* has been mapped to 99 minutes on the chromosome (2). The 19.5-kDa DnaT protein (formerly protein i) is required for bacteriophage FX174-type primosome assembly (12) and functions in transferring DnaB from the DnaB–DnaC complex to the PriA–PriB–DNA complex (46). This gene is found immediately upstream of *dnaC*, where it is transcribed along with dnaC and an unknown gene, *p18*, from a promoter located approximately 100 base pairs upstream of *dnaT* (10).

4. Helicase Genes

The *dnaB* gene of *E. coli* encodes a DNA helicase, DnaB, required to unwind double-stranded DNA at the replication fork (47). The *dnaB* gene consists of 1413 base pairs (48) and is found at 92 minutes on the chromosomal map (2). This gene lacks a typical Shine-Dalgarno sequence, while a potential promoter sequence at nucleotides –32 to –37 has been identified (48). The *dnaB* genes of *S. typhimurium* and *E. coli* are identical in length (49), are 93% identical in their corresponding amino acid residues (49), and are functionally interchangeable (50). DnaB-like proteins include gene 4 helicase of coliphage T7 (49), gene 12 protein of *Salmonella* phage P22 (49), and ban (b analog) of P1 phage (12). The *dnaC* gene of *B. subtilis* is 42% identical to *E. coli dnaB* (17), but the *dnaC* gene product's potential role as a helicase has not been demonstrated.

5. Primase Genes

The 1740 base pair (51) *dnaG* gene of *E. coli* has been mapped to 67 minutes on the chromosome (2) and encodes DNA primase, a 65.6-kDa enzyme responsible for the synthesis of small RNA that serve as primers for initiation of replication (46). Homologues of *dnaG* have been found in *S. typhimurium* (52), *B. subtilis* (formerly called *dnaE*) (12), and *Rickettsia prowazekii* (53). The *dnaG* gene is part of a macromolecular synthesis operon, which contains genes for multiple processes such as translation, replication, and transcription (54). In *E. coli*, *dnaG* is the second gene in this operon, which also contains *rpsU* (encodes S21 protein) and *rpoD* (encodes the sigma 70 subunit of RNA polymerase). The key regulatory features of this operon include tandem promoters found upstream of *rpsU*, a termination codon between *rpsU* and *dnaG*, and an RNA processing site separating *dnaG* and *rpoD* (55). In addition, a poor ribosome binding site and the use of rare codons keeps primase levels relatively low compared to those of S21 and the sigma subunit (55). The gene order *rpsU-dnaG-rpoD* is found in at least 11 gram-negative species (54), including *S. typhimurium* (56) and *Pseudomonas putida* (57). The regulatory sequences within this operon are also somewhat conserved (54).

The macromolecular synthesis operons of *B. subtilis* and *Listeria monocytogenes* also contain the *dnaG* gene upstream of *rpoD*. However, unlike the *E. coli* operon, upstream of *dnaG* these operons contain **open reading frames**, *orf23* and *orf17*, respectively, whose products are homologous with each other, but not with *E. coli* S21 (58, 59). Like the *E. coli* operon, that of *B. subtilis* is regulated by multiple promoters. The use of rare codons in the *orf23* and primase genes keeps their expression at somewhat lower levels than that of *rpoD* (58).

6. DNA Polymerase Subunit Genes

In *E. coli*, DNA polymerase III is the replicative polymerase, and many of its subunits are encoded by *dna* genes. The core polymerase a-subunit is encoded by the *dnaE* gene (60), which is 4600 base pairs long (61), is found at 4 minutes on the chromosomal map (2), and is in a proposed operon containing at least seven genes (62). The *dnaE* gene of *S. typhimurium* also encodes the a-subunit. The product of this gene is similar in size and 97% identical to the corresponding *E. coli* protein (62). In *B. subtilis*, the a-subunit is encoded by the *dnaF* gene. Mutations of this gene can result in either a slow- or fast-stop in DNA synthesis (12). Inherent in the *dnaF* gene product is a 3′ to 5′ exonuclease activity that is encoded by a separate gene in *E. coli*, *dnaQ*. As such, the amino-terminal domain of the *B. subtilis dnaF* gene product has 26% homology to the ε-subunit encoded by *E. coli dnaQ* (63). Given that the exonuclease activity is inherent in the core polymerase product of the *dnaF* gene in *B. subtilis*, it has been suggested that the *dnaQ* gene of gram-negative bacteria may have evolved from the *dnaF* gene of gram-positive bacteria (64).

The b-subunit (**sliding clamp**) of *E. coli* DNA polymerase III is encoded by the *dnaN* gene (65), which maps to 83 minutes on the chromosome (2). This subunit is responsible for the great processivity and high rates of association and dissociation of the holoenzyme from one template to another. Homologues of this gene have been identified in *B. subtilis* (formerly called *dnaG*) (12), *C. crescentus* (5), *M. luteus* (66), *M. capricolum* (67), and *B. burgdorferi* (9). In most organisms, the *dnaN* gene is found in an operon between *dnaA* and *recF* (68). In *E. coli*, the expression of the *dnaN* gene is dependent on three promoters within the translated region of *dnaA*. Although *dnaA* and *dnaN* are part of the same operon, transcription from these promoters can occur independently of transcription of *dnaA*, thus uncoupling the regulated expression of *dnaN* and *dnaA* . In addition, *dnaN* can be cotranscribed with *dnaA* from the two *dnaA* promoters, *dnaA*1p and *dnaA*2p (69).

The *dnaQ* (also called *mutD*) gene of *E. coli* encodes the 27.5-kDa ε-subunit that functions as a 3′ to 5′ exonuclease (70). The *dnaQ* gene is the only *dna* gene that does not exhibit either a slow- or a fast-stop phenotype. Instead, mutants of this gene display a **mutator** phenotype in which there is an increased rate of spontaneous mutations (46). The *dnaQ* gene is adjacent to the gene encoding ribonuclease H, *rnhA*. The two genes are transcribed in opposite directions from promoters located in an intervening 64 base pair region (71). In *S. typhimurium*, *dnaQ* also encodes the ε-subunit (72).

The t- and g-subunits of *E. coli* polymerase III are both encoded by the *dnaX* gene (12) located at 11 minutes on the chromosome (2). The 71-kDa t-subunit, the full-length product of the *dnaX* gene, functions in dimerization of the core polymerase to coordinate leading and lagging strand synthesis (73). The 47-kDa g-subunit is encoded by only a portion of the *dnaX* gene. The g-subunit is a component of the g-complex, which functions in the loading of the b sliding clamp onto primed DNA (74). The g-subunit was originally identified as a product of the *dnaZ* gene, which was later mapped within *dnaX*. Synthesis of the smaller g-subunit occurs via an interesting mechanism during translation of the *dnaX* message; a –1 translational **frameshift** at a stretch of six adenines preceding a stable hairpin results in a UGA stop codon that terminates translation and thus produces the smaller g-subunit (12). *DnaX* homologues encoding t and g-subunits, as well as the frameshift signal, have been identified in *Thermus thermophilus* (75), *S. typhimurium* (76), and several other organisms. *C. crescentus* also contains a *dnaX* homologue whose expression, as for many of the replication genes of this organism, is under cell cycle control (77).

7. Other Bacterial *Dna* Genes

Mutations in the *dnaC* gene of *C. crescentus* (78) and the *dnaH* gene of *B. subtilis* (12) result in an immediate stop in replication. However, the exact roles of the gene products are unknown, and these genes do not appear to be homologous to any *E. coli* genes. In *E. coli* the *dnaY* gene encodes an arginine transfer RNA for a rare **codon**, and mutations in *dnaY* induce a fast-stop phenotype (12). Mutants of *B. subtilis dnaI* are inhibited for chromosomal replication at an unknown step, possibly primosome assembly. This gene, which has no known *E. coli* homologue, maps to 250 degrees on the chromosome and is cotranscribed with the *dnaB* gene (16).

8. Yeast *Dna* Genes

Yeast mutants defective in **mitotic** DNA replication have led to the identification and designation of numerous *dna* genes (79). Many of these have since been shown to be identical to genes known to be involved in progression through the cell cycle. For example, *DNA1, DNA6, DNA19, DNA33, DNA39*, and *DNA43* are identical to *CDC22, CDC34, CDC36, CDC65, DBF3*, and *MCM10*, respectively (80-82).

The essential *DNA2* gene of *S. cerevisiae* encodes a structurally unique 172-kDa 3′ to 5′ helicase. Biochemical and genetic evidence suggest that the *DNA2* helicase is involved in the resolution of Okazaki Fragments (83-85).

DNA Glycosylases

Base excision repair is the system for repairing abnormal bases in DNA. The abnormal bases and simple base lesions are removed from DNA by the combined actions of DNA glycosylases (1-3) and AP (apurinic/apyrimidinic) endonucleases. The basic reaction carried out by glycosylases is the cleavage of the glycosylic bond joining the base to deoxyribose. Some of the glycosylases cleave both the glycosylic bond and the phosphodiester bond 3′ to the resulting AP site in a more or less concerted reaction. Hence, these DNA glycosylases have been classified as either “pure” glycosylases or as glycosylase/AP lyases.

1. Uracil DNA Glycosylases

Uracil in DNA arises from two sources: (i) direct misincorporation into DNA in place of thymine by **DNA polymerases** and (ii) deamination of cytosine. Most DNA polymerases cannot discriminate between dTTP and dUTP; hence the rates of incorporation of thymine and uracil into DNA are proportional to the concentrations of the corresponding dNTPs in the nucleotide pool. The dTTP:dUTP ratio is about 1000:1, so about one uracil is incorporated into each Okazaki fragment during DNA replication. The second source of uracil in DNA is that produced by deamination of cytosine. Cytosine deaminates at normal pH and temperature at a rate of $10^{-16}s^{-1}$ for double-stranded DNA and at a rate of $10^{-10}s^{-1}$ for single-stranded DNA. The deamination rate is greatly accelerated by low pH, high temperature, and oxidants. Uracil in DNA is removed by uracil glycosylases. Two have been identified in *Escherichia coli* and in humans (4): (i) uracil glycosylase and (ii) the double-strand-specific thymine glycosylase, which has also been shown to act on uracil residues in double-stranded DNA.

1.1. Uracil DNA Glycosylase (UDG)

The classic UDG is a 25- to 30-kDa monomeric protein with no cofactor or metal ion requirement. The enzyme is highly conserved between prokaryotes and eukaryotes, and it is the major uracil glycosylase in most organisms examined. The enzyme acts on single- and double-stranded DNA with equal efficiency. UDG is one of the several known DNA modification/repair enzymes that during catalysis flip out the base from inside the helix into a cavity within the enzyme (5-7). After cleaving off the base, the enzyme dissociates from DNA. This UDG has no detectable AP lyase activity.

1.2. Thymine–DNA Glycosylase (TDG)

In humans, this enzyme specifically removes thymines from T-G mismatches and uracils from U-G mismatches within double-stranded DNA (4-6). It is thought that the major source of mismatched thymines in mammalian cells is deamination of 5-methylcytosine bases, which creates a T-G mismatch. Because about 20% of cytosine bases are methylated in mammalian cells, even low-frequency deamination of MeCyt generates high levels of T-G mismatches. Hence it is likely that TDG plays an important role in preventing mutations and maintaining genomic stability.

Even though DNA glycosylases in general, and UDG in particular, are considered to be highly specific enzymes, recent work has shown that UDG removes from double-stranded DNA many oxidized pyrimidines generated by ionizing radiation, and even normal pyrimidines (7). The $\boldsymbol{K_m}$ and k_{cat} catalytic parameters for removal of these lesions were found to be within the physiologically relevant range, so it is possible that UDG and TDG also perform auxiliary functions in repairing DNA damage caused by oxidative stress, in addition to their primary roles.

2. Thymine Glycol DNA Glycosylase

The prototype of thymine glycol DNA glycosylases is *E. coli* endonuclease III (8). It is a 40-kDa polypeptide chain with a [4Fe–4S] cluster (9) (see Iron–Sulfur Proteins). This enzyme has been detected in various organisms by one of its multiple activities and, accordingly, was given various names: endonuclease III, UV endonuclease, redoxendonuclease, and others. The enzyme has been highly conserved during evolution. Enzymes with sequence and functional homology to *E. coli* endonuclease III exist in yeast and humans (10). These enzymes have a relatively wide substrate spectrum and act on ring-saturated, ring-contracted, and ring-rearranged pyrimidines. The crystal structure of *E. coli* endonuclease III has been determined (11). The enzyme flips out of damaged base into the active site and cleaves the glycosylic bond and the 3′ phosphodiester bond of the resulting AP site, before dissociating from DNA. The iron–sulfur center within the protein has no catalytic role. Catalysis does not involve **redox** chemistry, but it occurs by a simple lyase reaction involving the ϵ-amino group of a lysine residue.

