PREFACE

The Wiley Biotechnology Encyclopedias, composed of the *Encyclopedia of Molecular Biology*, the *Encyclopedia of Bioprocess Technology: Fermentation, Biocatalysis, and Bioseparation*, the *Encyclopedia of Cell Technology*, and the *Encyclopedia of Ethical, Legal, and Policy Issues in Biotechnology*, cover very broadly four major contemporary themes in biotechnology. The series comes at a fascinating time in that as we move into the twenty-first century, the discipline of biotechnology is undergoing striking paradigm changes.

Biotechnology is now beginning to be viewed as an informational science. In a simplistic sense, there are three types of biological information. First, there is the digital or linear information of our chromosomes and genes, with the four-letter alphabet composed of G, C, A, and T (the bases Guanine, Cytosine, Adenine, and Thymine). Variation in the order of these letters in the digital strings of our chromosomes or our expressed genes (or mRNAs) generates information of several distinct types: genes, regulatory machinery, and information that enables chromosomes to carry out their tasks as informational organelles (eg, centromeric and telomeric sequences).

Second, there is the three-dimensional information of proteins, the molecular machines of life. Proteins are strings of amino acids employing a 20-letter alphabet. Proteins pose four technical challenges: (i) Proteins are synthesized as linear strings and fold into precise three-dimensional structures as dictated by the order of amino acid residues in the string. Can we formulate the rules for protein folding to predict three-dimensional structure from primary amino acid sequence? The identification and comparative analysis of all human and model organism (bacteria, yeast, nematode, fly, mouse, etc.) genes and proteins will eventually lead to a lexicon of motifs that are the building block components of genes and proteins. These motifs will greatly constrain the shape space computational algorithms must search to successfully correlate primary amino acid sequence with the correct three-dimensional shapes. The protein-folding problem will probably be solved within the next 10 to 15 years. (ii) Can we predict protein function from knowledge of the three-dimensional structure? Once again the lexicon of motifs with their functional as well as structural correlations will play a critical role in solving this problem. (iii) How do the myriad of chemical modifications of proteins (eg, phosphorylation, acetylation) alter their structures and modify their functions? The mass spectrometer will play a key role in identifying secondary modifications. (iv) How do proteins interact with one another and/or with other macromolecules to form complex molecular machines (eg, the ribosomal subunits)? If these functional complexes can be isolated, the mass spectrometer, coupled with a knowledge of all protein sequences that can be derived from the complete genomic sequence of the organism, will serve as a powerful tool for identifying all the components of complex molecular machines.

The third type of biological information arises from complex biological systems and networks. Systems information is four-dimensional because it varies with time. For example, the human brain has 1012 neurons making approximately 1015 connections. From this network arises systems properties such a memory, consciousness, and the ability to learn. The important point is that systems properties cannot be understood from studying the network elements (eg, neurons) one at a time; rather, the collective behavior of the elements needs to be studied together. To study most biological systems, three issues need to be stressed. First, most biological systems are too complex to study directly; therefore they must be divided into tractable subsystems whose properties in part reflect those of the system. These subsystems must be sufficiently small to analyze all their elements and connections. Second, high-throughput analytic or global tools are required for studying many systems elements at one time (see below). Finally, the systems information needs to be modeled mathematically before systems properties can be predicted and ultimately understood. This will require recruiting computer scientists and applied mathematics into biology—just as the attempts to decipher the information of complete genomes and the protein folding and structure/function problems have required the recruitment of computational scientists.

I would be remiss not to point out that there are many other molecules that generate biological information—amino acids, carbohydrates, lipids, etc. These too must be studied in the context of their specific structures and specific functions.

The deciphering and manipulation of these various types of biological information represent an enormous technical challenge for biotechnology. Yet major new and powerful tools for doing so are emerging.

One class of tools for deciphering biological information is termed high-throughput analytic or global tools. These tools can study many genes or chromosome features (genomics), many proteins (proteomics), or many cells rapidly: large-scale DNA sequencing; genome-wide genetic mapping; cDNA or oligonucleotide arrays; two-dimensional gel electrophoresis and other global protein separation technologies; mass spectrometric analysis of proteins and protein fragments; multiparameter, high-throughput cell and chromosome sorting; and high-throughput phenotypic assays.

A second approach to the deciphering and manipulation of biological information centers around combinatorial strategies. The basic idea is to synthesize an informational string (DNA fragments, RNA fragments, protein fragments, antibody combining sites, etc.) using all combinations of the basic letters of the corresponding alphabet—thus creating many different shapes that can be used to activate, inhibit, or complement the biological functions of designated three-dimensional shapes (eg, a molecule in a signal transduction pathway). The power of combinational chemistry is just beginning to be appreciated.

A critical approach to deciphering biological information will ultimately be the ability to visualize the functioning of genes, proteins, cells, and other informational elements within living organisms (*in vivo* informational imaging).

Finally, there are the computational tools required to collect, store, analyze, model, and ultimately distribute the various types of biological information. The creation presents a challenge comparable to that of developing of new instrumentation and new chemistries. Once again, this means recruiting computer scientists and applied mathematicians to biology. The biggest challenge in this regard is the language barriers that separate different scientific disciplines. Teaching biology as an informational science has been a very effective means for breeching these language barriers.

The challenge is, of course, to decipher these various types of biological information and then be able to use this information to manipulate genes, proteins, cells, and informational pathways in living organisms to eliminate or prevent disease, produce higher yield crops, or increase the productivity of animal products and meat.

Biotechnology and its applications raise a host of social, ethical, and legal questions; for example, genetic privacy, germline genetic engineering, cloning animals, genes that influence behavior, cost of therapeutic drugs generated by biotechnology, animal rights, and the nature and control of intellectual property.

The challenge clearly is to educate society so that each citizen can thoughtfully and rationally deal with these issues, for ultimately society dictates the resources and regulations that circumscribe the development and practice of biotechnology. Ultimately, I feel enormous responsibility rests with scientists to inform and educate society about the challenges as well as the opportunities arising from biotechnology. These are critical issues for biotechnology that are developed in detail in the *Encyclopedia of Ethical, Legal, and Policy Issues in Biotechnology*.

The view that biotechnology is an informational science pervades virtually every aspect of this science—including discovery, reduction to practice, and societal concerns. These Encyclopedias of Biotechnology reinforce the emerging informational paradigm change that is powerfully positioning science as we move into the twenty-first century to more effectively decipher and manipulate for humankind's benefit the biological information of relevant living organisms.

COMMONLY USED ACRONYMS AND ABBREVIATIONS

Å	angstrom (10^{-10} m)
Ab	antibody
Ac	acetyl group
ADP	adenosine diphosphate
Ala	alanine residue (also A)
AMP	adenosine monophosphate
Arg	arginine residue (also R)
Asn	asparagine residue (also N)
Asp	aspartic acid residue (also D)
ATP	adenosine triphosphate
ATPase	adenosine triphosphatase
Bq	becquerel
bp	base-pair
BSA	bovine serum albumin
C	cytosine base
cal	calorie (4.18 J)
cAMP	3′,5′-cyclic AMP
CD	circular dichroism
CoA	coenzyme A
cDNA	complementary DNA
cGMP	3′,5′-cyclic GMP
Cmc	critical micelle concentration
Cys	cysteine residue (also C)
Da	dalton
DMSO	dimethyl sulfoxide
DNA	deoxyribonucleic acid
DNase	deoxyribonuclease
DTT	dithiothreitol
EDTA	ethylenediamine tetraacetic acid
EG	[ethylenebis(oxonitrilo)] tetraacetic acid
EGF	epidermal growth factor
ELISA	enzyme-linked immunosorbent assay
EM	electron microscopy
EPR, ESR	electron paramagnetic (or sign) resonance
ER	endoplasmic reticulum
EXAFS	extended X-ray absorption fine structure
FAD	flavin-adenine dinucleotide
fMet	*N*-formyl methionine
FMN	flavin mononucleotide
FPLC	fast protein liquid chromatography
G	Gibbs free energy of a system
G	guanine base
G-protein	guanine-nucleotide binding regulatory protein
GABA	g-aminobutyric acid
GalNAc	*N*-acetylgalactosamine residue
GdmCl	guanidinium chloride (guanidine hydrochloride)
GDP	guanosine diphosphate
Glc	glucose residue
GlcNAc	*N*-acetylglucosamine residue
Gln	glutamine residue (also Q)
Glu	glutamic acid residue (also E)
Gly	glycine residue (also G)
GMP	guanoine monophosphate
GSH	glutathione, thiol form
GSSG	glutathione, disulfide form
GTP	guanosine triphosphate
GTPase	guanosine triphosphatase
H	enthalpy of a system
h	hour
His	histidine residue (also H)
HLA	histocompatibility locus antigen
HPLC	high pressure liquid chromatography
Hz	hertz, frequency
IEF	isoelectric focusing IgG, IgA, IgM, etc. immunoglobuin G, A, M. etc.
Ile	isoleucine residue (also I)
Ins	inositol residue
IR	infrared
J	joule
K	degrees Kelvin, absolute temperature
k	rate constant for a specified reaction
K_a	association constant
K_d	dissociation constant
K_{eq}	equilibrium constant for a specified reaction
K_m	Michaelis constant
kb	kilobases
kcal	kilocalorie (4.18 kJ)
kDa	kilodalton
LDL	low density lipoprotein
Leu	leucine residue (also L)
Lys	lysine residue (also K)

m	meter
mAb	monoclonal antibody
Met	methionine residue (also M)
MHC	major histocompability locus
min	minute
mol	mole
M_r	relative molecular mass
mRNA	messenger RNA
MS	mass spectroscopy
mtDNA	mitochondrial DNA
Mur	muramic acid residue
MurNAc	*N*-acetylmuramic acid residue
NAD^+	nicotinamide adenine dinucleotide (oxidized)
NADH	nicotinamide adenine dinucleotide (reduced)
$NADP^+$	nicotinamide adenine dinucleotide phosphate (oxidized)
NADPH	nicotinamide adenine dinucleotide phosphate (reduced)
NMR	nuclear magnetic resonance
PAGE	polyacrylamide gel electrophoresis
PBS	phosphate-buffered saline
PCR	polymerase chain reaction
PEG	polyethylene glycol
pH	negative logarithm of hydrogen ion concentration
Phe	phenylalanine residue (also F)
P_i	inorganic phosphate
PP_i	inorganic pyrophosphate
p.p.m.	parts per million
Pro	proline residue (also P)
R	gas constant (8.21451 J/(K^1 mol^{-1}))
RIA	radioimmunoassay
RNA	ribonucleic acid
RNase	ribonuclease
RNP	ribonucleoprotein
rRNA	ribosomal RNA
S	entropy of a system
S	Svedberg sedimentation unit (10^{-13} s)
s	second
s	sedimentation coefficient
SDS	sodium dodecyl sulfate
snRNA	small nuclear RNA
SRP	signal recognition particle
T	temperature
T	thymine residue
TF	transcription factor
Thr	threonine residue (also T)
T_m	midpoint of temperature induced transition
Tri	tris(hydroxymethyl) aminomethane
tRNA	transfer RNA
Trp	tryptophan residue (also W)
TTP	thymidine triphosphate
Tyr	tyrosine residue (also Y)
U	uracil residue
UDP	uridine diphosphate
UMP	uridine monophosphate
UTP	uridine triphosphate
UV	ultraviolet
V	volume
V_{max}	maximum enzyme catalyzed velocity
Val	valine residue (also V)
WT	wild-type
Xyl	xylose residue

CONVERSION FACTORS

SI Units (Adopted 1960)

The International System of Units (abbreviated SI), is being implemented throughout the world. This measurement system is a modernized version of the MKSA (meter, kilogram, second, ampere) system, and its details are published and controlled by an international treaty organization (The International Bureau of Weights and Measures) (1).

SI units are divided into three classes:

BASE UNITS

length	meter[†] (m)
mass	kilogram (kg)
time	second (s)
electric current	ampere (A)
thermodynamic temperature[‡]	kelvin (K)
amount of substance	mole (mol)
luminous intensity	candela (cd)

SUPPLEMENTARY UNITS

plane angle	radian (rad)
solid angle	steradian (sr)

DERIVED UNITS AND OTHER ACCEPTABLE UNITS

These units are formed by combining base units, supplementary units, and other derived units (2–4). Those derived units having special names and symbols are marked with an asterisk in the list below.

Quantity	Unit	Symbol	Acceptable equivalent
*absorbed dose	gray	Gy	J/kg
acceleration	meter per second squared	m/s^2	
*activity (of a radionuclide)	becquerel	Bq	1/s
area	square kilometer	km^2	
	square hectometer	hm^2	ha (hectare)
	square meter	m^2	
concentration (of amount of substance)	mole per cubic meter	mol/m^3	
current density	ampere per square meter	A/m^2	
density, mass density	kilogram per cubic meter	kg/m^3	g/L; mg/cm^3
dipole moment (quantity)	coulomb meter	C·m	

[†]The spellings "metre" and "litre" are preferred by ASTM; however, "-er" is used in the *Encyclopedia*.

[‡]Wide use is made of Celsius temperature (t) defined by

$$t = T - T_0$$

where T is the thermodynamic temperature, expressed in kelvin, and $T_0 = 273.15$ K by definition. A temperature interval may be expressed in degrees Celsius as well as in kelvin.

Quantity	Unit	Symbol	Acceptable equivalent
*dose equivalent	sievert	Sv	J/kg
*electric capacitance	farad	F	C/V
*electric charge, quantity of electricity	coulomb	C	A·s
electric charge density	coulomb per cubic meter	C/m^3	
*electric conductance	siemens	S	A/V
electric field strength	volt per meter	V/m	
electric flux density	coulomb per square meter	C/m^2	
*electric potential, potential difference, electromotive force	volt	V	W/A
*electric resistance	ohm	Ω	V/A
*energy, work, quantity of heat	megajoule	MJ	
	kilojoule	kJ	
	joule	J	N·m
	electronvolt†	eV†	
	kilowatt-hour†	kW·h†	
energy density	joule per cubic meter	J/m^3	
*force	kilonewton	kN	
	newton	N	$kg{\cdot}m/s^2$
*frequency	megahertz	MHz	
	hertz	Hz	1/s
heat capacity, entropy	joule per kelvin	J/K	
heat capacity (specific), specific entropy	joule per kilogram kelvin	J/(kg·K)	
heat-transfer coefficient	watt per square meter kelvin	$W/(m^2{\cdot}K)$	
*illuminance	lux	lx	lm/m^2
*inductance	henry	H	Wb/A
linear density	kilogram per meter	kg/m	
luminance	candela per square meter	cd/m^2	
*luminous flux	lumen	lm	cd·sr
magnetic field strength	ampere per meter	A/m	
*magnetic flux	weber	Wb	V·s
*magnetic flux density	tesla	T	Wb/m^2
molar energy	joule per mole	J/mol	
molar entropy, molar heat capacity	joule per mole kelvin	J/(mol·K)	
moment of force, torque	newton meter	N·m	
momentum	kilogram meter per second	kg·m/s	
permeability	henry per meter	H/m	
permittivity	farad per meter	F/m	
*power, heat flow rate, radiant flux	kilowatt	kW	
	watt	W	J/s
power density, heat flux density, irradiance	watt per square meter	W/m^2	
*pressure, stress	megapascal	MPa	
	kilopascal	kPa	
	pascal	Pa	N/m^2
sound level	decibel	dB	
specific energy	joule per kilogram	J/kg	
specific volume	cubic meter per kilogram	m^3/kg	
surface tension	newton per meter	N/m	
thermal conductivity	watt per meter kelvin	W/(m·K)	
velocity	meter per second	m/s	
	kilometer per hour	km/h	
viscosity, dynamic	pascal second	Pa·s	
	millipascal second	mPa·s	
viscosity, kinematic	square meter per second	m^2/s	
	square millimeter per second	mm^2/s	
volume	cubic meter	m^3	
	cubic diameter	dm^3	L (liter) (5)
	cubic centimeter	cm^3	mL
wave number	1 per meter	m^{-1}	
	1 per centimeter	cm^{-1}	

†This non-SI unit is recognized by the CIPM as having to be retained because of practical importance or use in specialized fields (1).

In addition, there are 16 prefixes used to indicate order of magnitude, as follows:

Multiplication factor	Prefix	Symbol	Note
10^{18}	exa	E	
10^{15}	peta	P	
10^{12}	tera	T	
10^{9}	giga	G	
10^{6}	mega	M	
10^{3}	kilo	k	
10^{2}	hecto	h[a]	[a]Although hecto, deka, deci, and centi are SI prefixes, their use should be avoided except for SI unit-multiples for area and volume and nontechnical use of centimeter, as for body and clothing measurement.
10	deka	da[a]	
10^{-1}	deci	d[a]	
10^{-2}	centi	c[a]	
10^{-3}	milli	m	
10^{-6}	micro	μ	
10^{-9}	nano	n	
10^{-12}	pico	p	
10^{-15}	femto	f	
10^{-18}	atto	a	

For a complete description of SI and its use the reader is referred to ASTM E380 (4).

A representative list of conversion factors from non-SI to SI units is presented herewith. Factors are given to four significant figures. Exact relationships are followed by a dagger. A more complete list is given in the latest editions of ASTM E380 (4) and ANSI Z210.1 (6).

Conversion Factors to SI Units

To convert from	To	Multiply by
acre	square meter (m^2)	4.047×10^{3}
angstrom	meter (m)	$1.0 \times 10^{-10\dagger}$
are	square meter (m^2)	$1.0 \times 10^{2\dagger}$
astronomical unit	meter (m)	1.496×10^{11}
atmosphere, standard	pascal (Pa)	1.013×10^{5}
bar	pascal (Pa)	$1.0 \times 10^{5\dagger}$
barn	square meter (m^2)	$1.0 \times 10^{-28\dagger}$
barrel (42 U.S. liquid gallons)	cubic meter (m^3)	0.1590
Bohr magneton (μ_B)	J/T	9.274×10^{-24}
Btu (International Table)	joule (J)	1.055×10^{3}
Btu (mean)	joule (J)	1.056×10^{3}
Btu (thermochemical)	joule (J)	1.054×10^{3}
bushel	cubic meter (m^3)	3.524×10^{-2}
calorie (International Table)	joule (J)	4.187
calorie (mean)	joule (J)	4.190
calorie (thermochemical)	joule (J)	$4.184^{\dagger}$
centipoise	pascal second (Pa·s)	$1.0 \times 10^{-3\dagger}$
centistokes	square millimeter per second (mm^2/s)	$1.0^{\dagger}$
cfm (cubic foot per minute)	cubic meter per second (m^3/s)	4.72×10^{-4}
cubic inch	cubic meter (m^3)	1.639×10^{-5}
cubic foot	cubic meter (m^3)	2.832×10^{-2}
cubic yard	cubic meter (m^3)	0.7646
curie	becquerel (Bq)	$3.70 \times 10^{10\dagger}$
debye	coulomb meter (C·m)	3.336×10^{-30}
degree (angle)	radian (rad)	1.745×10^{-2}
denier (international)	kilogram per meter (kg/m)	1.111×10^{-7}
	tex[‡]	0.1111
dram (apothecaries')	kilogram (kg)	3.888×10^{-3}
dram (avoirdupois)	kilogram (kg)	1.772×10^{-3}
dram (U.S. fluid)	cubic meter (m^3)	3.697×10^{-6}
dyne	newton (N)	$1.0 \times 10^{-5\dagger}$
dyne/cm	newton per meter (N/m)	$1.0 \times 10^{-3\dagger}$
electronvolt	joule (J)	1.602×10^{-19}
erg	joule (J)	$1.0 \times 10^{-7\dagger}$

†Exact.

A-DNA

A-DNA was first recognized as a DNA structure using fiber X-ray diffraction analysis. B-DNA can be converted to A-DNA under conditions of low hydration, and the process is reversible. The A-DNA double helix is short and fat, with the base pairs and backbone wrapped farther away from the helix axis (see Fig. 2 of DNA Structure). The base pairs are significantly tilted (~19°) with respect to the helix axis. The major groove has a very narrow width of ~3 Å and a depth of ~13 Å, whereas the minor groove has a broad width of 11 Å and a shallow depth of 3 Å. The base pairs also display a minor propeller twist.

There is increasing evidence that A-DNA may play an important role in biological processes such as protein recognition and transcription regulation, as in the TATA-box sequence bound with the TATA-box binding proteins (1, 2). There is a sequence-dependent propensity to form A-DNA. Guanine-rich regions readily form A-DNA, whereas stretches of adenine resist it. The crystal structures of DNA oligonucleotides having guanine-rich sequences showed a characteristic intrastrand guanine–guanine stacking interaction in the A-DNA double helix, which may explain the propensity of these sequences to adopt the A-DNA conformation. Moreover, the packing of the helices in the crystal lattice revealed a characteristic pattern of the terminal base pairs from one helix abutting the minor groove surface of the neighboring helix, thus minimizing the accessibility of solvent to the wide minor groove. Since a low humidity environment favors formation of A-type helix, the displacement of surface solvent molecules by **hydrophobic** base pairs provides a driving force in stabilizing short oligonucleotides in the A-DNA conformation. Recently, it has been demonstrated that complex ions such as spermine, cobalt(III)hexamine, and neomycin can facilitate the B-DNA to A-DNA transition for DNA containing stretches of $(dG)_n \cdot (dC)_n$ sequences.

Finally, the crystal structures of a number of DNA:RNA hybrids, such as the self-complementary r(GCG)d(TATACGC), showed that DNA–RNA hybrid helices are of the A-DNA type. All the ribose and 2′-deoxyribose sugars are in the C3′-*endo* conformation. The 2′-hydroxyl groups of the ribose are involved in different types of hydrogen bonding to the adjacent nucleotides in the chain.

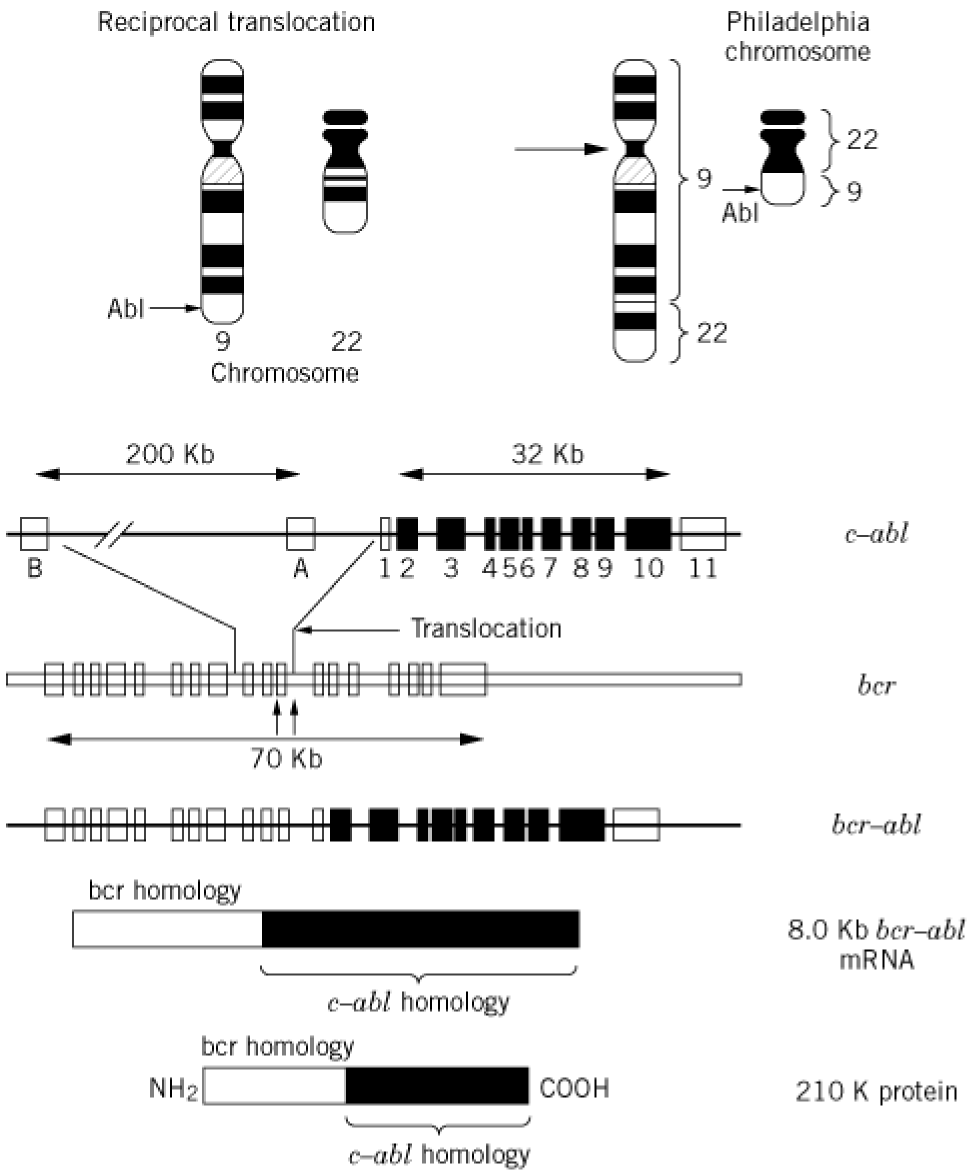
abl Oncogenes

The *abl* gene was first identified as the transforming element of Abelson murine leukemia virus (A-MuLV), a replication-defective retrovirus that was isolated after inoculating Moloney murine leukemia virus (M-MuLV) into prednisolone-treated BALB/c mice (1). A-MuLV induces **B-cell** lymphomas *in vivo* and transforms both lymphoid and fibroblastic cells *in vitro*. The proviral genome of A-MuLV encodes a single polypeptide chain that is a fusion product of the virally-derived gag and cell-derived *abl* sequences (2). Sequence analysis of c-*abl* sequences revealed that, like the ***src* gene**, the *abl* gene codes for a **tyrosine kinase** that also contains the unique, SH3, SH2, and tyrosine kinase domains (3). Unlike the *src* gene, however, the *abl* gene product contains an additional C-terminal domain whose function is not entirely clear. In addition, the gene product of c-

abl does not contain the negative-regulatory **tyrosine** residue at its C-terminus. The tyrosine kinase activity of the c-Abl protein is negatively regulated by its SH3 domain, which is deleted from the v-*abl* gene product. Interestingly, it was also found that the v-*abl* gene product contains a point mutation in its C-terminal sequence, which enhances its tyrosine kinase and transforming activities (4). Thus, both the v-*src* and v-*abl* genes have alterations in their regulatory sequences that result in the constitutive activation of their tyrosine kinase activities, which correlates with their transforming function.

Gene mapping studies have established that the c-*abl* oncogene is located on human chromosome 9q34, the location where the break point occurs in the Philadelphia chromosome. The Philadelphia chromosome is generated when a portion of the c-*abl* gene is **translocated** to chromosome 22 and is fused to a portion of the gene called *bcr*, which itself is disrupted during the translocation process (Fig. 1). This process results in generating a new gene, called *bcr-abl*, that has enhanced oncogenic activity and whose expression leads to the development of leukemia (5, 6). It is interesting to note that the BCR-ABL gene is structurally similar to the *gag-abl* gene encoded by the Abelson murine leukemia virus. Both the *gag-abl* and *bcr-abl* genes exhibit high levels of tyrosine kinase activity, which is essential for their transforming activity.

Figure 1. Generation of the bcr-abl oncoprotein by chromosomal translocation. The abl gene in a normal cell, is located on chromosome 9 and encodes a tyrosine kinase. During malignant transformation of myeloid cells, a portion of chromosome 9 that contains the abl locus translocates to chromosome 22 at the breakpoint cluster region (bcr) locus and generates the chimeric bcr-abl oncoprotein. Because the translocation results in deleting the sequences that negatively regulate abl tryosine kinase activity, the fusion protein has constitutive and increased levels of enzymatic activity.



The function of c-abl in normal cell growth is not fully established. The c-abl gene codes for two 145-kDa proteins as a result of alternative splicing of the two first exons (see RNA Splicing and Introns, Exons). This results in synthesizing two proteins that differ in their amino-terminal sequences. Both forms of c-Abl are found in the cytoplasm and in the nucleus. The c-Abl protein can bind to DNA and to cell-cycle regulators like the **retinoblastoma** protein. Recent studies show that c-abl gene expression is induced during cellular stress caused by agents, such as ionizing radiation and certain other genotoxic agents. These agents induce the formation of a complex involving c-Abl, DNA-dependent protein kinase, and Ku antigen (7). The DNA-dependent protein kinase in this complex is activated by **DNA damage** and in turn phosphorylates and activates c-Abl. Recent studies have also shown that c-Abl associates with the product of the ATM gene, which in turn activates c-Abl in response to ionizing radiation. DNA damage also induces binding of c-Abl to p53 and contributes to cell-cycle arrest at the G1-phase, which is mediated by p53. Recent studies also show that the c-Abl protein binds to **protein kinase C**-δ and phosphorylates the latter, resulting in its activation and translocation to the nucleus, where it participates in inducing apoptosis (8). Thus, a substantial amount of evidence gathered in the past few years indicates that c-Abl protein has a pivotal role in mediating cellular growth arrest and the apoptotic effects that occur during exposure to ionizing radiation and genotoxic stress.

Abscisic Acid

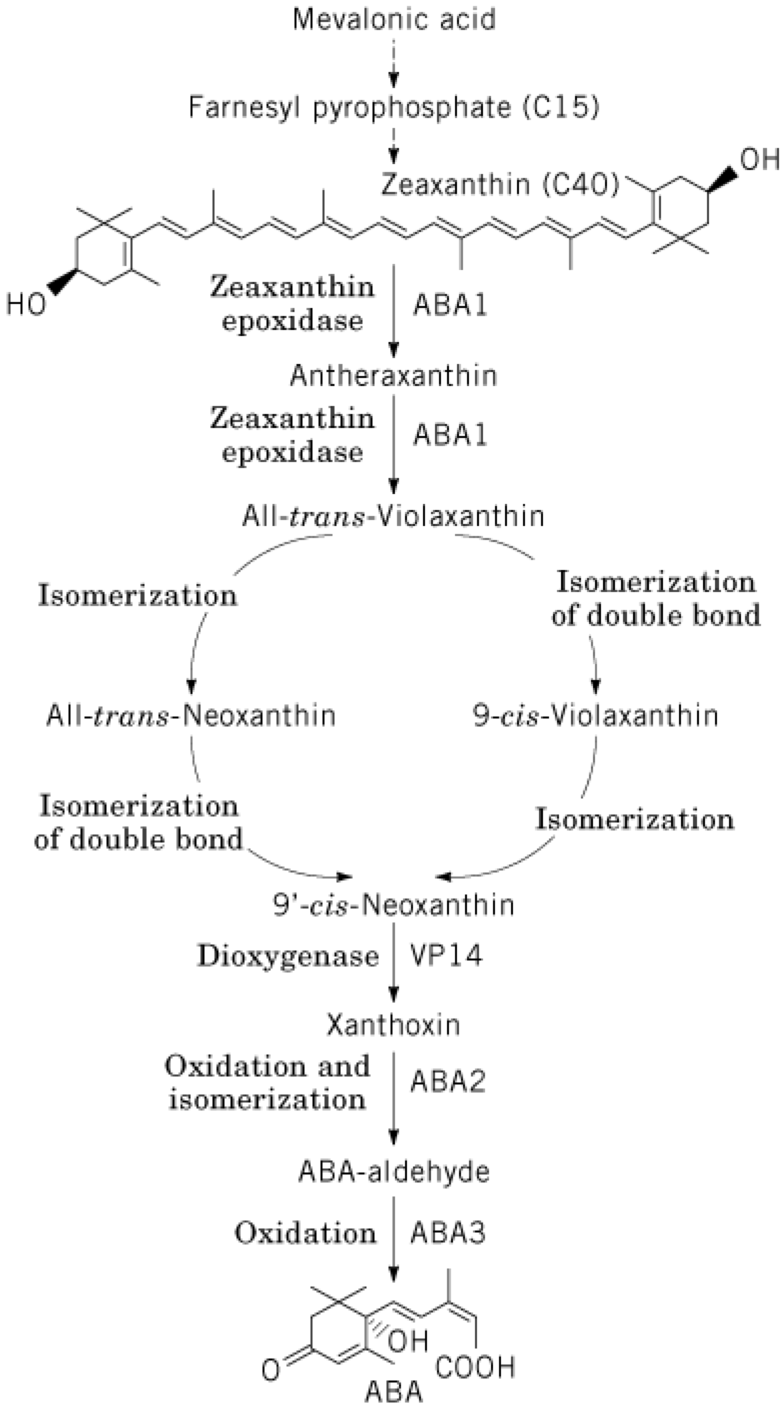
1. History

The first evidence for the existence of an acidic inhibitor of coleoptile growth that promoted abscission and seed maturation dates back to the early 1950s, but it was not until 1963 that abscisic acid (ABA) was identified by Frederick Addicott and coworkers (1, 2). Addicott's team was studying compounds that stimulated abscission in cotton fruits and had named the active substances *abscisin I* and *abscisin II*; the latter proved to be ABA. Two other independent efforts also culminated in the discovery of ABA. A British group headed by Wareing (3) was investigating bud dormancy of woody plants and called the most active molecule *dormin*. In New Zealand, van Stevenick (4) studied compounds that accelerated abscission of flowers and fruits of *Lupinus luteus*. In 1964, it became evident that the three groups had discovered the same plant hormone, which was renamed *abscisic acid* 3 years later.

2. Biosynthesis and Metabolism

ABA is a universal compound in vascular plants; it is not found in bacteria, but has been reported in green algae, certain fungi, and mosses (5). ABA is a sesquiterpenoid, with mevalonic acid as a precursor. In certain fungi, ABA is produced by a direct, C15 pathway from farnesyl pyrophosphate. In higher plants, ABA is derived from xanthophylls, via an indirect C40 pathway (Fig. 1). Substantial progress in understanding the ABA biosynthetic pathway has been achieved by a combination of molecular and genetic techniques, primarily on mutants in *Arabidopsis thaliana, Zea mays, Nicotiana plumbaginifolia*, and tomato. Arabidopsis mutants impaired in ABA biosynthesis were isolated on the basis of their lack of seed dormancy due to ABA deficiency and their ability to overcome a gibberellin requirement for germination, which allowed them to germinate in the presence of inhibitors of gibberellin biosynthesis or in a gibberellin-deficient background (6, 7). ABA-deficient mutants show a wilty **phenotype** when subjected to water stress.

Figure 1. ABA biosynthesis in higher plants. Steps mediated by ABA1, ABA2, and ABA3 in *Arabidopsis* and by VP14 in *Zea mays* are indicated. (Adapted from Ref. 19.)



Mevalonic acid is converted to farnesyl pyrophosphate, a C15 compound, via several intermediates (Fig. 1). The subsequent conversion of farnesyl pyrophosphate to zeaxanthin, a C40 carotenoid, again involves multiple steps (8). A number of *viviparous* (*vp*) mutants of maize identify loci corresponding to these early conversions. The transformation of zeaxanthin to all-*trans*-violaxanthin consists of two epoxidations at the double bonds in both cyclohexenyl rings, with antheraxanthin as an intermediate. The *aba1* mutant impaired in zeaxanthin epoxidase activity has been characterized biochemically in *Arabidopsis* (6, 9, 10). The *N. plumbaginifolia ABA2* **gene** encoding zeaxanthin epoxidase was recently cloned by transposon tagging (11). The gene encodes a **chloroplast**-imported polypeptide chain with similarity to bacterial monooxygenases and oxidases. When the Nicotiana *ABA2* gene was expressed in *Escherichia coli* heterologously, the protein was shown to catalyze both epoxidations *in vitro*. Moreover, the complementary DNA (cDNA) complemented both the *N.*

plumbaginifolia aba2 mutant and the *Arabidopsis aba1* mutant. The ortholog in *Arabidopsis* (*ABA1*) was cloned by homology with *Nicotiana ABA2* (11). Although presumably a null **allele**, the *Nicotiana aba2* mutant retains up to half the ABA content of wild type in the absence of water stress. This characteristic might indicate the existence of a secondary biosynthetic pathway for ABA. Downstream of all-*trans*-violaxanthin, two isomerizations yield 9′-*cis*-neoxanthin.

The subsequent oxidative cleavage with xanthoxin as a product is thought to be the rate-limiting step in ABA biosynthesis (12, 13). A gene that most probably encodes the enzyme performing this reaction was cloned from maize, and by homology also from *Arabidopsis* (*VP14*) (13). Its overproduction in *E. coli* indicated that VP14 is probably a member of a novel class of dioxygenases.

Xanthoxin is subsequently converted to ABA-aldehyde by oxidation and isomerization. Biochemical analysis indicates that the *Arabidopsis aba2* mutant is blocked at this step in the pathway (7, 14). A final oxidation, catalyzed by ABA-aldehyde oxidase, produces ABA. Mutants in this step have been identified in several species (8). The *Arabidopsis aba3* mutant lacks several aldehyde oxidase activities that require a molybdenum cofactor (14). Yet the mutation blocks modification of the mobybdenum cofactor, rather than impairing the activity of the apoprotein. Cloning of the *ABA2* and *ABA3* genes should provide further clues as to the regulation of ABA biosynthesis in these final steps.

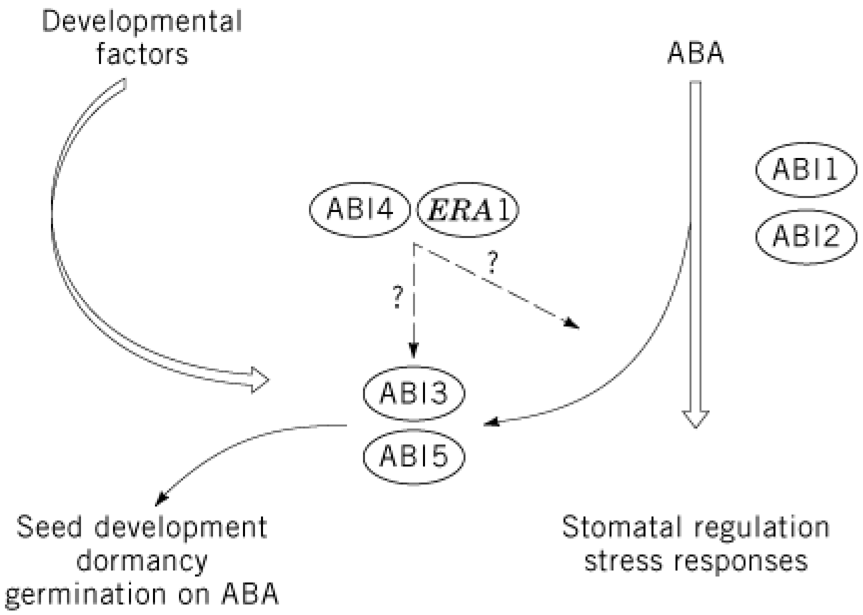
Metabolism of ABA is mainly to phaseic acid, dihydrophaseic acid, and their respective conjugates (15, 16). Direct conjugation of ABA to an ABA glucose ester, or an ABA-b-glucopyranoside, can also occur. Conjugation of ABA does not lead to its storage, probably because it is irreversible and yields unstable compounds. With the exception of phaseic acid, none of the metabolites carries biological activity (16).

3. Signal Perception and Transduction

Insight into the molecular basis of ABA responses was gathered by a combination of molecular-genetic, biochemical, and electrophysiological studies (12, 17-20). Currently, little is known about the perception of ABA, despite numerous efforts to isolate ABA receptors using different approaches (20). Two groups of mutants, ABA-insensitive and ABA-hypersensitive, have largely contributed to the understanding of ABA signal transduction. Whereas the five *abscisic acid-insensitive* (*abi*) mutants of *Arabidopsis* were identified by their ability to germinate on inhibiting concentrations of ABA (21, 22), the three *enhanced response to ABA* (*era*) mutants showed an increased dormancy in the presence of low ABA concentrations, compared to wild type (23). Besides their effects on seed development and dormancy, these mutants show altered responses to drought adaptation. The *abi* mutants differ from the above-mentioned *aba* mutants, because they do not have reduced endogenous ABA content and their phenotype cannot be reverted by exogenously supplied ABA. The characterization of *abi* mutants revealed that at least two ABA-response pathways exist: one primarily active in vegetative tissues, involving ABI1 and ABI2, and a second one operating predominantly during seed development and involving ABI3, ABI4, and ABI5 (19). Genes corresponding to four loci have been **cloned**. *ABI1* and *ABI2* encode highly homologous serine/threonine kinases and phosphatases 2C (24-26). These phosphatases might act in a phosphorylation/dephosphorylation cascade, as the protein phosphatase activity of recombinant ABI1 has been demonstrated *in vitro* (27). The functions of ABI1 and ABI2 are partially redundant (25). *ABI3* encodes a putative transcription factor that acts mainly during seed development and is the ortholog of *VP1* in maize (28-30). The suggested function of ABI3 consists of either activating the maturation program or preventing germination (30, 31). Finally, the predicted amino acid sequence of ERA1 shares similarity with the b-subunit of farnesyl transferases. In yeast and mammalian systems, this enzyme is known to modify signal transduction proteins for membrane anchoring (23). In wild-type *Arabidopsis*, ERA1 is proposed to modify a negative regulator of ABA signaling.

The current model of ABA signal transduction integrates ABI1/ABI2-dependent cascades in both seeds and vegetative tissues (Fig. 2). These cascades interact with the ABI3 protein in seeds only, because ABI3 is expressed exclusively in seeds (32). The role of ABI3 is not confined to ABA signaling (19); it is also thought to mediate developmental signals. This role is supported by the seed phenotype of *abi3*, which is more complex than that of *abi1, abi2*, or *aba1* mutants (19). The evidence that VP1 can also regulate transcription independently of ABA further supports the possibility of a less strict limitation of ABI3 to ABA signaling (33, 34). The same holds true for ABI4 and ABI5 (2).

Figure 2. A model for ABA signal transduction.



Intermediates in the ABA transduction chain were revealed by microinjection of putative second messengers into hypocotyl cells of the *aurea* mutant of tomato (35). Following injection of ABA-inducible *KIN2* and *RD29A* **promoters** linked to b-glucuronidase, coinjection of either Ca^{2+}, cyclic ADP-ribose (cADP), ADP-ribosyl cyclase, or inositol (1,4,5)-triphosphate (IP_3) (see Calcium Signaling) resulted in expression of the ABA-inducible genes in the absence of ABA, implying that cADP ribose, a Ca^{2+}-mobilizing second messenger, is involved in ABA responses. At present, it is difficult to integrate these data into the current model for the ABA signal transduction pathway (19). Electrophysiological studies (voltage clamp or patch clamp) on the ABA-insensitive mutants *abi1* and *abi2* have clearly shown an altered **ion channel** behavior in their stomatal guard cells and provided further evidence that phosphorylation/dephosphorylation cascades are involved in ABA signaling (36, 37).

Given the power of mutational approaches to identify signal transduction components, several groups are currently aiming at the identification of additional ABA signal transduction factors, exploiting novel screening procedures in *Arabidopsis* (12). At least eight *growth control via ABA* (*gca*) loci have been identified on the basis of their insensitivity to ABA inhibition of root growth (38). Furthermore, a *freezing sensitive* (*frs1*) mutant with a wilty phenotype appeared to be nonallelic to other ABA-deficient or -insensitive mutants of *Arabidopsis* (39). Other screens employ **transgenic** lines carrying chimeric promoter-**luciferase** constructs with promoters derived from ABA-responsive genes. Putative mutants are identified by aberrant expression of these genes in the mutagenized progeny (40). The identification of intragenic or extragenic enhancers and **suppressors** of known signaling components is yet another alternative.

Whereas part of the ABA signaling pathway is well established in seeds and stomatal guard cells, the implications of ABA signaling in the function of the vegetative meristem remain to be clarified. Furthermore, it will be most interesting to characterize the regulatory influence of light on ABA signaling, as well as the crosstalk with gibberellins, which are known to counteract ABA in many physiological processes (5).

4. Downstream Targets

Of all the plant hormones, ABA is probably best known from the point of view of responsiveness at the target gene level. ABA-responsive genes encode proteins with diverse functions and are often induced under water stress (drought, salinity, low temperature). It is important to mention, however, that certain water stress-related genes are independent of ABA (17, 18). ABA-responsive genes can be classified into two groups. Primary ABA response genes are rapidly induced and are independent of **protein biosynthesis**, implying that *trans*-acting factors controlling these genes are under post-translational control. A second class of ABA response genes consists of those that require the expression of other genes.

Cis-acting and trans-acting elements involved in ABA induction of **gene expression** have been studied extensively, often in relation to water stress (17, 18). A bipartite model for regulation of transcription of the primary response genes is proposed, as for the barley *HVA1* and *HVA22* genes (41, 42). The specificity of ABA responsiveness relies on the combination of an ABA response element (ABRE) and a coupling element. The ABRE has a **consensus sequence** (PyACGTGGC) that contains a G-box core sequence and has been shown to interact with bZIP factors (eg, wheat *Em* gene-binding protein EmBP-1) (43). A set of unique coupling elements would provide specificity in ABA response at the level of individual genes. In addition, in the case of *Em* induction, it has been demonstrated that a conserved domain of 18 amino acid residues of the VP1 protein enhances DNA-binding activity of the EmBP-1 bZIP factor, thereby acting as a DNA chaperone (44). A yeast two-hybrid system screen was used to identify proteins that interact specifically with VP1 on the promoter of the *Em* gene. One such protein was related to 14–3–3 proteins (45) and thus may help to stabilize and/or activate the regulatory complex at the *Em* promoter (20).

ABREs are not the only *cis* elements that confer ABA responsiveness. Both in the case of seed desiccation and in water stress conditions, other promoter elements can be involved. For example, ABA responses can be mediated in conjunction with the Sph box in germination-specific promoters. A direct interaction between the Sph box and a 140-residue conserved domain in the *C*-terminal region of VP1 has been demonstrated (46).

The second pathway for ABA-dependent gene expression requires protein biosynthesis, exemplified by the *Arabidopsis* ABA-inducible *RD22* gene. A 67-bp region in the promoter of this gene contains conserved motifs for MYC and MYB factor binding (47) (see Oncogenes, Oncoproteins). Factors binding to these promoter elements (RD22BP-1 and ATMYB2) were shown to activate transcription of *RD22* in transient transactivation assays (48). Cooperative binding of these factors has been proposed to control ABA-dependent expression of *RD22*.

One of the challenges for the future consists in making the link between the ABA-induced proteins and the tissue- and development-specific physiological responses, summarized below.

5. Effects

Although abscission was originally considered to be a process regulated by ABA, and the hormone was named accordingly, it is now clear that ethylene is the primary factor controlling abscission. Nevertheless, ABA also plays a key role in such diverse plant growth and developmental processes as seed maturation, germination, root growth, and stomatal closure (5). Stomatal movements involve changes in ion fluxes that occur very rapidly in response to ABA and do not require gene expression.

Furthermore, ABA is a major stress signal orchestrating responses to dehydration stress, including water stress induced by drought and high-salt concentration as well as by low-temperature conditions.

Absorption Spectroscopy

Light in the ultraviolet (UV) and visible (vis) range of the electromagnetic spectrum shows an energy that is equivalent to about 150 to 400 kJ/mol. Light with the appropriate energy is used to promote electrons from the ground state to an excited state. The absorption of energy from the incident light as a function of its wavelength is measured in absorption spectroscopy. Molecules with electrons that participate in delocalized aromatic systems often absorb light in the near-UV or visible region.

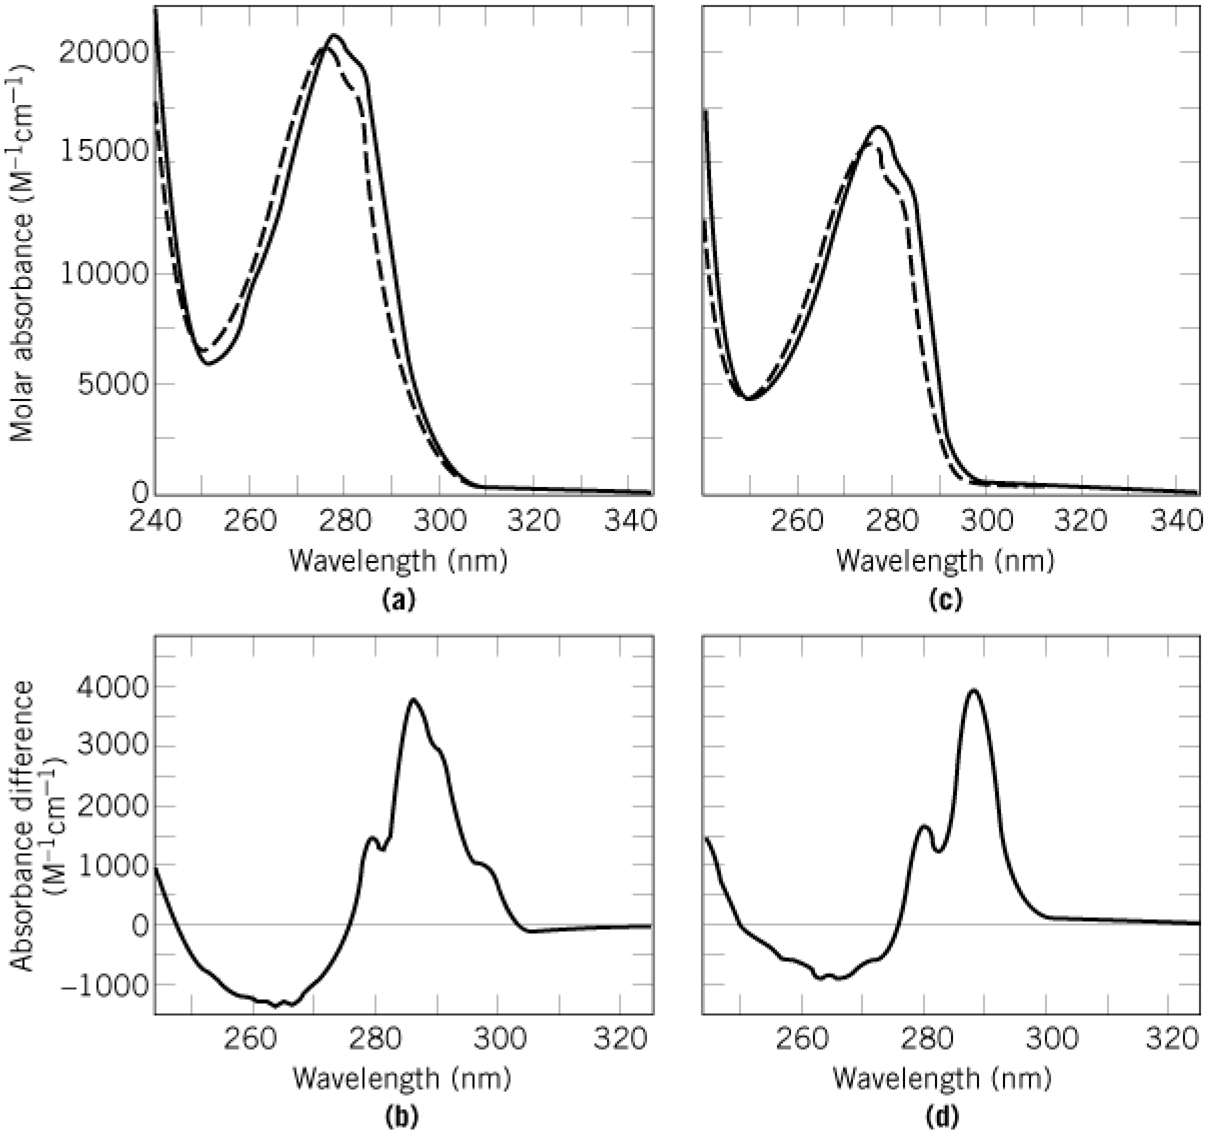
Absorption spectroscopy is usually performed on solutions of molecules in a transparent solvent. The absorbance of a solute depends linearly on its concentration, and therefore absorption spectroscopy is ideally suited for quantitative measurements. The spectral properties of a molecule depend on the molecular environment and the mobility of its chromophores. Absorption spectroscopy and difference spectroscopy (see Difference Spectroscopy) are therefore well-suited to follow **enzyme**-catalyzed reactions, **ligand binding**, and conformational transitions in proteins and nucleic acids. Spectroscopic measurements are very sensitive, nondestructive, and require only small amounts of material for analysis. Spectrophotometers are standard laboratory equipment, and the measurement of absorbance is technically simple.

1. Absorbance of Proteins

In proteins, the peptide bond absorbs light in the range of 180 to 230 nm (which is called the "far-UV" range). The aromatic residues, **tyrosine** (Tyr), **tryptophan** (Trp), and **phenylalanine** (Phe), also absorb light in this region and, in addition, show bands near 260 to 280 nm (in the "near-UV"). Disulfide bonds absorb weakly near 260 nm. Some protein cofactors, such as the heme group, show absorbance in the visible range. When the peptide groups and aromatic residues are part of an asymmetric structure, or when they are immobilized within an asymmetric environment (as in folded proteins), left- and right-handed circularly polarized light is absorbed to different extents. This phenomenon is called circular dichroism (CD).

Spectra of the aromatic amino acids and model proteins are found in (1). In the near-UV, the molar absorbance of a phenylalanine residue is much smaller than that of a tyrosine or a tryptophan, and the spectrum of a protein between 240 and 300 nm is therefore dominated by the contributions from the Tyr and Trp side-chains. Phe residues contribute fine structure ("wiggles") to the spectrum between 250 and 260 nm. The aromatic amino acids do not absorb above 310 nm, and therefore protein absorbance should be zero at wavelengths greater than 310 nm. Proteins without Trp residues do not absorb above 300 nm (see Fig. 1**c**).

Figure 1. Ultraviolet absorption spectra of (**a**) the wild-type form and (**c**) the Trp59Tyr variant of RNase T_1. The spectra of the native proteins (in 0.1 *M* sodium acetate, pH 5.0) are shown by the continuous lines. The spectra of the unfolded proteins (in 6.0 *M* GdmCl in the same buffer) are shown by broken lines. The difference spectra between the native and unfolded forms are shown in (**b**) and (**d**). Spectra of 15 μM protein were measured at 25°C in 1-cm cuvettes in a double-beam instrument with a band width of 1 nm at 25°C. The spectra of the native and unfolded proteins were recorded successively, stored, and subtracted. From Ref. 1.



A fraction of the aromatic residues are buried in the **hydrophobic** core of a native, folded protein molecule (see Protein Structure). When these residues become exposed to the aqueous solvent upon unfolding, their absorption is shifted slightly to shorter wavelengths. This is clearly seen for two forms of **ribonuclease T$_1$** (Figs. 1**a** and 1**c**). The difference spectra in Figures 1**b** and **d** show that the maximal differences in absorbance occur in the 285 to 295 nm region. The **difference spectrum** for the form without a Trp residue (Fig. 1**d**) shows a prominent maximum at 287 nm. It is typical for proteins that contain Tyr residues only. The form with a single Trp residue (Fig. 1**b**) shows additional shoulders between 290 and 300 nm in the difference spectrum. They originate from the single Trp residue of this protein. The differences in the absorption spectra between the native and unfolded state of a protein are generally small, but they can be determined with good accuracy and are extremely useful for monitoring conformational changes of a protein.

Spectroscopic methods are, in general, the methods of choice (i) to investigate changes in the behavior of a protein under different solvent conditions, and (ii) to compare the properties of related molecules, such as homologous or mutated forms of a protein. In addition, they are widely used to measure protein stability and to follow structural transitions such as unfolding and refolding under a variety of conditions. Absorbance changes during fast reactions that occur in the milliseconds range can be followed by using rapid mixing techniques, such as in stopped-flow spectrometry (see Kinetics).

2. Absorbance of Nucleic Acids

Nucleic acids show a strong absorbance in the region of 240 to 275 nm. It originates from the $\pi \rightarrow \pi^*$ transitions of the **pyrimidine** and **purine** ring systems of the nucleobases. The bases can be protonated, and therefore the spectra of DNA and RNA are sensitive to pH. At neutral pH, the absorption maxima range from 253 nm (for guanosine) to 271 nm (for cytidine), and therefore polymeric DNA and RNA show a broad and strong absorbance near 260 nm.

In native DNA, the bases are stacked in the hydrophobic core of the double helix, and therefore their absorbance is considerably decreased relative to the absorbance of single-stranded DNA, and even more so relative to oligonucleotides. This phenomenon is called hypochromism. It is widely used to follow the melting of DNA double helices.

3. Absorbance to Determine Concentrations

Absorbance measurements are the methods of choice to determine the concentration of proteins or nucleic acids in solution. Spectrophotometers are standard laboratory equipment, and absorbance can be measured quickly and accurately. The absorbance A is related with the intensity of the light before I_0 and after I passage through the protein solution by Equation 1, and the absorbance depends linearly on concentration, according to the Lambert–Beer relationship (Eq. 2):

$$A = -\log_{10}(I/I_0) \qquad (1)$$

$$A = \varepsilon \times c \times l \qquad (2)$$

where c is the molar concentration, l the pathlength in cm, and ε the molar absorption coefficient. The concentration of a substance in solution can be determined very rapidly and accurately from its absorbance by using Equation 2. The measurement of absorbance values greater than 2 should be avoided, because only 1% of the incident light is transmitted through a solution with an absorbance of 2 (and is quantified by the photomultiplier). The value of e can be determined by a number of experimental techniques (2) or can be calculated for proteins by adding up the contributions of the constituent aromatic amino acids of a protein (2, 3).

The absorbance of nucleic acids does not vary much. The concentrations of nucleic acids in solution are routinely determined from the absorbance at 260 nm. In fact, amounts of nucleic acid are often given as "A_{260} units." For double-stranded DNA, one A_{260} unit is equivalent to 50 µg DNA; for single-stranded DNA, it is equivalent to 33 µg DNA; for single-stranded RNA, it is equivalent to 40 µg RNA. All these amounts would produce an A_{260} of 1 when dissolved in 1 mL and measured in a 1-cm cuvette. Proteins absorb much more weakly than nucleic acids. In a 1:1 mixture of nucleic acids and proteins, the proteins contribute only about 2% to the total absorbance at 260 nm. Consequently, these quantities of contaminating protein hardly affect the concentrations of nucleic acids measured by A_{260}.

4. Absorbance Spectrophotometers

Absorbance is measured by a spectrophotometer. Spectrophotometers consist usually of two light sources: a deuterium lamp, which emits light in the UV region, and a tungsten/halogen lamp for the visible region. After passing through a monochromator (or through optical filters), the light is focused into the cuvette, and the amount of light that passed through the sample is detected by a photomultiplier or photodiode. In diode array spectrophotometers, the sample is illuminated by the full lamp light; after passage through the cuvette, the transmitted light is spectrally decomposed by a prism into the individual components and quantified by an array of diodes, often in intervals of 2 nm. In diode array spectrometers, the entire spectrum is recorded at the same time and not by a time-dependent scan as in conventional instruments. This is of advantage for measuring time-dependent changes at several wavelengths simultaneously (see Kinetics).

5. Buffers for Absorbance Spectroscopy

Good buffers for measuring difference spectra ideally should not absorb light in the wavelength range of the experiment. For work in the near-UV, buffer absorbance should be small above 230 nm, and indeed most of the solvents commonly used in biochemical experiments do not absorb in this spectral region (1). Buffer absorbance is a major problem, however, in the far-UV region below 220 nm, because buffers that contain carboxyl and/or amino groups absorb light in this wavelength range. Buffers with negligible absorbance in the far-UV include phosphate, cacodylate, and borate. Detailed procedures for the measurement of difference spectra are found in Ref. 1.

Acceptor Stem

The acceptor stem is the site of attachment of amino acids to transfer RNA (tRNA). It is formed by 7 base pairs and has 4 single-stranded nucleotides. Nucleotides 1 to 7 from the 5′ end of the tRNA base pair with nucleotides 72–66, respectively, from the 3′ end of the molecule. Whereas the 5′ end of the RNA has a monophosphate group, the 3′ end contains a 3′-hydroxyl group, which is the site of esterification to the amino acid. The four 3′-end single-stranded nucleotides include residue 73, the discriminator base and the well-conserved nucleotides C74, C75, A76, the 3′-CCA sequence. In the three-dimensional structures of tRNA, the acceptor stem is stacked on the T arm, forming the acceptor "branch" of the L-shaped RNA fold (see Fig. 1 of Transfer RNA). The acceptor branch usually forms a regular A-type double helix, with the four single-stranded nucleotides extending in a regular helical continuity. In tRNA-like domains of some **viruses**, the acceptor stem is formed by a single RNA chain that folds into a helix due to the presence of a **pseudoknot** (1).

Specific aminoacylation of tRNA by their cognate aminoacyl-tRNA synthetases is dependent on the presence of a series of identity elements. Limited in number, these elements are preferentially located in the anticodon loop and in the acceptor stem (2-4). Residue 73, next to the CCA end, is called the “discriminator” base. The hypothesis that it contributes to discrimination of tRNA by cognate aminoacyl tRNA synthetases (5) has been largely confirmed. Residue 73 contributes strongly to specific aminoacylation of 17 different *Escherichia coli* tRNAs (6). It is the element making the major thermodynamic contribution toward aminoacylation of *E. coli* $tRNA^{Cys}$, *E. coli* $tRNA^{His}$, yeast $tRNA^{His}$ and *E. coli* $tRNA^{Leu}$. Replacement of A73 to G73 in human $tRNA^{Ser}$ converts it to a tRNA for isoleucine (7). The crystallographic structures of two tRNA-cognate synthetase complexes suggests two possible mechanisms by which the discriminator base contributes to aminoacylation specificity. One is a direct mechanism, involving direct hydrogen interactions with the synthetase. The other is an indirect mechanism that confers a conformational change to the acceptor end of the tRNA to facilitate aminoacylation. In the complex of yeast $tRNA^{Asp}$/aspartyl-tRNA synthetase, nucleotide G73 fits into the active site, forming hydrogen bond interactions with side chains of the synthetase. It does not cause a conformational change in the acceptor stem (8). Alternatively, the 2-amino group of G73 of *E. coli* $tRNA^{Gln}$ hydrogen bonds with the phosphate oxygen of the previous nucleotide, folding the backbone of G73 back toward the 3′ end of the tRNA. The formation of this fold-back hairpin enables the synthetase to open the first base pair of the acceptor stem and reach the second and third base pairs for specific interactions (9). In both complexes, additional contacts exist between the enzyme and the acceptor stems of the tRNA. The aspartyl-tRNA synthetase interacts with the $tRNA^{Asp}$ acceptor stem via the major groove of the RNA helix, whereas glutaminyl-tRNA synthetase interacts via the minor groove.

Acceptor stem identity-element nucleotides, as well as additional structural features, are important for synthetase recognition. Alanyl-tRNA synthetase is sensitive to both the exocyclic NH_2 group of G3 and local conformation of the helix due to structural characteristics of the G-U **wobble** pair (10-13). Alanine acceptance by alanyl-tRNA is modulated by additional signals within the acceptor stem, namely, A73, G1-C72, G2-C71 and G4-C69. The 5′ end of histidine-specific tRNA has an additional nucleotide, residue number –1, which is a guanosine. This nucleotide, opposite the discriminator base, does form a base pair with the discriminator in many, but not all, histidyl-tRNA. This –1 guanosine is the major histidine identity element. Its influence is complemented by base pairs U2-A71 and G3-C70. Base pairs 1–72, 2–71, 3–70, and/or 4–69 contribute to aminoacylation in several cases. Glutamine identity requires a weak 1–72 base pair, G2-C71, G3-C70, in addition to signals elsewhere in the tRNA. Glycine identity is dependent on C2-G71, G3-C70 sequences, and serine identity involves G2-C71, among other signals. Methionine identity is based on the presence of A73, G2-C71, C3-G70, in addition to the CAU anticodon.

At the three-dimensional level, tRNA molecules fold into a two-domain L-shaped structure with the amino acid acceptor terminus and the anticodon at opposite ends. Minihelices (small RNA molecules containing only part of a tRNA) that mimic the amino acid acceptor domain, specifically, the acceptor stem stacked on top of the TY stem, have been shown to be useful tools for determining the contribution of the acceptor stem to tRNA function (14, 15). Minihelices containing the identity elements from a tRNA are efficient substrates for its cognate aminoacyl-tRNA synthetases. Thus, alanyl-tRNA synthetase, glycyl-tRNA synthetase, and histidyl-tRNA synthetase aminoacylate minihelices efficiently. Minihelices containing partial identity sets of six additional tRNAs are specific substrates for their cognate synthetases. Since identity elements are located very close to the CCA end, minihelices may be reduced in size to microhelices, consisting only of the amino acceptor stem closed by a loop and remain active. The smallest substrate for an aminoacyl-tRNA synthetase is derived from yeast $tRNA^{Asp}$ and consists of only 14 nucleotides. There are three base pairs closed by a tetraloop, plus the discriminator base and the CCA sequence (16). Double-stranded RNA duplexes and RNA/DNA heteroduplexes may also be aminoacylated (15).

The aminoacylation efficiency of minihelices is generally reduced significantly compared to that of the corresponding full-length tRNA. The amino acid charging is, however, very specific and depends on just a few nucleotides. These minimal RNA substrates are devoid of the anticodons that read the genetic code and provide the link between amino acid and **codon**. Since the relationship between the sequences and structures of the minisubstrates and the specific amino acids is maintained, there appears to be an *operational RNA code* for primitive aminoacylation. This operational code may be the primitive code from which the contemporary genetic code evolved (17-20)

Acceptor stem properties are important for tRNA recognition by proteins other than synthetases. Aminoacylated initiator tRNA in **prokaryotes** is a substrate for a methionyl-tRNA transformylase that converts methionyl-$tRNA^{Met}$ to formylmethionine $tRNA^{Met}$. Recognition of initiator tRNA by the formylase depends on the presence of methionine. Sequence and/or structural elements in the tRNA that are important for formylation by methionyl-tRNA transformylase are clustered at the end of the acceptor stem (21). The key determinants appear to be a mismatch or a weak base pair between nucleotides 1 and 72, a G-C base pair between nucleotides 2 and 71, and a C-G or, less preferably, a G-C base-pair between nucleotides 3 and 70. Mutations at G4-C69 also affect formylation kinetics slightly. In addition to the positive elements A73, G2-C71, C3-G70, and G4-C69, the occurrence of a G-C or a C-G base pair between positions 1 and 72 acts as a major negative determinant for the formylase. Formylation is a prerequisite for interaction with initiation factor IF2, which delivers the initiator tRNA to the P site of the ribosome. Special structural features within the acceptor stem of eubacterial initiator tRNA contribute to their discrimination from elongator tRNA. They lack a Watson–Crick base pair between nucleotides 1 and 72 at the end of the acceptor stem. Eukaryotic initiator tRNA almost always has an A1-U72 pair, a feature not found in eukaryotic elongator tRNA.

A high-resolution X-ray crystallography structure of the ternary complex, formed by aminoacylated yeast $tRNA^{Phe}$, **elongation factor** Tu from *Thermus aquaticus*, and an analog of GTP, revealed numerous contacts between the protein and the acceptor stem of the tRNA (22). These contacts include specific interactions with residue A76, with phosphates 74, 75, 67, 64, 3, and with riboses 2, 3, 63, 64, 65 along the acceptor stem and the T stem.

The stability of the 1–72 base pair also governs the degree of sensitivity of a peptidyl-tRNA to peptidyl-tRNA hydrolase. This enzyme converts the peptidyl-tRNA of *N*-acetylaminoacyl-tRNA into free tRNA plus peptides or *N*-acetyl amino acids. It is believed to play a role in the translational apparatus through the recycling of free tRNA from immature peptidyl-tRNA created by abortive protein synthesis (23).

The acceptor stem also contains specific information required during synthesis of the tRNA. Ribonuclease P, an enzyme that removes extra nucleotides from the 5′ end of tRNA during tRNA biosynthesis, recognizes the -74CCA76- sequence in addition to nucleotides within the TY loop. Moreover, this enzyme locates its cleavage site by “measuring” the length of the helix formed by the amino acid acceptor stem fused to the TY stem. Processing at the 3′ end of the tRNA, as well as the addition and repair of the conserved CCA sequence by ATP(CTP)-tRNA nucleotidyltransferase, requires information within the acceptor stem. This enzyme interacts with tRNA at the corner of the structure, where the T and D loops interact, and extends that interaction across the aminoacyl stem to the 3′ end (24, 25).