3. Methylpurine DNA Glycosylase (MPG)

The MPG enzyme was originally identified as “3-methyladenine DNA glycosylase”; hence it is also referred to by that name (12, 13). There are two enzymes in *E. coli* with MPG activity, one that has a narrow substrate spectrum called TagI, and a second, TagII, with a much greater substrate range (14). The eukaryotic enzymes, including that in humans, are more similar to TagII with respect to their substrate preference than to TagI of *E. coli*. MPGs act on 3-methyladenine, 7-methyladenine, and O^4-methylthymine. They clearly also repair alkylated bases other than methyl purines, and hence “alkylated purine DNA glycosylase” would perhaps be a more appropriate name for this group of enzymes. They have no overt AP lyase activity.

4. 8-Oxoguanine Glycosylase

This enzyme was first identified as “formamidinopyrimidine DNA glycosylase” for the name of the substrate (FAPy) that is generated from guanine by ionizing radiation (15). Subsequently, it was found that the enzyme is very active on 8-oxoguanine, which is generated in vast quantities in the DNA by ionizing radiation and by oxidative stress. The enzyme is a 20-kDa monomer with no requirement for cofactors or divalent cations. The enzyme is widespread in the biological world, having been found in *E. coli*, yeast, and humans. It is a glycosylase and an AP lyase. In addition to cleaving the 3′ phosphodiester bond by b-elimination, it also cleaves the 5′ phosphodiester bond by d-elimination. Thus, this is a unique glycosylase that performs glycosylase/b-d-elimination by a concerted mechanism; in doing so, it generates a one-nucleotide gap.

5. Pyrimidine Dimer Glycosylase

This enzyme has been found in two sources thus far: **T4 phage** and *Micrococcus luteus*. The enzymes from the two sources share sequence homology and are presumed to act by the same mechanism. Both are 18-kDa monomers, with no cofactor and no requirement for divalent cations. The enzyme cleaves the glycosylic bond of the 5′ base of cyclobutane dimer and the intradimer phosphodiester bond by b-elimination. Thus, the cleavage generates a 3′-OH end and a 5′ terminus with a dangling pyrimidine dimer (16). The 5′ end must be further processed by a 5′- to 3′-exonuclease before DNA polymerase can produce a ligatable product. The structure of T4 endonuclease V complexed with substrate indicates that the enzyme flips out one of the adenine bases opposite the pyrimidine dimer (17). This binding mechanism explains the high specificity for pyrimidine dimers in double-stranded DNA.

6. A-G Mismatch DNA Glycosylase

The 8-oxoguanine lesion is a frequent product of ionizing radiation and oxidative damage to DNA. Most often, 8-oxoguanine mispairs with adenine during replication. The resulting adenine-8-oxoguanine mispair is the substrate for A-G mismatch DNA glycosylase (18). This 30-kDa enzyme has limited sequence similarity to endonuclease III (thymine glycol endonuclease) and also has a [4Fe–4S] center. The protein in *E. coli* is encoded by the *mutY* gene; hence the enzyme is also referred to as MutY glycosylase. The enzyme also cleaves A residues in A-G mismatches, albeit at a lower efficiency than A-8-oxoG mismatches. In addition to glycosylase activity, it also possesses AP lyase activity and thus cleaves the 3′ glycosylic bond 3′ to an AP site, either as part of glycosylase/AP lyase concerted reaction or as an independent AP lyase acting on an isolated AP site.

DNA Helicase

Transient production of single-stranded **DNA** from the double helix is necessary prior to several DNA metabolic reactions, such as DNA replication, DNA repair, recombination, and transcription. DNA helicases unwind duplex DNA into two single DNA strands, ie, they disrupt the hydrogen bonds of double helical DNA by successively translocating along DNA, using the energy from hydrolysis of nucleoside triphosphates (NTP, usually ATP). Since the NTP hydrolysis is coupled to DNA binding, all helicases have DNA-dependent NTPase activity (see ATPase). Due to the involvement of helicases in various cell functions, most organisms have more than 10 helicases, and indeed, at least 12 helicases have been identified in *Escherichia coli* since the discovery of helicase I in 1976 (1). During DNA replication, a specific class of helicase unwinds duplex DNA ahead of the **replication fork**, which is the so-called "replicative helicase" and indispensable for cell proliferation. In addition to multiple helicases in cells, **bacteriophages** and eukaryotic **viruses** have their own helicases, which function in their specific propagation processes.

Unwinding of a DNA duplex by helicases is assayed independently of their particular DNA metabolic function, using partial duplex DNA that carries a short DNA annealed to a longer single-stranded DNA. The unwinding activity is manifested by the release of the short DNA from the duplex, which is detected as a faster-migrating DNA band in gel electrophoresis. The unwinding reaction proceeds in a unique direction defined as either a 5′-3′ or 3′-5′polarity with respect to the strand of DNA on which the helicase is bound. The polarity used to classify the enzyme (Table 1) is determined by similar unwinding assays using two duplex DNA carrying either 5′ or 3′ extensions of single-stranded DNA (Fig. 1).

Figure 1. Helicase assay and determination of the polarity by electrophoresis.

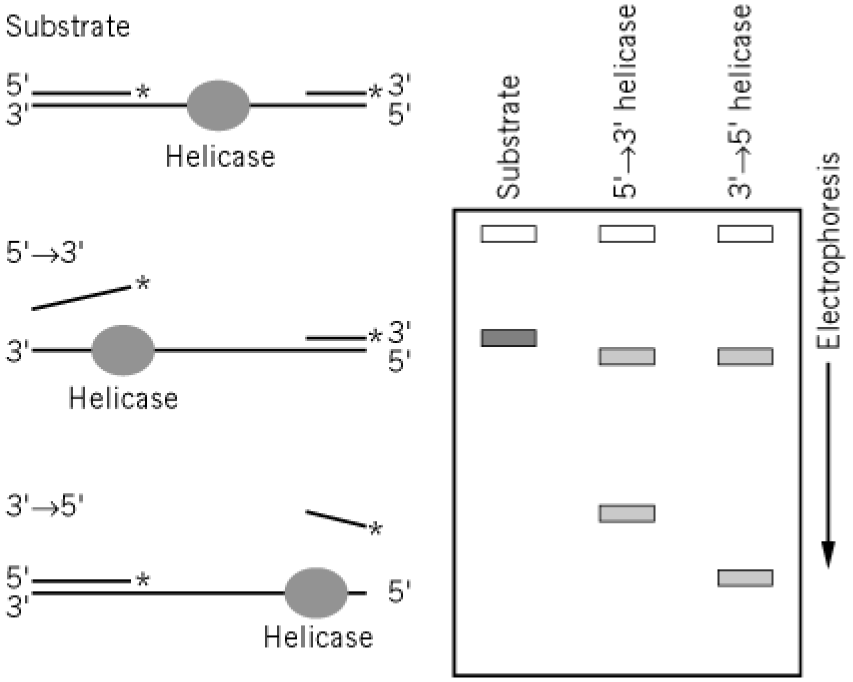

Table 1. DNA Helicases and Their Properties

Function	Helicase	Assembly State[a]	Polarity[a]	Source
Replication	DnaB	Heaxmer	$5' \rightarrow 3'$	*E. coli*
	T4 gene 41	Haxamer	$5' \rightarrow 3'$	T4 phage
	T7 gene 41	Hexamer	$5' \rightarrow 3'$	T7 phage
	SV40 T antigen	Hexamer	$3' \rightarrow 5'$	SV40 virus
	DNA2	Nd	$3' \rightarrow 5'$	Yeast
	Rep	Dimer	$3' \rightarrow 5'$	*E. coli*
Repair	RuvB	Hexamer	$5' \rightarrow 3'$	*E. coli*
	RecBCD	Trimer (hexamer)	Nd	*E. coli*
	RAD26	Nd	Nd	Yeast

	(CSB/ERCC6)			(human)
Repair and transcription	RAD25 (XPB/ERCC3)	Nd	$3' \rightarrow 5'$	Yeast (human)
	RAD3 (XPD)	Nd	$5' \rightarrow 3'$	Yeast (human)
Transcription termination	Rho	Hexamer	$5' \rightarrow 3'$	*E. coli*
Conjugation	Helicase I/Tra I	Oligomer	$5' \rightarrow 3'$	F plasmid
Unknown	Helicase III	Oligomer	$5' \rightarrow 3'$	*E. coli*
	ATPase B	Nd	$5' \rightarrow 3'$	Mouse

[a] Nd = not determined.

Comparison of the primary structures of helicases revealed the presence of conserved motifs, which define several classes of the helicase family (2). A subfamily of helicases carry seven conserved motifs, but other subfamilies, which include most hexameric helicases (see below), retain only subsets of the motifs. Among the motifs, two called “A” and “B” are commonly detected in all helicases and function as a **nucleotide-binding** site. These two motifs are necessary but not sufficient for helicase functions, since the B motif corresponds to the so-called **DEAD** or DExH box, which is also observed in several RNA-binding proteins. Therefore, many putative DNA or RNA helicases are proposed on the basis of just their predicted primary structures, without the identification of actual biochemical activities.

Although the precise mechanisms of their unwinding action are not understood, their characteristic oligomeric states, mainly as dimer or hexamer, propose simple explanations for their biochemical reactions. The dimeric form, such as the *E. coli* Rep helicase, provides an unwinding mechanism promoted by a rolling or inchworm movement, using two DNA-protein contacts. In this case, two DNA-binding sites alternate binding of single-stranded and duplex DNA, catalyzing unwinding. In the case of hexameric helicases, such as DnaB, T7 phage gene4 protein, and SV40 virus large T Antigen, they have a common ring structure, with a central hole through which DNA passes, as analyzed by electron microscopy. It is still unclear how DNA passes through the hexamer and how the unwinding reaction occurs within the molecule. Interestingly, these hexameric helicases are often members of large functional protein complexes, as in the case of typical replicative helicases, and are expected to have roles as motor molecules that may simultaneously unwind the DNA and transfer the protein complexes along DNA.

Replicative helicases have been identified only from bacteria, bacteriophage, and viruses, not from eukaryotic cells. This is mainly because there has not been any reliable *in vitro* replication system in eukaryotes to confirm whether a helicase of interest is functional in replication or not. A yeast essential gene, *dna2*, has been identified as a DNA replication mutant by screening using a permeabilized cell replication assay (3). Since this gene product has five conserved helicase motifs and actually exhibits helicase activity, it is a candidate for the yeast replicative helicase, although there is insufficient direct evidence. The known replicative helicases often have close connections with other replication activities and sometimes possess additional characteristics; eg, primase activity in T7 gene4 helicase and replication origin binding in SV40 T antigen. T antigen also interacts physically with several replication proteins and cooperatively promotes the initiation of viral DNA replication. The *E. coli* replicative helicase, DnaB, exhibits the closer physical and functional link with the replication fork components, and the rate of helicase movement is coordinately stimulated by interaction with the DNA polymerase (4).

Recent improvements in identifying the causative genes of many human heritable diseases revealed that the defects of certain helicase functions cause several human diseases, including Xeroderma pigmentosum, Cockayne's syndrome, Bloom's syndrome Werner's syndrome, and ATR-X syndrome (5). These diseases are apparently related to the defects of genes whose functions are involved in nucleotide excision repair, recombination, replication fidelity, and chromosome transmission, and they exhibit cancer-prone **phenotypes** because of the difficulty in maintaining genome integrity. Such human disease-related helicases are conserved among eukaryotes, and their counterparts are often identified as RAD genes in yeast (Table 1).

DNA Libraries

Recombinant DNA technologies developed in the early 1970s (1-6) form the core of all DNA-based molecular combinatorial libraries. Genetic sequences of interest are recombined with a replication-competent DNA vector, such as a plasmid or bacteriophage. Each individual genetic sequence fragment is enzymatically ligated into a receptive vector, to form a unique recombinant clone. The population of individual recombinants is then reintroduced into an appropriate host cell in order to constitute a functional library. Modern cloning technologies allow the preparation of up to 10^9 recombinants in a single library, with greater numbers requiring a substantial scale-up that is beyond the resources of most researchers.

A different type of recombinant design is seen in some oligonucleotide-based libraries that require no vector for their survival (7-9). The replication elements in these oligonucleotides are built into their sequences in the form of primer binding sites. These libraries can be amplified *in vitro* by the polymerase chain reaction (PCR) using additional oligonucleotides capable of annealing to the termini of the library molecules (10). Other amplification technologies can be used to replicate oligonucleotide libraries, including the ligase chain reaction (11), self-sustained sequence replication (12), and strand displacement amplification (13). Because oligonucleotide-based libraries are prepared chemically and require no cloning steps, they can achieve very high sequence complexities on the order of 1×10^{15} different species or more.

Recent technological advances have introduced a novel type of oligonucleotide-based DNA library in which defined sets of sequences are synthesized chemically and displayed in a two-dimensional array. A highly publicized approach developed by Affymetrix employs photolithographic masking procedures to construct very high-density oligonucleotide arrays on silicon chips. One such product developed by Affymetrix is the p53 chip, which displays a large number of common disease-related p53 gene mutations represented as oligonucleotide sequences. Any clinical specimen can be rapidly assayed over this chip by hybridization of nucleic acids in order to determine the genotype of p53 genes expressed by the specimen tissue. The development of further disease-related gene chips has enormous potential to carry clinical diagnosis to the molecular level where appropriate highly individualized therapies may be ascertained (eg, pharmacogenomics (14)) (see DNA Chips).

The intended use of recombinant libraries determines numerous aspects of library design and construction. The vector provides essential functions, such as an **origin of replication**, that enable replication and survival of the recombinant clone within the host cell. A selectable marker such as an antibiotic-resistance gene provided by the vector provides a means to eliminate any cells that have not taken up a recombinant clone. Unique restriction enzyme sites in the vector allow efficient insertion of foreign DNA fragments into defined contexts. Various expression control elements engineered into the vector permit selective expression of RNA or protein encoded by the cloned DNA fragment. Vectors that contain certain viral signal sequences can be packaged into viral particles in infected cells, thereby enabling highly efficient viral-mediated gene transfer into noninfected cells. In addition, cloning vectors often provide genetic markers that confer desirable properties upon the expression products. For example, DNA encoding an open reading frame may be fused in frame to the *C*-terminus of glutathione-S--transferase (GST) (15). The resulting GST-fusion protein can then be easily purified by affinity chromatography over **glutathione**-agarose resin. Finally, “shuttle” vectors contain multiple origins of replication, supporting growth of the recombinant clone in bacteria as well as in relevant experimental systems, such as yeast and mammalian cells.

Plasmid vectors are by far the most commonly used cloning vectors for relatively short DNA fragments ranging from several hundred to several thousand nucleotides. This size range is sufficient to carry the coding sequence portions of most genes. However, because genes from many organisms contain varying amounts of nonexpressed intervening sequences (**introns**), cloning of complete genes or gene clusters often requires the use of vectors that can accommodate DNA inserts exceeding 10 kilobase pairs (kbp) or more. The lambda phage particle can package approximately 50 kbp of DNA, but the lambda phage itself requires at least 30 kbp of essential phage genes for viability, limiting its insert carrying capacity to no more than 20 kbp. Some improvement is seen with “cosmid” vectors, which are composite vectors containing both plasmid replication elements and the lambda phage cos packaging signal. One type of cosmid vector can package up to 40 kbp of foreign DNA into lambda phage capsids (16). Gene mapping studies and investigations into chromosome structure require cloning vectors with even larger capacity, called *artificial chromosomes* (ACs). Thus, YACs are yeast artificial chromosomes that contain yeast centromere, telomere, and **autonomous replication sequence** (ARS) elements, as well as appropriate yeast selection markers (17, 18). YACs allow the cloning and maintenance of fragments of genomic DNA up to several hundred kilobase pairs in length. Similarly, ACs have been constructed that allow introduction of large foreign sequences into bacteria (called BACs) and mammalian cells (called MACs) (19).

DNA libraries may be categorized according to the source and the context of foreign DNA within the library. Genomic libraries often contain relatively large DNA inserts in phage or AC vectors. These inserts are typically not expressed, although there are exceptions. **cDNA library** inserts are derived from DNA copies of messenger RNA that are generated by the enzyme **reverse transcriptase**. mRNA is a useful source for protein-coding DNA sequences, as the nonexpressed intervening sequences have been removed through the process of pre-mRNA processing. Thus, protein-coding sequences that are interspersed throughout a gene are arranged contiguously within a cDNA, whereupon it becomes trivial to infer the encoded protein sequence using the genetic code. cDNA libraries usually provide some means to express open reading frames encoded within the DNA insert, both as RNA transcripts and protein translation products. Expression libraries may, however, also be based on genomic DNA and oligonucleotides, either cloned into a vector or as linear molecules that can be amplified *in vitro*.

“Virtual libraries” are a relatively new concept in DNA libraries. Sequence information emerging from large-scale sequencing projects is incorporated into ever-expanding computer databases, where cross-references can be established between any sequence and its associated functional information. Thus, a database can serve as a virtual library that can greatly expedite the identification and recovery of molecules with desired properties. Examples of public sequence databases include

GenBank and the Cancer Genome Anatomy Project (CGAP). Such virtual libraries enable tasks that once required working with actual molecules *in vitro* to be accomplished much more rapidly *in silico* using only the information contained within those molecules. For example, a scientist that identifies a sequence fragment of a protein associated with a particular disease can, through the genome databases, identify a full-length DNA sequence associated with that protein. The DNA sequence in turn provides a great deal of useful information, including the likely sequence and structure of the protein, as well as a set of primer sequences that can be used to clone the full-length gene representing that protein. Many modern database resources also maintain banks of cosmid or AC clones that are (or will be) correlated with every sequence in the database. Such resources make it possible to move from an unknown protein band obtained through gel electrophoresis to a cloned and expressed gene for that protein in a matter of days—a task that often required several years to accomplish only a decade ago.

DNA Ligase

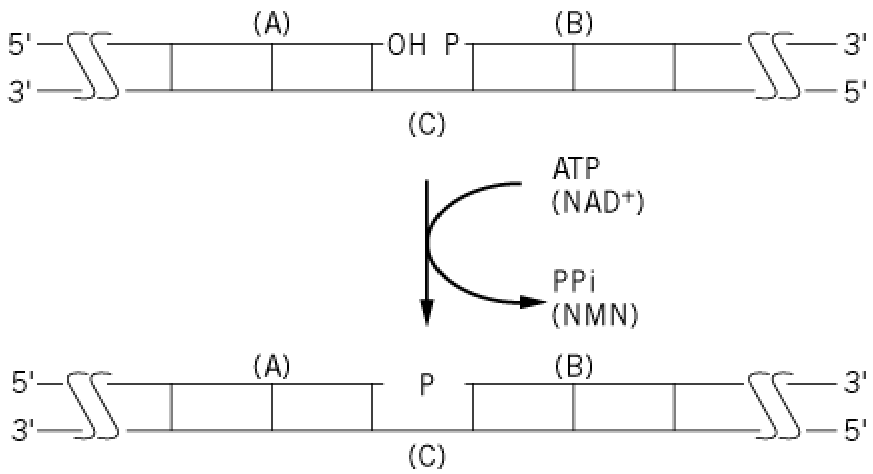
1. Physiological Functions

Several fundamental biological processes involve one or more steps in which an enzyme, DNA ligase, catalyzes the covalent joining of one piece of **DNA** to another (1-3). For example, DNA altered spontaneously or by environmental causes is restored to its original base sequence by DNA repair. DNA is duplicated by DNA replication and rearranged by homologous recombination. All these processes require DNA ligase activity to link preformed pieces of DNA to one another.

During one form of DNA repair, damaged nucleotides are removed by enzymes to leave ultimately a gap in one strand of the duplex DNA, which is then filled by a **DNA polymerase** to form a product with a discontinuity (nick) between two adjacent nucleotides in the phosphodiester backbone. Likewise, semidiscontinuous DNA replication leads to the formation of Okazaki Fragments that abut one another on the complementary parental DNA template strand so that a nick exists between their termini. Finally, pieces of DNA from two different chromosomes become associated during recombination so that similar nicked duplexes are formed in each chromosome. DNA ligase catalyzes the covalent joining of the DNA strands to seal the nicks and form intact, recombined duplexes. The enzyme is involved in other functions as well; whenever two pieces of DNA must be covalently joined or a DNA molecule circularized, DNA ligase probably catalyzes the reaction.

DNA fragments with appropriate termini that are aligned on a complementary strand so that their ends are juxtaposed can be joined by DNA ligase to form a phosphodiester bond (Fig. 1). For effective joining, the two strands (A and B) must be directly abutted without a gap (no missing base pairs) and must also have a 3′-OH on strand A and a 5′-PO_4 on strand B. The 3′-hydroxyl (-OH) of fragment A is ligated to the 5′-PO_4 of B to form a 3′ → 5′ phosphodiester bond. These two strands are abutted by base pairing with a complementary, intact strand (C). Since the formation of a phosphodiester bond is endergonic, ATP or NAD^+, depending on the source of the enzyme, acts as a cofactor to supply the energy.

Figure 1. The overall DNA ligase reaction. A nick with a 3′-hydroxyl (━OH) on strand (A) adjacent to a 5′-phosphate (P━) terminated strand (B) on a complementary strand (C) is converted to an intact phosphodiester bond (━P━). ATP or NAD^+ supply the energy for bond formation (see text), and PP_i or NMN, respectively, is the other product of the reaction. Long horizontal lines represent DNA strands with the polarity indicated; vertical lines represent base pairs.



2. Distribution

All free-living organisms are believed to produce one or more DNA ligases. Until recently, **bacteria** were thought to contain a single DNA ligase that performed all their DNA joining reactions (see text below). **Yeast** appears to have two DNA ligases. Some **bacteriophage** and animal **viruses** also encode DNA ligases. Higher **eukaryotes** probably contain four different DNA ligases that are specialized to perform particular tasks. The DNA ligases from animal and **plant** cells, **archaebacteria**, bacteriophage, and animal viruses use ATP as the energy-supplying cofactor for the ligation reaction. **Eubacteria**, with a single reported exception, use NAD^+ for this purpose. Cheng and Shuman (4) have shown that *Haemophilus influenzae* contains an ATP-dependent ligase, in addition to the expected NAD^+-dependent enzyme. Whether this finding represents an anomaly in the general cofactor-utilization classification scheme awaits the demonstration of additional ATP-dependent activities in other eubacteria. Searches of the sequences of the genomes of several other eubacteria reveal potential open reading frames that share homologies with both the expected NAD^+-dependent enzymes and with ATP-dependent DNA ligases. It will be important to determine whether any of these organisms also produce ATP-dependent DNA ligases and, if so, how they relate functionally to the NAD^+-dependent enzymes.

DNA ligase is essential because of its role in the crucial DNA transactions of the cell. Cells containing **conditional** mutants of the enzyme in *Escherichia coli* are lethal when the ligase activity is severely inactivated. They display abnormal replication, repair, and recombination **phenotypes**. Because *E. coli* cells normally contain many copies of the enzyme, small amounts of residual activity can maintain viability. The enzymes in bacteria seem to act independently in their multiple roles, that is, not in specific association with other proteins. For example, the NAD^+-dependent enzyme of *E. coli* can substitute for the inactivated bacteriophage ATP-dependent DNA ligase of an infecting bacteriophage. In eukaryotes, specific proteins may associate with DNA ligases to form complexes involved in particular functions.

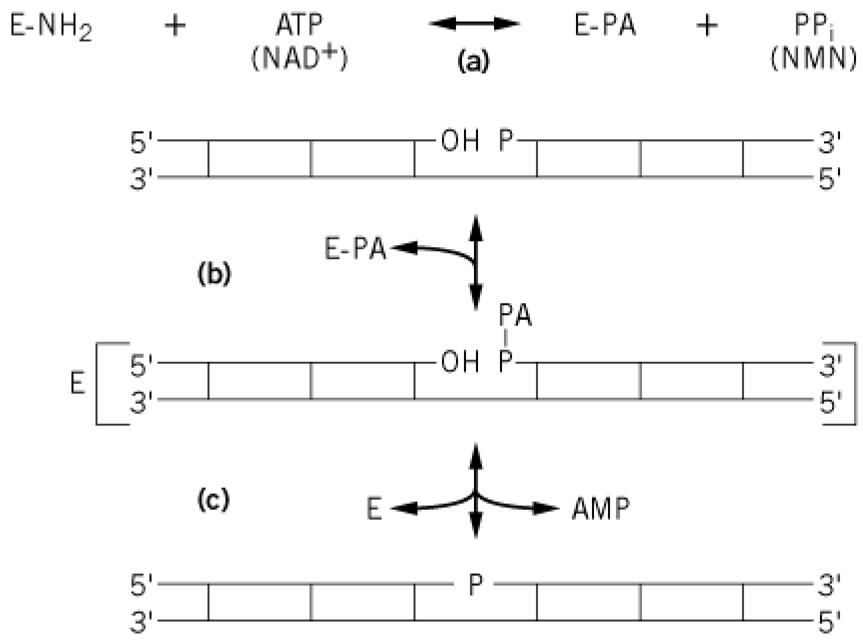
3. Properties

The DNA ligases comprise single polypeptide chains with molecular weights ranging from approximately 40 kDa to greater than 100 kDa, and they probably act as monomers. The **genes** of many DNA ligases have been sequenced, and several have been overexpressed and the enzymes isolated, purified, and characterized in detail. Several bacterial and bacteriophage DNA ligases are commercially available. Analyses of the sequences of genes encoding DNA ligases reveals conserved amino-acid sequence motifs among the ATP-dependent enzymes and other conserved regions among the NAD^+-dependent group. Sequence comparisons also reveal that the ATP-dependent DNA ligases are part of a superfamily that includes RNA ligases and **RNA capping** enzymes (5). The structure of only the bacteriophage T7 DNA ligase, a small, ATP-dependent enzyme, has been determined (6). It forms a bilobal structure that is reminiscent of the structures of the methyltransferases used for DNA modification.