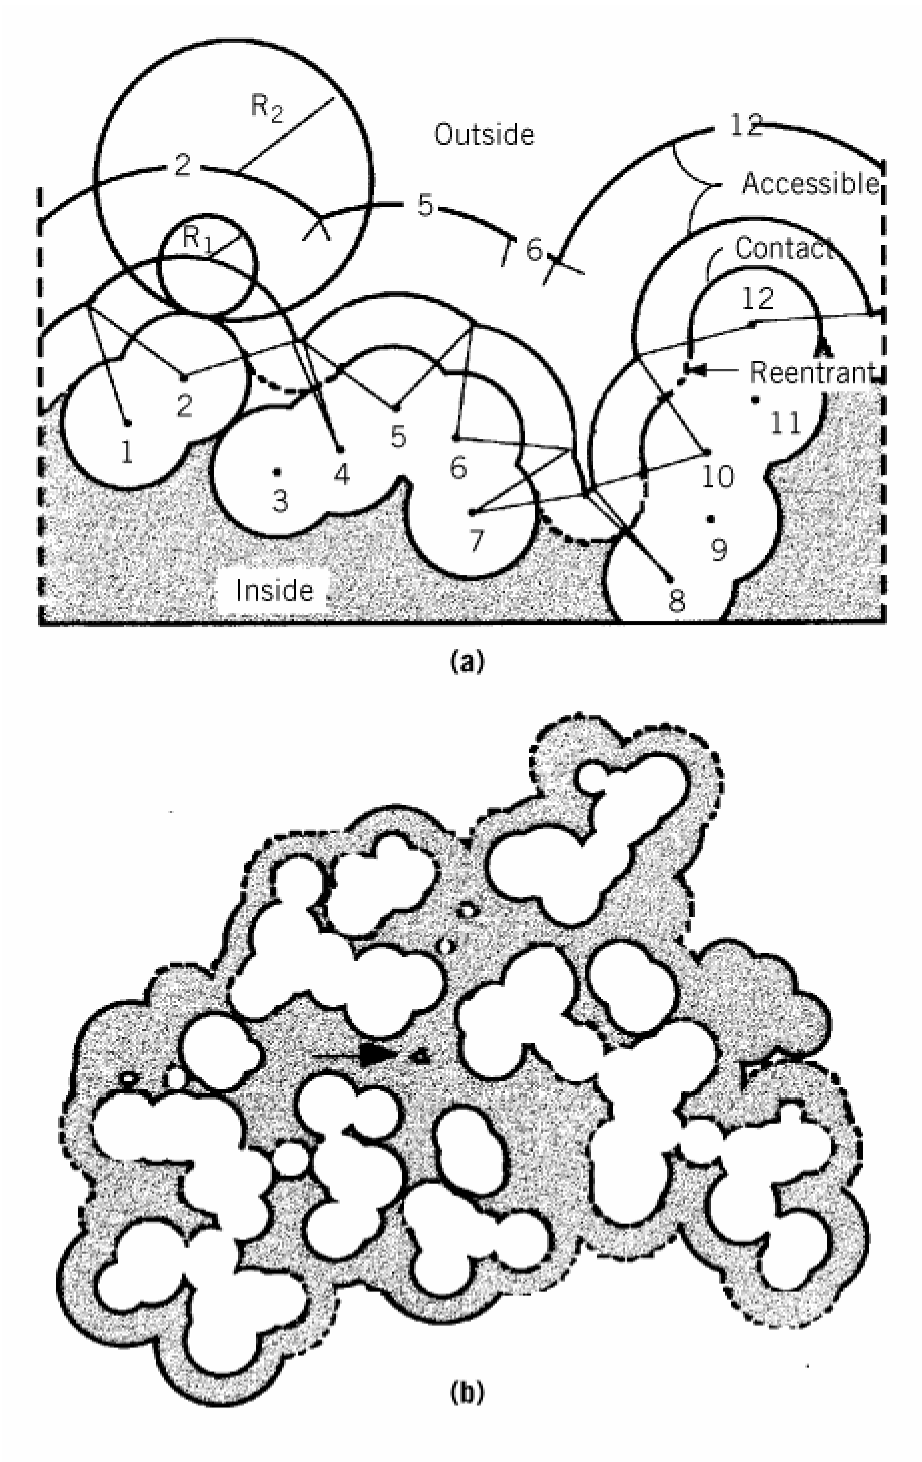
Accessible Surface

The surfaces of folded macromolecules, especially proteins, and the internal packing of their atoms have generally been analyzed using the procedure of Lee and Richards (1). The cross section of part of the surface of a native protein is depicted in Figure 1, which demonstrates a number of different surfaces and volumes (see Protein Structure). The **van der Waals surface** is defined by the spherical atoms that comprise the structure, but it is not very relevant to a folded macromolecule like a protein, where internal atoms and cavities are normally inaccessible to the solvent.

Figure 1. Schematic representation of possible molecular surface definitions. (**a**) A two-dimensional section through

part of the van der Waals envelope of a hypothetical protein including 12 atoms with the centers numbered 1–12. R_1 and R_2 show the radius of the probes. (**b**) Superposition of sections through the van der Waals and accessible surfaces of ribonucrease S. In places, the accessible surface is controlled by atoms above or below the section shown. The solid outline is the surface of carbon and sulfur atoms; the dashed outline nitrogen and oxygen. The arrow indicates a cavity inside the molecule large enough to accommodate a solvent molecule with a radius of 1.4 Å.[Taken from F. M. Richards (1977) *Ann. Rev. Biophys. Bioeng.* **6**, 151–176; B. Lee and F. M. Richards (1971) *J. Mol. Biol.* **55**, 279–400.]



The most relevant surface is the accessible surface, which is defined by its contact with molecules of the solvent. This surface is defined by rolling a spherical probe of appropriate radius R_1 on the outside of the molecule, while maintaining contact with the van der Waals surface. For most purposes, the appropriate probe is a water molecule. The accessible surface is that depicted by the center of the probe as it moves over the surface of the protein. In Figure 1 the probe does not contact atoms 3, 9, or 11, and they have no accessible surface area. Such atoms are considered to be interior atoms, not part of the surface of the molecule. Those parts of the van der Waals surface in contact with the surface of the probe are designated the contact surface; they comprise a series of disconnected patches. When the probe is simultaneously in contact with more than one protein atom, its interior surface defines the reentrant surface. The contact surface and reentrant surface together make a continuous surface, which is defined as the **molecular surface**.

The accessible surface area depends on the size of the probe. When the radius of the probe increases from R_1 to R_2, the number of noncontact or interior atoms in Figure 1 increases from three to eight, and the accessible surface is much smoother. Thus, the smaller the probe, the larger the number of features that will be revealed. The probe is frequently taken to be a water molecule and approximated as a sphere with a radius of 1.4 Å. The accessible surface areas of individual amino acid residues are given in Table 1.

Table 1. Accessible Surface Areas of Amino Acid Residues

Residue	Accessible surface area[a] ($Å^2$)
Ala	113
Arg	241
Asn	158
Asp	151
Cys	140
Gln	189
Glu	183
Gly	85
His	194
Ile	182
Leu	180
Lys	211
Met	204
Phe	218
Pro	143
Ser	122
Thr	146
Trp	259
Tyr	229
Val	160

[a] Values estimated for a Gly-X-Gly tripeptide in an extended conformation (3).

The structures of protein determined by X-ray crystallography indicate that the total accessible surface area A_s of a protein is approximately proportional to the two-third power of its molecular weight. The A_s (in Å^2) of a typical small monomeric protein is usually related to its molecular weight M_w by the approximate relationship (2)

$$A_s = 6.3 M_w^{0.73} \tag{1}$$

For oligomeric proteins

$$A_s = 5.3 M_w^{0.76} \tag{2}$$

These equations are usually accurate to within ±4% on average for monomers and 5% for oligomers. Equations 1 and 2 imply that an oligomeric protein has a larger accessible surface area (by 7 to 13%) than a monomeric protein of the same molecular weight in the molecular weight range up to 35,000.

For an unfolded polypeptide chain, the total accessible surface area A_t in an extended conformation is directly proportional to its molecular weight, within ±3%

$$A_t = 1.45 M_w \tag{3}$$

Thus, for those proteins whose accessible surface area is given by Equation 1, the potential surface area buried by the protein's folding A_b will be approximately given by

$$A_b = 1.45 M_w - 6.3 M_w^{0.73} \tag{4}$$

This indicates that 55 to 75% of the surface area of the unfolded polypeptide chains is buried in the folding process.

The methodology of Lee and Richards (1) is also applicable to the calculation of the accessible surface area of **nucleic acids** (4). Two-thirds of the water-accessible surface area become buried on **double-helix** formation of **DNA** and **RNA**. When a probe corresponding to a single water molecule is used, the total accessible surface area is similar for A-DNA and B-DNA, although marked differences appear in the major and minor groove exposures. For the larger probes, there exist considerable differences in accessible surface area between the two conformations.

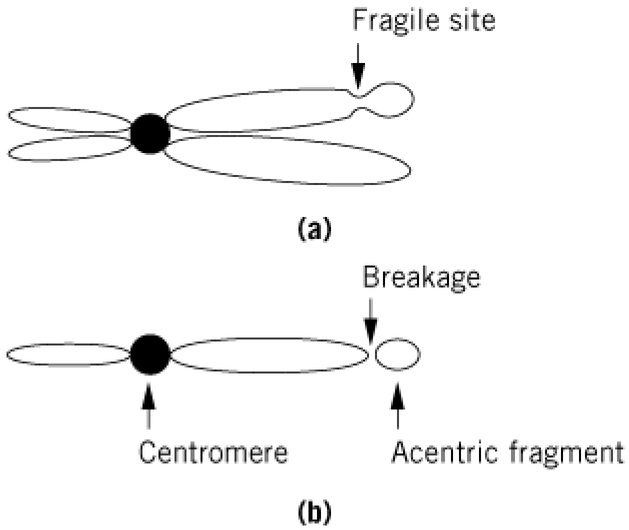
Acentric Fragment

Fragments of chromosomes that lack centromeres are described as acentric fragments (Fig. 1). They are formed as a result of chromosomal damage. Lacking a centromere, there is no means of attachment to the mitotic spindle, which leads to a failure to segregate replicated chromatids in the acentric fragments to the daughter cells during cell division. Therefore, the acentric fragments are normally lost from most cells with progressive cell cycles. The breakage of the chromosome that separates the acentric fragment from the remainder of the chromosome containing the centromere can be a result of either inherent chromosomal fragility, radiation damage, or defective DNA repair mechanisms.

Figure 1. (**a**) A mitotic chromosome is shown with a fragile site, indicated. (**b**) Mitosis can create forces that break the chromosome at the fragile site, creating a residual chromosome that contains the centromere and an acentric fragment as indicated.



Chromosome fragile sites lead to acentric fragments in humans. The majority of recurrent cancer chromosome breakpoints are found at fragile sites (1). These breakpoints may promote oncogenic rearrangements and translocations. Chromosomal fragile sites can be induced by growing cells under abnormal conditions, by the addition of drugs or chemicals, and by infection with viruses. Fragility seems to be a consequence of incomplete compaction of the chromatin. A more open and accessible chromatin structure might explain the tendency of these sites to break, to recombine with other chromosomal regions, and to be sites of viral integration (2). A fragile site associated with a form of inherited mental retardation known as fragile X mental retardation has been characterized in some detail (5). A gene called FMR-1 (fragile X mental retardation gene 1) is present in the fragile site. This gene contains within it a trinucleotide repeat of CGG. A normal individual has between 6 and 50 of these trinucleotide repeats. Individuals with fragile X syndrome contain expansions of these repeat sequences such that they have several hundred CGG triplets. This expansion leads to chromosome fragility, to inactivation of FMR-1 gene expression, and to methylation of regulatory DNA within the gene. The expansion of the CGG trinucleotide sequences is associated with the assembly of an aberrant chromatin structure (3).

Defective chromosomal repair mechanisms lead to a much higher number of chromosomal breaks and translocations than found in normal cells. This high degree of chromosomal damage can eventually lead to malignancy. For example, in Bloom's syndrome there is a very high rate of sister chromatid exchange, and in Fanconi's anemia and ataxia telangiectasia there is a high incidence of chromosomal breakage and rejoining, leading to multicentric chromosomes and acentric fragments. Individuals with these syndromes are especially sensitive to environmental insults, such as chemical mutagens and ionizing radiation, which further increase chromosomal damage (4). Detection of acentric fragments is diagnostic of serious abnormalities in chromosomal metabolism.

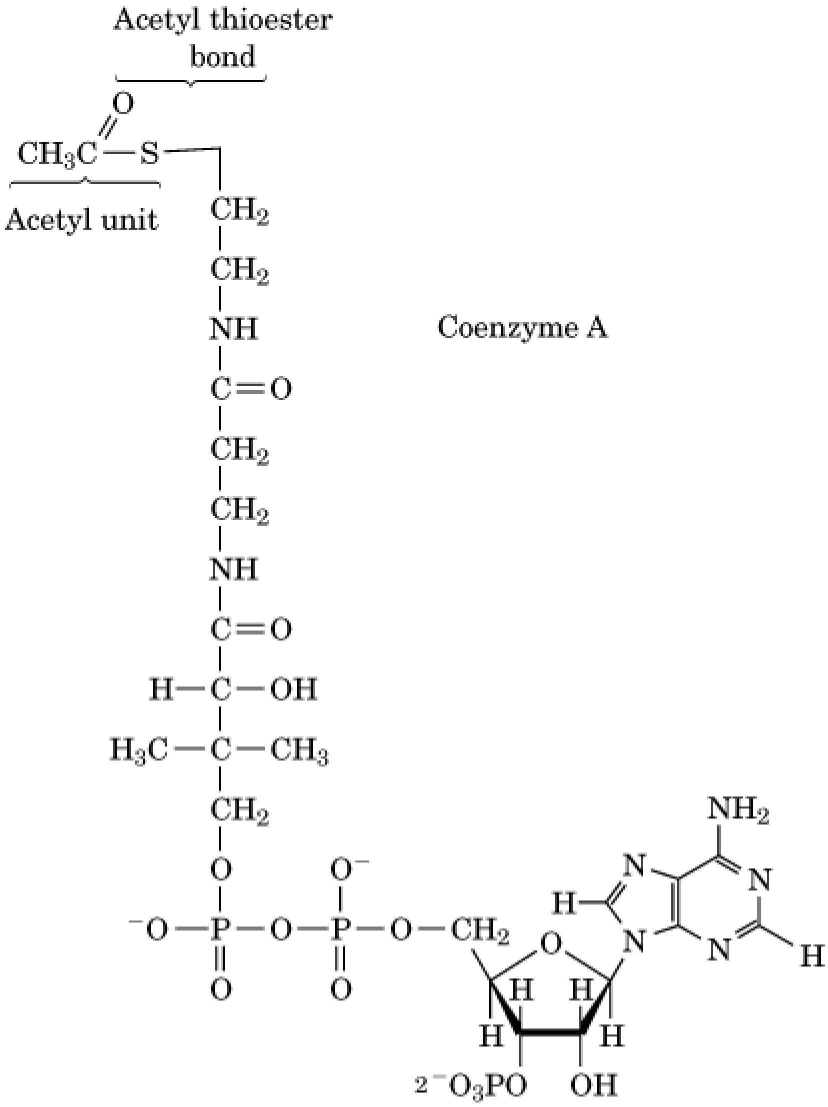
Acetyl Coenzyme A

Acetyl coenzyme A (acetylCoA) consists of a two-carbon activated acetyl unit attached to coenzyme A in thioester linkage. AcetylCoA is central to energy generation from the degradative pathways of oxidative fuel metabolism and to a number of biosynthetic pathways that utilize the activated two-carbon acetyl unit. In aerobic cells, it is the product of all the major catabolic pathways of fuel metabolism, including b- oxidation of fatty acids, ketone body degradation, glycolysis and pyruvate oxidation, ethanol oxidation, and the oxidative degradation of many amino acids. The two-carbon acetyl unit of acetylCoA formed from these pathways can be completely oxidized to CO_2 in the tricarboxylic acid cycle (TCA cycle), thus providing aerobic cells with energy from the complete oxidation of fuels. The acetyl unit of acetylCoA is also the basic building block of fatty acids, cholesterol, and other compounds, and it can be transferred to other molecules in acetylation reactions (eg, synthesis of N-acetylated sugars).

1. Structure

The ability of acetylCoA to participate in these diverse metabolic pathways is derived from the thioester bond formed between the acyl carbon of the acetyl unit and the sulfhydryl group of coenzyme A (CoASH) (Fig. 1). Because sulfur does not share its electrons, the carbonyl carbon of the thioester bond carries a more positive partial charge than that of an oxygen ester, and electrons are pulled away from the C-H bonds of the terminal methyl group. This distribution of charge facilitates nucleophilic attack at the carbonyl carbon and enhances the ability of the terminal methyl carbon to act as an electrophilic agent in condensation reactions. The acetylCoA thioester bond is a high energy bond, with a $DG^{O'}$ for hydrolysis of –32.2 kJ/mol. Transfer of the acetyl unit to other molecules, therefore, usually occurs with the release of energy.

Figure 1. Structure of acetyl coenzyme A (acetyl CoA).



2. Formation of AcetylCoA in Oxidative Pathways

Three basic types of reactions exist in the oxidative pathways of fuel metabolism that generate acetylCoA: the activation of acetate, the thiolytic cleavage of b-ketoacyl CoAs and b-hydroxy acids, and the oxidative decarboxylation of pyruvate (Figure 2). In mammalian cells, acetate is the end product of ethanol metabolism and of threonine degradation. It is activated to acetylCoA in a single ATP- requiring step by the enzyme acetylCoA synthetase (Table 1). In an alternate route, bacterial cells can synthesize acetyl phosphate from acetate and then transfer the activated acetyl group to CoASH. Thiolytic cleavage of b-ketoacyl or b-hydroxy acylCoA derivatives to acetylCoA occurs in the pathways for oxidation of fatty acids, synthesis of the ketone bodies acetoacetate and b-hydroxybutyrate, and oxidative degradation of the amino acids isoleucine, leucine, lysine, tryptophan, phenylalanine, and tyrosine. (Most biochemistry textbooks contain general outlines of these pathways.) This type of reaction is illustrated by the b-oxidation spiral for fatty acids, in which one molecule of the C_{16}-fatty acid palmitate is converted to eight molecules of acetylCoA by enzymes that sequentially oxidize the molecule to a b-ketoacyl compound and then cleave acetylCoA from the carboxylic acid end (Table 1). The third type of reaction, the oxidative decarboxylation of pyruvate by the pyruvate dehydrogenase complex, provides the connecting link between pathways that produce pyruvate and the TCA cycle. The inhibition of the pyruvate dehydrogenase complex by acetylCoA has a regulatory role in controlling the flow of carbon into the various pathways of intermediary metabolism.

(4) $\text{citrate} + \text{CoASH} + \text{ATP} \xrightarrow{\textit{Citrate lyase}} \text{acetyl CoA} + \text{oxaloacetate} + \text{ADP} + \text{P}_i$

3. Oxidation of the Acetyl Unit of AcetylCoA in the TCA Cycle

It is estimated that about two thirds of the energy requirements of aerobic cells is met by the complete oxidation of the acetyl group of acetylCoA to CO_2 in the TCA cycle (also called the citric acid cycle or the Krebs cycle.) In this cyclical sequence of reactions, acetylCoA condenses with oxaloacetate to form citrate in a reaction catalyzed by the enzyme citrate synthase. Subsequent reactions of the cycle donate electrons to the **coenzymes NAD$^+$** and **FAD** for ATP generation from oxidative phosphorylation, regenerate oxaloacetate, and release two carbons as CO_2. The net reaction of the TCA cycle is:

$$
\begin{aligned}
&\text{acetylCoA} + 3\ \text{NAD}^+ + \text{FAD} + \text{GDP} + \text{P}_i \\
&\qquad + 2\ \text{H}_2\text{O} \rightarrow \text{CoASH} + 2\ \text{CO}_2 \\
&\qquad + 3\ \text{NADH} + \text{FAD(2 H)} + 3\ \text{H}^+ + \text{GTP}
\end{aligned}
$$

Most of the pathways that produce acetylCoA in aerobic cells of **eukaryotic** organisms are located in the **mitochondrial** matrix, and most of the biosynthetic pathways that utilize acetylCoA are outside of the mitochondrion. AcetylCoA is not directly transported through the inner mitochondrial membrane but is “transferred” from the mitochondrial matrix to the **cytosol** as citrate. It is then regenerated in the cytosol by the enzyme citrate lyase.

4. AcetylCoA as a Precursor in Biosynthetic Reactions

The two-carbon acetyl unit of acetylCoA is the precursor of a number of compounds synthesized in cells. It is the basic building block of fatty acids, cholesterol, and other compounds derived from the five-carbon isoprenoid unit (Figure 3). In the synthesis of fatty acids, acetylCoA is carboxylated to malonylCoA by the **biotin**-requiring enzyme, **acetylCoA carboxylase** (Table 2). Subsequent reactions build the C_{16} fatty acid palmitate and other fatty acids from successive additions of the portion of malonyl CoA derived from acetylCoA, thereby providing the cell with the diverse fatty acids required for membrane lipids. In the synthesis of cholesterol, acetyl units from three acetylCoA molecules condense to form 3-hydroxy 3-methylglutaryl CoA (HMG CoA), which is subsequently decarboxylated and converted to the five-carbon isoprenoid unit isopentenyl pyrophosphate. This isoprenoid unit is one of the most common structural units of a number of compounds in mammalian cells, bacteria, and plants. AcetylCoA also contributes one carbon to compounds synthesized from the five-carbon intermediate a- ketoglutarate in the TCA cycle. The acetyl unit of acetylCoA can also be transferred either to hydroxyl groups of compounds to form an acetyl oxygen ester (eg, the neurotransmitter acetylcholine; see Acetylcholine Receptor) or to an amino group to form an amide in an N-acetylation reaction (eg, acetylated amino sugars such as N-acetylglucosamine).

Figure 3. The central role of acetyl CoA in biosynthetic pathways.

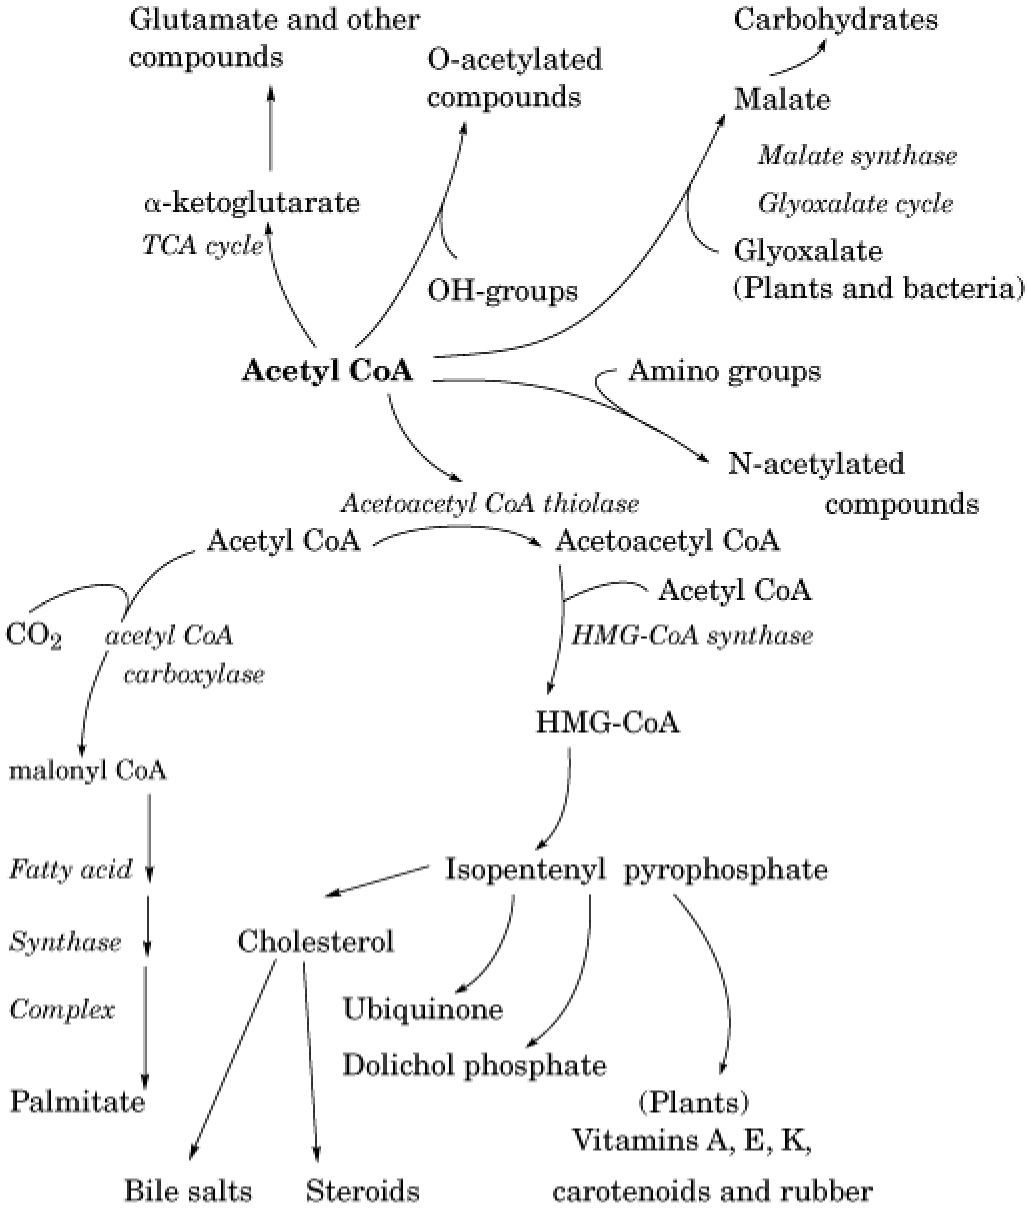

Table 2. Enzymes That Utilize AcetylCoA

$$\text{(5) acetyl CoA + oxaloacetate} \xrightarrow{\textit{Citrate synthase}} \text{citrate + CoASH}$$

$$\text{(6) acetyl CoA} + CO_2 + \text{ATP} \xrightarrow{\textit{AcetylCoA carboxylase (biotin)}} \text{malonyl CoA + ADP} + P_i$$

$$\text{(7) 2 acetyl CoA} \xleftrightarrow{\textit{AcetoacetylCoA thiolase}} \text{acetoacetyl CoA + CoASH}$$

$$\text{(8) acetyl CoA + acetoacetyl CoA} \xrightarrow{\textit{HMGCoA synthase}} \text{HMG CoA + CoASH}$$

$$\text{(9) acetyl CoA + choline} \xrightarrow{\textit{Choline acetyltransferase}} \text{acetylcholine + CoASH}$$

$$\text{(10) acetyl CoA + glyoxalate} \xrightarrow{\textit{Malate synthase}} \text{malate + CoASH}$$

In mammalian cells, acetylCoA cannot provide a net source of carbon for the synthesis of glucose or other sugars. However, plants, yeast, and bacteria contain the glyoxylate cycle, which serves as a bypass of the TCA cycle. The net result of the glyoxylate cycle is the conversion of two molecules of acetylCoA to succinate, utilizing TCA cycle enzymes plus isocitrate lyase and malate synthase. As a result, *Escherichia coli* and many other bacteria are able to convert acetate to carbohydrates and amino acids and can thus utilize and grow on acetate as their sole carbon source.

Sly, and D. Valle, eds.), McGraw Hill, New York: pp. 1981–2030. Covers certain aspects of pathway regulation for the synthesis of cholesterol from acetylCoA, which is of great interest for protection from heart disease.

Acetylcholine Receptor

Acetylcholine (ACh) is a widely distributed neurotransmitter in both the peripheral and central nervous systems (1). It is synthesized by the enzyme choline acetyltransferase within the cholinergic nerve terminal, where it is packaged into cholinergic vesicles. Arrival of an action potential at a cholinergic nerve terminal triggers quantal release of ACh by fusion of these vesicles with the presynaptic membrane and concomitant exocytosis of their contents into the synaptic cleft. The ACh released **diffuses** across the synapse to the postsynaptic membrane, where it activates its target, the acetylcholine receptor (AChR). Termination of transmission at cholinergic synapses involves rapid hydrolysis of ACh, by the enzyme acetylcholinesterase (AChE), which hydrolyzes it to choline and acetic acid (2).

The early observations of Dale (3) showed in various pharmacological preparations that ACh evoked responses similar to those evoked by either nicotine or muscarine. This provided the basis for the grouping of all AChRs into two families, nicotinic (nAChRs) and muscarinic (mAChRs). Dale's pioneering classification, based on the action of these two plant alkaloids, is still valid and used, although subtypes have been recognized and defined within each of the two families, both on the basis of specificity with respect to binding of agonists and antagonists and, in recent years, on the basis of gene cloning. Two additional plant alkaloids, *d*-tubocurarine and atropine, also provide useful tools by serving as specific antagonists of nAChRs and mAChRs, respectively (4).

nAChRs are ligand-gated **ion channels**, and their activation, by ACh or other agonists, causes a rapid change in ion permeability of the membrane in which they are embedded. mAChRs are members of the family of G-protein-coupled receptors and produce much slower responses, either excitatory or inhibitory, via their corresponding second messengers (5). Initial molecular cloning studies provided the primary structures of both nAChRs (6) and mAChRs (7), revealing that they belong to distinct families of proteins that share neither sequence identity nor a similar fold. As will be discussed in detail below, nAChRs are composed of pentamers of one or more subunits that display substantial sequence homology and, most likely, similar overall folds and transmembrane topologies. Muscarinic receptors are glycoproteins of molecular weight ~80,000 which, as already mentioned, belong to the family of G-protein-coupled receptors (8). Just as for other members of this family, hydrophobicity plots predict seven **transmembrane** sequences (8). The nAChR belongs to a larger family of ligand-gated ion channels, with which it too appears to share an overall fold, a common pattern of transmembrane sequences and other structural similarities (9, 10; see text below).

The recognition that the large electric organs of electric fish such as the electric eel, *Electrophorus electricus*, and the electric ray, *Torpedo* sp., provide a highly enriched and homogeneous preparation of cholinergic synapses (11) led to their use as an experimental model and also as the source of choice for purification and characterization of the nAChR, of AChE, and of homogeneous cholinergic synaptosomes and synaptic vesicles (2). The fact that the cholinergic synapse at the neuromuscular junction was the parallel system of choice for studying the electrophysiological characteristics of synaptic transmission (12), as well as many ultrastructural and developmental parameters (for recent reviews see Refs. 13-15), meant that many of the structural data garnered by use of the electric organ model system could be directly correlated with the functional data obtained with the neuromuscular preparation (2). Thus, the nAChR of electric organ closely resembles that of muscle (16), and the molecular forms of AChE present in electric organ tissue are homologous to those found at muscle endplates (17, 18).

The finding that injection into rabbits of purified nAChR elicited an **autoimmune** condition closely resembling the human muscle disease myasthenia gravis (19) was followed by detection of circulating antibodies to the nAChR in patients suffering from the disease. This opened up a fertile area of research in which clinical aspects were closely coupled to advances in basic research on the nAChR (20).

The cholinergic synapse has thus served as the prototypic synapse for understanding many fundamental aspects of synaptic transmission at chemical synapses. Even now, when improved electrophysiological techniques, and approaches such as Ca^{2+} imaging, allow better access to the CNS, and when genetic engineering allows expression of the receptor of choice in a system like the *Xenopus* oocyte that is amenable to user-friendly patch-clamp techniques, as well as in sufficient amounts to carry out structural characterization, the neuromuscular junction and electric organ tissue still occupy a position at the center of the stage.

1. The Nicotinic Acetylcholine Receptor

1.1. Identification and Characterization

As early as 1955, it was suggested by Nachmansohn (21) that the nAChR might be a protein in which a conformational change elicited by the neurotransmitter ACh could induce a change in permeability that would trigger the postsynaptic response, and it was in his laboratory, in the 1960s, that the first evidence was presented that the nAChR is indeed a protein. Thus, Karlin and Bartels (22), using the electric eel electroplaque preparation, showed that the response of the nAChR to carbamylcholine could be modified reversibly by reagents that either modified thiol groups or reduced disulfide bonds. Subsequently, Karlin and co-workers (23, 24) and Changeux et al. (25), also in the Nachmansohn laboratory, demonstrated *in situ* affinity labeling of the nAChR in the intact electroplaque. O'Brien and co-workers (26, 27), using specific binding of the reversible ligand muscarone and homogenates of electric organ tissue of *Torpedo*, were able to obtain a good estimate (~2 nmol/g tissue) of the number of nicotinic binding sites.

A major breakthrough in the identification of the nAChR, its localization, and its molecular characterization came about by use of (a) the neurotoxin a**-bungarotoxin** (aBgt), a 74-residue polypeptide chain purified by Lee and co-workers from the venom of the banded krait, *Bungarus multicinctus* (28), and (b) the homologous a-**neurotoxins** purified from cobra venom (29). Lee's group presented electrophysiological and pharmacological evidence that these neurotoxins acted as very high-affinity (dissociation constant in the pico-to-femtomolar range) antagonists of the nAChR (30). ^{125}I-aBgt was developed as a powerful tool for localization and quantification of the nAChR by high-resolution autoradiography (31). It was shown to be present as a dense quasi-crystalline array at the top of the folds of the postsynaptic membrane of skeletal muscle, opposite the putative ACh-release sites on the presynaptic membrane, with a density very similar to that in purified preparations of postsynaptic membranes obtained from *Torpedo* electroplax. A further step forward was taken when it was shown that binding of ^{125}I-aBgt was retained after solubilization in nonionic detergents, such as Triton X-100 and cholate, and that a single toxin-binding component, migrating at ~9 S, could be identified on sucrose gradient sedimentation velocity centrifugation (32, 33). Furthermore, the receptor so solubilized could be purified by affinity chromatography using resins to which either the a-neurotoxin (34) or a quaternary nitrogen ligand (35) had been attached. This permitted characterization of the nAChR as a multisubunit protein. Thus it was shown that it was a pentamer, of molecular weight ~250,000 (36), that contains four polypeptide subunits, a, b, g, and d, with apparent molecular weights of 39,000, 48,000, 58,000, and 64,000 and a stoichiometry of a$_2$bgd. In the electron microscope, such purified preparations displayed a rosette-like appearance (37), closely resembling similar, highly organized arrays of rosettes observed in purified postsynaptic membrane preparations (38). This led to the working hypothesis, still currently accepted, that the five subunits lie in the plane of the plasma membrane, surrounding the ion channel running through the center. A fifth polypeptide, the 43-kDa polypeptide (now known as rapsyn), which was found to be weakly associated with the pentamer (39), is believed to be involved in nAChR-clustering and anchoring to the cytoskeleton at the synapse (13). In skeletal muscle the g subunit is present in the nAChR of embryonic muscle, but is replaced by the ε subunit in adult muscle (40).