4. Mechanism

Phosphodiester bond formation between template-aligned, abutted 3′-OH and 5-PO_4 termini proceeds in three steps, with the formation of two covalent intermediates (Fig. 2). One of these intermediates involves the enzyme, the other the DNA. In the first step of the reaction, which can occur in the absence of DNA, the enzyme reacts with ATP (or NAD^+) to form a covalent enzyme–AMP complex. The adenylyl group is joined to the ε-amino group of a lysine residue at the active site by a phosphorus–nitrogen (phosphoamide) linkage that has a large **free energy** of hydrolysis (Fig. 2a). If ATP is the cofactor, PP_i is released; if NAD^+ serves as the cofactor, nicotinamide mononucleotide (NMN) is released in this step. The free energy of hydrolysis of a phosphoanhyride bond in the ATP or NAD^+ is used to form the enzyme-bound, activated adenylyl group.

Figure 2. The DNA ligase reaction mechanism. (**a**) The enzyme [E–NH_2] is adenylylated on a specific lysine residue [E–PA] by reaction with ATP (or NAD^+) with the release of PP_i (or NMN). (**b**) The DNA is adenylylated [AP━P━] by transfer of the adenylyl group from the enzyme to the 5′-PO_4 at the nick. (**c**) The enzyme catalyzes an attack of the 3′-OH at the nick on the activated phosphate, to form the 3′ → 5′ phosphodiester bond and release the enzyme. Long horizontal lines represent DNA strands with the polarity indicated; vertical lines represent base pairs.

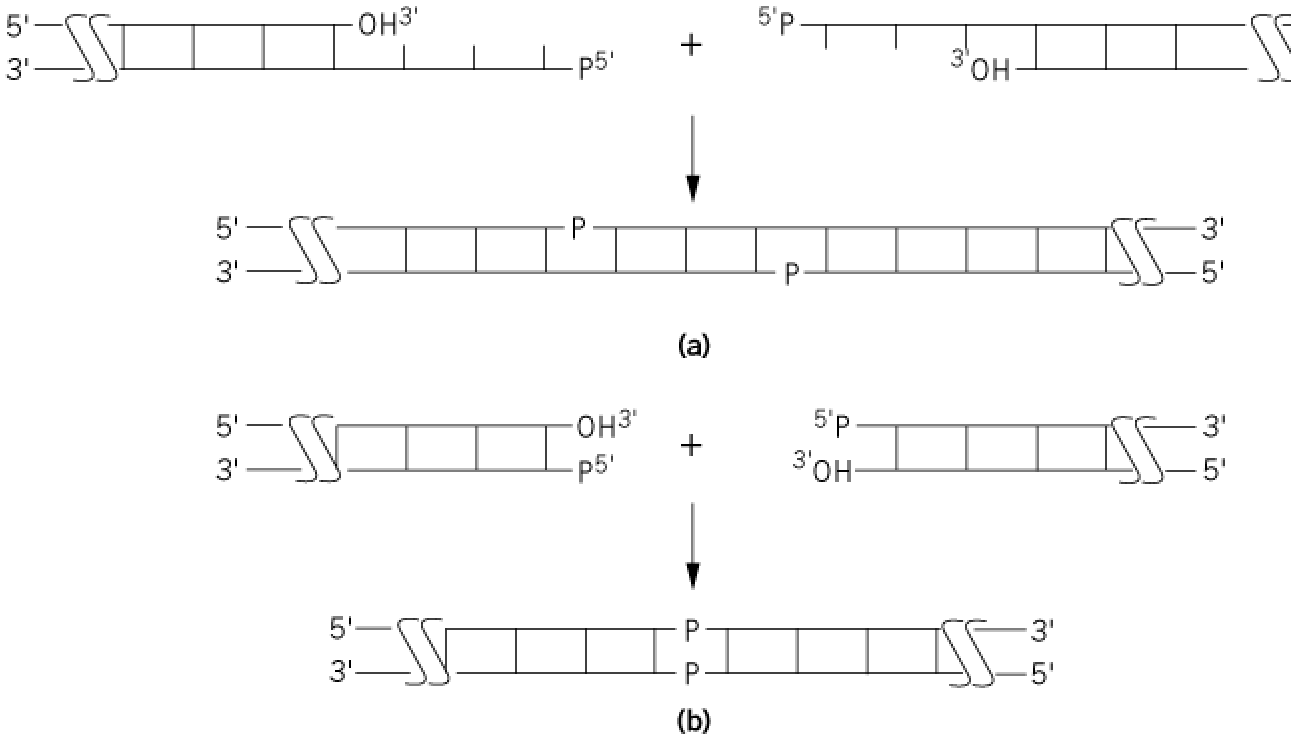


In the next step, the second covalent intermediate is formed when the adenylyl group is transferred from the enzyme to the terminal 5′-PO_4 at the DNA nick, to form an AMP (5′ → 5′) DNA phosphoanhydride linkage (Fig. 2b). In the final step of the reaction, which requires the free (unadenylylated) form of the enzyme, the AMP is displaced from the DNA by a nucleophilic attack of the 3′-OH of the adjacent DNA fragment to form the phosphodiester bond and to release the AMP from the DNA Fig. 2c).

Both covalent intermediates in the reaction have been isolated and are kinetically competent in the reaction. The reaction requires a divalent metal cation, most likely Mg^{2+} in the cell. Steady-state kinetic analysis of the *E. coli* enzyme shows that it follows ping-pong kinetics—consistent with the described mechanism (see Kinetic Mechanisms, Enzyme). The overall reaction is reversible. The first step is readily reversed, as indicated by the facile ATP–PP_i or NAD^+ NMN **isotope exchange reactions** catalyzed. The enzyme also catalyzes an AMP-dependent nicking–closing (topoisomerase) activity that will relax positively or negatively supercoiled DNA (see DNA Topology), indicating that the second step is also reversible.

The nature of the ends of DNA fragments affects the ability of DNA ligase to join them together. For example, duplex substrates with so called cohesive, “sticky” ends are readily joined by all DNA ligases (Fig. 3**a**). These substrates are formed from DNA fragments that contain short, complementary single-stranded extensions at their termini; two or more such nucleotides are required for efficient joining. These extensions can be of either strand, so long as they allow the two duplexes to anneal to one another and provide the requisite abutted 3′-OH and 5′-PO_4 termini. The ends of these duplex fragments hybridize to form a substrate in which there is a ligatable discontinuity in each strand. In essence, the complementary strands serve to convert the intermolecular joining of the two DNA pieces into an intramolecular reaction by bringing them together. Another class of duplex substrates, specifically, those with **blunt ends** (Fig. 3**b**), which have no single-stranded extensions, are much less efficiently ligated, because the fragments to be joined are not brought into proximity by a template strand. The efficiency of this intermolecular blunt-end joining reaction depends greatly on the particular ligase. Bacteriophage T4 ligase performs the reaction best and has been extensively used for this purpose, whereas the enzyme from *E. coli* will join blunt-end duplexes only in the presence of excluded-volume agents, such as **polyethylene glycol**. Other DNA structures, such as those with noncomplementary, protruding ends or nonabutted fragments creating a gap on a template strand, can be ligated, but inefficiently. T4 DNA ligase is again more tolerant of these unusual structures than is the bacterial enzyme.

Figure 3. Common DNA ends joined by DNA ligase. (**a**) Fragments with a 5′ extension (shown here) or with a 3′ extens and complementary bases (sticky ends) form a ligatable structure. (**b**) Ligation of blunt ends. Long horizontal lines repre DNA strands with the polarity indicated; vertical lines represent base pairs.



5. Polynucleotide Substrates

The physiological polynucleotide substrates for DNA ligase are predominantly DNA chains brought into proximity by a third, complementary DNA template strand as shown in Figure 1. Studies of various combinations of RNA and DNA substrates reveal that DNA ligases will also sometimes use RNA *in vitro*. RNA can be joined to RNA on either a DNA or RNA template. RNA with a 3′-OH can also be joined to DNA with a 5′-PO_4 on a DNA template. Likewise, DNA with a 3′-OH can be joined to RNA with a 5′-PO_4 on a DNA template. The exact combinations of oligonucleotide types and the efficiencies of the joinings again depend on the particular enzyme used and the reaction conditions employed. T4 DNA ligase is again often more permissive in these “unnatural” ligations than is the *E. coli* enzyme. On binding to the DNA, the ATP-dependent enzymes may specifically recognize a nick in the duplex that contains the requisite 3′-OH and 5′-PO_4 termini (7). Vaccinia virus DNA ligase appears to require a B-DNA helix to the 5′ side of the nick, suggesting that substrate conformation is another parameter that can influence recognition (8). It should be noted that some studies of substrate requirements were carried out with homopolymeric substrates and that the results might be quantitatively different for substrates containing heterogeneous sequences.

6. Assays

Several assays have been used to quantify DNA ligase activity. [^{3}H]poly d(A-T) folds on itself to form base pairs that create a dumbbell-like structure with a nick that can be sealed by DNA ligase to form a covalently closed, single-stranded circle. This product of the ligase reaction is resistant to **exonuclease** III, whereas the unsealed substrate is hydrolyzed to deoxyribonucleotides by the exonuclease. The rejoining, as determined by gel electrophoresis, of a mixture of fragments formed by a restriction enzyme digestion of a **plasmid** is a common, qualitative assay. Synthetic oligodeoxyribonucleotides allow the scheme outlined in Figure 1 to serve as an assay. If strand A is labeled at its 5′ end with ^{32}P, DNA ligase will convert the radiolabeled 5′-phosphate into a product with a phosphomonoester-resistant bond that can be quantified directly; alternatively, the longer product can be detected by gel electrophoresis. Analogously, [5′-^{32}P]d(pT)$_n$ oligonucleotides aligned on a long poly d(A) template serve as substrates for a similar assay in which the products can be quantified. The restoration of transforming activity to DNA that has been partially inactivated by **deoxyribonuclease** treatment has also served as an assay. Finally, the adenylylated enzyme formed in the first step of the reaction can be assayed by using an appropriately **radiolabeled** ATP or NAD^+ and determining the acid-precipitable, protein-bound label, or by observing the difference in migration of the free and adenylylated enzyme during polyacrylamide electrophoresis. The first step of the reaction can also be assayed by measuring an ATP–PP_i or NAD^+-NMN exchange reaction.

7. Applications

DNA ligase is extensively used in recombinant DNA technology. The most frequently used enzymes are produced from the cloned genes of *E. coli, Thermus aquaticus*, and bacteriophage T4. Whenever one wishes to join two DNA fragments together, DNA ligase can be employed. For example, it is widely used in **vector** constructions to link DNA fragments to form chimeric molecules. DNA ligase is also used to attach duplex oligodeoxyribonucleotide linkers or adapters to a longer DNA to facilitate its further manipulation. A number of site-directed mutagenesis protocols depend on DNA ligase, in conjunction with a DNA polymerase, to form an intact, sequence-altered strand of DNA on an unaltered, circular template strand. Upon transfection and replication, progeny duplex molecules containing the mutation are produced. DNA ligase has often been used to join chemically synthesized, appropriately hybridized oligodeoxyribonucleotides for *de novo* gene synthesis. Because of the strict requirements for the structure and nature of its DNA substrate, the enzyme can also be used to determine whether a 3′-OH or 5′-PO_4 exists at a DNA nick or if a gap is present in one strand of a DNA duplex. It can be used to quantify the number of nicks in a DNA molecule by using a radiolabeled adenylylated enzyme and measuring the amount of radioactive AMP released. When used to circularize short fragments, the enzyme has been used to study the stiffness, twisting, bending, and helical repeat of DNA. For example, because the ends of a fragment must be brought into proper alignment for effective ligation, one can learn about the number of base pairs per turn of the DNA. Similarly, DNA ligase can be used to study the ability of another protein to bend DNA on binding, because the bending can facilitate the ligation by bringing the ends of the duplex fragment into proximity. The enzyme has also proved useful for the synthesis of defined-sequence RNA by efficiently joining RNA strands on a DNA template (9). The ligase chain reaction, which depends on two pairs of oligodeoxyribonucleotides annealing to the top and bottom strands of a denatured target duplex at a given locus to form ligatable complexes, serves as an efficient DNA amplification method (10). The amplification is based on the principle that the products of the ligations on each strand can themselves serve as templates for further ligations of the excess starting oligonucleotides, leading to an exponential increase in product on sequential heat denaturations and ligations. Use of a thermostable DNA ligase allows repeated denaturations of the nucleic acids without the need for addition of further enzyme. Because conditions can be chosen so that ligase strictly requires fully base-paired nucleotides at the nick, the ligase chain reaction can be used to detect mutations through the use of appropriately designed oligonucleotides (11). Oligonucleotides that hybridize to the target so that the nick is fully base-paired are amplified, whereas those that do not are unreactive. DNA ligase has also been used to enhance DNA sequencing by hybridization on microchips by joining fully base-paired oligonucleotides to form longer, detectable products (12). Although alternative schemes that do not require DNA ligase have been devised for accomplishing some of these functions, the enzyme remains a staple for nucleic acid manipulations.

DNA Polymerase I and Klenow Fragment

Escherichia coli DNA polymerase I (pol I) has served for several decades as the prototype **DNA-dependent DNA polymerase**. Pol I, one of three such polymerases found in *E. coli*, has important roles during DNA replication, genetic recombination, and DNA repair. Pol I, the first polymerase discovered in bacteria, is required for rapid, efficient growth in rich media. This enzyme contains three activities: 5′-3′ polymerase, 3′-5′ exonuclease (for proofreading), and 5′-3′ exonuclease (for **nick translation**, excision repair, and hydrolysis of the RNA primers during DNA replication). Mild proteolytic digestion of *E. coli* DNA polymerase I (103 kDa) results in forming of two products: (1) the large Klenow fragment (68 kDa) that contains both the DNA polymerase and 3′-5′ exonuclease (proofreading) activities and (2) a smaller fragment (35 kDa) that contains the 5′-3′ exonuclease activity. Pol I is the most abundant polymerase in *E. coli* (400 molecules per cell), and it functions primarily to fill DNA gaps during repair and replication. The early cloning and overexpression of the Klenow fragment (1) and the determination of its three-dimensional structure (2) have allowed better understanding of polymerization mechanisms, molecular mechanisms of 3′-5′ exonuclease activity, and structure-function relationships of polymerases.

1. Subunits of Pol I and Their Properties

DNA polymerase I, a product of the *PolA* gene which maps at minute 86 of the *E. coli* K12 chromosome (3), is a single-subunit enzyme that functions autonomously of other replicative factors. Pol I is cleaved into two subunits by mild **proteolysis** with **trypsin**. The N-terminal 5′-3′ exonuclease **domain** contains 323 amino acid residues, and the C-terminal fragment contains 605 residues (4, 5), which is frequently called the Klenow fragment.

Much of the biochemical understanding of the polymerase and 3′-5 exonuclease functions stems from studies of the Klenow fragment. The Klenow fragment incorporates individual deoxyribonucleotides at a relatively modest rate of 50 nucleotides/s (6), and is moderately processive (on average, it synthesizes 50 nucleotides after binding and before dissociation). The Klenow fragment also acts as a **reverse transcriptase** by copying RNA templates (7), albeit distributively (i.e., incorporating one to two nucleotides per binding event), but the biological relevance of this activity is not known. The fidelity of Klenow polymerase during DNA-templated DNA polymerization is approximately 1/50,000 (i.e., one misincorporation per 50,000 nucleotides), and this fidelity is derived in part from its 3-5′ editing activity. Mutant Klenow fragments that have nonfunctional proofreading activity have an approximate fidelity of 10^{-3} (8). Both the fidelity and processivity of the Klenow fragment are influenced by reaction conditions. Both parameters are enhanced when the pH is decreased from 9.8 to 6.2 (9).

The smaller 35-kDa domain that has 5′-3′ exonuclease activities functions in pol I to degrade DNA and RNA to monomers and small oligomers. The polymerase and 5′-3′exonuclease domains act in concert during nick translation to remove Okazaki Fragments by using the 5′-3′ exonuclease activity and to fill in the resulting gap. The entire *polA* gene can be deleted without effecting the viability of *E. coli* during growth in a minimal medium.

2. *In Vivo* Functions

Much of the understanding about the *in vivo* roles of Pol I has resulted from studying *PolA* mutants. These studies show that the entire *polA* gene can be deleted without affecting cell growth and viability during slow growth in minimal media. However, either the large 68-kDA fragment or the small 35-kDA fragment is necessary for growth in rich media (10). In the absence of sufficient pol I activity, either Pol III or Pol II (which lacks 5′-3′ exonuclease activity) and ribonuclease H (the enzyme that removes RNA from RNA/DNA hybrids) potentially substitute for Pol I. The mutant strains lacking the *polA* gene are susceptible to UV light and DNA damage resulting from the alkylating agent methylmethane sulfonate. The *polA*-deficient strains also remove Okazaki fragments 10-fold slower that the wild type. A *polA* mutant that contains an amber mutation (i.e., a stop codon that produces a truncated protein), resulting in diminished (10^{-2}) polymerase activity but nearly normal exonuclease activity, is sensitive to UV and DNA alkylation damage, suggesting pol I has an essential role during DNA repair (11). Further genetic studies with *polA-lacZ* gene fusion showed that exposure to DNA-damaging agents, including 4-nitroquinoline- *N*-oxide, UV light, mitomycin C, and methyl methanesulfonate, augments Pol I expression (12).

The importance of Pol I's role in nucleotide excision repair is well accepted. Nucleotide excision repair functions to remove bulky DNA adducts and pyrimidine dimers that occur after UV exposure.

During removal of pyrimidine dimers, the UvrABC protein complex binds to the lesion and forms nicks about 11 nucleotides apart that flanking the damaged residue. Next, the **helicase** UvrD displaces the DNA between the nicks, thus removing the damaged portion. Lastly, Pol I fills the resulting 11-nucleotide gap. Pol I uses its essential 5′-3′ exonuclease activity to cleave the 5′ nucleotides of the gap. The balance of polymerase activity and simultaneous 5-3′ exonuclease activity ensures proper closure of the gap, leaving behind a nick. The last step in this repair process is ligation of the nick by a DNA Ligase. DNA pol I also uses this nick translation activity to polymerize DNA and remove Okazaki fragments simultaneously during replication.

3. Structure of Klenow Fragment

The Klenow fragment was the first polymerase whose three-dimensional structure was solved (2). The **X-ray crystallographic** structure of the Klenow fragment morphologically resembles the human right hand, complete with finger, palm, and thumb domains (Fig. 1). The structure illustrates that the N-terminal 3′-5′ exonuclease domain and the C-terminal polymerase domain are separated by about 30 Å. The structure of the Klenow fragment complexed with double-stranded DNA in an "editing mode" shows that about 5 to 8 bp of DNA are housed by the Klenow fragment in a large positively charged cleft, and about 4 nucleotides of the primer from the 3′ end need to be melted from the template and then shifted to the exonuclease site during exonuclease degradation of the primer strand (13). If the DNA were housed in the polymerase active site, it is predicted that there would be a 90° bend, similar to that in the HIV-1 **reverse transcriptase** /DNA structure (14, 15).

Figure 1. Ribbon diagram of the Klenow fragment in the absence and presence of DNA. The Klenow fragment morphol

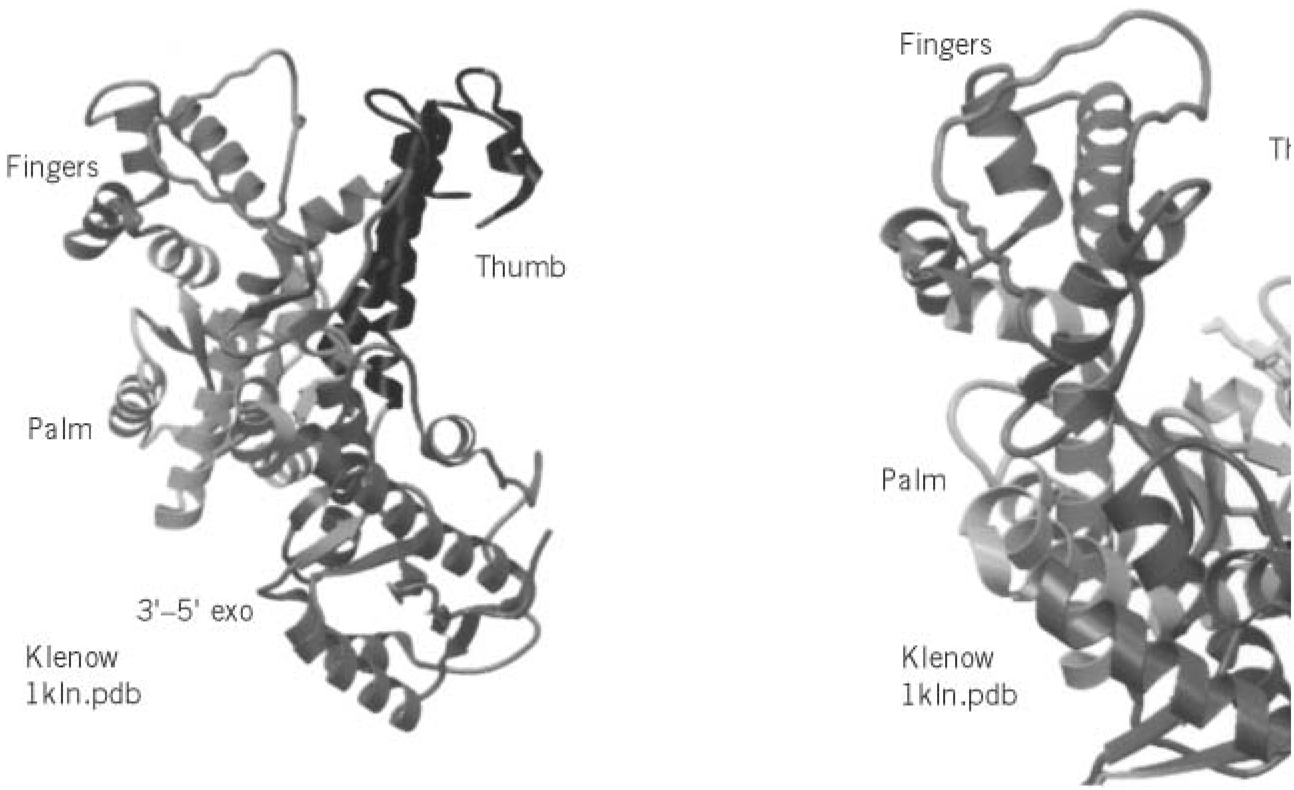
conformational change involves transferring the primer terminus across 30 Å, complete hybridization of the primer-temp
subdomain.



The polymerase active site, where dNTP binding and the chemical catalytic steps occur is located in the palm subdomain. It is thought from numerous biochemical and sequence alignment studies that the triphosphate of the incoming dNTP/divalent metal complex binds at the conserved Asp882, Glu883, and Asp705, whereas the base of the incoming nucleotide and its base pairing with the template is sensed by Tyr766 located in the conserved **a-helix** O. There is currently some confusion about the roles of Arg754 and Lys758, the two other conserved residues of helix O. Some believe that these residues bind the phosphates of the incoming dNTP. However, it is more likely that these residues are involved in template binding or perhaps pyrophosphate exchange (16).

The Klenow/double stranded DNA complex locked in an “editing mode” has given us numerous insights into the mechanism of the 3′-5′ exonuclease activity. In the structure, the exonuclease domain binds four bases of partially melted single-stranded DNA. The catalytic triad of Glu357, Asp355, and Asp501 bind two divalent cations, which facilitate a nucleophilic attack on the 3′ primer residue. The current model for the nucleophilic attack mechanism is that one of the metals deprotonates a water molecule, thus creating a nucleophile that, in turn, attacks the phosphate group of the 3′ primer residue. The two metals are in position to stabilize the resulting pentavalent phosphorous intermediate created by the nucleophilic attack, thus reducing the activation energy of the reaction (17). A similar two-metal phosphoryl-transfer mechanism has been proposed at the polymerase active site for the Klenow fragment (18), HIV-1 reverse transcriptase (19), and DNA polymerase b (20).

4. Kinetic Scheme of DNA Polymerization

A detailed kinetic mechanism has been presented using the Klenow fragment (21). The general mechanism involves these sequential steps: (1) binding of the polymerase to its template-primer, (2) binding of the appropriate dNTP to the pol-DNA complex; (3) a protein conformational change that positions the a phosphate of the incoming nucleotide near the 3′-OH group of the primer, (4) nucleophilic attack, resulting in phosphodiester bond formation (5) release of the pyrophosphate; and (6) translocation toward the new 3′-OH of the primer. Of these six steps, the protein conformational change is the slowest or rate-limiting step. The conformational change and nucleophilic attack step function together to sense proper **Watson–Crick base pairing** and thus contribute to the fidelity of this enzyme. If an improperly paired base is inserted, incorporation of the next base is very slow. This allows time for partitioning of the primer to the exonuclease site and the subsequent cleavage of the incorrect nucleoside. The presence of this proofreading 3′-5′ exonuclease activity aids in promoting the fidelity of the enzyme four- to seven-fold.

5. Uses in Molecular Biology

The Klenow fragment has been cloned, overexpressed, and purified, and it is widely used in laboratories. Among its uses today include incorporating radiolabeled nucleotides onto 3′ DNA ends, conducting fill-in reactions of gaps in double-stranded DNA, and synthesizing blunt DNA ends after restriction digestion.