Studies on model systems were important in establishing the role of the nAChR in signal transduction at the cholinergic synapse. Thus the microsac preparation (41) was used to show that ACh could induce a permeability change in such nAChR-enriched vesicles. Furthermore, prolonged exposure to high concentrations of ACh was shown to produce a closed state, with high affinity for ACh (42), equivalent to the desensitized state first described in skeletal muscle by Katz and Thesleff

(43). The availability of purified native receptor permitted reconstitution studies into liposomes and into lipid bilayers, permitting recording of single channels induced in the presence of ACh (44, 45). The purified pentamer thus contained not only the ACh-binding site, but also the ion channel and the transducing elements involved in activation and desensitization (16).

Affinity labeling studies by Karlin and co-workers (46), using a radioactive reagent, established that the disulfide bond that was susceptible to reducing reagents, as originally demonstrated by Karlin and Bartels (22), was located on the a subunit, in proximity to the binding site for ACh and various quaternary ligands.

An important step forward was the finding of Raftery et al. (47) that the NH_2-terminal sequences of all four subunits display substantial **sequence homology**. When, not long after, the subunits were cloned (6), it was found that such homology extends throughout the whole polypeptide chain, and the receptor pentamer can be viewed as displaying pseudo-fivefold symmetry. One issue that still remains open is the arrangement of the subunits around the lumen. This has been approached primarily by electron microscopy using subunit-specific antibodies, with supplementary information coming from use of affinity labels directed toward the ACh-binding site, which label both the a subunit and an adjacent subunit (see text below). As many as 12 permutations are possible, but it is generally accepted that the two a-subunits are not adjacent to each other (48), and discussion focused on which of the b-, g-, and d-subunits is flanked on both sides by the a-subunit. Karlin et al. (49) proposed that it is the g-subunit that lies between the two a-subunits. Although Kubalek et al. (50) proposed that the b-subunit might occupy this position, the assignment of Karlin and co-workers is generally favored (for detailed discussions see Refs. 10 and 51).

Advances in cloning and expression, taken together with development of the patch-clamp technique, had a dramatic influence on research on the nAChR, just as they did on research on other receptors and on ion channels. In the case of the nAChR, however, the availability of large amounts of highly purified receptor from *Torpedo* electric organ resulted in fruitful synergy between these new techniques and the techniques of protein chemistry and structural biology.

In general, research has proceeded on two fronts, one concerned with the structure of the ACh-binding site and the other with that of the ion channel, with the eventual objective of understanding the physical mechanism by which ligand-binding causes channel opening. In the following, the overall topology of the receptor and of the individual subunits will first be reviewed briefly. The current status of our knowledge of the ACh-binding site, and then of the ion channel, will be summarized, followed by a discussion of the recent structural work from the laboratory of Unwin, which is beginning to give us a first glimpse of how the receptor may be functioning. For a number of recent reviews that cover these issues in more detail than is possible here, see Refs. 9, 10, 16, and 52, as well as the recent paper of Unwin (53), which summarizes the current status of the structural work.

1.2. Conformation and Topology

Analysis of the sequences of the four subunits, obtained on the basis of their complementary DNA sequences, showed that they shared a very similar topology: A long extracellular NH_2-terminal domain is followed by three putative transmembrane a-helices, identified on the basis of hydrophobicity, M1–M3, by a cytoplasmic loop containing ~100–150 residues, and finally, by a fourth transmembrane helix, M4, so that the COOH-terminus is believed to be on the extracellular side of the postsynaptic membrane (54). Other ligand-gated ion channels that belong to the same superfamily, including receptors for g-aminobutyric acid, glycine, and serotonin, display a similar topology (9, 10). A number of consensus sites for N-Glycosylation are present in the extracellular domains, giving rise to a sugar content of ~7% (for literature see Ref. 55); and a number of consensus sites for **phosphorylation**, present on the cytoplasmic loops, presumably fulfill regulatory functions (56).

Photoaffinity labeling, using lipid-soluble probes, has been used to assign the arrangement of the transmembrane sequences in relation to the lipid bilayer and the putative central ion channel (57-59). From such studies, it has been concluded that the M4 sequence, which is also the least conserved, is the most exposed to the lipid environment, with the M1 and M3 sequences displaying more limited exposure to the lipid environment, and M2 facing the lumen of the ion channel. This assignment of M2 as making the principal contribution to the lining of the ion channel is also supported by labeling by channel blockers and by use of the SCAM technique (see text below).

Various spectroscopic techniques show that the nAChR contains substantial amounts of both a-helices and b-sheets (for literature see Ref. 10). In particular, Naumann et al. (60), using Fourier transform infrared (FTIR) spectroscopy on native receptor-rich membranes, have shown a predominance of b structure, 36 to 43%, and an a-helical content of 32 to 33%. Of particular interest are the putative conformations of the membrane-spanning sequences. Görne-Tschelnokow et al. (61) attacked this problem directly, by performing FTIR spectroscopy on membrane preparations from which the extramembrane domains had been shaved by **proteolysis**. Their data suggested **a** beta-sheet content of ~40% for the transmembrane sequences. Modeling studies also suggested a substantial b-sheet component (62). Various labeling studies, which attempt to correlate the degree of labeling of residues with orientation toward either the ion-channel lumen or the lipid bilayer, and thus with either an a-helical or a b-strand pitch, yield complex results (see, for example, Refs. 9, 10, 59, and 63); and precise assignments will, most likely, have to await a high-resolution 3D protein structure.

1.3. ACh-Binding Site

Identification of the residues comprising the ACh-binding site of the nAChR was approached by affinity labeling. Karlin and co-workers used the same radioactive affinity label that they had used to label the a subunit selectively, a quaternary derivative of maleimide, to identify the residues labeled. Because they had demonstrated that labeling occurred subsequent to reduction of the receptor, it was not surprising that they found that the residues labeled were the adjacent cysteines, Cys192 and Cys193, which apparently form an intrachain disulfide bond in the native nAChR, and which are present only in the a-subunit (64). As predicted, these residues are localized in the sequence that had been assigned to the extracellular domain, and would thus be the natural candidate for the ACh-binding site. The importance of this region for agonist and antagonist binding was confirmed by the observation that short synthetic peptides containing Cys192 and Cys193 (eg, from residue 185 to 196) displayed specific binding to aBgt, albeit with much lower affinity than the native receptor (65). Moreover, the a-subunits of the nAChR of both snakes and of the mongoose, which are resistant to aBgt, display mutations in this region that can provide a structural basis for resistance (66).

Changeux and co-workers conducted an extensive study of the residues labeled by the tertiary photoaffinity label, DDF (67). In addition to Cys192 and Cys193, this probe labeled primarily aromatic residues, including Tyr93, Trp149, Tyr190 and Tyr198, all, again, in the putative cytoplasmic domain. Use of other labeling agents, by other laboratories, broadly confirmed these assignments and identified additional aromatic residues (for literature see Ref. 68). Thus the ACh-binding pocket of the nAChR can be viewed as an “aromatic basket” (16) in which the quaternary group of ACh interacts with these aromatics via the p electron–cation interactions (69) which X-ray crystallographic studies have shown to play a prominent role within the “aromatic gorge” of AChE (70, 71).

Although the studies discussed above indicate a prominent role for the a-subunit in binding of both agonists and antagonists, numerous labeling studies have revealed contributions of adjacent subunits to ligand-binding. These studies have been critically reviewed by Hucho et al. (10). Taken together, the data clearly indicate that the two ACh-binding sites are at the interfaces between the two a-subunits and the g- and d-subunits. This, in turn, implies structural difference between the two sites that can serve to explain nonequivalence of the two binding sites in terms of affinity for both a-neurotoxins (72) and antagonists (73).

1.4. Ion Channel

Pharmacological studies on the nAChR revealed a number of noncompetitive antagonists, both natural and synthetic, that blocked the change in permeability elicited by ACh without inhibiting the binding of ACh itself. It was, therefore, suggested that at least some of these compounds act by entering the ion channel and sterically blocking ion movement through it (for literature see Refs. 9, 10, and 16). Based on the currently held view that the ion channel is the hole in the rosette seen in the electron microscope, such “channel blockers” are believed to exert their action by plugging this hole. Some channel blockers, such as chlorpromazine (74) and trimethylphosphonium (75), bind irreversibly upon UV irradiation; and their labeled derivatives can, accordingly, be used to identify putative elements of the channel lining. Rapid-mixing studies, using nAChR-enriched microsacs, showed that exposure to ACh leads, initially, to greatly increased labeling, followed by diminished incorporation which is consistent with desensitization as measured by ion flux measurements (76). Such labeling studies showed dominant labeling of the residues in the M2 transmembrane sequences of all four subunits, suggesting that they make the principal contribution to the lining of the lumen of the ion channel, in the open state of the channel. One such noncompetitive channel blocker, quinacrine azide, was, however, shown to label amino acid residues in M1 (77).

In parallel to such labeling studies on the purified receptor, use of site-directed mutagenesis, combined with expression in *Xenopus* oocytes (78) and use of the patch-clamp technique, permitted assessment of the contributions of individual amino acid residues to the conductance properties of the ion channel, an approach pioneered by the joint efforts of the Numa and Sakmann laboratories (see, for example, Refs. 79 and 80).

A third approach, developed more recently, is the substituted-cysteine-accessibility method, abbreviated as SCAM (81), which combines site-directed mutagenesis with chemical modification, so as to identify the amino acid residues lining the ion channel and their involvement in function. Thus, residues believed to line the ion channel (primarily from the M2 transmembrane sequence, but also from M1) are replaced one-by-one by cysteine residues, using site-directed mutagenesis, and expressed in *Xenopus* oocytes. The reactivity of their thiol groups with thiol reagents bearing negative or positive charges is examined *in situ*, both in the presence and absence of ACh, thus permitting assessment of their accessibility in both the closed and open states of the channel. Furthermore, these sulfhydryl reagents can be added both intra- and extracellularly, yielding information concerning accessibility of channel-lining residues from both surfaces (63).

These various experimental approaches have led to the identification of residues within the M2 sequences of all five subunits that determine the conductance and selectivity of the nAChR channel. In particular, using nAChR mutants expressed in *Xenopus* oocytes, three rings of negatively charged residues which may be referred to as the extracellular (or outer), the intermediate, and the cytoplasmic (or inner) ring, have been shown to play important roles in determining channel conductance (80). A ring of polar (serine and threonine) residues, named the central ring, is located above the intermediate ring, forming a constriction that may serve as part of the selectivity filter (82, 83). The bulk of the transmembrane sequence of M2 lies between this central ring and the outer ring.

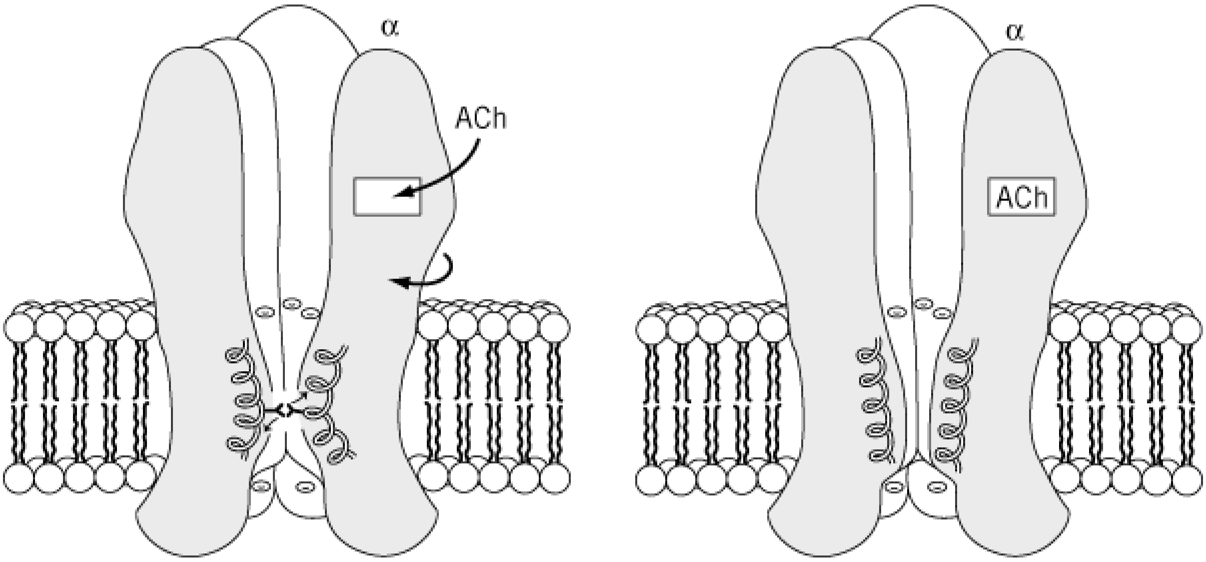
A more detailed topographical picture has been obtained by the SCAM technique, as summarized by Karlin and Akabas (9). Thus, broadly speaking, the residues in M2 of the a-subunit can be fitted to an Amphipathic helix so that, with one exception, all the residues on one face of the helix are labeled in the SCAM protocol; some are equally accessible in the presence and absence of ACh, some are more accessible in its presence, and some are more accessible in its absence. Furthermore, certain residues at the extracellular end of the M1 helix of the a-subunit are also labeled. The pattern of labeling of M2 in the absence of ACh is consistent with an a-helical conformation, except for a short stretch in the middle (aLeu250 to aSer252), while in the presence of ACh it is consistent with an uninterrupted a-helix. The pattern of labeling of M1 cannot be ascribed to a specific conformational motif, although it too is changed in the presence of ACh. Karlin and Akabas (9) hypothesize that a movement of M1 and M2 relative to each other, with a concomitant change in **secondary structure**, may flip open the gate of the channel. More recently, the SCAM technique has also located the gate, using comparative studies in which labeling was carried out from either the extracellular or cytoplasmic sides (63). In the absence of ACh—that is, in the closed state of the channel—there is a barrier to the sulfhydryl agents, when added to either side, reacting with residues aGly240 and to aThr244. ACh binding removes this barrier, which serves as an activation gate. Residues aGly240, aGlu241, aLys242, and aThr244 line a narrow part of the channel in which this gate is located. It should be noted that the second of these residues, aGlu241, belongs to the inner anionic ring, and aThr244 to the central ring, as defined above (80, 82).

1.5. Structural Studies

Despite the extensive studies performed on the characterization of the ACh-binding site and of the ion channel, the question with which all structural and functional studies on the nAChR are ultimately concerned is how binding of ACh is transduced into a permeability change in the ion channel. This is ultimately a problem best addressed by a structural biology approach. In spite of attempts from many laboratories to obtain nAChR crystals that would diffract X-rays (for a published example, see Ref. 84), this has not yet been achieved. Our current structural knowledge is, therefore, derived from the work of Unwin (for a recent summary see Ref. 53). As mentioned above, the postsynaptic membrane of *Torpedo* electric organ contains densely packed, partially crystalline arrays of nAChR (38). When isolated, such membranes have a natural propensity to recrystallize in tubular form (85, 86). Since the early 1980s, Unwin has been using electron microscopy to probe the structure of the nAChR from *Torpedo marmorata* and is now able to compare the receptor in its open and closed states at 9 Å resolution (53). The receptor is revealed as an elongated structure, ~125 Å long; the extracellular portion of each subunit extends ~60 Å above the membrane surface, and the intracellular portions extend ~20 Å from the cytoplasmic surface. A density underlying each receptor most likely represents the cytoskeletal protein rapsyn (see text above), normally present in 1:1 stoichiometry with the receptor (87). A view from above shows the five subunits arranged around a fivefold axis of pseudosymmetry, as predicted. The opening of the putative ion channel in the center is about 20 Å at its entrance, narrowing sharply at the membrane surface. At the current resolution, it is possible to begin to glimpse some elements of secondary structure. Thus in each subunit, in a region about 30 Å away from the extracellular surface, a group of three short rods can be detected, presumably a-helices. The two subunits identified as a-subunits (50) contain cavities shaped by these rods, which may correspond to the ACh-binding pockets. The narrowest portion, corresponding to the pore, appears to be shaped by five bent a-helical rods, each contributed by one of the subunits (Fig. 1, left). The bends in the rods, near the middle of the membrane, are the parts closest to the axis of the pore and may represent the gate. In order to visualize the open state of the nAChR, Berriman and Unwin (88) devised a rapid-freezing device, designed to trap the open state, after application of ACh, by preventing the transition to the desensitized state. Comparison of the ACh-activated receptor with the nonactivated form revealed only slight changes (Fig. 1, right). Concerted twisting motions appeared to occur within the rods lining the putative ACh-binding pockets, which were consistent with the requirement that two ACh molecules, binding simultaneously to both a-subunits, are required to open the channel. These localized disturbances were associated with small rotations extending along the axis of all the subunits, and with a switching of the helices within the pore from the bent shape seen in the nonactivated receptor to a tapered, more open configuration. If it is assumed that the threonine side chains of the central ring, which are believed to serve as the pore (see text above, along with Ref. 83) face into the pore, a minimum diameter of 10 Å can be estimated, comparable to the diameter obtained by use of various organic cations (89). Such a concerted rotation of the transmembrane sequences surrounding the lumen of the putative ion channel is consistent with the data accumulated by the various studies using site-directed mutagenesis and labeling, some of which were discussed above (see, in particular, Refs. 59 and 63).

Figure 1. Simplified diagram of the nAChR in its closed (left) and open (right) states, as suggested by the structural results. An ACh molecule first enters a binding site in one of the a-subunits (rectangle), but significant displacements are blocked by the neighboring subunit, lying between the two a-subunits. Interaction of a second ACh with the other

site then attempts to draw the neighboring subunit out of the way. A concerted localized displacement thereby takes place, initiating small rotations of the subunits along the shaft to the membrane. The rotations disrupt the gate by disrupting the association of a-helices around the pore in the closed state (left), switching over to an alternate configuration in which a widened polar pathway for ion movement is created. (From Ref. 53, with permission.)



Obviously, when higher-resolution images become available, a more detailed mechanistic description will be feasible, but the conceptual stage appears to have been set.

1.6. Neuronal Nicotinic Receptors

Already in the late 1970s, it was proposed, on the basis of ^{125}I-aBgt-binding studies, that nAChRs were present not only in skeletal muscle, but also in the central nervous system (90, 91). These studies were not the subject of widespread attention, primarily due to the fact that functional correlates were lacking. When, in the mid-1980s, cloning techniques revealed the presence in brain of an nAChR gene family homologous to, but clearly distinct from, those of electric organ and muscle, and widely distributed in different brain areas (92, 93), it became obvious that nAChRs, like muscarinic receptors, must have important functions in brain. For many years, however, the lack of specific agonists and antagonists for a given neuronal nAChR subtype severely hampered the identification of functional nAChRs in various brain areas. These difficulties were further aggravated by the unusually fast kinetics of inactivation of some nAChR subtypes, compared to their peripheral counterpart (for literature, see Ref. 94). Development of techniques permitting rapid application and removal of agonists was necessary to overcome this limitation (see, for example, Refs. 95 and 96).

The cloning approach revealed the existence of a large number of AChR receptor subunits in the brain. In contrast to muscle and electric organ, however, these appear to fall into only two categories, a and b. By now nine a-subunits (97) and nine b-subunits have been described in vertebrate brain (98), and multiple nAChR subunits have also been described in invertebrates such as *Caenorhabditis elegans* (99) and *Drosophila* (100).

As discussed by Sargent (98), the various subtypes of subunits are expressed differentially in one brain region or another. The most recently discovered a9-subunit, for example, has a pattern of expression restricted to cochlear hair cells (97). The pharmacology of neuronal nicotinic receptors in relation to such topics as nicotine addiction (101) and Alzheimer's disease (102) are currently topics of intensive investigation; so too is their involvement in brain plasticity (103) and in behavior, learning, and memory (104, 105). A recent development is the observation that choline serves as a selective agonist for a7 nAChRs in rat hippocampal neurons (106), in line with earlier reports for a7 ectopically expressed in oocytes (107, 108). Because a7 belongs to what appears to be the evolutionarily oldest group of nAChrs (109), it is feasible that choline, rather than ACh, was the primeval transmitter for cholinergic receptors.

Neuronal nAChRs have not yet been purified or expressed in large amounts. Thus, essentially all our knowledge of their functional properties comes from studies in which subunits were expressed singly or in combination, most frequently by injection into *Xenopus* oocytes. Such expression studies were augmented, as for *Torpedo* and muscle nAChRs, by site-directed mutagenesis. These studies have been reviewed in detail by Sargent (98), and only a few points will be discussed here briefly.

Presence of an a-subunit is necessary to obtain a functional receptor; and in the case of the a7-subunit, injection of it alone into oocytes is sufficient for it to form functional oligomers (110). Changeux, Bertrand, and co-workers took advantage of this experimental system to perform expression, combined with site-directed mutagenesis, which showed that the ligand-gated ion channel produced by the a7-subunit closely resembles that of the pentameric muscle and *Torpedo* receptors (see, for example, Ref. 111 and the review in Ref. 16). Direct experimental evidence for a pentameric stoichiometry was provided for the chick nAChR produced in oocytes by expression of the a4 and b2 subunits with radioactive label incorporated into them. The stoichiometry of the subunits in the purified receptor was consistent with an $a4_2b2_3$ pentamer (112). This does not mean, however, that expression of the mRNAs for any mixture of a-subunits, with or without a b-subunit, will produce a functional oligomer. Thus far, only a7 has been shown to produce functional oligomers containing only a subunits. Furthermore, a recent study of Yu and Role (113) has shown that a5 can participate in the function of an ACh-gated ion channel only if it is coexpressed with another a- and a b-subunit. The structural basis for such restrictions with respect to assembly and/or function are, at this stage, unknown. Patrick and co-workers (114) observed, however, that a Cyclophilin is required for expression of functional homo-oligomeric, but not hetero-oligomeric, nAChRs. They raise the possibility that the a-subunits in the homo-pentamer may not assume identical folds. Cyclophilins may thus play a critical role in the maturation of such homo-oligomers, acting directly or indirectly as prolyl *cis/trans* Isomerases or as **molecular chaperones** (115).

Achaete–Scute Complex

A central theme in developmental biology is to understand how the mechanisms that specify particular cell types integrate with those that govern where and when cell type-specific structures form during animal development. Over the better part of the past century, the development of the *Drosophila* nervous system has served as a model with which to unravel the interconnected processes of cell fate specification and pattern formation. The **genes** of the *achaete–scute* complex (AS-C) bridge these two processes. The AS-C is composed of four related genes found within ~90 kbp of DNA in the distal tip of the X-chromosome. The four genes—*achaete* (*ac*), *scute* (*sc*), *lethal of scute* (*l'sc*) and *asense* (*ase*)—all encode for basic **helix-loop-helix** transcriptional activator proteins and were initially identified by mutational analysis. Loss-of-function mutations in the AS-C remove sensory organs in the peripheral nervous system (PNS) and neural structures in the central nervous system (CNS), whereas gain-of-function mutations induce the formation of ectopic neural structures. The "proneural" *ac*, *sc*, and *l'sc* genes are expressed prior to neural precursor formation in precise patterns of cell clusters that forecast where neural precursors will form. During both embryonic and adult development, the primary patterning genes in *Drosophila* act through a large array of cis-acting regulatory regions found within the AS-C to create the stereotyped pattern of AS-C-expressing proneural cell clusters. Within each cluster (equivalence group), a cell communication process mediated by the Notch signaling pathway (lateral inhibition) restricts AS-C gene expression to a single cell. Within this cell, *ac*, *sc* and *l'sc*, either alone or in combination, are thought to activate a cassette of genes that directs this cell to acquire the neural precursor fate. All other cells within the cluster extinguish AS-C gene expression and are directed towards epidermal development. One target of the AS-C proneural genes in neural precursors is *ase*, which promotes the differentiation of neural structures. The AS-C thus links the process of cell fate specification to that of pattern formation: the AS-C genes receive and interpret global positional information through their regulatory regions and translate this information through their function into the formation (and differentiation) of a two-dimensional array of neural structures.

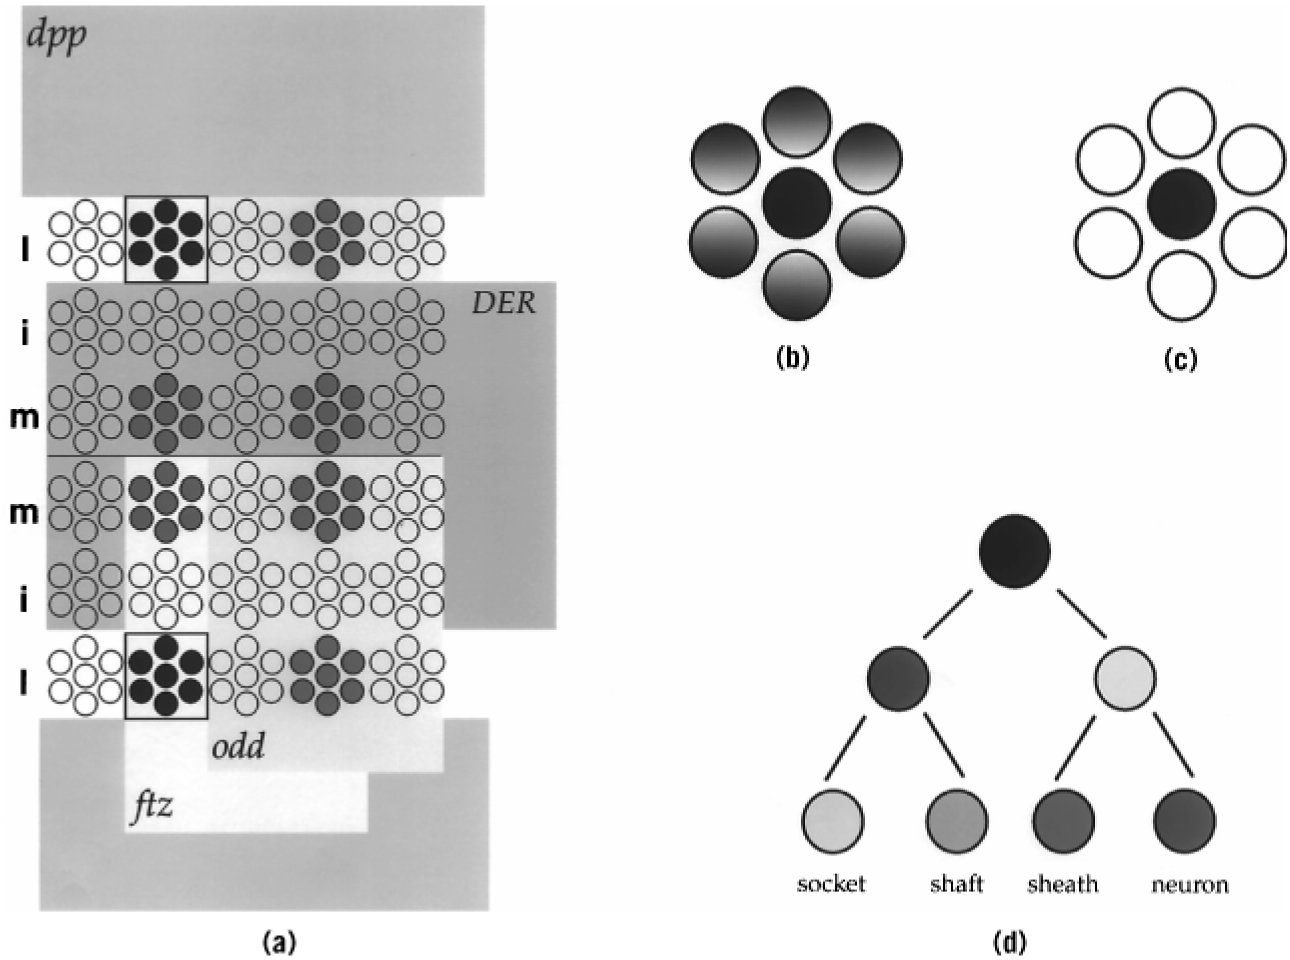
1. Genetic and Molecular Characterization of the *Achaete–Scute* Complex

The embryonic and adult *Drosophila* nervous systems are composed of a variety of different neural structures, each organized in reproducible but distinct patterns. For example, the neural precursors of the embryonic CNS form in orthogonal rows, whereas in the adult PNS large innervated bristles arise in an irregular, yet stereotyped pattern. Each bristle, or sensory organ, forms from a single neural precursor cell that occupies a fixed location in the developing fly. Cell migration is limited in the *Drosophila* PNS and CNS. Thus, the initial neural precursor pattern largely determines the later pattern of neural structures.

Genetic analyses identified a set of four genetic activities, designated the AS-C, located near the distal tip of the X-chromosome critical for the formation, patterning, and differentiation of neural structures (1). Loss-of-function mutations in any one of these genes remove neural structures, although the precise set of structures removed differs for each gene. For example, loss of *l'sc* activity primarily affects the CNS, whereas loss of *ac* or *sc* activity primarily results in PNS defects. Loss of *ase* function removes sensory organs along the wing blade but also causes differentiation defects in other sensory organs. Conversely, mis-expression of any AS-C gene promotes the formation of ectopic neural structures. These analyses suggested that the AS-C promotes the initial commitment of a cell to become a neural precursor and that their gene products are at least partially redundant. Detailed genetic mosaic analyses in the *Drosophila* wing imaginal disc (the larval structure that generates the wing and notum of the adult fly) showed that the activities of *ac* and *sc* define zones of neural competency from which neural precursors arise (2). These zones of neural competency are known as proneural cell clusters and are "equivalence groups" within which all cells can (although only one or a few will) become a neural precursor.

The genes *ac*, *sc*, and *l'sc* are each expressed in a complex and dynamic pattern of cell clusters, each of which quickly resolves to a single cell, the putative neural precursor (Fig. 1). The gene expression patterns of *ac* and *sc* are identical throughout neurogenesis and partially overlap with the expression pattern of *l'sc*. On the other hand, *asense* is expressed exclusively in neural precursors and their progeny. Based on mutant phenotypes and expression patterns, *ac, sc*, and *l'sc* are called proneural genes whereas *ase* is called a neural precursor gene.

Figure 1. Patterning and specification of neural precursors. (**a**) Patterning of AS-C gene expression. Schematic representation of the ectoderm of a *Drosophila* embryo. The expression of the *ac* and *sc* genes in four proneural clusters per hemisegment is shown in red and blue. The activity of the early patterning genes *ftz*, *odd*, *DER*, and *dpp* subdivide the embryo and lead to the activation of *ac/sc* gene expression in reproducible quadrants. For example, the combined action of *ftz* activation and *odd* repression leads to *ac/sc* gene expression in domains that express *ftz* but not *odd* (yellow). Along the D/V axis, *dpp* (light blue) and *DER* (green) restrict *ac/sc* expression to the lateral column. Together, the action of these four genes delimit *ac/sc* gene expression within one proneural cluster, shown in blue. Note that other factors can overcome *DER* mediated repression in the medial column. (**b**) Singling out of a neural precursor. Within each proneural cluster, a single cell (in this example, the central cell) comes to express the AS-C proneural genes to the highest level, and this cell becomes the presumptive neural precursor (dark blue cell). (**c**) Resolution of cell fate within a proneural cluster. The presumptive neural precursor retains proneural gene expression and acts through the *Notch* signaling pathway to remove proneural gene expression in the other cells of the cluster (white). These cells are directed toward epidermal development. (**d**) Neural precursor lineage. Each neural precursor goes through an invariant cell lineage to produce a particular neural structure. The lineage of a sensory bristle of the PNS is shown. The neural precursor divides to yield two differently fated daughter cells, which in turn divide to produce a total of four cells. Each cell acquires a different fate, and together the four cells make up a functional sensory organ—an innervated bristle.



The molecular cloning of the AS-C in the 1980s identified all four genes as encoding putative transcriptional activator proteins that belong to the class B type of basic helix-loop-helix (bHLH) proteins. These four genes are contained within ~90 kbp of DNA, separated from one another by an average of ~30 kbp of DNA replete with *cis*-regulatory regions required to activate different members of the AS-C in complex and partially overlapping patterns (3). Transcriptional activation requires the formation of a heterodimer between A and B class bHLH proteins (4); these heterodimers recognize the core DNA sequence CANNTG, where N is not specified (an 'E' box). An A-class bHLH protein with which AS-C gene products heterodimerize and activate transcription is the product of the *daughterless* (*da*) gene. Heterodimers of one AS-C gene product and Da mediate transcriptional activation of genes expressed throughout proneural clusters and in neural precursors. The *da* gene is expressed ubiquitously throughout *Drosophila* development, and AS-C genes are expressed in complex yet invariant patterns of cell clusters that predict where neural precursors form. Thus, the spatiotemporal specificity of where and when neural precursors develop is a function of the pattern of AS-C gene expression.

2. Cis- and Trans-Regulation of Proneural Gene Expression

Activation of the proneural genes of the AS-C in precise and reproducible patterns of proneural clusters is the first step in the formation of the stereotyped two-dimensional pattern of neural precursors in the *Drosophila* nervous system. The genetic regulatory mechanisms that dictate where and when AS-C expressing proneural clusters form are best understood for the development of the embryonic CNS (5). The anterior/posterior (A/P) and dorsal/ventral (D/V) register of AS-C-expressing cell clusters in the early embryo suggests that the segmentation genes, which segment the embryo along the A/P axis, and the dorsoventral genes, which specify pattern along the D/V axis, function to lay down directly the initial pattern of AS-C proneural clusters. A similar process mediated by ***wingless*** and decapentaplegic (*dpp*), as well as the genes of the *iroquois* complex (6), probably acts directly on the AS-C to create the pattern of AS-C-expressing cell clusters in adult structures.