DNA Repair

DNA repair is the set of enzymatic reactions that correct two types of structural anomalies in **DNA** (1). The first class of anomalies involves normal bases in an abnormal sequence context and includes mismatches, loops (extra nucleotides in one strand relative to the complementary strand), and bulges (a stretch of >1 noncomplementary base within the duplex). The second class, which is referred to as **DNA damage** or DNA lesions, encompasses abnormal nucleotides (modified, fragmented, cross-linked) within a normal or noncomplementary sequence context.

1. Mismatch Repair

Mismatches and related anomalous structures arise from errors in DNA replication and from recombination between partially **homologous** (homeologous) sequences. In addition, deamination of methylcytosine spontaneously or by acidic pH is a major cause of converting a G-C base pair to a G · T mismatch (2). The other source of simple mismatches is incorporation errors by **DNA polymerases** and the presence of a small fraction of bases in the template or in the nucleotide pool in **tautomeric** forms that lead to abnormal, yet complementary, **hydrogen bonding** and misincorporation. Loops often result from slippage/dislocation of template or nascent strand at monotonous sequences, such as oligo dA · dT tracts or microsatellite DNA consisting of di- or trinucleotide repeats. Bulges are often caused by recombination between two related sequences with a noncomplementary sequence surrounded by homologous sequences.

Mismatches are repaired by two general mechanisms: **base-excision repair** and the general mismatch repair system (3). In the base-excision repair pathway, the mismatched base (eg, the T in the G · T mismatch) is released by a glycosylase enzyme, and the resulting abasic sugar is removed by the combined actions of *AP lyase*, which cuts the polynucleotide chain 3′ to the apurinic/apyrimidinic (AP) site, and *AP endonuclease*, which cuts 5′ to the AP site. The resulting one-nucleotide gap is filled in by a **DNA polymerase** and sealed by a ligase (see Base Excision Repair). In the general mismatch repair system, an endonuclease incises the newly synthesized strand anywhere from 100 to 1000 nucleotides away and either 5′ or 3′ to the mismatch. The intervening region is removed past the mismatch by exonucleases, and the resulting gap is filled in by DNA polymerase and is ligated to restore the normal duplex (see Mismatch Repair).

Defects in the general mismatch repair system (nucleotide excision/long-patch repair) cause hereditary nonpolyposis colorectal cancer (HNPCC) in humans. In addition, mismatch repair defects have been found in several sporadic cancers (3).

2. Damage Repair

DNA damage in the form of base modification, base adduction, base fragmentation, and phosphodiester bond cleavage is caused by many agents including radiation in the form of X-rays (4), ultraviolet (5, 6), and microwave; and chemicals (7) ranging in reactivity from the relatively inert water to highly reactive oxygen radicals and activated polyaromatic hydrocarbons (Table 1). The most common lesions induced in DNA by ionizing radiation and active oxygen species are oxidized and fragmented purines, pyrimidine hydrates and glycols, abasic sites, and single- and double-strand breaks (8, 9). The major lesions induced by ultraviolet light are cyclobutane pyrimidine dimers and [6–4] dipyrimidine photoproducts. There is a virtually infinite variety of lesions produced in DNA by chemical agents. Among those, benzo[*a*]pyrene-, aflatoxin-, and acetylaminofluorene–guanine adducts are carcinogenic DNA lesions produced by natural and synthetic compounds. Similarly, some anticancer drugs cause DNA damage. Mitomycin C, cisplatin, and cyclophosphamide form monoadducts with guanine bases or cause interstrand cross-links between guanines in each of the two strands of the duplex. Psoralen makes intrastrand thymine monoadducts or interstrand thymine–psoralen–thymine cross-links. Alkylating agents such as methyl methane sulfonate, nitrosoguanidine, and nitrogen– and sulfur–mustard attack essentially all nucleophilic groups in DNA, producing at least 12 different base alkylation adducts and phosphorothioesters (7).

Table 1. Causes and Types of DNA Lesions and Mechanisms of DNA Repair

Type of DNA lesion	Cause	Repair Mechanism
A. Base mismatches, loops and bubble structures	Replication errors	1. Base excision
	Recombination	2. General mismatch repair
	Spontaneous deamination	
B. DNA lesion/base lesions		

1. Deamination and depurination	Heat	1. Base/nucleotide excision
2. Alkylation/aryl adducts	Natural and synthetic alkylators	2. Base/nucleotide excision
3. Intrastrand cross-links	Ultraviolet light, cisplatin	3. Nucleotide excision
4. Interstrand cross-links	Psoralen, melphalen, cisplatin	4. Nucleotide excision/recombination
C. Strand discontinuities		
1. Single-strand break	Ionizing radiation, oxidative stress	1. Ligation
2. Double-strand break	Ionizing radiation	2. Ligation/recombination

DNA lesions in the form of modified or adducted bases, interstrand cross-links, or discontinuity in one (nick) or both (break) strands interfere with replication, transcription and recombination of DNA; they also cause mutations or cell death, due to the inability to replicate or to a mutation in an essential gene. Furthermore, because many of the agents that cause damage are present in the cell's normal habitat, DNA damage is a frequent occurrence that the cell must deal with on a continuous basis in order to maintain its integrity and survival (9). Hence, cells possess many biochemical reaction pathways (DNA repair mechanisms) to eliminate damage from their chromosomes. These pathways fall into three main categories (1, 10): (i) base excision, (ii) nucleotide excision (or simply excision), and (iii) direct repair mechanisms. As should be apparent from this enumeration, there are extensive functional similarities between the mismatch and damage repair systems. This is not surprising, because the double-helical nature of DNA dictates the types of operations that can be applied to it to remove a mismatched or a damaged base: The mismatch or damage may be removed in the form of a base (11, 12) or a (oligo)nucleotide (10), which creates a single-stranded gap that can be filled using the intact (correct) strand as a template. However, damage repair includes additional mechanisms in its repertoire. One of these is direct repair (1). In this type of repair the chemical bonds that comprise the lesion are broken to restore the normal bases. An example of this type of repair includes photoreactivation by **photolyase**, which breaks the two sigma bonds between adjacent thymines to restore the dimer to a thymine dinucleotide (13) (see Photolyase/Photoreactivation), and O^6-methylguanine DNA methyltransferase, which breaks the single bond between the O6 of guanine and the alkyl group and thus restores the normal base (14) [see O6-Methylguanine-DNA Methyltransferase (MGMT)]. Ligation of a single-strand or double-strand break that is not accompanied by base loss may also be considered an example of direct repair. Finally, recombinational repair is also a repair mechanism unique to damaged DNA. This repair mechanism is employed by the cell when both strands of the duplex are damaged so that the duplex cannot be fixed by direct repair or by base and nucleotide excision repair systems, because these systems rely on an intact strand in the duplex (1). In this rather elaborate repair mechanism, the damaged region of the duplex is replaced by using a homologous duplex to retrieve genetic material and/or information. This repair system uses the enzymes of both nucleotide excision repair and genetic recombination systems (see Recombinational Repair).

DNA Replication

DNA replication in a chemical sense is the process by which an exact copy of a **DNA** molecule having a specific base sequence is synthesized. Exact copies of a linear DNA molecule can be replicated *in vitro* using purified **DNA polymerases** and proper primers. A recent advance in the long **PCR** method has made it possible to amplify DNA molecules as long as several tens of kilobases. In biology, however, DNA replication is defined as the duplication of the entire genome DNA in the cell. Basic mechanisms of replication of **plasmids**, **bacteriophages**, animal **viruses**, and bacterial chromosomes have been elucidated at the molecular level. On the other hand, knowledge of the replication of **eukaryotic** genomes is still limited, although increasing rapidly. A variety of structures and types of replication are known among plasmids, bacteriophages, plant and animal viruses. Mitochondria genomes are known to have a unique mode of replication. Here, replication of the genomes (conventionally called chromosomes) of **prokaryotes** (bacteria) and eukaryotes will be described, since the replication of genome DNA is a process essential for basic cellular functions, cell cycle, cell division, and cell differentiation.

1. Prokaryotic Genomes (Chromosomes)

Bacterial genomes usually consist of circular DNA of one to eight megabases and comprise a single replication unit, a replicon. The general aspects of genome replication have been elucidated in *Bacillus subtilis* and *Escherichia coli*, representatives of **Gram positive** and Gram negative bacteria, respectively. In both genomes, replication is initiated from a genetically defined site, oriC (see Replication Origin), proceeds bidirectionally and symmetrically at about the same elongation rate, and terminates at the defined region, terC, of the genome (Fig. 1) (see Termination Of DNA Replication). Isolation of *dna* temperature-sensitive mutants has revealed that the three processes, initiation, elongation, and termination of replication, are regulated independently by multiple gene products. Genetic and biochemical studies subsequently revealed multiple protein complexes, the *primosome* and *replisome*, for the initiation and replication machinery, respectively (see DNA Replication Proteins). In contrast, termination is achieved by a single protein, Rtp.

Figure 1. Replication of circular prokaryotic chromosome. Replication of a circular chromosome is schematically shown. Replication is initiated by unwinding of a specific site of the chromosome, the origin of replication (oriC), followed by the synthesis of two leading strands and lagging strands in opposite directions. Elongation proceeds bidirectionally, with the same rate of synthesis at the two replication forks. Elongation terminates at a specific site, the terminus of replication.

Terminus of replication

Regulatory DNA elements required for initiation, oriC, were identified by cloning of sequences that confer upon circular DNA the ability of autonomous replication as extra chromosomal elements in the cell (1). The oriC was first identified in *E. coli*, and it was then found that one of the *E. coli* Dna proteins, DnaA, functioned as an initiator of replication by binding to a sequence-specific element, the DnaA-box, to activate oriC and to unwind the AT-rich region within oriC (2). The combination of the DnaA-box and the DnaA protein functioning as *cis* and *trans* regulatory elements in the initiation of replication was subsequently found to exist commonly in many **eubacteria** (3). A replicon mechanism consisting of two regulatory elements, the replicator in *cis* and initiator in *trans*, that was proposed as early as 1963 (4) has been confirmed in prokaryotes (see Replicon).

The elongation of replication is much more complicated than it was thought in the late 1950s when semi-conservative DNA replication was demonstrated and Kornberg discovered DNA polymerase I, which apparently copied double-stranded DNA *in vitro*. This complexity is due to the fact that the two strands of DNA are oriented in opposite directions in terms of the phosphodiester bonds and DNA polymerases can function in only one, the 5′ to 3′ direction. Extensive analysis of growing replication forks in *E. coli* led to the discovery of asymmetric discontinuous DNA replication in which synthesis of the 5′ to 3′ strand proceeds sequentially (the **leading strand**), whereas the opposite strand (lagging strand) is synthesized in short pieces, using an RNA primer, and subsequently joined together. The small RNA–DNA fragments of some 500 to 1000 bases synthesized during the discontinuous replication were named Okazaki Fragments after the researcher who discovered this mechanism (5). At least five enzymes, DNA helicase, primase, DNA polymerase I and III, and DNA Ligase, are involved in this process (Fig. 2) (see DNA Replication Proteins). These proteins are assumed to form a supramolecular complex, the replisome, and may be attached to the cell membrane. The initiation of replication is the synthesis of the first primer RNA–DNA molecule on both strands of DNA at the unwound region of oriC, which eventually become leading strands extended in both directions. The formation of the replisome at oriC requires the activation of oriC by DnaA and subsequent formation of the primosome complex, which includes the DNA helicase, DnaB in *E. coli*. The synthesis of lagging strands may be initiated after the formation of a considerable size of single-stranded region by elongation of the leading strand, but the detailed mechanism of synthesis of neither the first primer RNA nor the first lagging strands is known (Fig. 3).

Figure 2. Semiconservative and RNA-primed discontinuous replication. The mode of synthesis of leading strand and lagging strand at the replication fork is shown schematically. (**1**) Unwinding of double strand by helicase, (**2**) stabilizatio of single-stranded regions by single-strand DNA binding proteins (SSB) in prokaryotes (= p) or RPA in eukaryotes (= e) (**3**) primer RNA synthesis by primase (in p) or polymerase a-primase complex (in **e**), (**4**) lagging strand synthesis by DN polymerase III (in p) or polymerase d/e (in **e**), (**5**) degradation of primer RNA by polymerase I (in p) or ribonuclease H (**e**), and (**6**) leading strand synthesis by polymerase III (in p) or polymerase d/e (in **e**).