During development of the embryonic *Drosophila* CNS, the AS-C proneural genes are expressed in an invariant orthogonal pattern of proneural cell clusters. For example, *ac* and *sc* are co-expressed in two rows of cell clusters in the medial and lateral—but not intermediate—columns of each segment. Prior to AS-C gene activation, the activities of different A/P and D/V patterning genes have subdivided the early embryo into an orthogonal pattern of squares, reminiscent of a checkerboard. Each square expresses a unique combination of these patterning genes, and the borders of the AS-C proneural clusters match precisely the limits of these squares (Fig. 1). This suggests a model whereby the combined activities of particular combinations of patterning genes within a square either does or does not activate a member of the AS-C. The composite pattern of AS-C-positive cell clusters would then result from the integration of the activities of each square.

Support for the checkerboard model comes from genetic analyses that assayed the expression of AS-C genes in embryos mutant for various known patterning genes. For example, the anterior border of every fourth transverse row of *ac/sc*-positive cell clusters coincides with the anterior edge of the expression of the *fushi-tarazu* (*ftz*) pair-rule gene, and the posterior border of these proneural clusters abuts the anterior border of the *odd-skipped* (*odd*) pair-rule gene (Fig. 1). In embryos mutant for *ftz*, this row of *ac/sc*-expressing proneural clusters disappears, whereas in embryos mutant for *odd* it expands posteriorly to fill the entire *ftz* domain. Thus, the combined action of *ftz* activation and *odd* repression defines the anterior and posterior boundaries respectively, of proneural clusters in this row. The D/V patterning genes control the mediolateral extent of AS-C proneural clusters. For example, the medial boundary of the lateral column of AS-C proneural clusters abuts the lateral border of the activity of the *Drosophila* epidermal growth factor (EGF) receptor (*DER*), and the lateral boundary of these clusters abuts the medial boundary of *dpp* activity (Fig. 1). In embryos mutant for *DER*, the lateral column of AS-C-expressing proneural clusters expands medially, whereas in *dpp* mutant embryos these clusters expand laterally. Thus, *DER* and *dpp* together restrict *ac/sc* gene expression to the lateral column in the developing CNS. The concerted action of *ftz* and *odd* along the A/P axis, and *DER* and *dpp* along the D/V axis, can account for the activation of *ac/sc* in one eighth of its proneural clusters. Combinations of other patterning genes probably act similarly to initiate AS-C proneural gene expression in the other regions of the developing CNS and PNS.

Scattered throughout the AS-C are regulatory regions that decode the positional information contained within the checkerboard pattern of spatial regulators and translate it into the transcriptional activation of *ac*, *sc*, and *l'sc*. The locations of many of these regulatory regions have been identified through the use of DNA rearrangements within the AS-C and of reporter gene constructs that contain specific genomic regions from the AS-C region (7). For example, *ac* and *sc* share a number of regulatory regions located between the two genes that function to activate *ac* and *sc*, but not *l'sc*, in identical patterns throughout development. It is thought that the gene products of many of the patterning genes act directly through these regulatory regions to create the precise and invariant pattern of AS-C-expressing proneural clusters.

3. Resolution of Proneural Cell Clusters: The Singling out of the Neural Precursor

Within each proneural cluster, AS-C expression quickly becomes restricted to one (or a few) cells (Fig. 1). This cell initiates *ase* expression, enlarges, and segregates as a neural precursor to a position below the proneural cluster from which it arose. All clusters exhibit identical dynamics of proneural gene expression, which directly reflect the cell-fate decisions made by the cells of a cluster. Initially, all cells express one or more of the proneural genes; proneural gene expression confers on all cells the ability to become a neural precursor. Then, via a cell-cell communication pathway mediated by the *Notch* signaling pathway, one cell comes to express the proneural genes to the highest level. This cell is the presumptive neural precursor; it then acts, again through the *Notch* pathway, to inhibit and eventually to extinguish proneural gene expression from all other cells of the cluster (8). The cells that lose proneural gene expression are directed toward the epidermal fate. Thus the fate of cells within a proneural cluster correlates—not with the initial expression of the proneural genes—but rather with the fate of proneural gene expression in that cell: cells that retain proneural gene expression become neural precursors, whereas cells that lose proneural gene expression are directed toward the epidermal fate.

The analysis of the AS-C provides a paradigm for how specific cell fates (and cellular structures) arise in reproducible and invariant patterns, but many questions still remain with respect to the AS-C. For example, roughly half of all CNS neural precursors still form in embryos devoid of AS-C function. Thus other "proneural genes" must exist that promote neural precursor formation in the CNS. In addition, AS-C function is not restricted to the nervous system. The gene *l'sc* mediates the initial selection of muscle progenitor cells in the mesoderm in much the same way that it (as well as *ac* and *sc*) single out neural precursors in the ectoderm. Furthermore, Galant et al (9) recently demonstrated that a butterfly AS-C **homologue** is expressed in, and thus may promote the formation of, the precursors to the pigment-producing scale cells that cover the butterfly wing. Thus, AS-C genes may mediate additional developmental events in *Drosophila* and other animals. Finally, in *Drosophila* the AS-C is an integral unit composed of four structurally related genes. Has the overall genomic structure of the AS-C and the relative position and expression of each AS-C gene been strongly conserved throughout evolution, as is observed for the genes of the **homeobox** clusters? Or does the AS-C and its constituent genes display significant plasticity over evolutionary time? Research on the AS-C has led to an understanding of some of the molecular mechanisms that specify particular cell types and those that determine where and when these cell types form. It is likely that further insights will derive from continued analysis of AS-C expression, regulation, and function.

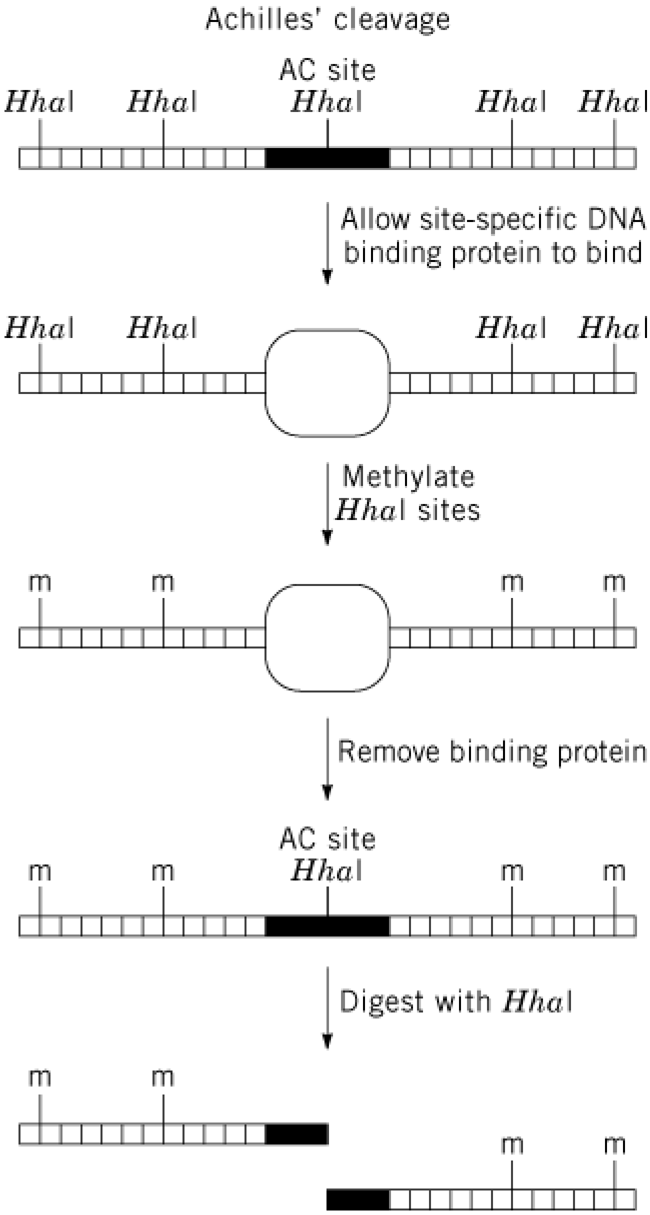
Achilles' Cleavage

Achilles' cleavage (AC) is a procedure developed to permit cutting double-stranded **DNA** at a single site (the AC site) in a complex genome (Fig. 1). The AC site is first protected from **methylation** by a sequence-specific DNA-binding protein, and the methylated genome is subsequently cut by a methylation-sensitive restriction enzyme. Other sites in the genome containing the same restriction/methylation site as the AC site are methylated and thus are not cut. The two key components of any AC system are (i) a restriction site that is recognized by both a methylation-sensitive restriction enzyme and its corresponding methyltransferase and (ii) the ability to block methylation of the chosen AC site by sequence-specific binding of a protein to that site. The overlap of the AC site and the recognition sequence for the DNA binding protein can occur naturally, or it can be engineered using recombination or site-directed mutagenesis. These requirements somewhat limit the applications of the AC technique.

Figure 1. Achilles' Cleavage. Diagram of the method used to prevent restriction enzyme digestion at all sites except for the Achilles' cleavage (AC) site. Horizontal lines connected by short vertical lines represent double-stranded DNA. *Hha*I restriction sites are marked by bold vertical lines above the double-stranded DNA. The binding site for the DNA-binding protein is represented by a solid rectangle. The DNA-binding protein is represented by an empty oval. Sites of methylation are indicated by a vertical line and the letter ‘m.’



Koob et al. (1) originally developed this procedure using two different **repressor/operator** systems. In one instance, **plasmids** carrying the operator of the lac operon were incubated with the Lac repressor and then methylated by the *Hha* I methyltransferase. Repressor binding prevented methylation of the *Hha* I site located within the *lac* operator. The methyltransferase and the operator protein were subsequently removed, leaving only the unmethylated AC site free to be cut by *Hha* I (1). Variations of the original AC method were also used to demonstrate the ability to make only one or a few cuts in the genomes of **yeast** and *Escherichia coli* (2), to turn frequent-cutting restriction enzymes into rare cutters (3), and to analyze the strength of protein-DNA interactions (4).

1. RecA-AC and RARE

The original AC method was made more universally applicable by using **RecA** protein and a sequence-specific **oligonucleotide** to form the protective complex, obviating the need for a sequence-specific binding protein. Two groups simultaneously developed this procedure, and their protocols were designated RecA-AC (5) and RARE (6). The RecA-AC/RARE technique still requires selection of a cleavage site that is recognized by both a restriction enzyme and its cognate methyltransferase. An oligonucleotide of 40 to 60 nucleotides in length is designed that matches the

DNA sequence containing the cleavage site. In the presence of Mg^{2+} and a non-hydrolyzable ATP analogue [eg, ATP(g-S)], RecA protein will bind to the oligonucleotide, forming a complex. When double-stranded DNA is added, the complex will bind to the matching genomic sequence to form a so-called 'triple-stranded' synaptic complex. This complex protects the cleavage site from methylation. As in the AC procedure, the methyltransferase and the RecA protein are removed after methylation, before the methylation-protected site is cleaved with the appropriate restriction enzyme.

As an alternative, the RecA complex can be used to protect specific restriction sites from restriction enzyme digestion, rather than from methyltransferase. This technique can be useful in some cloning procedures.

The RecA-AC/RARE technique has been used in various genome mapping experiments, for example to map gaps in human contiguous (**contig**) DNA and to map telomeres (7). The ability to cut genomic DNA at a few specific sites allows mapping large pieces of DNA by using pulsed-field gel electrophoresis and **Southern blotting** techniques to size DNA between two cleavage sites, or between a marker and the end of a telomere (7).

The RecA-AC/RARE technique is a useful technique for mapping and manipulating DNA and should continue to prove helpful in large-scale genome analysis studies of the future. One limitation to the technique is the number of sequences recognized by both a restriction enzyme and a methyltransferase. As more restriction enzyme/methyltransferase pairs are isolated or developed, the technique will be come even more useful.

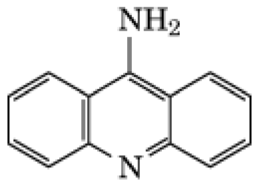
Acridine Dyes

Acridines are fused linear tricyclic aromatic molecules of planar geometry. Aminoacridine (Fig. 1) was originally developed as a topical antibacterial agent and is one of the most widely used and studied acridines. It is a strong base (pK_a 9.9) due to the resonant amino group and is largely ionized at physiological pH. Acridines are typical DNA-**intercalating** ligands, binding tightly but reversibly to double-stranded DNA by insertion of the aromatic chromophore between adjacent base pairs, with the long axis of the acridine parallel to the base-pair axis, ensuring maximum overlap in the binding site (1, 2). It was originally hypothesized by Brenner et al. (3) that acridine-induced mutations arise through the addition or deletion of a single base pair, an event described as **frameshift mutagenesis**.

Figure 1. Structure of the mutagen 9-aminoacridine.



9-Aminoacridine is a strong mutagen in the rII region of **bacteriophage** T4 (4), in the CI gene of lambda phage (5), at various loci in *Escherichia coli* (6), and at the hisC3076 locus in *Salmonella typhimurium* (7). This and related simple acridines cause frameshift mutagenesis, especially in monotonous runs of repeated sequences. In mammalian cells their activity is somewhat weak and variable. They appear not to be causing frameshifts (at least in the most commonly used mammalian assays), but are mutagenic through weak ability to break chromosomes (8).

Substitutions on the acridine ring profoundly affect the mutagenic characteristics of these compounds, which have been divided into seven subgroups according to their distinctive mutagenic characteristics (2). 9-Aminoacridine and related simple compounds form the first group, while proflavine and other 3,6-diaminoacridines form the second group. The 3,6-diamino groups increase DNA binding affinity, and these compounds resemble 9-aminoacridine in having frameshift mutagenic activity, but are also substrates for metabolic activation (9). They are also readily activated by visible light into other products that are mutagenic in the *Salmonella* mutagenicity test (Ames test) (10). Some of these compounds and also the third class of quaternized acridines have considerable affinity for mitochondrial DNA. The fourth group of acridines retain DNA intercalation activity, but also act as topoisomerase II (topo II) poisons (see DNA Topology).

Type II topoisomerases produce double-strand breaks in DNA during replication and transcription, permitting strand passage through the transient break, which is then resealed by the enzyme. The potent antitumor activity of 9-anilinoacridines of the fourth group, such as amsacrine (Fig. 2), is thought to relate to their ability to stabilize the cleavable complex formed between topo II enzymes and DNA, thereby leading to an accumulation of double-strand breaks (11). These DNA breaks also result in these compounds showing strong clastogenic and recombinogenic properties. A clastogen is a physical, chemical or viral agent that produces chromosome breaks and other chromosomal mutagenesis. The fifth group of benzacridines are characterized by a higher susceptibility to metabolic activation, primarily through oxidative mechanisms (12). Benzacridines are primarily base-pair substitution mutagens, producing a spectrum of mutagenic events that is fundamentally different from that produced by other acridines and in which the acridine ring plays only a minor role. The sixth group of acridines, epitomized by those originally developed in the Institute of Cancer Research, Philadelphia, and widely known as ICR compounds (13), all carry an alkylating moiety, usually a nitrogen mustard. These compounds are not only potent frameshift mutagens in various organisms, but also cause base-pair substitution events in mammalian cells (2, 14). Although the nitroacridines can be distinguished as a seventh group, they may alternatively be considered as a subgroup of the previous class, because they can act as either simple acridines or as alkylators, depending upon the position of the nitro substitution and the nitroreductase capability of the organism concerned.

Acrocentric Chromosome

An acrocentric chromosome has a single centromere that is localized at or near one end of the chromosome (acro = extremity). One of the most common forms of chromosomal translocation occurs when two acrocentric chromosomes fuse at the ends containing the centromeres (1). This is called a Robertsonian event (Fig. 1). This generally leads to the formation of a metacentric chromosome, where the new centromeric region appears at or near the middle of the new chromosome. Robertsonian events lead to a decrease in the apparent number of chromosomes. Much of the variation in the number of chromosomes in the members of a family or genus is related to this type of acrocentric chromosomal fusion. Whereas the number of chromosomal arms remain relatively constant, counting two for a metacentric chromosome and one for an acrocentric, the number of chromosomes can vary widely. For example, most dogs have either 32 to 38 or 18 to 21 autosomes (any chromosome other than the X- or Y-chromosomes), but 34 to 38 chromosomal arms. Those with the greater number of autosomes have larger numbers of acrocentric chromosomes (2, 3). In genomes whose karyotypes contain exclusively acrocentric chromosomes (e.g., that of the house mouse, *Mus musculus*), rapid chromosome identification can be achieved via whole-chromosome painting techniques, e.g., spectral karyotyping (4).

Figure 1. Robertsonian translocation occurs when two acrocentric chromosomes fuse to create a single metacentric chromosome.

Acrosome

The acrosome is an organelle of the spermatozoon that covers the apical part of the sperm head. This organelle comprises an outer acrosomal membrane, an inner acrosomal membrane, and plasma membranes. The acrosome plays an important role during the early stages of fertilization, in that the acrosome and its associated molecules mediate recognition of the egg to be fertilized. Although acrosome morphology varies with the species, the function of the acrosome and its contents as regulating elements during the early stages of fertilization are fairly similar among species. The acrosome contains **proteolytic** enzymes (see Proteinases) as well as proteins for binding to the zona pellucida and plasma membrane of the Egg (1). Therefore, the associated molecules of the acrosome have been proposed as targets for nonhormonal antifertilization agents.

1. Primary Ligands

The primary ligands are proteins that are located on or close to the acrosome; their function is to ensure that recognition between the gametes is species-specific. This is especially necessary in animals with extracorporal fertilization (eg, frog and sea urchin). On the surface of the acrosomal cap, there is a plethora of adhesion molecules (2), but their origin is not in all cases clear. Sperm adhesins become associated only upon ejaculation (3). Many of these primary ligands, such as galactosyltransferase (4), are lectins and bind to O-linked oligosaccharides and glycans of the ZP3 receptor of the oocyte's extracellular matrix, the zona pellucida (5, 6). Other proteins were discovered that induce metabolic events; a 95-kDa protein was detected that induces **phosphorylation** events (7).

One of the most fascinating events during the early stages of fertilization is the acrosome reaction . After the initial contact of the sperm with the zona pellucida of the oocyte, and under the influence of progesterone (8), a unique event called the acrosome reaction takes place, which is calcium-dependent (9). Although in mammals the acrosome reaction can be induced without zona pellucida glycoproteins, they act in a catalytic manner (10). The acrosome reaction involves exocytosis of the outer membrane, causes the formation of hybrid vesicles, and leads to exposure of the inner contents of the acrosome. In many invertebrates, such as starfish, sea cucumbers, or sea urchin, a polymerization event takes place that results in the formation of actin filaments. In mollusks, the actin filaments are already present in the unreacted spermatozoon and exposed on activation.

Recent investigations report the presence of the **inositol phosphate** system in mammalian sperm. It involves the activation of a sperm **receptor** that stimulates a **G-protein**. This activates phospholipase C, which cleaves subsequently phosphatidyl inositol diphosphate (PIP_2) into **diacylglycerol** and inositol triphosphate (IP_3). IP_3 triggers the release of calcium from intercellular stores, and diacylglycerol activates protein kinasekinase C, which is calcium-dependent. This causes proteins to be phosphorylated and leads subsequently to the acrosome reaction (11). Upon their exposure, the molecules within the acrosome become important for the fertilization process.

2. Secondary Ligands: Acrosin/Proacrosin

A major component of the inner acrosome is the protein proacrosin . This is the best-characterized molecule of those involved in the early stages of fertilization. It is important for local lysis of the zona pellucida and therefore plays a central role at the stage of sperm penetration. Proacrosin is stored as its inactive form, a zymogen. On raising the pH, or on contact with zona pellucida glycoproteins, the zymogen converts into its active proteolytic form, acrosin . This is accomplished by several intramolecular reorganizations (12). Proacrosin is a two-polypeptide chain molecule and, typical of serine proteinases, the heavy chain starts at residue Val24. Major alterations of the molecule involve proteolytic cleavage of the proline-rich C-terminal tail, cleavage of the light chain, and linkage to the heavy chain via disulfide bonds.

Proacrosin is a multifunctional protein; it does not act solely as a proteinase, but is also a fucose-binding protein (13). The molecule shows high binding affinity for fucoidan, heparin, and zona pellucida glycoprotein preparations (14). The primary mechanism of proacrosin binding to the zona pellucida is not only an interaction with carbohydrates, but involves positively charged amino acid residues of the proacrosin and negatively charged sulfate groups of the zona pellucida glycoproteins. **Homology modeling** of proacrosin revealed that the groove for binding to the zona pellucida contains loops in which the positively charged amino acids are located. The active site for proteolytic activity is located in the center, surrounded by the positively charged amino acids. The binding groove and proteolytic center appear to form a single reactive unit, even though they are located on different regions on the polypeptide chain. The proteolytic activity could be blocked without affecting proacrosin's binding characteristics.

The arrangement of the binding site and proteolytic center suggests two major tasks of the enzyme during fertilization. The molecule recognizes the zona pellucida specifically, binds to it, and digests it locally to promote sperm entry through the extracellular matrix. However, there must be further binding and proteolytic proteins involved in fertilization, as mouse **knockout strains** lacking the proacrosin gene did not produce infertile males (15); other molecules must be able to take over the role of proacrosin. On the other hand, male mice with a functionally active proacrosin gene demonstrated a significantly greater fitness in terms of reproductive success in a competition-mating experiment with the proacrosin knockout mice (16). Although proacrosin is the major compound of the acrosomal vesicle, there are further adhesion proteins. Fertilin , formerly designated PH-30, is a molecule that is involved in interactions between the sperm and egg (17, 18).

Actin

Actin is one of the most ubiquitous and conserved eukaryotic proteins. While actin was originally isolated and studied as part of the contractile apparatus of muscle (see Thin Filament), we now know that actin is found in virtually all eukaryotic cells and can be the most abundant protein present. Actin forms part of the cytoskeleton in nonmuscle cells and is involved in the maintenance of cell shape as well as cell dynamics and motility. The active form of actin is a helical polymer called F-actin (F for filamentous), assembled from monomeric subunits of G-actin (G for globular). Actin exists in a number of very similar isoforms (88% amino acid identity between yeast cytoplasmic actin and human muscle actin), and these isoforms display tissue, rather than species, specificity (1, 2). Thus, human cytoplasmic actin is much closer in sequence to yeast cytoplasmic actin than it is to human muscle actin. The actin monomer contains 374–376 residues, varying with the isoform, and is about 42k MW.

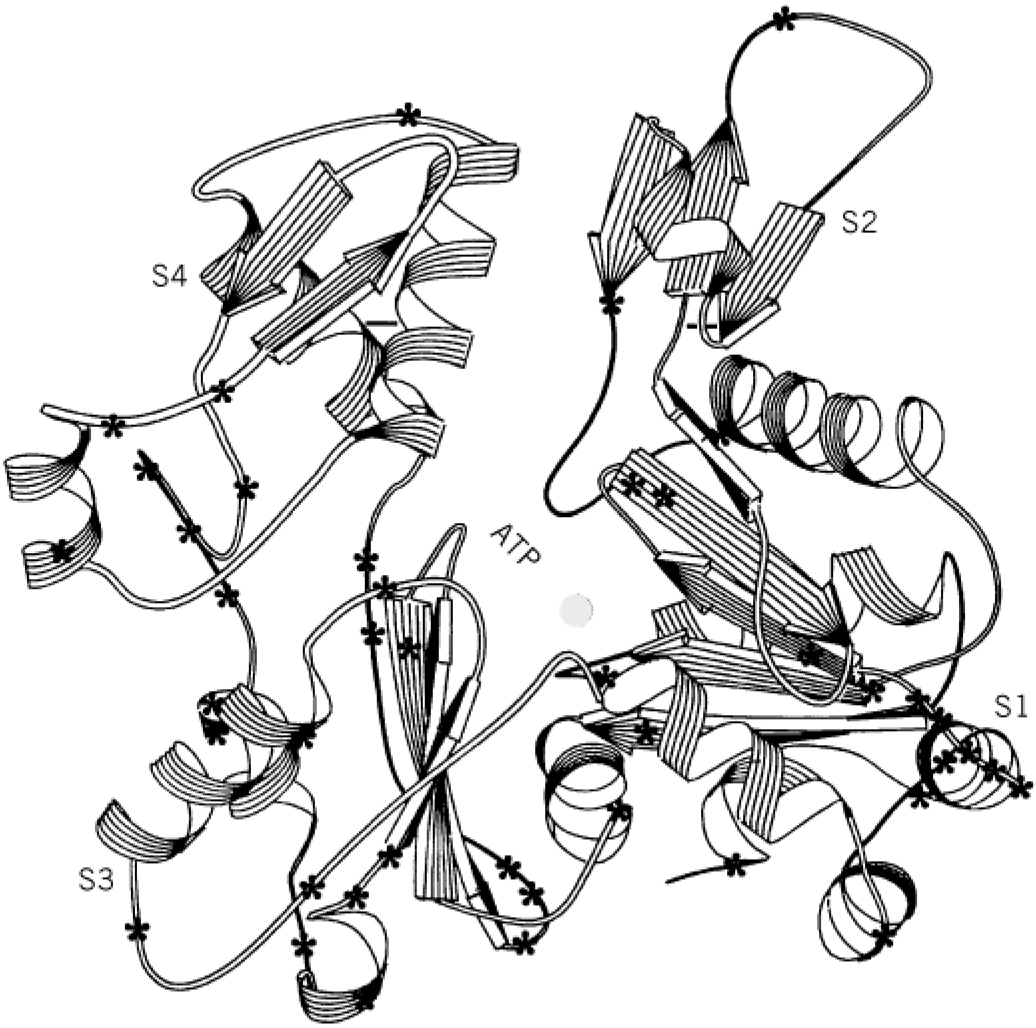
Actin interacts specifically with over 40 other proteins, and many of these interactions fall into separate classes. There are proteins that control the polymerization state of actin by nucleating, capping, or severing filaments [such as gelsolin, profilin, cofilin, and the b-thymosins (3-7)], proteins that crosslink actin filaments together into gels and bundles [such as a-**actinin**, villin, and fimbrin (8-10)], and proteins that regulate the interactions of **myosin** with actin [such as **tropomyosin**, **troponin**, calponin, and caldesmon (11), (see Thin Filament)]. In addition, many glycolytic enzymes bind actin, and it has been suggested that this provides spatial organization to metabolic processes via an association with the cytoskeleton (12). Other high-affinity interactions, such as between G-actin and the endonuclease DNase I (see DNase 1 Sensitivity) (13), do not lend themselves to simple explanations at this time.

Extensive biochemical, structural, and genetic studies have explored the properties of both G- and F-actin. The most detailed structural information exists for G-actin, since X-ray crystal structures have been obtained for complexes of G-actin with DNase I (13), gelsolin segment 1 (14), and profilin (15). The G-actin structure consists of two domains, each with two subdomains. These domains were originally called the “large” and “small” domains, but this terminology is not appropriate, as we now know that the “large” domain only contains 51% of the mass of the subunit. The N- and C-terminii are both located in the largest subdomain, subdomain-1. Between the two domains is a nucleotide-binding cleft, normally occupied by ATP in G-actin and ADP in F-actin, as well as the high-affinity metal-binding site. The subunit structure of G-actin is homologous to that of yeast hexokinase and the ATP-binding domain of HSC-70, a chaperonin, suggesting a common evolutionary origin for all of these proteins (16). It has been proposed that the bacterial protein FtsA has the same fold (17), which would indicate that FtsA is a prokaryotic ancestor of the eukaryotic actins. It has already been established that the bacterial FtsZ protein has a common structure with eukaryotic tubulins. Since neither hexokinase nor HSC-70 polymerize, it is evident that actin's ability to polymerize does not reside in any unique features of the secondary or tertiary structure, but rather evolved later. Thus, establishing that FtsA has a common subunit structure with actin will not, in and of itself, reveal any information about possible quaternary structures for FtsA.

Electron microscopic observations of F-actin (18-20) have been very useful in defining the orientation of the subunit in the filament, as well as revealing aspects of structural dynamics. X-ray fiber diffraction from oriented gels of F-actin has led to an atomic model for F-actin (21, 22), which provides a starting point for understanding the molecular details of the interactions of actin with many other proteins and ligands. However, many of the atomic details are still underdetermined by the method of fitting the monomeric structure into the filament, since the X-ray fiber diffraction pattern does not introduce all of the constraints needed. We thus have a general picture of the orientation of the subunit in the filament, but still lack information about many of the atomic interactions.

The subunit is oriented in the filament so that the two domains are nearly perpendicular to a plane containing the helix axis (Fig. 1). The resulting filament is about 100 Å in diameter, and subunits are spaced axially by a 27.3 Å rise along the filament axis. The change in the axial rise per subunit is less than .08 Å per subunit (<0.3%) when actin filaments in muscle are placed under full tension (23, 24), establishing that these filaments are relatively inextensible. Nevertheless, this amount of extensibility is enough to complicate the interpretation of muscle mechanics. Subunits are related to their axial neighbors by an ~167° rotation about the filament axis, giving rise to a 59 Å pitch left-handed helix (sometimes called the genetic helix). An interesting property of the actin filament is the ability of subunits to rotate within the helix (25), and it has recently been shown that an actin-binding protein, cofilin, can change the twist of the actin filament by 5° per subunit, without significantly changing the axial rise per subunit (7). The helical geometry of actin also gives rise to two right-handed long-pitch strands containing actin subunits related by a 54.6 Å axial separation. These strands typically have a mean pitch of ~700–760 Å (with the differences in the mean being due to the isoform, preparative conditions, associated proteins and ligands, etc.). The double-stranded character of these helices give rise to “crossovers” in projection at half of the pitch, or about 350–380 Å, but these crossover spacings can be variable due to the angular freedom within the actin filament (25, 26).

Figure 1. The G-actin subunit is shown by a ribbon representation (39) based upon the structure determined by X-ray crystallography (13). The degree of sequence conservation in actin is indicated by the fact that the only residues (45 out of 375) that differ between vertebrate striated skeletal muscle and yeast cytoplasmic actin are indicated by the asterisks. The four subdomains of actin are labeled S1–S4, and the most conserved part of the molecule is subdomain 2, with only 2 substitutions out of 38 residues between these two isoforms. The cleft between the two domains is occupied by ATP and a bound metal (indicated by the sphere). Adapted from Orlova et al. (40).



Every subunit in the actin filament is oriented with the same polarity, which gives rise to the overall polarity of the filament. This polarity has been described as the filament having a “barbed” end and a “pointed” end, based upon the morphological polarity that appears in electron micrographs when actin filaments are extensively decorated by the binding of proteolytic fragments of myosin, such as S1 or HMM (heavy meromyosin). This decoration generates a chevron appearance caused by all myosin molecules binding to the actin filament with an angle of about 45°. The morphological polarity has been related to a kinetic polarity apparent during *in vitro* polymerization, since the barbed end is the fast-growing end and the pointed end is the slow-growing end.

The helical symmetry of the actin filament is often described as 13/6 or 28/13, meaning that it has a helical repeat of 13 subunits in 6 turns of the 59 Å helix, or 28 subunits in 13 turns. The helical repeat is the distance that a subunit must be translated axially to bring it into register with another subunit. An ideal 13/6 helix would have crossovers every 355 Å, with each crossover containing a helical repeat, while an ideal 28/13 helix would have crossovers every 382 Å, with two crossovers per helical repeat. However, there is no reason to believe that the helical symmetry needs to be described as a ratio of small integers, as there is an infinitesimally small change in structure from a symmetry of 13/6 to one of 1301/600 (a rotation of ~0.1° per subunit), but the helical repeat changes from 355 Å to 35,517 Å! The actual symmetry of the actin filament is entirely defined by the interactions between one actin subunit and four nearest neighbors (–2 and 2 along the same long-pitch strand, and –1 and +1 on the opposite strand). In the absence of accessory proteins [such as **tropomyosin**, which binds to seven actin subunits along the same long-pitch strand (see Thin Filament)], all changes of state must be propagated by such local interactions. Nevertheless, many *in* *vitro* experimental observations have shown that pure actin (in the absence of accessory proteins) can have long-range cooperative interactions within a filament (20, 27-29).

The flexibility of the actin filament has been studied by many methods, including spectroscopy (30), light microscopy (31), and electron microscopy (32, 33). Most studies have suggested a persistence, or correlation, length of about 6–7 µm. This indicates that an actin filament much shorter than 6–7 µm can be treated as a rigid rod, while a filament much longer than 6–7 µm can be treated as a random coil. The persistence length does not suggest that a 6–7 µm filament is approximated well by a rigid rod, since an actin filament only 0.6 µm in length (one-tenth of the persistence length) will have a characteristic fluctuation of tangents at the two ends of about 25°.

Actin polymerization has been studied *in vitro* in great detail and is induced by raising the salt concentration. As for almost all other protein polymers in the cell, the assembly process involves the noncovalent binding of subunits to each other, such that every subunit (with the exception of subunits at the filament ends) is in the same environment. Probably more is known about the *in vitro* polymerization of actin than for any other protein polymer, but new findings suggest that the *in vivo* regulation of actin assembly involves the interactions with many other proteins and may be greatly different from what occurs *in vitro* (34). Polymerization can occur *in vitro* when the subunit concentration is above the critical concentration, which is the concentration of the monomer that would be at equilibrium with a population of polymers (see Treadmilling). Polymerization *in vitro* also requires that a monovalent salt, such as NaCl, be present at a concentration of ~100 m*M*, or a divalent salt such as $MgCl_2$ be present at ~1 m*M*.

Actin has a single high-affinity metal binding site, which has a greater affinity for Ca^{2+} than for Mg^{2+}. However, due to the much higher concentrations of Mg^{2+} than Ca^{2+} present *in vitro*, it is expected that this site will be occupied by Mg^{2+}. This has been shown experimentally to be true in muscle (35), where the Mg^{2+} concentration is three orders of magnitude higher than the Ca^{2+} concentration. Actin also has 5–10 lower affinity metal binding sites (36). The spontaneous nucleation of actin filaments is often the rate-limiting step in actin polymerization *in vitro*, since the subsequent growth of existing filaments can occur rapidly. Within the cell, however, there is good reason to believe that actin polymerization occurs under the control of other proteins which serve to nucleate and cap growing filaments, and it is possible that spontaneous self-nucleation of actin filaments may never occur.

Actin polymerization is also loosely coupled to the hydrolysis of the bound nucleotide. While almost all attention has been focused on the primary nucleotide-binding site, actin also has a second nucleotide-binding site with mM affinity (37). Since this site is likely to be occupied in cells such as muscle where there exists a millimolar concentration of ATP, it remains to be seen whether this second site plays a physiological role. It is known that the nucleotide hydrolysis is not required for polymerization, since G-ADP actin can polymerize, as can G-actin subunits containing nonhydrolyzable analogs of ATP. The role of ATP hydrolysis is to actually destabilize the filament (38), allowing for depolymerization to occur more readily. ATP hydrolysis lags behind the initial polymerization event and occurs once a subunit is part of the polymer. The cell therefore uses the energy of ATP hydrolysis to allow for the dynamic assembly and disassembly of actin filaments, in contrast to less dynamic components of the cytoskeleton, such as intermediate filaments. The energy of ATP hydrolysis can also be used to drive treadmilling, where there is a unidirectional flux of subunits through a filament.

Actin-Binding Proteins

1. The Actin Microfilament System

Actin was identified more than 50 years ago as an essential element of the force generating apparatus of muscle cells (1, 2). Together with myosin, tropomyosin, and a large number of other proteins, actin filaments constitute sarcomeres, which are ordered serially along contractile myofibrils (3, 4). In the mid 1960s, actin (5) and myosin (6, 7) were recognized as major structural components of the eukaryotic cytoplasm (8-10); for an early review of the field see (11). The unexpected observation that actin was the inhibitor of DNase I (12), and that the DNase inhibitor could be crystallized (13), led to the identification of the actin monomer-binding protein, profilin (14). The properties of profilin seemed to explain how unpolymerized actin could exist at high concentrations in cells without spontaneously polymerizing (15). It is now known that there are several other proteins controlling actin polymerization, and today the family of actin-binding proteins contains over 100 members including proteins that sequester actin monomers (profilins, thymosins), sever (gelsolins), depolymerize (cofilins), and cross-link (villin, fimbrin) actin filaments. Further characterization of the nonmuscle myosins (16), and an increased appreciation of the role of polymerization of actin suggests how cells can extend pseudopods and drag themselves along extracellular matrices (17, 18), and exhibit the high degree of motility seen on the surface of lymphocytes and in malignant cancer cells. This entry will describe general characteristics of actin-binding proteins, the analysis of which in many cases has reached the atomic level.

Actin is an obligatory component of all eukaryotes, and is one of the most highly conserved proteins during evolution. Its sequence has varied less than 10% during the last 1200 million years (19). In mammalian cells, six different isoforms are known, of which the muscle specific a-isoform and the nonmuscle b-isoform are the most studied [for review, see (20)]. On the basis of structural homology an actin-related protein, FtsA, which is involved in cell division, has been recognized in prokaryotes (21). Also, in eukaryotes, there are several actin-related proteins, ARPs (22).

Actin can be kept in a monomeric form only under low salt conditions or in the presence of actin **sequestering** proteins (review 20). Under physiological salt conditions, actin polymerizes into long filaments. In this form, actin participates in force generation and motile activity. The actin filament is polar, with a rapidly growing (+)-end (barbed end) and a slow growing (–)-end (pointed end). In the cell, actin filaments grow by addition of monomers at the (+)-end, which is located at the outer edge of cell surface protrusions: lamellipodia and filopodia. In the submembraneous zone all round the cell, actin filaments are organized into sheets and bundles held together along their lengths by a variety of crosslinking proteins, which differ in length and flexural rigidity.

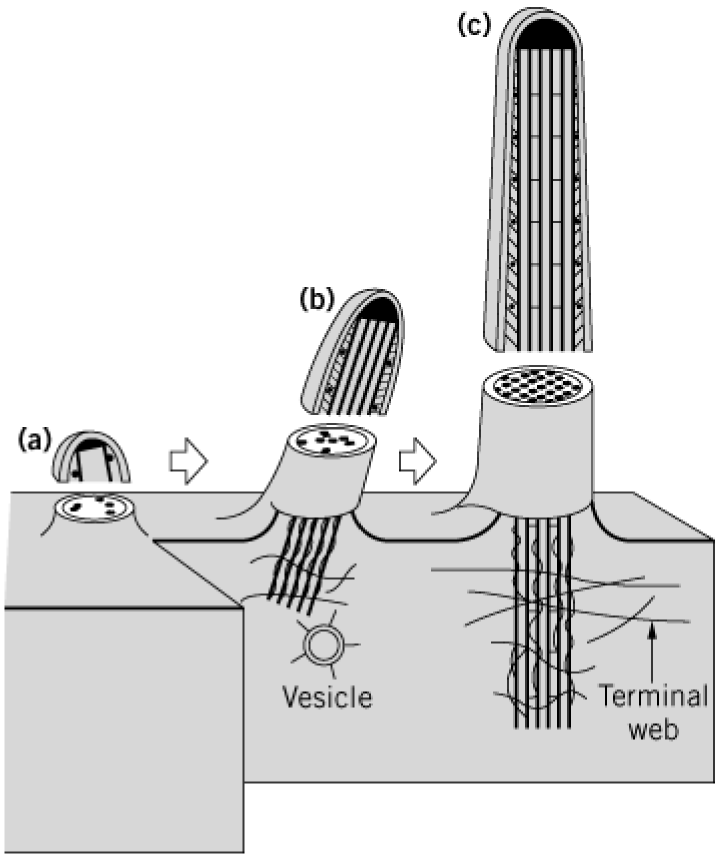
The myosins vary in structure; some are globular in shape, like myosin I, and do not polymerize, whereas others have a long a-helical, supercoiled, rod domain and can form filamentous superstructures in the cytoplasm (16). Together, actin and myosin transduce chemical free energy of adenosine trisphosphate (ATP) to mechanical work, not just in muscle cells, but in all eukaryotic cells. In different states of organization, the actomyosin system, is responsible for muscle contraction, cell locomotion, and cell division, and for many different local cellular transport processes (4). In nonmuscle cells, the actomyosin system is referred to as the microfilament system.

It is based on the organization of actin filaments, whose formation, organization and activity depend on the activity of a large number of actin-binding proteins, including myosin.

Microfilaments are present in particularly high concentrations in close apposition to the inner leaflet of the lipid bilayer (23-27), where they are directly or indirectly linked to cell surface proteins (receptors and adhesion proteins) continuously probing the extracellular environment. The lipid bilayer of the plasma membrane has been likened with “light machine oil” (28). It is an excellent electrochemical barrier, but it is the dense cortical weave of microfilaments which confers mechanical stability and deformability to the cell surface. Thus, the microfilament system can be viewed as an integral part of the physical barrier that separates the cellular contents from the outside world.

One of the first submembraneous actin-containing superstructures to be characterized was the red blood cell cortical network consisting of actin and the actin-binding proteins **tropomyosin**, spectrin and **band 4.1** (29). Linkage to the plasma membrane is provided by the spectrin-binding protein ankyrin, which binds to the transmembrane anion channel band III, and band 4.1 (an ERM protein, see below), which interacts directly with the transmembrane protein glycophorin. The adaptability of the shape of the red blood cell to the compressive forces present in the low-bore blood capillaries reflects the elastic properties of the spectrin:actin network. In the intestinal epithelium (30, 31, and refs. therein), microvilli on the apical surface of the cell are formed by tightly packed actin filament bundles stabilized by the actin crosslinking proteins villin and fimbrin (Fig. 1). The presence of nonmuscle myosin in these structures suggests that active movement may be involved in the resorptive process.

Figure 1. Structural organization of a microvillus. Among the simplest and best studied cell surface structures are the microvilli on polarized epithelial cells, especially those on cells of the intestinal epithelium. The majority of the proteins involved in the architecture of the microvillus have now been identified and characterized. Most of them are essential for the survival of the organism. In some cases their three-dimensional structure has been determined. It is still unclear how the assembly of the microvillus takes place and how it is controlled, how dynamic microvilli are, and what their contribution to uptake of nutrients is. The construction of a microvillus on apical surface of an intestinal epithelial cell is shown here. Many of the microvillar proteins also occur in other cell surface structures. An exception is villin, which is confined to the microvilli of a few cell types. In addition to villin, the major actin-binding proteins of the microvillar core are ezrin, fimbrin, and myosin-I. Drawing from Fath and Burgess 1995, *Curr. Biol.* **5**, 591–593.



Specializations of the membrane-associated actomyosin system are found in all sensory organs, ie chemomechanical transduction in the actomyosin system is essential to the ability of the organism to perceive perturbations in the environment. For instance, the cellular basis for the sense of hearing lies in the microfilament-rich stereocilia in the hair cells of the inner ear, which convert subtle changes in the ambient air pressure to electrical signals transmitted to the brain via nerve impulses (32). Similarly, the mechanosensory cells in the skin confer the sense of touch (33).

Macrophages, lymphocytes, and neutrophils, which are highly motile cells, exploit the full potential of the cortical microfilament system as they forcibly move through and along extracellular matrices. When macrophages contact foreign invaders, the versatility of the cell cortex allows them to adapt their own surface structures as they engulf the pathogen.

The process of cell migration depends on the coordination of four major events involving microfilament reorganization: extension at the leading edge of membrane lamellae and filopodia, attachment to extracellular structures via transmembrane adhesion molecules, development of intracellular tension, and release of trailing end attachments with retraction of trailing ends (18, 27, 34, 35). The protrusion of lamellae at the advancing edge is driven by polymerization of actin filaments at focal complexes containing their fast growing ends at the plasma membrane, and crosslinking of formed filaments (24, 25, 36, 37). Clustering of transmembrane adhesion proteins, integrins, gives rise to focal adhesion sites (Fig. 2) linking extracellular matrix proteins to bundled actin filaments on the inside of the plasma membrane (38). The importance of the focal adhesions in transmembrane signalling is emphasized by their association with kinases regulating signal transducing protein:protein interactions and enzymes generating second messengers controlling not only the microfilament system, but also gene transcription (39). Several actin-binding proteins are targetted to these sites, contributing to formation of the integrin:actin filament linkage. The association of linkage proteins like talin, tensin, and vinculin appears to be controlled by phosphorylation. Myosin is activated through Ca^{2+}-dependent processes (40, 41), and the regulated deployment of myosin molecules leads to the generation of the forces needed for cell motility and other translocation processes. Release of adhesion at the trailing end of a migrating cell is controlled by Ca^{2+} and is followed by endocytosis of the integrins and their recycling to advancing cell edges (42). Used filaments are depolymerized, a process which involves the actin monomer- and filament-binding protein ADF (or cofilin) (17), and sequestered forms of unpolymerized actin are reformed (see Fig. 3).

Figure 2. Proteins of focal adhesion sites. Adherens junctions comprise both cell:extracellular matrix contacts, exemplified by focal adherens in tissue cultured cells, and intercellular junctions such as the zonula adherens between epithelial cells. The regulated assembly of adherens junctions is essential to a diversity of cellular functions including wound healing, anchorage-dependent cell proliferation, adhesion, and migration. Assembly of an adherens junction may be initiated when an integrin of the b1 subfamily binds to its extracellular matrix ligand, when a cadherin recognizes an identical molecule on a neighboring cell, or when a growth factor activates its receptor. These ligand–receptor interactions result in establishment of a physical connection between the extracellular ligand and the actin cytoskeleton. Efforts to elucidate these linkages have implicated vinculin as one of the connecting molecules in a chain that involves binding of the b1 subunit of integrin to talin, talin to vinculin, vinculin to a-actinin, and a-actinin to filamentous actin. It is now known that vinculin also can bind directly to actin filaments. How the initial ligand–receptor interactions trigger recruitment and organization of the multiple proteins found at an adherens junction is unknown, but recent evidence suggest that the activities of tyrosine kinases, tyrosine phosphatases, protein kinases and members of the Rho family of small GTPases are involved. (Drawing from M. C. Beckerle (1997) *Bioassays* **18**, 949–957)

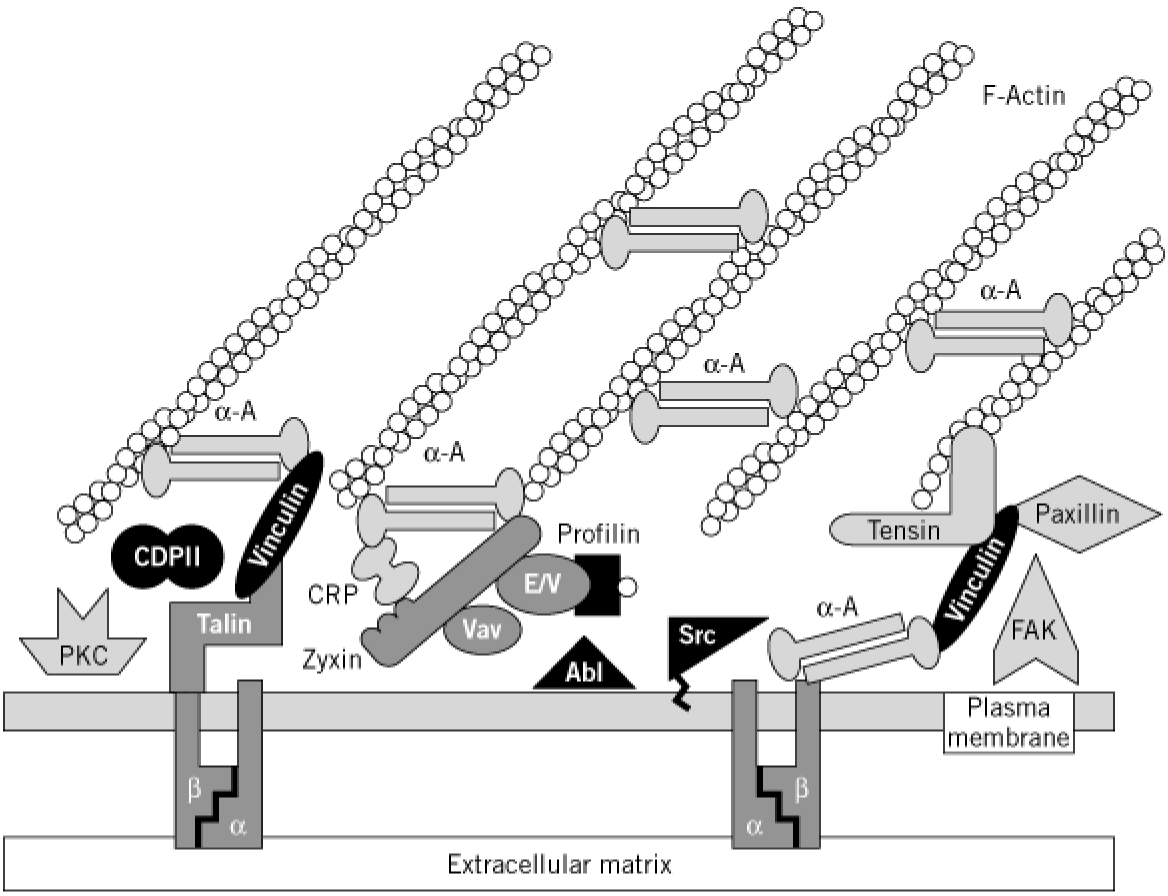


Figure 3. Links between the phosphatidylinositol and the cell motility cycles. Binding of growth factors like platelet-derived growth factor and epidermal growth factor to their cognate receptors activate the kinases activities of the receptors resulting in phosphorylation of a number of tyrosines on the cytoplasmic part of the receptor. This leads to activation of the signal transduction elements Cde42, Rac and Rho which control outgrowth of filopodia, membrane lamellae and the formation of stress fibers, respectively (64). There is only little information so far regarding the

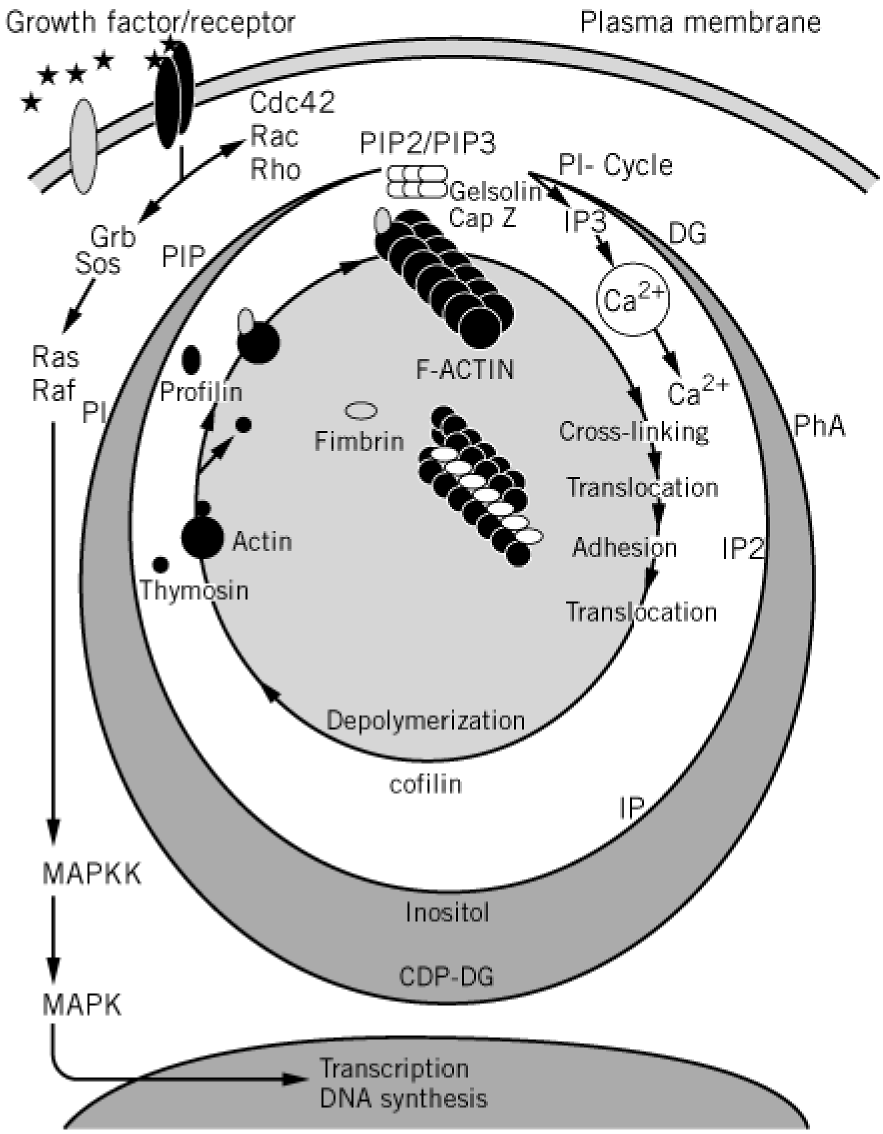
mechanism of activation of these small GTPases and how they relay the signal to the phosphatidylinositol (PI) cycle. Receptor activation is followed by an immediate increase in the activity of kinases that form PtdIns 4,5-bisphosphate (PIP2) and PtdIns 3,4,5-trisphosphate (PIP3). Profilin, gelsolin, CapZ, a-actinin, vinculin, the ERM family of proteins all bind these phosphoinositides, which influence their activity in the microfilament-based cell motility cycle (CM-cycle). Phosphoinositides binding to CapZ or gelsolin unblock the (+)-end of actin filaments allowing incorporation of profilin:actin at that site. Profilin:actin is then dissociated and the actin monomer becomes stably incorported into the growing filament. Cross-linking of filaments by proteins like fimbrin gives rise to the ensembles of filaments seen in membrane lamellae and filopodia which function together with myosin in the contractile phase of cell motility. Calcium ions play important roles in regulating both the actomyosin interaction and the depolymerization of actin filaments. The depolymerization is facilitated by the dephosphorylated form of cofilin and the actin monomer sequestering proteins thymosin and profilin (rev. 163). Another branch of signal transduction from the growth factor receptor activates the gene program that leads to DNA synthesis and cell division. Grb and Sos are small proteins acting as signal transduction elements activating the small GTPases Ras, which in turn activates the serine/threonine kinase Raf. The further signalling pathway is complex invlving mitogen activated protein kinases, MAPKK and MAPK (for review, see *Cell* 1998, **95**, 447–450). Other abbreviations: IP3, inositol trisphosphate; IP2, inositol bisphosphate; IP, inositol monophosphate; DG, diacylglycerol; Pha, phosphatidic acid; CDP-DG, cytidyldiphosphate-diacylglycerol; PI, phosphatidylinositol.



Thus, the combined action of protein factors controlling polymerization, crosslinking and tension development in the cell cortex is initiated by transmembrane signalling. Controlling the timing and position of sites of polymerization at the cell surface is a potent means of regulating shape change. An astonishing variety of well-ordered, yet dynamic, structures are possible, reflecting the mechanical properties and specificities of the different kinds of actin bundling proteins and junctional connectors. Their timed and coordinated formation prevents the appearance of random rigid networks, which would be incompatible with the well-orchestrated movements seen.

2. Signal Transduction and Restructuring of the Actin Microfilament System

Cell surface receptors continuously monitor the extracellular milieu and pass signals to the cytoplasm by generating second messengers of various kinds which either stimulate or inhibit the activity in the microfilament system. Addition of growth factors to serum-starved cultured cells causes the immediate outgrowth of membrane lamellae and filopodia, events that depend on the polymerization and organization of actin. About 60 seconds later, there is a generalized increase in motile activity of the cells, including restructuring of the actin-containing stress fiber system and translocation of the cell. Observations of this kind have been made both with epidermal growth factor (EGF) (43) and platelet-derived growth factor (26). In the case of EGF, a significant fraction of the receptors was found in direct association with microfilaments, and a binding site for actin on the receptor has been identified (44, 45).

The phosphatidylinositol-cycle (PI cycle) is coupled to activation of the microfilament system (46). Ligand-induced, receptor-mediated activation of kinases generate phosphatidyl inositol 4,5-bisphosphate (PtdIns 4,5-P2) and phosphatidyl inositol 3,4,5-trisphosphate (PtdIns 3,4,5-P3) (47, 48), both of which affect the activity of actin-binding proteins. Profilin, gelsolin, a-actinin, vinculin, ERM family of proteins, and myosin all bind PtdIns 4,5-P2, and/or PtdIns 4,5-P3. Stimulation of platelets with low concentrations of thrombin causes a transient increase in polyphosphoinositides during the first 10 sec (49). This is accompanied by an equally transient transformation of unpolymerized actin into filaments. This initial polymerization is over in about 10–20 sec (49). The immediate precursor for this polymerization appears to be profilin:actin, since increased amounts of free profilin appears in cell extracts after stimulation. Within 2 min, these filaments become organized into supramolecular structures by the action of crosslinking proteins stabilizing the protrusions seen on the platelet surface (50-52). Simultaneous activation of phospholipase Cg-1 results in the hydrolysis of PtdIns 4,5-P2, releasing the second messenger inositol trisphosphate, which causes release of Ca^{2+} ions from intracellular Ca^{2+} stores (53). Calcium ions are involved in activation of the actomyosin interaction and thereby force generation.

In addition to connections to the phosphatidyl inositol signal transduction cycle, the microfilament system is linked to the cAMP-dependent signalling system. Agonists causing increasing levels of cAMP often inhibit actin polymerization (54). A connection between adenylate kinase pathways and the actin monomer-binding protein profilin was suggested by genetic studies showing that increased levels of profilin could compensate for the deletion of the C-terminal domain CAP of the cyclase (55, 56). In platelets, the actin-binding protein, vasodilator-stimulated protein VASP is phosphorylated by cAMP- and cGMP-dependent kinases (57), which then correlates with the inhibition of microfilament reorganization.

The proteins involved in controlling the organization and function of the microfilament system are part of multiprotein signal transduction complexes. Several of these proteins have been identified as products of protooncogenes, ie proteins which in mutated form may cause cancer (58, 59). In these signal transduction complexes the proteins are linked together by adaptor modules in linker proteins such as SH2, SH3, and WW domains which recognize specific features of short polypeptide stretches, especially phosphotyrosine-containing and polyproline sequences (60). An example is the oncogene product **Vav** that has several such binding motifs suggesting how it links signal transduction at the cell surface to restructure the cortical cytoplasm (61). Vav possesses many of the homology domains commonly found in signal transduction complexes, comprising a phosphotyrosine-binding SH2 domain, two proline-rich peptide recognizing SH3 domains, a phosphatidyl inositol 4,5-bisphosphate recognizing PH domain, a guanine nucleotide exchange factor DH-domain, two cysteine-rich nuclear transcriptionally important LIM domains, and an actin-binding calponin homology domain. The clearest demonstration that these functional linkages actually lead to nuclear transcription is that the production of Interleukin-2 (IL2) requires Vav-dependent actin cap formation in activated T-cells (62, 63).

Outgrowth of filopodia and membrane lamellae, and the formation of stress fibers, which are manifestations of the activation of the microfilament system by different kinds of ligand:receptor interactions, all depend on the activation of members of the Rho subfamily of small GTPases for their control. The small GTPase Cdc42 appears to control formation of filopodia, Rac controls membrane lamellae and Rho stress fibers (64). There is only little information so far as to how the receptor-mediated transmembrane signal is relayed to the GTPases and what their downstream targets are. It has been shown with permeabilized platelets that ligation of the thrombin receptor, and activated Rac, uncap actin filament (+)-ends through phosphoinositide synthesis (65). Some of the microfilament-controlling, signal transduction elements mentioned below interact with small GTPases. Interestingly, moesin (see below), an actin-binding protein linking actin filaments to transmembrane receptors, is required for Rho and Rac effects on the actin filament system (66).

VASP belongs to a growing collection of related proteins that are involved in stimulation of assembly of actin filaments *in vivo* (67-69). In moving cells, it is found in highly dynamic membrane regions and in integrin-rich adhesion plaques. Molecular cloning of VASP has established that it has both a central proline-rich core, which interacts directly with profilin (68, 70), and an actin-binding site. In cells, the primary site of growth of actin filaments is thought to be at advancing cell edges, and profilin:actin heterodimers are believed to be guided into this site by VASP (71). High concentrations of VASP appear to be targetted to focal adhesion sites by zyxin (72). Zyxin also binds a-actinin and Vav suggesting that orderly assembly of crosslinked actin networks can proceed at these locales. In addition to binding profilin and zyxin, VASP binds to the SH3 domains of the src-family of protein kinases (69), thus integrating signal transduction via phosphorylation with the ordered assembly of cortical structures in locally specialized sites (63). VASP and vinculin complexes can be immunoprecipitated out of cell extracts with either antivinculin or antiVASP antibodies, and recent experiments have demonstrated that the interaction between the two proteins is enhanced by PtdIns 4,5-bisphosphate binding to vinculin (73).

VASP has come to prominence owing to its relevance to the understanding of the movement of the bacterium *Listeria* through the host cell cytoplasm (74). *Listeria* expresses a proline-rich protein on its surface called ActA (zyxin-like), which binds to the modular proline-binding SH3-domain of VASP. Apparently, VASP can attract profilin:actin complexes to sites of polymerization on the surface of the bacterium, generating a propulsive force. There are many examples of pathogenic microorganisms that have acquired host cell genes that code for proteins that modulate the behavior of the microfilament system for the purpose of invasion, locomotion in the cytoplasm, and cell-to-cell spreading.

WASP is a multidomain, actin-binding protein, which is defective in patients afflicted with Wiskott-Aldrich syndrome (75, 76), a disease characterized by severe thromifocytopenia and immunodeficiency. WASP is specific to hematopoietic cells, which in case of WAS have a paucity of surface filopodia and other shape abnormalities (77). The small GTPases Cdc42 and Rac bind directly to WASP (78-80). WASP is also a binding partner for Src family of protein tyrosine kinases (81).

A protein homologous to WASP, N-WASP, is more widely distributed. N-WASP is concentrated at nerve terminal regions in the post synaptic density, and coexpression of Cdc42 and N-WASP induces extremely long actin-based filopodia in cells (82, 83). Its involvement in the formation of membrane lamellae and filopodia may be controlled by phosphoinositides in the plasma membrane. It contains a pleckstrin homology PH domain and a cofilin homology domain. Furthermore, N-WASP has been shown to be essential for the actin polymerization-dependent movement of the bacterium *Shigella flexneri* (84).

WIP is a recently discovered WASP interacting protein that is important for cortical actin assembly (85). WIP contains both profilin- and actin-binding regions, which like in VASP, are near each other in the protein sequence suggesting that they constitute the binding site for a profilin:actin heterodimer to be added to a growing actin filament. The small signal transduction GTPase Cdc42 binds to WASP (78, 79), but not to WIP. Thus, WIP function may be regulated by Cdc42 via WASP. Stimuli that activate Cdc42 may target the WASP-WIP complex to the actin filament system via interactions between the WH1 domain of WASP and the proline-rich ABM1 motifs of structural proteins such as zyxin and vinculin. The presence of SH3 binding motifs in both WIP and WASP, and the capacity to bind to the adaptor protein Nck (86), suggest that the WASP-WIP complex couples additional signaling pathways to the actin filament system.

Formins are profilin and actin-binding proteins from *S. cerevisiae*. They direct the determination of cell polarization and cytokinesis (87 for refs.). In response to a-mating factor, the formin Bni1p forms complexes with the active form of Cdc42, actin, profilin, and actin associated protein Aip3p (88-90). These proteins localize to the tips of mating projections suggesting that the formin is a target for Cdc42, linking the pheromone response pathway to activation of the actin system.

The formin family of proteins is also important in limb and kidney development in vertebrates (91). Mutations in formins lead to defects in the contractile ring formation during cytokinesis, causing the appearance of multinucleated cells. Formins are localized both in the cytoplasm and the nucleus of the cells. FH-proteins, defined by the presence of 'formin homology' regions, are important for a number of actin-dependent processes, including polarized cell growth and cytokinesis. They are large, probably multi-domain, proteins and their function may in part be mediated by an interaction with profilin.

IQGAP is yet another actin-binding, multidomain, regulatory protein (92). It was originally described as a 190-kD protein with extensive sequence similarity to the catalytic domain of RasGaps (91). These proteins control the activity of small regulatory GTPases by stimulating their GTPase activity. Subsequently an IQGAP2 was described as a liver-specific protein with a 62% homology to IQGAP1 (93). However, so far no GAP activity has been found in relation to the GTPases examined. Both IQGAPs have several copies of a ca 50 amino acid long internal repeat (IR), a single WW (SH3-like) domain presumably binding to proline-rich sequences, a number of calmodulin-binding IQ motifs, and a putative actin-interacting calponin homology CH domain. In transient transfection of COS-7 cells with epitope-tagged Cdc42, it was demonstrated that IQGAP is present in the advancing lamellae of motile cells, and a major *in vivo* target of activated Cdc42 (94). The IQGAP1 binds to filamentous actin *in vitro* via its N-terminal domain and cross-links actin filaments in a Cdc42-dependent manner (95). Recently IQGAP1 was implicated in the regulation of E-cadherin-mediated cell-cell adhesion (96).

In fission yeast, *Schizosaccharomyces pombe*, the rng2 gene codes for an IQGAP-related protein, rng2p. The rng2p is located in the actomyosin ring and the spindle pole body and is required for the assembly of the actomyosin ring at cytokinesis (97).

Paxillin is not known as an actin-binding protein, but it is involved in the control of the microfilament system at the adhesion contacts. It was detected as a 68-kD phosphotyrosine-containing protein in RSV-transformed cells, and was later purified from smooth muscle cells (98, 99). Many features of paxillin suggest that it functions in signalling events at the adhesive membrane. It is concentrated at focal adhesions, and it is tyrosine phosphorylated in response to extracellular matrix binding and cell transformation. It binds *in vitro* to the elongated tail domain of vinculin, and thereby links vinculin to the SH3 domain of the $pp60^{csrc}$, a component of focal contacts. Integrins, which are the principal transmembrane proteins at these sites, do not seem to bind directly to paxillin, and paxillin does not seem to bind either a-actinin or actin, but there is evidence for direct association of paxillin to growth factor receptors. Adhesion of cells to an extracellular matrix like fibronectin or laminin via transmembrane integrins results in increased tyrosine phosphorylation of paxillin, and a similar increase in phosphorylation takes place in connection with clustering of integrins in the plane of the membrane with antibodies. This phosphorylation appears to be caused by activation of the focal adhesion-associated tyrosine kinase, pp125^{FAK}, and tyrosine phosphorylation of paxillin and pp125^{FAK} initiated by cell adhesion is accompanied by the appearance of organized actin-containing stress fibres. Mutagenesis of paxillin has identified one of the paxillin LIM domains as being responsible for targetting this protein to focal contacts (100)

Zyxin is a low-abundance phosphoprotein localized at sites of cell-substratum adhesion in fibroblasts (72). It has an architecture of an intracellular signal transducer with a proline-rich domain, a nuclear export signal, and three copies of the LIM motif. LIM is a double **zinc finger** domain found in many proteins that play central roles in regulation of cell differentiation. Zyxin interacts with a-actinin, members of the cysteine rich protein CRP family, proteins that display Src homology 3 (SH3 domains) and Vasp/Ena family members, which in turn bind to both actin and profilin. Zyxin and its partners have been implicated in the spatial control of actin filament assembly as well as in pathways important for cell differentiation. Based on its repertoire of binding partners and its behaviour, zyxin is thought to serve an organizing centre for the assembly of multimeric protein machines that function both at sites of cell adhesion and in the nucleus.

In summary, the major signal transduction pathways and mechanisms of activation have been shown to be linked to the changes in the dynamic restructuring of the actin cortex: the phosphatidyl inositol cycle and the cAMP second messenger systems and the small GTPase coupled signal transduction mechanisms. All of this points to the growing realization that cytoplasmic signal transduction and transcriptional events in the nucleus are so interwoven that discussions of sequential control by one system or the other are oversimplifications. The idea that actin cortical movements are "downstream" events of "upstream" effectors is similarly unjustified, since actively motile cells are required for the generation of the signal itself.