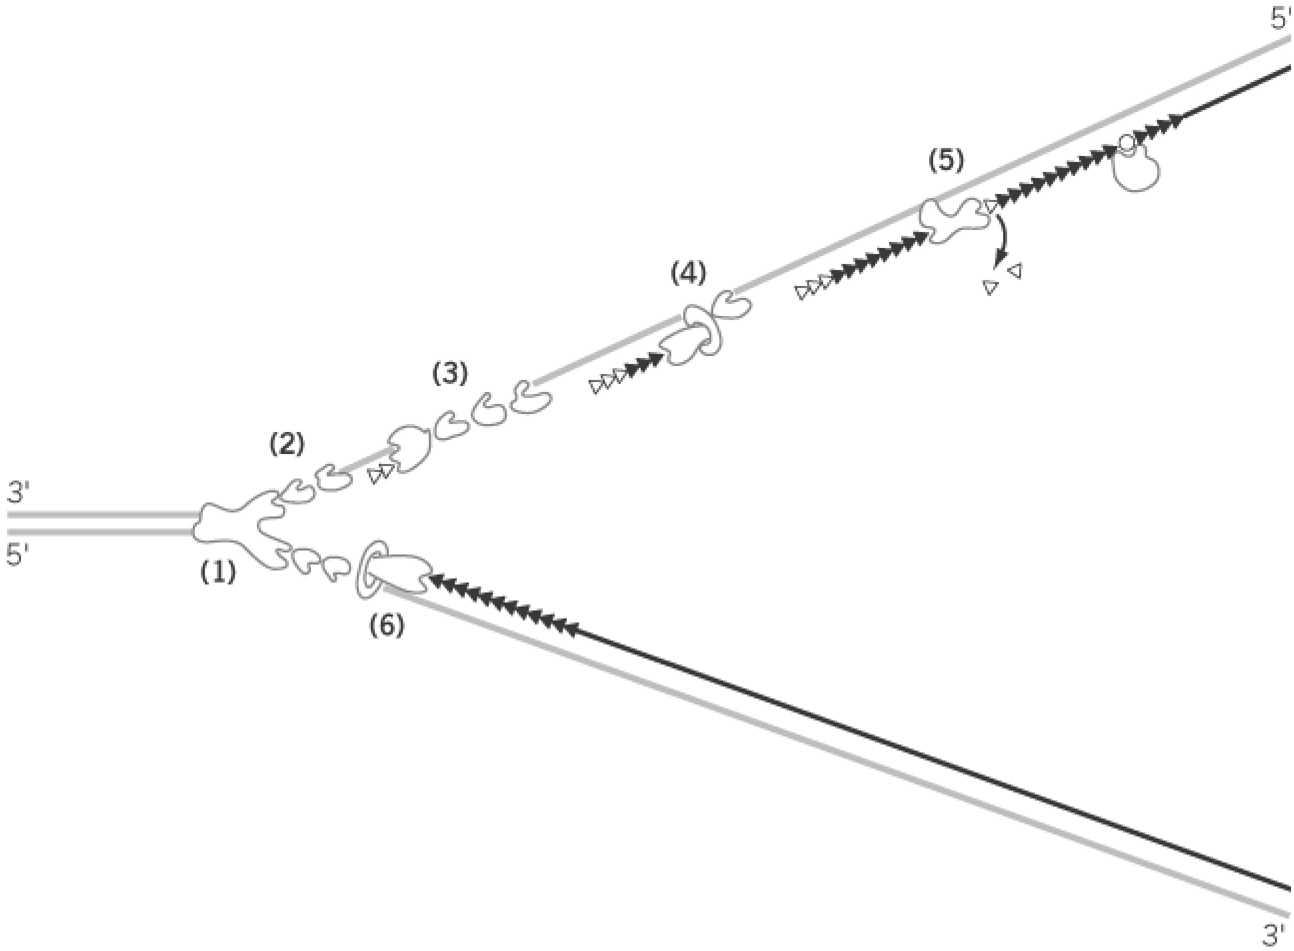

Figure 3. Mechanism of initiation of replication of prokaryotic chromosomes. The OriC of *E. coli* and initiation from the oriC by the function of DnaA protein followed by DNA helicase and finally by assembly of the replication machinery is shown schematically. The DnaA box is a 9-mer sequence (consensus sequence is TTATCCACA) and DnaA protein is conserved in many eubacteria. The DnaB helicase is also conserved in at least *E. coli* and *B. subtilis*.

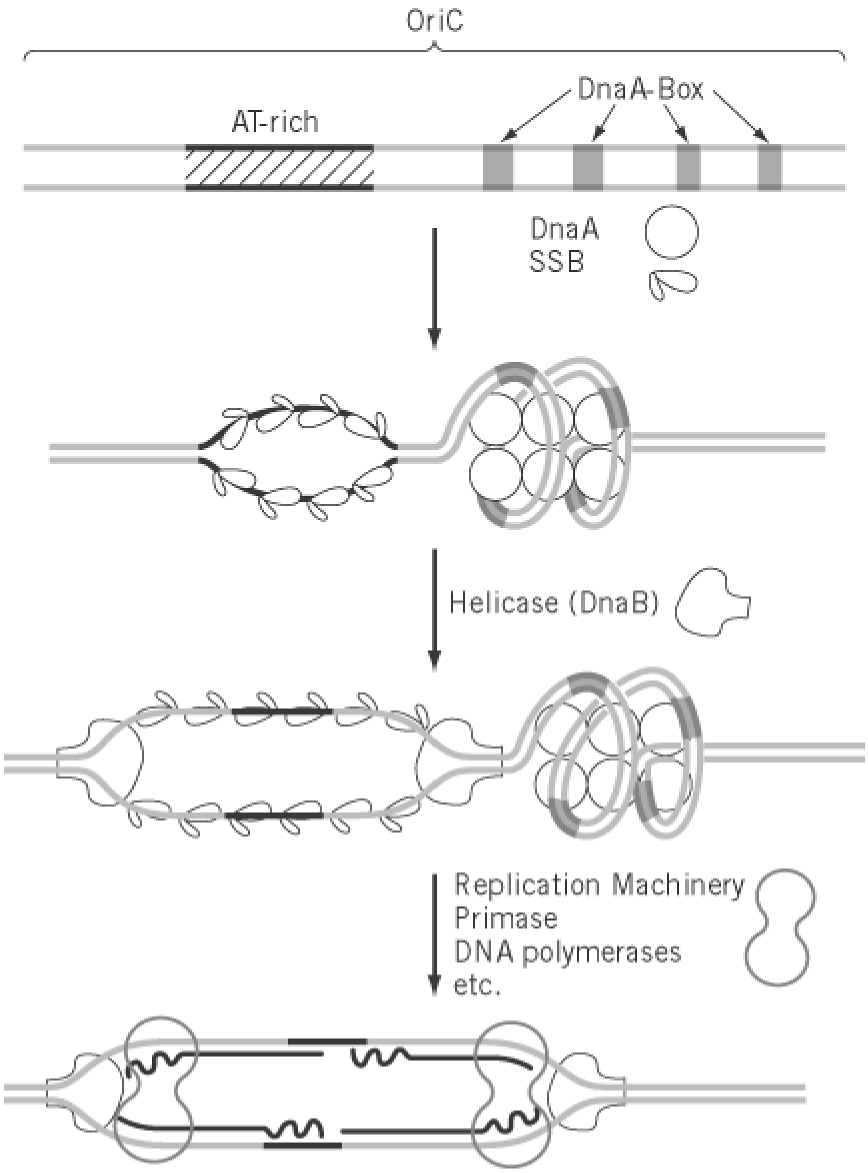


Elongation at the macroscopic scale proceeds bidirectionally along the circular genome at about the same rate, 50 kilobases/min, and completes at the fixed region, the terminus where two forks meet (s Termination Of DNA Replication). Two sets of three (a total of six) termination signals, oriented in opposite directions, are found in both E. coli (6) and B. subtilis (3) chromosomes at about 180o from oriC, to which a protein known as replication termination proteinein, Rtp, binds and inhibits the elongation in one direction. The distance between the nearest two signal sets is 270 kb in *E. coli* and 59 kb in *B. subtilis*. Although the mechanism of termination is basically the same in *E. coli* and *B. subtilis*, there is no homology in these terC sequences nor in the primary structures of Rtp. This is in sharp contrast to the extensive conservation of the DnaA protein and the DnaA-box sequence among eubacteria. The tertiary structure of *B. subtilis* Rtp protein reveals the mechanism of inhibition of DN replication at the molecular level (7). Termination of replication results in the two daughter chromosomes entwined about one another. Resolution of such a structure into two separate chromosomes can be achieved by the action of DNA gyrase (8) (see DNA Topology). In addition to the termination site, pausing sites where DNA replication slows down significantly are found near th termination sites of the *E. coli* chromosome, and their possible involvement in recombination has be discussed (9).

2. Eukaryotic Chromosomes

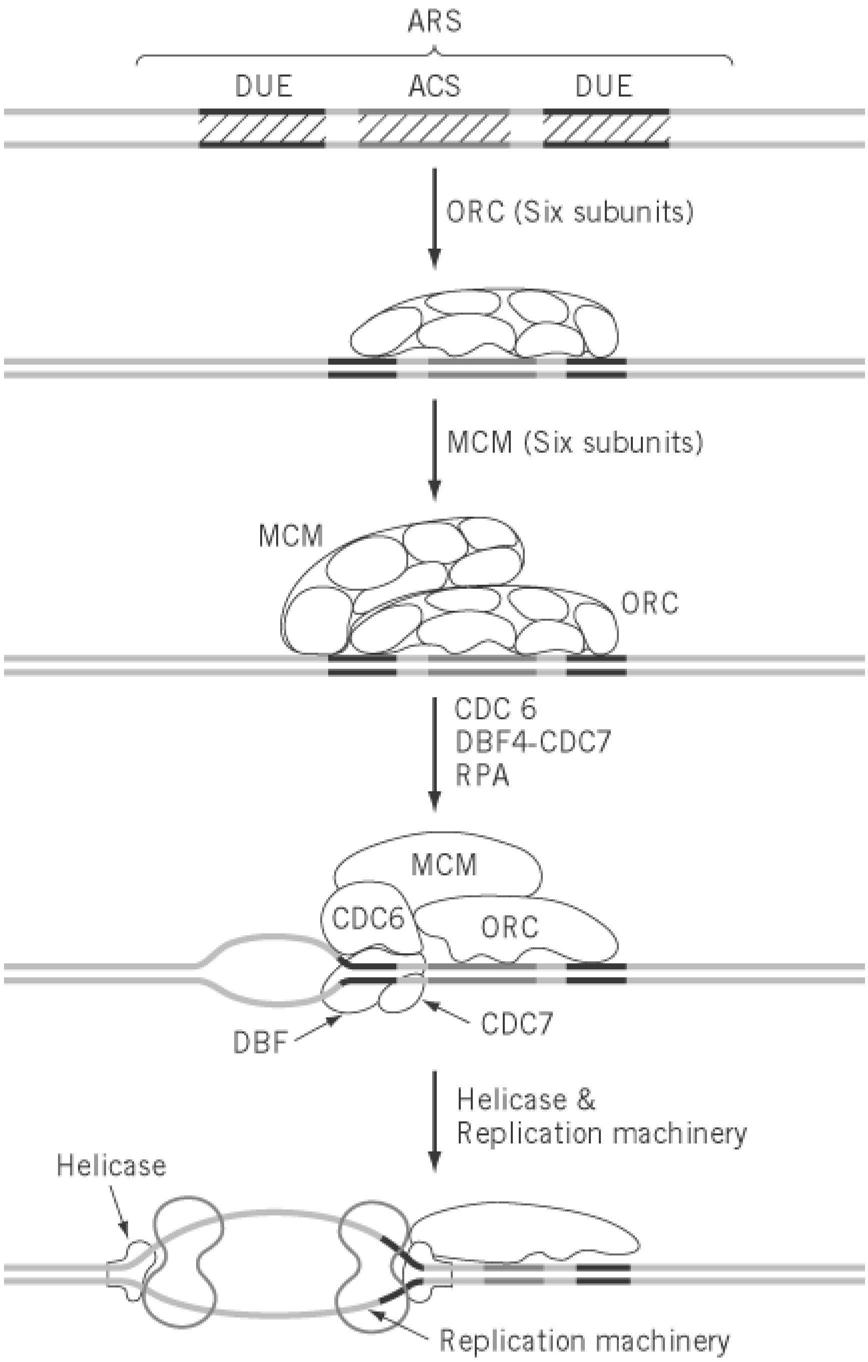
Studies on the replication of a viral genome, SV40, have provided the basic knowledge about DNA replication in eukaryotic cells, because it replicates using host proteins, except for a single viral protein, T Antigen. T antigen was first identified as a protein responsible for tumor transformation o mammalian cells by the tumor virus and hence was named as Tumor antigen. Subsequently, it was found that the T antigen is an initiator protein and a helicase that acts on the origin of the 3-kb circul SV40 genome (10). Success in reconstitution of an *in vitro* replication of the entire SV40 genome le to the identification and purification of enzymes and protein factors involved in the initiation and elongation of replication and separation of replicated molecules (see DNA Replication Proteins). Th basic mechanism of synthesis of leading strand by DNA polymerase d/e and of lagging strand by the combination of the DNA polymerase a-primase complex and polymerase d/e has been elucidated (11 (Fig. 2). In addition, various factors, such as RPA, RFC, and proliferating cell nuclear antigen (**PCNA**), were identified to facilitate the efficient and progressive replication of the viral genome (1 A topoisomerase, topoisomerase II, was found essential for resolving the concatenated structure formed at the end of replication of the circular genome. Since no *in vitro* replication system is availa using cellular genome DNA as template, the molecular mechanism of replication established by the study of SV40 genome is still the sole model of eukaryotic DNA replication and serves as a unique system to identify factors involved in DNA replication and its regulation (see Replication Fork (Y-Fork Intermediate)) (13).

The mechanism of initiation of replication of the SV40 genome is similar to, and rather simpler than that of bacterial genome, because T antigen acts as helicase as well as the initiator. However, it did n provide a model for the initiation of replication of cellular chromosomes composed of multiple replicons, which was first demonstrated by the autoradiography of replicating chromosomes in 1968 Huberman and Riggs (14). In general, the genomes of eukaryotic cells are estimated to contain abou one origin every 10 to 330 kbp (15). Extensive searches for chromosomal replication origins through the cloning of autonomously replicating sequences (**ARS**) have mostly failed, except for **yeast** chromosomes of *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*. A number of ARS ha been isolated from the 16 chromosomes of *S. cerevisiae*. In particular, 14 ARS in a 200-kbp portion chromosome III (16) and 10 ARS in the 300-kbp entire chromosome VI (17) were identified. All AR contain a common sequence of 11 bp ARS consensus sequence (ACS) that is essential for autonomo replication, plus additional nonspecific AT-rich sequences whose deletion causes a significant reduction in ARS activity. In some cases, a binding site for a **transcriptional factor** is located near t ACS and enhances its ARS activity. The ARS from *S. cerevisiae* is unique, and no **homologous** sequence of the approximately 100-bp ACS was found in other eukaryotes. ARS cloned from the ot yeast *S. pombe* require a region of about 1 kbp containing several AT-rich clusters, with no single specific sequences like ACS essential for ARS activity. The two-dimensional gel electrophoresis of chromosomal fragments developed by Brewer and Fangman (18) has successfully detected the eye-form intermediates of replicating intermediates clearly separated from Y-form intermediates (see Replication Fork (Y-Fork Intermediate)). Using this method, some ARS are found to function as efficient origins of chromosomal replication in *S. cerevisiae*. However, some of the active ARS in plasmids were found to be very inefficient or silent on the chromosome, suggesting a role of chroma structure in origin activity. Not all origins are fired at the same time in **S phase**, but they are initiate sequentially in a fixed order (19). A regulatory factor determining the efficiency and timing of initiation of late replicating origins have been identified (24).

Origins from genomes of higher organisms are ambiguous. Attempts to isolate ARS from mammalia chromosomes are difficult to reproduce and therefore controversial. The best-studied origin, near the dihydrofolate reductase (DHFR) gene in the Chinese hamster genome, showed variation in size from 0.5 to 55 kbp, depending on the methods used to detect origin activity (20). Systematic studies on la chromosomal segments have revealed that most fragments longer than 10 kbp can provide some AR activity in mammalian cells, suggesting that DNA length is more critical than DNA sequence. In ma cases, initiation occurs randomly within several kilobases, which is called the initiation *zone* rather than the origin. The concept of a replicator that is proposed in the original replicon hypothesis shoul be reexamined in these complex origins, in terms of the recognition site of initiators and the actual si of initiation of replication (see Replicon).

As for *trans* factors for initiation, no single initiator protein like bacterial DnaA or SV40 T antigen h been found in eukaryotic cells. Instead, a complex consisting of six proteins was found to recognize yeast ARS through binding to the ACS and named accordingly as the origin recognition complex (ORC) (21). The ORC was subsequently found to be well conserved from yeast to humans. Howeve the mechanism of how ORC recognizes seemingly nonspecific origin sequences on chromosomes other than *S. cerevisiae* is not clear. An *in vitro* DNA synthesis system using a Xenopus egg extract and sperm chromosomes provided a unique system for studying the biochemistry of initiation of chromosomal replication, and it led to the discovery of the licensing factor that permits replication o multiple replicons of the chromosome once in the cell cycle (22, 23). Genes homologous to the Xenopus licensing factor were identified among MCM genes of *S. cerevisiae*, and a MCM complex composed of six proteins that binds to ARS through interaction with ORC was subsequently discovered. Genetic studies with *S. cerevisiae* show that the formation of the MCM–ORC–ARS complex is not sufficient to activate the origin of the chromosome, and additional factors, protein kinases that interact with MCM or ORC directly or indirectly, were being discovered. Extensive studies on the regulatory network of the replication complex are expected to elucidate the molecular mechanism of signal transduction from the cell cycle engine, cdk/cyclin kinase, to the chromosomal origin of replication. The MCM complex, as well as the factors interacting with MCM and ORC, are conserved widely in eukaryotes, suggesting that the molecular mechanism elucidated in the yeast an frog provides principles that guide the studies on more complicated chromosomes including human chromosome (Fig. 4).

Figure 4. Mechanism of initiation of replication of a *Saccharomyces cerevisiae* chromosome. Minimal structure of the ARS contains a 11-bp sequence-specific region (ACS) that is essential for the origin, and surrounding stimulative regio that are rich in AT and called DNA unwinding elements (DUE). The ORC binds to ACS throughout cell cycle. MCM (licensing factor) complex binds to ORC at the G2-M phase of the cell cycle, and the double complex may be activated by several protein kinases, including CDC6 and DBF4/CDC7, to produce a single-stranded region that serves as the ent site for helicase and eventually for the replication machinery. The mechanism is hypothetical, as the last two steps have not been proven experimentally.



Termination of replication of adjacent replicons occurs when two forks moving in opposite direction meet. Although specific termination sites between the two adjacent replicons have not been identifie the structure of replicated replicons at the termination sites must be similar to the ends of the circulaı chromosomes of bacterial and viral genomes and require topoisomerases to resolve the structure to separate two sister strands. Termination of the ends of linear chromosomes requires a more specific structure, the telomere, to prevent shortening of the chromosome due to the discontinuous replicatioı mechanism.

DNA Replication Proteins

Various DNA replication systems from bacteria, **plasmids**, **bacteriophage**, **viruses**, and **eukaryotic** cells have been studied to elucidate the mechanism of DNA replication. It emerged that most of them can complete the reaction with a limited number of enzymes called *replication proteins* (or factors) (Table 1). The primary experiments were identification, as **conditional mutants** for bacterial growth and DNA synthesis, of the ***dna* genes** from *Escherichia coli* that encode replication proteins (1, 2).

About a dozen *dna* genes were identified and grouped as quick- or slow-stop mutants, which indicate whether the gene products are involved in the elongation or initiation stages, respectively. Development of *in vitro* DNA replication systems with *E. coli* crude lysates for single-stranded DNA phage and the *E. coli* chromosomal origin made it possible to identify and purify replication proteins by complementation of the missing activity caused by these mutations. In addition, some replication proteins were identified as proteins harboring known enzymatic activities required for replication, such as DNA Ligase, single-stranded DNA binding protein, ribonuclease H, topoisomerase I, and DNA gyrase (see DNA Topology). DNA gyrase subunits were also identified as drug-sensitivity gene products.

Table 1. Essential Replication Proteins from Prokaryotes and Eukaryotes

Stage	Function	*E. coli*	l phage	T4 phage	Mammalian (SV40)	*S. cerevisiae*
Pre-initiation		DnaA	O protein			
	Initiator			?	ORC? (Tag)	ORC (1 ~ 6)
		DnaC	P protein			
					MCM?	MCM (2 ~ 7)
	Activator	RNA polymerase			CDK/cyclin?	CDK/cyclin?
					CDC6?	DCD6?
					CDC7/DBF4?	CDC7/DBF4?
Initiation	Replication	DnaB		Gene 41	MCM? (Tag)	DNA2?
	DNA helicase					
	ssDNA binding protein	ssb		Gene 32	RPA (replication protein A)	yRPA (RFA1, 2, 3)
	Primase	DnaG		Gene 61	DNA polymerase a/primase	primase (PRI1, PRI2)
Elongation	DNA polymerase	DNA polymerase III		Gene 43	DNA polymerase a/primase	DNA polymerase I (pola: POL1 = CDC17)

				DNA polymerase s	DNA polymerase II (pol e: POL2)
				DNA polymerase e	DNA polymerase III (pol d: POL3 = CDC2)
	DNA polymerase	bsubunit	Gene 45	PCNA (proliferating cell nuclear antigen)	yPCNA (POL30)
	Accessory proteins				
		g complex	Gene 44/62	RFC (replication factor C)	yRFC (CDC44 = RFC1, RFC2, RFC3, RFC4, RFC5)
	Swivel	Gyrase	T4 Topo	Topoisomerase I	TOP 1
		TopA		Topoisomerase II	TOP 2
Maturation	Decatenation	Gyrase		Topoisomerase II	TOP 2

Some proteins that have roles in other cellular processes function as replication proteins at specific stages in DNA replication; eg, **RNA polymerase** is necessary to activate several replication origins or to synthesize primer RNA; a **heat-shock** protein, grpE, is required to initiate lambda phage DNA replication, and thioredoxin is involved in T7 phage DNA polymerase.

Replication of T4 phage DNA is dependent primarily on its own encoded proteins, and a search for its replication proteins was carried out by the **conditional mutant** technique. As a result, seven replication proteins essential for the DNA synthesis, and many proteins with related functions, were identified.

Reconstitution of these replication reactions revealed that the replication factors do not react with a template DNA individually, but as a multimeric protein complex. Furthermore, the configurations and functions of the complex alter successively, from pre-initiation to elongation stages. For example, an assembly of DNA helicase and primase (and the assembly factors in some cases), called the *primosome*, is formed at the replication origins (or the assembly sites); subsequently, the addition of two DNA polymerase subunits and their accessory proteins in this complex generates a *replisome*, a super-protein complex that synthesizes **leading and lagging** DNA strands coordinately at a replication fork (2).

Due to the difficulty of applying **genetics** to most eukaryotes, the identification of eukaryotic replication proteins was started by a search of activities known to be involved in replication, such as DNA polymerases, topoisomerases, and DNA ligases. In contrast, a unicellular eukaryote, the **yeast** *Saccharomyces cerevisiae*, is exceptionally adaptable for genetic analysis, and many genes necessary for the cell cycle to progress have been identified. However, it was difficult to identify their biochemical activities and distinguish their requirement in DNA replication, due to the absence of any *in vitro* replication systems. The first breakthrough in studies of eukaryotic replication proteins occurred with the development the SV40 virus *in vitro* DNA replication system using human cell lysates (for a review, see (3)). Replication of this virus largely relies on the replication functions of the cell, so fractionation could identify the required proteins; this has isolated several replication proteins also involved in cellular chromosomal DNA replication. Furthermore, because these replication proteins are highly conserved throughout eukaryotes, several yeast replication genes were identified by homology searches (Table 1). Using previously and newly identified replication proteins, the process of SV40 DNA replication was totally reconstituted, and the functions of the proteins in DNA replication have been well elucidated (4). The replication reaction can be roughly divided into four stages: pre-initiation, initiation, elongation, and segregation (maturation), and specific sets of replication proteins are required to process these stages. The SV40 replication system primarily reproduced the cellular replication reaction from elongation to maturation but, in contrast, insufficient information about cellular initiation proteins was obtained from this viral system. One characteristic feature of eukaryotic DNA elongation obtained from the analysis is the involvement of multiple DNA polymerases in one replication fork.

Another breakthrough was the discovery of the origin recognition complex (ORC) from yeast (5) and licensing factor (MCM) from Xenopus (6). ORC specifically binds to the yeast replication origin sequence in an ATP-dependent manner and is a strong candidate for the initiator protein. MCM is a key player in the licensing reaction, and yeast MCM forms a pre-replicative complex at the origin, together with ORC. Through studies on their functions, the understanding of yeast chromosomal DNA replication has progressed drastically. Furthermore, these proteins are also highly conserved among eukaryotes, implying the existence of a common mechanism to initiate eukaryotic chromosomal DNA replication.

Another specific feature of eukaryotic replication proteins is that the replication process is tightly linked with several eukaryote-specific processes, such as cell-cycle control and chromatin assembly, so the boundary between replication and these processes is ambiguous. Therefore, **cyclin**-dependent kinases, licensing factors, and chromatin assembly factors are part of replication factors in eukaryotes and, indeed, some of them form assemblies with major replication proteins at replication foci during **S phase**.

DNA Sequencing

One of the fundamental methods of molecular biology is determining the sequences of bases in specific segments of DNA. The sequence information can be used to help deduce the function of the DNA segment, map its chromosomal location, determine how it might be involved in regulating gene expression or replication, or elucidate how it interacts with proteins. For example, the sequence of an unknown complementary DNA (cDNA) can be used to deduce the sequence of the protein encoded by its parent messenger RNA. In turn, this protein sequence can be compared with the sequences of all known proteins, giving clues to function and evolutionary origin (see Sequence Analysis).