There are perplexing aspects of polymerization-based propulsion of bacterial pathogens, and by implication filopodial extension. WASP and N-WASP have actin-binding sequences. It is not clear what the role of these proteins is in the regulation of actin polymerization at focal growth sites. It is known that the polar actin filaments are oriented such that their fast growing ends are "pushing" against the moving bacterial wall, or against the membranes of the advancing edges of lamellipodia and filopodia. Actin-binding proteins such as WASP are anchored in these nascent growth complexes (to ActA in the case of *Listeria*). The problem is to explain what happens when an incoming actin monomer is presented as a profilin:actin precursor to the end of the growing filament, since it would appear to be blocked by WASP. Another problem is to account for the free energy of ATP hydrolysis that is made available by the actin polymerization reaction.

3. Further Links of Actin Filaments to the Extracellular Matrix

Cortactin is the name of two related proteins p80 and p85, which cross-link actin filaments close to the plasma membrane. Cortactin was first recognized as a substrate for tyrosine-phoshorylation in pp60^{src}-transformed cells, but its presence has also been demonstrated in a variety of nontransformed cells (101). Cortactins have internal repeats of 37 amino acid residues in the N-terminal end of the molecule, which are necessary for their binding to actin filaments. In the C-terminus there is an SH3-domain, and preceding that in the sequence there are proline and serine/threonine rich regions. These latter parts of the molecule are not needed for actin-binding, and their functions remain to be elucidated.

In non-transformed cells, cortactin is normally phosphorylated on serine and threonine, but becomes transiently phosphorylated on tyrosine in response to growth factor stimulation, and on transformation by activated cSrc. In platelets, cortactin becomes transiently tyrosine-phosphorylated in reponse to stimulation with thrombin. However, tyrosine phosphorylation of cortactin does not appear to affect its ability to bind to actin filaments, although it does influence its localization to the cortical actin filament system.

Stimulation of cultured cells with various growth factors and platelets with thrombin results in translocation of cortactin into the actin filament system of advancing lamellae and filopodia (102, 103). Activation of fibroblast growth factor receptor-1 results in an association of the activated receptor with cSrc, and a correlated association of cortactin with SH2 domain of cSrc. The redistribution from the cytoplasm into advancing lamellae (ruffles and lamellipodia) appears to depend on the Rac-1-induced activation of the serine/threonine kinase PAK1, a downstream effector of Rac1 and Cdc42 (104). These GTPases are involved in the control of kinases in the phosphatidyl inositol signalling pathway, and there is evidence that PtdIns 4,5-bisphosphate could be involved in the association of cortactin with the activated microfilament system (105).

Eps8 is a putative actin-binding protein which resembles cortactin in its distribution in the cell (106). It has an unusual Src homology-3 domain in the carboxy terminus, formed by an intertwined dimer of Esp8 molecules which may affect its peptide specificity. Eps8 is mostly localized in the perinuclear region. However, on stimulation of cells with growth factors, it accumulates in the peripheral cell extensions, where it is found colocalized with cortactin and filamentous actin. The Eps8 pool associated with newly formed lamellipodia and membrane lamellae appears to be mostly detergent-insoluble, as is the tyrosine phosphorylated population of Eps8 molecules generated by activation of vSrc kinase, suggesting Eps8 recruitment to specific sites during cell remodeling.

Ezrin, radixin, moesin (ERM) belong to the band 4.1 superfamily on the basis of their homology to the erythrocyte band 4.1, a protein that connects the actin/spectrin network to the erythrocyte membrane protein glycophorin C (31, 107, 108). Like cortactin, the ERM proteins appear to play structural and regulatory roles in stabilizing specialized organizations of actin filaments in connection with the plasma membrane both during development and in adult tissues. They are generally present in microvilli, filopodia, and membrane ruffles, sometimes together, but more often differentially distributed between different types of cells. They link transmembrane proteins with the cortical actin filaments, a process governed by signal transduction involving the Rho-GTPase (109). Ezrin has been shown to bind specifically to nonmuscle b-actin with high affinity (110).

The N-terminal domain of ezrin associates with plasma membrane components, and the C-terminal half connects these structures with the submembranous actin filaments. Purified ezrin exists in an inactive conformation that requires activation to expose sites that allow it to associate with the membrane components and with actin filament (107). It has been shown that binding of ezrin to the transmembrane hyaluronan receptor CD44 (111) requires activation of ezrin by PtdIns 4,5-bisphosphate binding to the N-terminal domain of ezrin (112-114). These are not the only transmembrane proteins binding ERM, since ERM proteins have a membrane location also in cells that do not express CD44. It is now known that ERM proteins, in addition to CD44, also bind to intercellular adhesion molecules, ICAM-1 and ICAM-2. A positively charged amino acid cluster of CD44, CD43, and ICAM2 positioned close to the lipid bilayer has been implicated in the binding (115).

A group of phosphorylated, 50–55 kDa, ezrin-binding protein has been purified from human placenta and bovine brain by affinity chromatography on immobilized N-terminal domains of ezrin or moesin (31). Isolated EBP50 has two peptide-binding PDZ domains in the N-teminal half of the molecule with capacity to bind to cytoplasmic tails of transmembrane proteins. The EBP50 can be coprecipitated with ERM and may serve to bind ERM members to one or more integral membrane proteins.

Cells opened up by the use of the detergent digitonin are still amenable to activation with non-hydrolyzable analogues of GTP. Addition of guanosine 5′-O-(3-thiotriphosphate), GTPgS, to such permeabilized cell models induces assembly of both actin filaments and focal adhesion complexes through activation of endogenous Rho and Rac (66). The sensitivity to GTPgS is lost after a few minutes of incubation, but can be restored by the addition of the actin-binding protein moesin indicating that moesin is required for the effect of Rho and Rac on actin filament system. This is an important step towards the resolution of the signal relay which initiates the reorganization of the microfilament system.

Talin is an elongated, flexible actin-binding protein first recognized in smooth muscle (116, 117) and platelets (118, 119). It is present in focal contacts in tissue cultured cells, in adhesion plaques formed by activated platelets, in myotendinous junctions, and in dense plaques of smooth muscle, but is absent from cell:cell interaction sites (for refs, see 38). In motile cells talin is present in membrane ruffles. It is a major protein in platelets constituting more than 3% of the total protein. In response to activation, it is redistributed to the actin-rich platelet cortex (120). Thus talin is clearly of central importance for the association of actin filaments to membrane components to sites where cells make close contact with extracellular matrix proteins, and it has been shown to interact with the cytoplasmic domains of transmembrane b1-integrin (116, 121).

Talin has a molecular mass of of 270 kD as estimated from the gene sequence (122). It is about 60 nm in length, and appears to be composed of a series of globular domains as judged by electron microscopy (123). In solution, it forms homodimers by antiparallel association of the monomers. It binds to integrin, vinculin, and actin *in vitro*. There are reports that talin can nucleate, cap and cross-link actin filaments, and that its activities may be controlled by phosphorylation by both serine/threonine and tyrosine kinases (124, 125). An N-terminal domain of talin is homologous to ezrin (122), and may be the part of the molecule which associates with membrane lipids. The larger C-terminal domain contains the binding site for vinculin (see (38) and (125) for further refs.). Disruption of the talin gene in embryonic stem cells leads to a disturbance in the formation of vinculin and paxillin-containing focal contacts and cell spreading (126). The talin (–/–) cells do form embryoid bodies, and notably two morphologically distinct cell types have been observed that were able to spread and form focal adhesion-like structures with vinculin and paxillin on fibronectin. Thus, although talin was essential for the expression of b1-integrin, a subset of differentiated cells managed without it. What substitutes for talin in these cells is unclear.

Vinculin is a 117-kD, actin-binding protein found concentrated at all sites of attachment of filamentous actin to transmembrane components of adherens junctions (38, 127-131). At these sites, it enters into multiple interactions with other proteins at the cytoplasmic face of the contacts. It is critically required as a structural component in the formation of the junctions. On ligand-induced clustering of integrins, vinculin is recruited from the cytoplasm to sites of integrin-ligand interaction, where it is a substrate for tyrosine phosphorylation by $pp60^{src}$.

There is electron microscopic evidence that the vinculin molecule can attain different conformational states. It is found either as a compact, globular molecule, or it is unfolded into a globular head with an extended tail (132-134). In the compact globular state, its actin-binding capacity is masked by an intramolecular association of the 95-kD head and 30-kD tail domains. The actin-binding site can be exposed by binding of acidic phospholipids to the protein suggesting that the affinity of vinculin for target molecules is regulated by modulation of the head-to-tail interaction, and that this may be used in the control of the assembly of adherens junctions (73, 135). The phospholipid PtdIns 4,5-bisphosphate binds to two descrete regions of the vinculin tail, disrupts the intramolecular head-tail interaction and induces vinculin oligomerization. The binding of PtdIns 4,5-bisphosphate to vinculin also enhances the association of vinculin to VASP the actin- and profilin-binding protein present in focal adhesion sites. The C-terminal tail region contains a binding site for the focal adhesion protein paxillin (136). Furthermore, vinculin has been identified as part of the cadherin-catenin junctional complex (137-139).

Tensin is a dimer of two 200 kD polypeptide chains. It is found in different types of cell contacts, including focal adhesions, zonula adherens, intercalated discs, and myotendinous and neuromuscluar junctions (140-143). It contains three distinct, actin-binding sites per monomer and appears to cap as well as cross-link actin filaments. Tensin also binds vinculin and possibly tyrosine kinase receptors through a Src homology 2 (SH2) domain (144). It has been suggested that a tensin dimer with its 6 actin-binding sites might wrap around the end of an actin filament, and bind it to a tyrosine kinase receptor through its SH2 domain. Induction of the formation of a focal contact, by the binding of extracellular ligands to integrins, causes tensin to be phosphorylated on tyrosine. Insertin, an actin-binding protein suggested to be involved in the actual incorporation of monomers into filaments, has been recognized as a proteolytic breakdown product of tensin (145).

4. Proteins Controlling Polymerization of Actin

DNase I (mw 31 000) was the first actin monomer-binding protein found (12). However it is doubtful whether DNase I plays a role as an actin monomer-binding protein in the cell. Since the enzyme is produced by acinar cells in the pancreas and secreted into the duodenum, it has been thought of as a digestive enzyme. However, intracellular forms of the enzyme have been observed, and there is evidence that it might be involved in programmed cell death, apoptosis. (146).

The crystallization of DNase I was reported in 1948 by Kunitz (147). The same year Laskowsky and collaborators described the presence of a proteinaceous inhibitor in tissues from vertebrates (148, 149). Two DNase I inhibitors (I and II) were isolated and crystallized in 1966 (13, 150). They were shown to form gelifying high molecular weight aggregates. Searching for the identity of the inhibitors eventually led to the finding that actin was the ubiquitous inhibitor of DNase I (12). Analysis of the crystals of the DNase I inhibitor II revealed that they contained actin together with an equimolar amount of a small protein, now known as profilin (14, 15). Later, the inhibitor I and II were identified as profilin in complex with g-actin and b-actin, respectively (151).

DNase I is a glycoprotein. It forms a stable 1:1 complex with monomeric actin, and when mixed with equimolar amounts filamentous actin, it causes depolymerization of the filaments and formation of the 1:1 complex with actin (152-154). Kabsch and coworkers provided the first insights into the structure of actin by solving the structure of the DNase I:actin complex (155; see special entry on actin). The high resolution structure of DNase I alone and complexed to an oligonucleotide has been reported as well (156, 157). The current model of the actin filament was arrived at using the structure of the actin monomer, as it occurs in the DNase I:actin crystal, together with diffraction data obtained with oriented gels of F-actin (158). This model is claimed to fit well into reconstructions of actin filaments from electron microscopic images (159, 160), and reconstructions of actin filaments with bound actin-binding proteins are interpreted in terms of this model (see below). However, doubts about this model being a relevant representation of the actin filament have been expressed, and an alternative way of deriving a model of F-actin has been suggested from the analysis of the organization of actin monomers in crystals of profilin and actin (161, 162). To ascertain the validity of the current model, independent information about the orientation of the actin monomer in the actin filament needs to be acquired.

Profilin (mw 12 000–15 000) is an abundant actin monomer-binding protein in eukaryotic cells (163, review). (See separate article Profilin.) Particularly high concentrations of profilin are found in lymphoid cells and brain cells. In lymphoid tissues the concentration of unpolymerized actin is about 100 μM and in platelets it may be as a high as 200 μM. In both cases about 50% of the unpolymerized actin can be accounted for by profilin:b-actin and profilin:g-actin isoforms. The remaining unpolymerized actin appears to be sequestered by b-thymosins (see below). For references on specific aspects of profilin, see (164-189).

Observations point at profilin being an important factor in the control of the release of inositol trisphosphate and thus of the generation of Ca^{2+} pulses in the cell. The primary targets for Ca^{2+} regulation in cells is the actomyosin system with global changes in structure and activity as the result. It is now known that many of the microfilament-associated proteins interact with components formed in the phosphatidylinositol-cycle as a result of receptor-mediated activation of the cell, and that these interactions modulate the activity of these proteins vis-a-vis actin. Although the exact physiological roles of these interactions remain to be elucidated, it suggests that the phosphatidylinositol-cycle is directly involved in controlling the microfilament-based motility cycle (see Fig. 3).

Beta thymosins constitute a conserved family of polypeptides (mw 5 000), the members of which were originally isolated from mammalian thymus and thought to be important for the immunoregulatory activities of this organ (190). Homologues of Tb4 have been found also in distantly related organisms (191). The thymosin b4 isoform is abundant in mammalian tissues, and has attracted much attention after the discovery of its association with unpolymerized actin in platelet extracts. It has a poorly defined structure as determined by NMR in solution (192). Binding studies suggested that it binds to the (+)-end of the actin monomer in competition with profilin. However, crosslinking studies imply a more complex interaction involving sites at both ends of the actin molecule (193).

Binding of thymosin b4 to actin monomers inhibits incorporation of actin monomers at both ends of the actin filament. Thymosin b4 has a rather low affinity for actin ($K_d = 5\ \mu M$), but since it is present in high concentrations in cells (in platelets ca 500 µM) it is considered to be the most important actin sequestering protein. In the presence of polymerization-inhibiting concentrations of thymosine b4, addition of profilin overcomes the thymosin effect, due to the higher affinity of profilin for actin ($K_d = 0.25\ \mu M$), and the fact that profilin:actin can add actin monomers onto the fast growing ends of actin filaments (see Profilin).

In vitro, thymosin can be shown to bind also to actin filaments and decrease the critical concentration for actin polymerization (194), and experiments on cultured cells indicate that b-thymosins may not be just actin sequestering factors (195). In the NIH3T3 cell line thymosin b10 is the predominant beta thymosin isoform, being present in about equimolar concentration to proflin and ADF/cofilin. Overexpression of thymosin b10 in these cells led to an increase in the cellular content of polymerized actin without any change in the total actin content of the cells. An intimate relationship with the regulation of the dynamic functioning of the microfilament system is also indicated by the increase in motility caused by overexpressing thymosin b10. Consonant with this an isoform of beta thymosine, thymosin b15, is upregulated in some forms of malignant cells (196).

The ADF/cofilin family of proteins include actin depolymerizing factor, cofilin, destrin, depactin, actophorin (197-199). These proteins are found in all kinds of eukaryotes, and when tested genetically they have proved to be essential. *In vitro*, they can form 1:1 complexes with actin monomers as well as with actin in filamentous form. The structure of the prototype ADF/cofilin, actophorin from *Acanthamoeba* have been solved by crystallography (200) and there are NMR structures of yeast cofilin and destrin (201, 202). It has recently been recognized that an ADF homology domain is present in each member of a newly identified protein family consisting of the ADF/cofilins, the twinfilins, and the drebrin/Abp1s (203).

In the cell, most of the ADF/cofilin is found in the perinuclear area, but there are also significant amounts in highly motile advancing lamella and filopodia, where the reorganization of actin through polymerization/depolymerization is most intensive. The interaction between ADF/cofilin and actin is sensitive to the pH of the medium, and as in the case of profilin, polyphosphoinositides interfer with the ADF:actin interaction. Physiologically, however, the most important mechanism controlling the activity of ADF/cofilin depends on phosphorylation/dephosphorylation of the protein. Phosphorylation of ADF/cofilin at a site near the N-terminus (S3) blocks its binding to actin. In cell extracts about 60% of the protein is phosphorylated, and in connection to receptor-mediated stimulation of cells dephosphorylation of ADF/cofilin takes place. The phosphatase involved in this reaction has not been identified, but a specific protein kinase, LIM kinase, has been found responsible for the *in vivo* phosphorylation of ADF/cofilin (204, 205).

The turnover of actin filaments inside living cells appears to be up to 100-fold faster than in *in vitro* experiments with actin alone. It has now been demonstrated in *in vitro* as well as in *in vivo* experiments that ADF/cofilin can accelerate the turnover of actin filaments (17, 199, 206-208). ADF/cofilin binds with higher affinity to ADP-containing actin, monomeric as well as filamentous, and facilitation of filament growth by active ADF/cofilin is likely to be brought about by increased depolymerisation of the actin filaments at their proximal ADP-containing ends increasing treadmilling activity. Nucleotide exchange, possibly enhanced by profilin, would in this model precede the reallocation of the ATP-containing precursor to the fast growing, distal (+)-end of the population of growing filaments. The presence of ADF in lamellipodia, where filaments are long, argues against a severing function *in vivo*, and the end-specific effects of ADF on filament assembly seen *in vitro* also indicate that the severing activity of ADF/cofilin is less important *in vivo*.

Twinfilin is a newly discovered protein composed of two cofilin-like regions (209). It was identified and characterized as an actin monomer-binding protein in budding yeast. Genes coding for homologous proteins have been recognized also in *Caenorhabditis elegans*, humans and mice. The two halves of the molecule twinfilin I and II resemble the corresponding domain from other species more than they resemble each other. Thus, twinfilins have evolved from a common ancestor and the twinfilins represent a single protein family (199). Twinfilin does not appear to act as an actin filament depolymerizing factor, but there are *in vivo* observations that suggest its involvement in the control of the dynamics of the microfilament system.

4.1. Arp

The first reports describing a family of actin-related proteins, the Arps, appeared a few years ago (2, 209). These are highly conserved proteins that share a 30–60% homology with actin, but are functionally distinct from actin. Two of these actin-related proteins, Arp2 (44 kD) and Arp 3 (47 kD) have attracted a great deal of attenion, since they were discovered to exist in a large complex together with five other proteins (40 kD, 35 kD, 19 kD, 18 kD, and 15 kD) that could be isolated by affinity chromatography on immobilized profilin (210). The Arp2/Arp3 complex has been reported to nucleate actin filament formation, to bind along the sides of actin filaments and to express filament crosslinking activity. A similar complex was identified in searching for factors that initiate actin assembly at the surface of Listeria (211). The Arp2/Arp3 complex is highly conserved among eukaryotes. Null mutations are lethal. It is localized in the cortex of amoebae and yeast and in the lamellipodia of higher eukaryotes (212, 213). In yeast, the Arp2/Arp3 complex is required for the integrity and motility of actin patches and for endocytosis (214). Thus the complex appears to play a major role in actin-based motility.

It has now been demonstrated that the Arp2/Arp3 complex isolated from *Acanthamoeba* binds profilin (215) and to the (–)-ends of actin filaments (168). It is not an efficient nucleator of actin polymerization. Capped filaments grow by the addition of monomers to the (+)-end. The complex can be seen by electron microscopy to attach the (–)-end of one filament to the side of another filament. This suggests that the Arp2/Arp3 complex might control the assembly of a branching network of actin filaments in the advancing lamellae of motile cells. Similar branching of actin filaments have been recognized earlier in electron microscopic pictures of the weave of microfilaments in advancing lamellae in moving keratinocytes (36). The cellular concentrations of the Arp2/Arp3 complex has been estimated to be high enough to cap the (–)-ends of all filaments in a cell. These observations imply that models assuming that actin filaments *in vivo* undergo an ADF/cofilin-aided depolymerization from the (–)-end during motile activity may be too simplistic, since there must also be mechanisms for the controlled uncapping of the (–)-ends of the filaments.

Further studies of the *Listeria* system have shown that the bacterial protein ActA, which is essential for the actin polymerization-dependent propulsion of the bacterium through the cytoplasm, acts synergistically with the Arp2/Arp3 complex *in vitro*. Working together, they eliminate the lag phase in the polymerization of actin and increase the initial rate of assembly 50-fold (216). This activity has been shown to reside in the N-terminal domain of the ActA protein. A cellular protein that corresponds to ActA has not yet been identified, but zyxin has been pointed out as a plausible candidate.

Capping protein Z (CapZ) is a heterodimeric protein, which was first detected in skeletal muscle sarcomers, where it is associated with actin filaments at the Z-line end of sarcomers, i.e. at the (+)-end of the filament (217). *In vitro*, it binds with high affinity ($K_d \approx$ nM) to the (+)-end of actin filaments. A homologous protein that exists in non-muscle cells, capping protein b_2 (CPb_2), is enriched at the edge of the advancing lamellum of spreading platelets. By binding to the (+)-end of actin filaments, it blocks the addition of actin monomers to that end, and since actin filaments *in vivo* appear to grow by assembly primarily at that end, these capping proteins may be important regulators of actin polymerization. The fact that CPb_2 is necessary for the proper organization of actin bundles in the morphogenesis of bristles in *Drosophila*, the view is strengthened that CPb_2, gelsolin in some cases, and Cap G may play active roles in actin-based motility in response to signaling. There is evidence also in this case that polyphosphoinositides are involved in the regulation of the protein.

4.2. Adducin
In erythrocytes there is, in addition to CapZ, a second actin filament (+)-end capping protein, adducin (218, 225). This protein is associated with the short erythrocyte actin filaments (one a,b heterodimer per filament). Adducin has been shown to bind to spectrin:actin complexes in the cell cortex, and promote the binding between these two proteins. It also appears to be able to bind directly to actin filaments and to bundle them. Adducin has a relatively low affinity for the filament (+)-end, but even so it appears to be the capping protein bound to the erythrocyte actin filaments, and not CapZ. Its binding to actin filaments is downregulated by calcium and calmodulin, an effect possibly modulated by reversible phosphorylation of the protein. The complex relationship between adducin and the spectrin:actin network indicates that adducin represents a new type of regulated actin filament-binding and barbed end capping protein. The entire molecule is required for capping activity, and the association of adducin with actin filaments seems to be regulated by Rho-associated kinase and myosin phosphatase.

Gelsolin is an abundant and ubiquitously expressed actin-binding protein, which confers calcium sensitivity to the regulation of the dynamics of the microfilament system (219). (See separate article Gelsolin.) For references on specific aspects of gelsolin, see (219-223).

Tropomodulin is a 43 kD protein that caps the (–)-ends of actin filaments in erythrocyte cortical network and in striated muscle sarcomeres (225). The interaction is particularly tight when tropomyosin is bound simultaneously. It is thought that tropomodulin is important in controlling the length of the actin filaments in these situations.

5. Architectural Elements of the Actin Cortex

The dynamic changes in cell surface morphology and motile behaviour, seen in response to growth hormones and other cell stimulating agents, reflect changes in the formation, organization, and activity of the microfilament system. Actin-binding proteins that cross-link actin filaments into tightly packed bundles and more loosely organized networks are necessary for the formation of the weave of microfilaments seen in membrane lamellae and filopodia and in the rest of the submembraneous zone around the cell. Actin-based surface projections on cells take many forms, such as the elaborate stereocilia of cochlear hair cells, microvilli of intestinal epithelium, and the membrane ruffles and filopodia on moving fibroblasts. The formation of these structures depends on the activity of actin-crosslinking proteins. Important members of this class of proteins belong to the spectrin superfamily which are reviewed in ref. 237.

Villin is closely related to gelsolin, an actin severing protein (described above), but distinguished from gelsolin by the presence of an additional domain comprised of 76-amino acid residues, called the “headpiece” (224-229). The headpiece contains an additional actin-binding site, which confers actin filament bundling activity to the protein. Villin is found in the microvilli of certain types of epithelia. Crosslinking of actin filaments occurs at low Ca^{2+} concentrations. Like gelsolin, villin severs actin filaments in the presence of micromolar concentrations of Ca^{2+}, and after breakage of the actin filament, villin remains bound to the (+)-end of one of the fragments. The actin-binding properties, tissue distribution and expression during cell differentiation suggest that villin is important in organizing the actin filament core of microvilli in epithelial cells forming brush borders. In support of this, villin expressed transiently in transfected fibroblasts, results in loss of stress fibers and appearance of large numbers of microvillar protrusions on the dorsal surface of the cells. Microinjection of high concentrations of villin into cells that normally lack this protein, lose their stress fibres, and incorporate the villin into cell surface microspikes and large microvilli, an activity which was shown to depend on the presence of the C-terminal head piece.

The N-terminal domain of villin (14T) consists of 126 amino acid residues. It binds calcium and actin. The structure of this domain has been determined by NMR (230). The 76-amino acid residue long, C-terminal domain of villin is an actin-binding module that is also used in another actin-bundling protein **dematin** (band 4.9), but whose core domain is unrelated to villin. The 3-dimensional structure of the stably-folded 35 residue long subdomain of the villin headpiece has been determined by NMR (231). It is the smallest autonomously folding protein unit found.

Fimbrin belongs to the plastin family of actin-binding proteins (31, 232, 237). Members of this family are present in all types of eukaryotic cells. Fimbrin is the smallest of the actin crosslinking proteins. It consists merely of an N-terminal EF-domain and two actin-binding domains, each composed of two CH domains. Fimbrin is present together with villin in the microvilli of the intestinal brush border, and in the membrane lamellae and microspikes of most other eukaryotic cell types. A fimbrin-binding site on actin has been suggested from analysis of actin mutations suppressing fimbrin mutations (233). The structure of the N-terminal actin-crosslinking domain of fimbrin has been solved by crystallography (234), and electron cryomicroscopic images of fimbrin-decorated actin filaments has been used to localize the fimbrin-binding site on the surface of the actin filament (235).

In a suggested scenario for the formation of a microvillus (236), the first phase consists of the “streaming” of actin filaments from electron-dense plaques on the apical plasma membrane. These filaments then gathered into loose bundles that extend into rudimentary microvilli. Villin may contribute to an initial bundling of the filaments. Ezrin (see section 3), a protein controlled by tyrosine phosphorylation, links the microvillar actin filaments to the membrane components. During a second phase, the microvilli elongate and become highly organized into a full core of hexagonally-packed actin filaments. This phase correlates in time with the localization of fimbrin to the core of the microvillus. In this way a stable surface protrusion is thought to take form. Similar schemes may apply to the development of surface protrusions on the surface of other types of cells.

ABP-280, filamin, and ABP-120, are all rod-like, dimeric, actin filament crosslinking proteins, where each monomer has an N-terminal actin-binding CH-domain and a long repeat region consisting of tandemly repeated, 100 amino acid residue long, homologous segments (237). The length of the repeat region is different in the different ABPs. The ABP120 was found in *Dictyostelium discoideum*. The vertebrate variants, ABP-280 and filamin, are major cellular proteins, and products of different genes. Filamin is located specifically in the Z-lines structure of the sarcomeres in muscles. ABP-280 is a major cellular protein in non-muscle cells, where it is present in the cell cortex. The function of ABP-280 appears to be to cross-link actin filaments into orthogonal networks. The 3D-structure of the repeat region of ABP-120 (gelation factor, 6 repeats) has been determined by NMR spectroscopy, which shows it to have an immunoglobulin-like fold (226). Both filamin and ABP-280 (24 repeats) share conserved residues that form the core of the gelation factor repetitive segment structure as determined by NMR. This distinguishes these actin crosslinking proteins from the spectrins and a-actinins, which have tandem repeats of an a-helical domain.

On the basis of their actin filament crosslinking activity, depending on the presence of a calponin homology CH domain, and their elongated shape, as seen by electron microscopy, these proteins have been grouped together with the spectrin and fimbrin families into a superfamily. It is true that the actin binding domains of all these proteins are homologous. However, the presence or absence of repeat domains, and the widely different structures of the repeat domains of the spectrin and filamin families, rather suggests that the three families should be considered as separate protein families employing a common actin-binding domain, since it is possible that the different families will turn out to have quite different functions in relation to the actin filament system.

Spectrin (fodrin) was first isolated as part of the matrix proteins of the erythrocyte plasma membrane (237-240). Underneath the lipid bilayer of these cells, and linked to transmembrane proteins glycophorin and the ion channel band 3, there is a regular organization of units consisting of five or six spectrin molecules attached to a short actin filament. The spectrin molecules are attached to spectrins of adjacent units to form a sheet of five- and six-sided polygons. The membrane skeletons, and isolated junctional complexes, reproducibly contain four proteins in the molar ratios of 1 spectrin dimer:2-3 actin monomers:1 band 4.1 protein:0.1–0.5 protein 4.9 (protein designations refer to mobility on gel electrophoresis). In addition tropomyosin, tropomyosin-binding protein and adducin are thought to be part of the junctional complex.

Spectrin consists of two subunits, an a and a b subunit, which form heterodimers, which in turn associate to form tetramers in the membrane lattice. The b-chain has an N-terminal actin binding CH domain and 12 a-helical repeat domains, whose structure has been determined by NMR spectroscopy (241). The a-chain associates in an antiparallel fashion with the b-chain. It has a C-terminal EF-hand domain, which is close to the actin-binding site of the b-chain followed towards the N-terminus by a binding site for protein 4.1, and a Src-like sequence in the middle of the somewhat longer repeat region. Between repeat 11 and 12, there is a calmodulin-binding sequence inserted. The structures of the spectrin repeat, the phosphoinositide-binding pleckstrin (PH) domain, the SH3 domain, and the CH domain have all been determined (241-246).

The spectrin-actin based network of proteins endows the erythrocyte with an exquisite elasticity which makes it possible for it to go through quite drastic shape changes. However, it is clear that the structural role played by the spectrin:actin system is not its sole function. The close relationship between the spectrin-actin system and transmembrane ion channels implies that the range of controlling functions is wider. The spectrin-actin system is not unique to the erythrocytes, but exists also in other tissues and in cells of as widely separated organisms as *Drosophila*, *Acanthamoeba*, *Dictyostelium*, echinoderms, and possibly also in higher plants.

Alfa-actinin is a classical skeletal muscle protein identified a long time ago (237, 247). It is highly enriched at the Z-disc-end of the actin filaments in the sarcomeres of the myofibrils. It is now known also to be an integral part of the microfilament system in nonmuscle cells, where an interaction between transmembrane b1 integrins and a-actinin has been demonstrated (see Fig. 2). There are several isoforms of a-actinin, which are products of three different genes. *In vitro*, it crosslinks actin filaments into regular ladder-like structures. It is therefore thought to contribute to the organization of actin in cells. Alfa-actinin is an elongated homodimer (200-215 kD) with antiparallel arrangement of the two subunits. Each subunit consists of a CH-domain, 4 a-helical domains (“spectrin repeats”), and an EF-hand domain. The binding of nonmuscle a-actinin to actin filaments is modulated by Ca^{2+} binding to the EF-domain, whereas the muscle isoform of a-actinin is insensitive to Ca^{2+}. The 3D-structure of the CH-domain is known by analogy to the structure of the corresponding domain from calponin solved by x-ray crystallography, and the structure of the repeated domain is known by analogy to the known a-helical repeat domain in spectrin, and the EF-hand can be compared with calmodulin.

Alfa-actinin can be extracted from myofibrils without major destruction of the sarcomeric organization of the actin filaments in the myofibril, and when added back to the myofibril preparation it rebinds at the Z-disc. This implies that a-actinin may serve some function, other than a structural, in relation to the actin filaments. In nonmuscle cells, a-actinin is found enriched in spots along stress fibres and in cell adhesion plaques.

Dystrophin is the product of the gene responsible for the X-linked myopathies Duchenne and Becker muscular dystrophy. It is an elongated protein of high molecular weight (430 kD) present in low amounts in muscle and nerve cells. A closely related protein, utrophin, is more widely distributed, and there are many dystrophin/utrophin isoforms produced, due to the operation of alternative promotors and alternative splicing. The structure of these proteins place them in the spectrin/a-actinin family of proteins. They are multidomain proteins; the largest isoform is comprised of 3 N-terminal and 2 internal actin-binding sites, a peptide-binding WW domain, a calcium-binding EF domain, a zinc finger domain. The N-terminal actin binding region has sequence homology with the calponin homology CH domains of the spectrin/a-actinin family of proteins.

Dystrophin/utrophin connect cortical actin filaments with transmembrane proteins, dystroglycans and sarcoglycans, which in turn associate with extracellular matrix proteins, laminin and merosin, respectively. Skeletal muscle dystrophin can be purified from muscle cells as a large multiprotein dystrophin-glycoprotein complex, which stabilizes actin filaments *in vitro* through lateral associations. Both dystrophin and utrophin bind with higher affinity to b- than to a-actin. Comprehensive reviews on the structure and function of the dystrophin/utrophins are found in ref 237, 248.

6. Ion Channel-associated Actin-binding Proteins

The spectrin-actin network in erythrocytes is involved in anchoring ion exchange proteins in the membrane via the linker protein ankyrin, a critical link in maintaining the characteristic biconcave shape of the cell (249). In axons, an interaction between actin, **fodrin**, and ankyrin appears to be responsible for concentrating sodium channels at the nodes of Ranvier (249). At the neuromuscular junction, the clustering of acetycholine receptors appears to be mediated by spectrin, actin, and the **rapsyn/43 kD actin-binding protein** (250). Various lines of evidence suggest that intact actin filaments, and perhaps actin polymerization itself, are required for calcium regulation of the postsynaptic response of NMDA receptors in the central nervous system (251). Postsynaptic excitatory synapses are most often found on the small actin-rich budlike structures, called spines, that protrude from the dendrites of highly arborized neurons such as cerebellar Purkinje cells (252). Dendritic spines have pronounced electron-dense (as seen by electron microscopy) post-synaptic densities, called PSD's, that are the likely sites of proteins linking receptors to actin. Candidate proteins include PSD-95/SAP90, chapsyn/PSD-93, SAP102, and **alpha-actinin-2**. Only alpha-actinin has a demonstrated actin binding affinity, and it has been suggested that clustering for some classes of receptors might be mediated by a looser, more “corral-like”, entrapment mechanism (253). The PSD contains brain dystrophin, an isoform of the muscle protein originally identified as the mutated gene product involved in muscular dystrophy that is known to link transmembrane ion channels to actin filaments (254).

The precise role for actin in the functioning of ion channels is unclear. The provision of clustered anchorage sites may confer cooperativity in the opening of channels, or support the formation of multiprotein complexes capable of integrating different signalling or environmental factors. It is not unlikely that the actin network might passively or actively transmit forces to the channels providing the impetus behind stretch-activated gating phenomena.

7. Myosin as an Actin-binding Protein

The myosins belong to a large superfamily of proteins, which together with actin transduce chemical energy to force generating tension and movements in the eukaryotic cells. Myosin II is the prime partner of actin in the generation of force in muscle, as well as in nonmuscle cells. Generally myosins are thought of as the force generators, and therefore referred to as motor molecules. However, the actual mechanism of force generation is still unknown. Although, the ATP-binding head domain is largely conserved, there are many different molecular forms of myosin serving in as diverse functions as muscle contraction, cell motility, membrane traffic, and sensory perception. Myosin hydrolysis ATP to ADP.Pi still bound to the head domain. Interaction with actin filaments brings about product release, and in the presence of actin filaments, there is a rapid ATP-dependent cycling of heads on and off the actin filaments as ATP is hydrolysed. A current review of the myosin superfamily and their functional involvements is found in ref. 255. For a more detailed account of the structure and function of myosin see the entry on myosin in this encyclopedia.

8. Regulators of the Actomyosin Interaction

The N-terminus of actin is involved in the binding of a large number of actin binding proteins, including myosin (S1), tropomyosin, troponin I, a-actinin, caldesmon, gelsolin, cofilin, actobindin. This actin interface is important for muscle contraction, since it is implicated not only in the activation of the myosin ATPase, but also in the regulation of actomyosin interaction by interacting with troponin I.

Tropomyosin is an elongated, dimeric, coiled-coil a-helical protein that binds along the actin filament (see special entry). The tropomyosin molecule has a sevenfold repeat of nonpolar and polar amino acid residues that bind seven actin monomers in the filament. Multiple genes for tropomyosin and alternative splicing can generate a number of tropomyosins that are differentially expressed during development and in different cell types. Muscle cells express 1–2 and most vertebrate nonmuscle cells 3–8 tropomyosin isoforms. Tropomyosin in complex with the heterotrimeric protein troponin makes muscle contraction Ca^{2+} dependent, but the function of tropomyosin in nonmuscle cells has not been clarified. However, the involvement of tropomyosin in the control of chemomechanical transduction also in nonmuscle cells is indicated by the occurrence of tropomyosin in tightly bundled and contractile organizations of actin filaments (stress fibres). For further information see special entry on tropomyosin.

Troponin is a heterotrimeric protein complex that interacts directly with actin through one of its subunits. Together with tropomyosin it confers calcium sensitivity to muscle contraction in striated muscles (see special entry).

Caldesmon is involved in the regulation of the actomyosin interaction in smooth muscle (256, 257). It inhibits actomyosin ATPase and filament sliding *in vitro* has been shown to bind to subdomain 2 of actin. Three-dimensional image reconstruction of reconstituted thin filaments consisting of actin and smooth muscle tropomyosin, both with and without a caldesmon derivative added has been reported. In filaments containing the caldesmon derivative, tropomyosin was found in a different position as compared to the situation in the absence of the caldesmon. The observations suggest that caldesmon causes changes in the relationship between tropomyosin and the actin filament, which are different from those seen with troponin.

The giant modular protein nebulin (mw 600- 900 kD) spans the whole length of the thin filament of the striated muscle sarcomeres in vertebrates, and has been proposed to function as a “ruler” for control of the length of actin filaments in sarcomeres (258-260). It is thought to bind and stabilize F-actin. It comprises 2-3 % of the myofibrillar protein mass of skeletal muscles. There are tissue and development-specific isoforms. The C-terminal part of human nebulin is anchored in the sarcomere Z-disk and contains an SH3 domain. The nebulin SH3 sequence from several species has been determined and found strikingly conserved. Its 3D-structure has been determined in solution by NMR spectroscopy, and its interaction with poly(L-proline) has been modelled. Nebulin consists of nearly 200 tandem repeats of homologous modules about 35 residues long. These are organized into about 20 tandem superrepeats consisting of 7 different modules, and this superrepeat segment is flanked near the N- and C-termini by single-repeat regions containing 8 modules of the same type. It has been proposed that the 35 residue module is the basic actin-binding domain and that the superrepeats reflect tropomyosin/troponin binding sites along the nebulin molecule. Exactly how the nebulin molecules are linked to actin filaments in the sarcomere of muscle is not yet known. Nebulin promotes actin nucleation and stabilizes actin filaments. Crosslinking experiments have identified the first two residues in actin to be involved in binding nebulin.

9. Future Directions

One of the most remarkable aspects of the contractile apparatus in muscle cells is the capacity of the system to ramp up its power output in response to increased demands for mechanical work. This phenomenon is known as the Fenn Effect, and it suggests that the acto-myosin system can increase its ATPase activity in response to higher imposed loads. It is apparently the lattice organization of filaments into sarcomeres that somehow enables the effect of external loads to be transmitted directly to the proteins producing the biochemical reactions that produce work from ATP hydrolysis. It remains to be seen if the bundles and meshworks found in non-muscle cells display similar, or even more unusual, chemomechanical feedback mechanisms. Muscle cells also perform work at nearly 100% thermodynamic efficiency, and it is interesting to ask whether the free energy transduction pathways in the cytoplasm are equally optimized for their tasks.

The newly discovered connections between the microfilament system and signal transduction raise a host of questions that will be the subject of future research. What roles do mechanical forces play in transmitting signals from the surfaces of cells to their nuclei? What regulates the assembly of these focal sites of signalling potential and what leads to their breakup after a signalling cascade has outlived its usefulness?

The large number of actin-binding proteins obscures the possible branching points that must have occurred during evolution to establish this incredibly diverse dynamical system. The analysis of evolutionary relationships in actin-binding proteins from amoeba, plants, and mammals will be of extraordinary interest for understanding how the immune system and the mammalian nervous system developed as specializations of more primitive motile mechanisms.

Actin Polymerization Toxins

Several bacteria release toxins that modify actin or proteins controlling its polymerization (1). A group of *Clostridia spp.* secrete binary toxins, whose most studied member is the C2 toxin released by *Cl. botulinum*. Botulinum C2 toxin is not neurospecific, as are botulinum neurotoxins, but it affects many nonneuronal cells (2). In the intestinal loop model, it induces an acute inflammatory reaction, characterized by the alteration of endothelia and a large increase in vascular permeability. At the same time, epithelial degeneration, exfoliation, and necrosis are also observed. In cultured cells, C2 causes rounding up, with formation of blebs, followed by cell death.

Two polypeptide chains, I (55 kDa) and II (100 kDa), are needed for cell intoxication. Chain I catalyzes the **ADP-ribosylation** of Arg177 of soluble G-actin, a residue located in an area involved in protein-protein contact within the polymerized form, F-actin. The ADP-ribosylated G-actin binds to the barbed end of F-actin and prevents polymerization, whereas depolymerization at the opposite end is unaffected (3). This leads *in vitro* and *in vivo* to the disassembly of actin microfilaments, with cell rounding and release of focal adhesion plaques.

Single-chain enzymes that catalyze the ADP-ribosylation of small G proteins are released by several bacteria (4). They cannot intoxicate cells because they lack the second polypeptide chain, but they are active after cell permeabilization or injection. C3 toxin is released by some strains of *Cl. botulinum*; it catalyzes the specific ADP-ribosylation of Asn-41 of Rho, a small GTP-binding protein involved in the regulation of actin polymerization. C3 induces the depolarization of F-actin, with rounding up and binucleation of injected cells. A different type of Rho modification is caused by cytotoxic necrotizing factors released by *E. coli* strains associated with gastroenteritis, urogenital infections, and septicemia (5). These factors cause cell ruffling, stress fiber formation, and multinucleation, by a covalent modification of Rho protein to lock it in its GTP-bound active form (6).

Clostridia spp. involved in the induction of diarrhea, associated with pseudomembraneous colitis, release in the intestine enterotoxins of very large dimensions (7). They are termed large clostridial toxins (LCTs) because of their size, which is in the range of 250 to 308 kDa. They are organized as A-B toxins, which are cleaved proteolytically into two polypeptide chains, A and B (see Toxins). The carboxyl-terminal part includes segments of 20 to 50 residues repeated 14 to 30 times, which are believed to mediate LCT binding to cell surface **receptors.** Such an organization in the absence of an oligomer of type B gives rise to a multivalent type of cell binding, as in the case of cholera toxin. Binding is followed by internalization of LCTs into coated **vesicles** and then into endosomes. By an unknown mechanism, the amino-terminal catalytic domain of the LCTs is released from the rest of the molecule and translocates into the cytosol, where it catalyzes the transfer of a sugar residue from the corresponding UDP derivative to an actin polymerization controlling protein (7, 8). All LCTs induce rounding of different cells in culture, but the effects of the various LCT toxins can be differentiated by staining actin filaments: *Cl. difficile* and *Cl. novyi* LCTs cause a breakdown of the F-actin microfilaments, whereas *Cl. sordellii* LCT induces the formation of filopodialike structures on the cell surface, with some membrane blebbing 7. This is related to the different protein(s) targeted by the LCTs. All of them modify a threonine residue of small GTP-binding protein(s) of the **Ras** superfamily, in such a way that its GTPase activity is unaltered but it can no longer interact with its effector molecule. This provides a further example of the ability of bacterial toxins to “choose” essential cell targets and to modify essential cell functions.

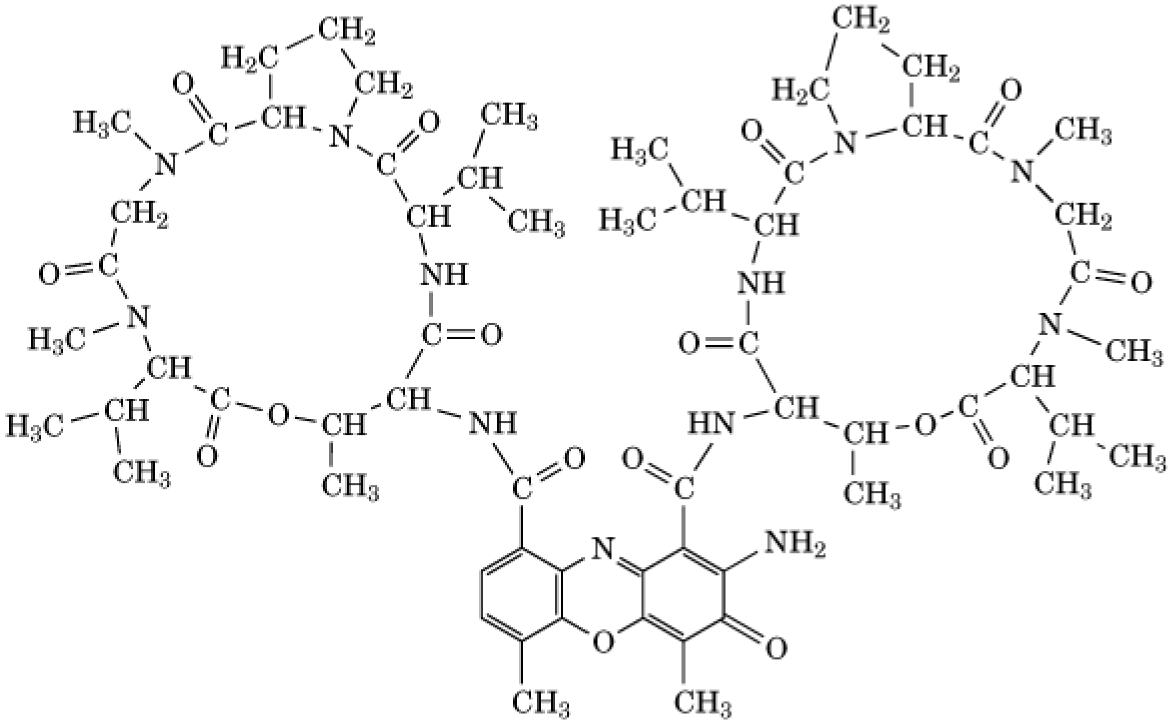
Actinomycin D

Actinomycins are chromopeptide antibiotics produced by various species of streptomycetes (1). They differ only in their content of certain amino acids in their peptide rings (Fig. 1). Actinomycin D, which is active against several forms of cancer, has the distinction of being the first antibiotic discovered (in 1943) to possess useful antitumor activity. It is still used in the clinic for that purpose. It occupies a unique place in the origins of molecular biology for quite a different reason, however, namely its astounding specificity as an inhibitor of DNA-dependent RNA synthesis, which enabled it to play a vital part in the discovery of messenger RNA and helped uncover the early evidence that **transcriptional** regulation of gene expression is fundamental to cell growth and development (2).

The result of its near-absolute specificity for binding tightly to double helical B-form DNA is a total blockade of transcription by **RNA polymerase**, leading to cessation of synthesis of all forms of RNA, stable as well as unstable. Elongation of growing RNA chains is promptly terminated; there is no particular effect on the process of initiation of transcription. Thus actinomycin was used in the 1960s to measure the kinetics of breakdown of pulse-labeled RNA, thought to reflect at least partly the turnover of mRNA, and to establish the requirement for new RNA transcription in such processes as induced enzyme synthesis, mechanisms of steroid hormone and peptide hormone action, and early embryonic development. Replication of DNA **viruses** is usually strongly inhibited by actinomycin, but many RNA viruses are completely insensitive to the antibiotic; this is clear evidence that their life cycles do not require the participation of DNA at any point. Because actinomycin acts essentially identically to block transcription in all cells, once it has gained access to the nucleus, it is equally applicable to the study of gene activity in eukaryotes as well as prokaryotes (it is generally ineffective against gram-negative bacteria simply because of a permeability problem, for if the walls of such cells are digested away, or otherwise weakened, the protoplast is revealed as fully sensitive to the antibiotic).

Figure 1. The structures of the actinomycin antibiotics.



actinomycin D

Actinomycin does not bind to RNA or to single-stranded DNA, and its affinity for double-helical DNA is related to the latter's content of guanine nucleotides; synthetic polynucleotides composed entirely of A · T base pairs do not interact with the antibiotic at all. It took some time to establish the nature of the actinomycin–DNA complex, and for many years the matter was controversial. Eventually the issue was resolved in favor of intercalation as a result of careful structure–activity comparisons (1), binding measurements with a wide variety of synthetic as well as naturally occurring DNAs (3, 4), hydrodynamic experiments with circular DNA (5), X-ray crystallography (6), and high-resolution nuclear magnetic resonance (**NMR**) (7). A landmark was the determination of the structure of a crystalline 1:2 actinomycin:deoxyguanosine complex, which revealed for the first time that the antibiotic has an axis of near-perfect twofold rotational symmetry, which allows it to react with two guanine nucleosides in a symmetry-related fashion (6). This observation immediately suggested plausible intercalation of the phenoxazinone chromophore between two G · C base pairs of DNA at a rotationally symmetrical site centered around a 5′-GpC-3′ step. The strong preference of actinomycin for such sites in DNA was elegantly confirmed by Footprinting experiments a decade later (8, 9). With its tricyclic aromatic chromophore firmly embedded between the base pairs, the cyclic pentapeptide rings of the antibiotic are left neatly filling the minor groove of the distorted B-form helix, where they form numerous additional **van der Waals** contacts that help to stabilize the complex; positioned this way, their intrinsic right-hand twisted disposition with respect to the intercalated chromophore makes perfect sense, and the whole antibiotic molecule occupies a site covering about six base pairs in the minor groove.

Detailed kinetic studies have revealed that both the association and dissociation reactions are complicated and require several rate constants to fit the data (3, 10). The slowest processes are characterized by time constants in the range of minutes, conspicuously slower than those measured for most other DNA-binding drugs, and there is a correlation between the slowest rate constant for the dissociation reaction and the efficiency of inhibition of chain elongation by RNA polymerase. This has led to the notion that reversibly bound actinomycin molecules serve as relatively long-lived blocks to the progression of the transcribing enzyme along its template, providing a partial explanation for the extreme effectiveness of actinomycin as an inhibitor of RNA synthesis. What is not so obvious is why the functioning of DNA as a template in replication should remain unaffected even at much higher concentrations of actinomycin (2).

The critical determinant that enables the antibiotic to recognize its preferred binding sites in DNA seems to be the 2-amino group of the guanine nucleotide, as is also true for numerous other ligands (11). If the 2-amino group is removed from guanines (leaving inosine–cytosine base pairs) and transferred to adenines (forming 2,6-diaminopurine-thymine base pairs), the sites to which actinomycin binds are relocated accordingly (11, 12). The molecular recognition process includes the formation of hydrogen bonds between the purine 2-amino groups and the carbonyl substituents of the L-**threonine** residues in the peptide rings of the antibiotic; there are also hydrogen bonds from the same threonine residues to the N(3) atoms of the purine nucleotides at the binding site (6, 12). Some of the kinetic complexity of the association/dissociation reactions no doubt reflects a "shuffling" process, whereby actinomycin initially interacts with a variety of potential binding sites on the DNA lattice, then migrates one-dimensionally to locate its preferred binding sites marked by a pair of purine 2-amino groups suitably disposed in the minor groove of the double helix (13).

Activation Energy

The kinetic rates of chemical and enzyme-catalyzed reactions depend on temperature. The relationship for this dependence is known as the Arrhenius law:

$$k = Ae^{E/RT} \tag{1}$$

where A and E are constants, R is the gas constant, and T is the absolute temperature in Kelvin units. The activation energy E is the height of the energy barrier that the reaction must exceed to pass from reactants to products. It is usually expressed in kilocalories per mole or in joules per mole. Equation 1 can be expressed as:

$$\log k = \log A - E/(2.303RT) \tag{2}$$

Therefore the magnitude of the activation energy can be obtained from the slope of a plot of the log of a rate constant for a reaction as a function of $1/T$. Many chemical and enzyme-catalyzed reactions increase the rate of reaction by two- to threefold for each 10°C increase in temperature. Although this relationship is useful in explaining the temperature dependence of reactions, it does not explain the rate in the thermodynamic terms of **enthalpy** H **entropy** S, or **free energy** G. This analysis comes from transition state theory. The Arrhenius activation energy does correspond to the standard enthalpy of the reaction in the van't Hoff equation (1).

Active Site

The folding of a polypeptide chain that produces the final protein structure of an enzyme also leads to formation of the active site. From X-ray crystallography studies, it is apparent that the active site of an enzyme is a groove, cleft, or pocket that has access to the solvent and forms only a small part of the total solvent-**accessible surface** of the protein. The relatively large sizes of enzymes are undoubtedly due to the need to obtain, at the active site, the correct spatial relationships of the amino acid residues that are involved in binding of substrates, catalysis, and the release of products, as well as for any conformational changes associated with these steps. The binding of substrates or inhibitors at the active site pocket of an enzyme involves matching up of the nonpolar groups of the substrate with the nonpolar side-chains of amino acid residues, **hydrogen bonding** between the polar appropriate groups on the substrate with the backbone NH and CO groups within the active site, and even **salt bridge** formation. For substrates, these initial interactions are followed by the conformational changes that lead to the formation of the transition-state complex (see Transition State Analogue) and the chemistry for catalyzing the reaction brought about by reactive groups with the correct alignments. These may be the acidic, basic, and nucleophilic groups of the protein component of the enzyme, or the electrophilic groups of a prosthetic group (see Coenzyme, Cofactor).

Active Site-Directed Irreversible Inhibitors

Active site-directed irreversible inhibitors of enzymes are also known as *active site-direcetd inactivating reagents*, *affinity labels*, and *photoaffinity labels*. They combine the features of a substrate, or substrate analogue, with those of a group-specific reagent, as in affinity labeling, and have been used to determine the amino acid residues that are present in the active site and involved in enzymic catalysis. They are capable of binding specifically and reversibly at the active site of an enzyme and then causing inactivation through time-dependent covalent modification of an adjacent amino acid residue. The functional group of the inhibitor is usually an electrophile that can interact with an appropriately positioned nucleophile of the enzyme, to generate a covalent bond between them. The electrophilic groups include epoxides and a-haloketones. Since these compounds are reactive in solution, they could also cause some nonspecific enzyme modifications.

The action of an active-site directed irreversible inhibitor I can be illustrated by

$$\mathbf{E} + \mathbf{I} \rightleftharpoons \mathbf{EI} \rightarrow \mathbf{E} - \mathbf{I} \qquad (1)$$

where EI represents a Michaelis complex (see Michaelis–Menten Kinetics) and $E - I$ denotes the covalently cross-linked form of the complex. On the basis of this formulation, it would be expected that at the early stages of the interaction, I would behave as a **competitive inhibitor** with respect to the substrate. Examples of the action of an active-site directed irreversible inhibitors are the acetylation of amino acid residues at the active site of prostaglandin synthase by aspirin (acetyl salicylate) (1) and the alkylation by L-**TPCK** (*N*-tosylphenylalanine chloromethyl ketone) of a **histidine** residue at the active site of a-**chymotrypsin** (2).

Photoaffinity labels, such as diazoketones and aryl azides, introduce a greater degree of specificity to the modification of amino acid residues, as they are not reactive in solution. It is only after the reversible interaction of the affinity label at the active site of an enzyme, and exposure of the resulting complex to light of the correct wavelength, that a highly reactive group is formed. Such treatment with diazoketones and aryl azides leads to the formation of carbenes and azines that are extremely reactive and can add across O—H bonds of unionized carboxyl groups or unsaturated carbon–hydrogen bonds (3).

Active-Site Titrants

For determination of values for the kinetic rate constants and **ligand-binding** stoichiometries associated with an **enzyme**-catalyzed reaction, it is necessary to know the concentration of functional active sites of the enzyme. The latter value cannot be calculated simply from the total concentration of protein and molecular weight of the enzyme; even when the enzyme preparation has been shown to be homogeneous by a variety of techniques, it is possible that inactive enzyme is present. The inactivity could be due to the inability of the enzyme to bind substrate or perform the chemistry of the reaction, or both. Therefore, before undertaking detailed kinetic investigations on any enzyme, it is important to determine the concentrations of the active sites that can both bind the ligands and are active.

The concentration of binding sites can be obtained from data for the reversible inhibition of an enzyme by a tight-binding substrate analogue that gives rise to competitive inhibition. Tight-binding inhibition occurs under conditions where the total inhibitor concentration I_t is comparable to the total enzyme concentration E_t, and a substantial fraction of the inhibitor is bound, so that allowance has to be made for the reduction of free inhibitor concentration as a result of formation of the enzyme-inhibitor complex (1). The variation of the steady-state velocity as a function of the concentrations of I_t and E_t is described by Equation 1:

$$v = \frac{kA}{2(K_a + A)}[\{(K_i' + I_t - E_t)^2 + 4K_i'E_t\}^{1/2} - (K_i' + I_t - E_t)] \quad (1)$$

where k denotes the maximum rate of product formation in terms of moles per mole of enzyme per second, K_a is the Michaelis constant for the substrate present at concentration A, and K_i' represents an apparent inhibition constant whose relationship to the true inhibition constant K_i for the interaction of I with E is given by

$$K_i' = K_i(1 + A/K_a)$$

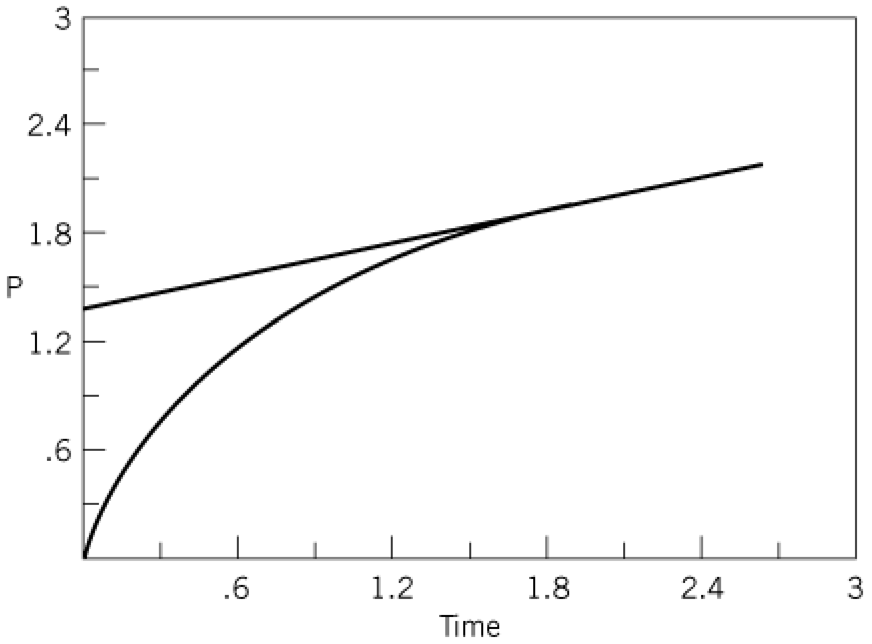
Equation 1 also applies to multisubstrate reactions, provided that the nonvaried substrates are present at saturating concentrations. When no assumptions are made about the purity of the enzyme, E_t of Equation 1 is replaced by aEx, where a represents the degree of purity of the enzyme and Ex denotes the total protein concentration. Fitting to the modified form of Equation 1 of steady-state velocity data obtained at varying concentrations of I_t and E_t would yield values for K_i' as well as a, which would yield a measure of the concentration of binding sites (2, 3).

The technique of active-site titration is used to determine the concentration of catalytically active enzyme (4, 5). It requires that on mixing enzyme and the titrating substrate, there is an initial rapid burst of product formation because of the accumulation of an enzyme-bound intermediate whose rate of breakdown is much slower than its rate of formation. The procedure can be illustrated by reference to the Uni–Bi reaction:

$$\begin{array}{ccccccc} E & \rightleftharpoons & EA & \rightarrow & EQ & \rightarrow & E \\ + & & & & + & & + \\ A & & EPQ & & P & & Q \end{array}$$

for which P is released before Q, and at a very much faster rate. Specific measurement of the release of P as a function of time would yield a plot (Fig. 1) that consists of curved (burst) and linear sections. The intersection of the extrapolated linear curve with the vertical ordinate would give the concentration of *P* that is equal to the concentration of functional active sites.

Figure 1. Active-site titration curve showing burst formation of a covalent enzyme-intermediate complex.



Active-site titrations may be performed with chromogenic or radioactive substrates, and rapid reaction techniques are often required. This is not the case, however, for determination of the active-site concentration of *hexokinase* (6). This can be done by incubating the enzyme with ^{14}C-glucose and ATP complexed with Cr^{3+}, rather than the usual Mg^{2+}, and separating the enzyme-CrADP-glucose-6-phosphate complex on a Sepharose column. In this case, the enzyme undergoes only a single turnover, and the product complex has a half-life of over 10 min, so the amount of ^{14}C associated with the enzyme gives a measure of the active-site concentration (6).

Comparison of the results obtained from tight-binding inhibition and active-site titration studies could yield information about the presence in an enzyme preparation of substantial proportion of sites that can bind substrate, but cannot catalyze the reaction.

Adenovirus

The adenoviruses constitute a large group of DNA **viruses**, the *Adenoviridae* family. Genera include *Mastadenovirus* (human, simian, bovine, equine, porcine, ovine, canine, and opossum) and *Aviadenovirus* (birds). Adenoviruses are nonenveloped icosahedral particles of 70 to 100 nm in diameter, with 252 capsomeres, of which 240 are hexons and 12 are penton bases. A projecting fiber attaches to each penton base to form a penton.

Human adenoviruses (Ads) include 47 serotypes, which can be classified into six subgroups, A to F, based on their ability for red-blood-cell agglutination and oncogenicity in rodents, plus their DNA homology. Ads cause respiratory tract infections, conjunctivitis, hemorrhagic cystitis, and gastroenteritis. Highly oncogenic group A (eg, Ad12 and Ad18), weakly oncogenic group B (eg, Ad3 and Ad7), and Ad9 of group D can induce tumors in rodents, but no conclusive evidence has been reported linking adenoviruses with malignant diseases in the human. All Ads that have been tested can transform cultured rodent cells. No infectious virus is present, but viral transforming genes (E1A and E1B) are present and expressed in tumors and in transformed cells induced by adenoviruses.

The viral genome consists of a single linear molecule of double-stranded DNA [MW ~23×10^6, size ~36 kilobase pairs (kbp)], varying somewhat with the type. Human adenovirus type 2 (Ad2), the first to be sequenced completely, has a total of 35,937 bp. The Ad genome has inverted terminal repeats of 103 bp to 163 bp, depending on the type, and two identical replication origins, one in each terminal repeat. A 55-kDa terminal protein (TP) covalently bound to each 5′ end of the viral DNA molecule serves as a primer for protein-primed viral DNA replication. The viral genome carries five early transcription units (E1A, E1B, E2, E3, E4), two delayed early transcription units (IX and IVa2), and one late transcription unit (major late), all of which are transcribed by **RNA polymerase II**. The viral genome also carries one or two (depending on the type) VA genes transcribed by RNA polymerase III. The *E1A, E1B, IX, major late, VA*, and *E3* are on the rightward reading DNA strands (r strand), and others are on the leftward reading DNA strand (l strand).

The E1A is the first transcription unit to be expressed shortly after infection, using cellular transcription factors, encoding two major mRNAs of 12S and 13S. The encoded E1A proteins are required for productive viral replication and play a key role in cell transformation. E1A proteins transactivate early and late viral genes and cellular transcription units, and they bind cellular proteins, including p300, a family member of CBP (CREB binding protein)/p300, plus the RB family members, RB (**retinoblastoma** susceptibility gene product, tumor suppressor), p107, and p130. Binding to these cellular proteins is required for cell transformation. Binding of E1A to RB disrupts the RB · E2F complex to activate a cellular transcription factor, E2F, resulting in the activation of E2F-dependent **cell-cycle**-related genes.

Two major proteins of 19 kDa and 55 kDa, encoded by 13S and 22S messenger RNAs, respectively, are generated from the E1B region. The E1B proteins are required for efficient viral growth and cooperate with E1A products to transform rodent cells, preventing E1A-induced apoptosis. The E1B 19-kDa protein has a functional similarity to the cellular anti-apoptotic Bcl-2, and the E1B 55-kDa protein interacts with **tumor suppressor** and apoptosis-related p53.

Region E2 encodes proteins involved in viral replication, including the viral terminal protein precursor, pTP (coded by *E2B*), viral DNA polymerase (coded by *E2B*), and the DNA-binding protein (coded by *E2A*). None of the *E3* proteins are required for productive infections of adenoviruses in cultured cells, but are important for *in vivo* infections in humans, suppressing host defense mechanisms by cytotoxic T lymphocytes or **tumor necrosis factor**-a. The E4 proteins are involved in transcriptional regulation, preferential transport of viral mRNA, and efficient viral DNA replication. Other functions of the E4 gene, such as transformation with E1A, tumor-suppressor p53 binding, and apoptosis-inhibiting activities, have been recently reported. The Ad9 E4 gene can oncogenically transform rat cells in the absence of the E1A and E1B genes and is required for mammary tumorigenesis.

The transcription of adenovirus late genes is triggered by the onset of viral DNA replication, yielding at least 18 distinct mRNAs by differential poly(A) site utilization and alternative splicing. Viral DNA replication activates a major late **promoter** (MLP) located at 16.4 map units of the viral genome, and one large primary transcript is generated, terminating at 99 map units at the right end of the genome. This transcript is processed to five families of late mRNAs, L1 to L5, based on the use of common poly(A) addition sites. The late mRNAs encode structural polypeptides of the viral particle and proteins involved in polypeptide processing, capsomere assembly, and packaging of the viral genomic DNA.

Adenoviruses are being used as **vectors** for delivery of therapeutic genes to target organs *in vivo*. Recombinant adenoviruses can be constructed by replacing the E1A and E1B genes with foreign ones. The E3 region also can be deleted without significant changes in virus growth. Recombinant adenoviruses can propagate efficiently in 293 cells, which complement the defect. The advantages are that the growth of recombinant viruses does not require host cell division, and a high titer of recombinant viruses can be easily obtained.

Adenylate Charge

The adenylate charge, or adenylate energy charge, is a linear measure of the energy stored in the adenylate system ([ATP] + [ADP] + [AMP]) in a living cell. It is analogous to the charge of a storage battery. Its value is defined by the expression:

$$\text{Adenylate charge} = \frac{[\text{ATP}] + 0.5[\text{ADP}]}{[\text{ATP}] + [\text{ADP}] + [\text{AMP}]}$$

The status of the adenylate system is best described by the adenylate charge and appears to be the most ubiquitous regulatory signal in metabolism; it affects the rates of nearly all metabolic conversions and the partitioning of metabolically available substances between oxidation, synthesis of cell substance, and production of storage compounds. In living organisms, the same controls that regulate metabolic partitioning also maintain the value of the adenylate charge near 0.9.

1. Background

Organisms are exquisitely regulated material- and energy-transducing systems. Material from the environment must be converted to the many compounds of which the organism is made, and energy, usually obtained either by absorption of sunlight or from oxidation of foodstuffs, must be converted for use in biosynthesis, movement, and membrane activities. Partitioning of material and energy between those functions must be adjusted continuously to meet the changing needs of the cell or organism. Transduction of energy through the adenylate system is an integral part of each of those functions.

Any system that is not at chemical and physical equilibrium can, in principle, supply energy. The two types of nonequilibrium situations that are mainly used in energy storage and transduction by organisms are (1) difference in electric charge or chemical potential across a membrane (see Membrane Potentials) and (2) a ratio of [ATP] to [ADP] that is far from equilibrium. All cells contain enzyme systems that catalyze transfer of energy between the two.

The energy status of a chemical storage system may be defined by either of two parameters: the molar Gibbs **free energy** change of the relevant chemical reaction or the mole fraction of the higher-energy state of the system. The two are computationally interconvertible but are not linearly related. The molar free energy change is a function of the ratio of activities of the products and reactants of the reaction; the mole fraction is a linear measure of the extent of reaction. In the familiar case of a lead storage battery, the free energy is measured by the voltage and the mole fraction by the charge (measured by a hydrometer in this case).

If a generic energy-transducing reaction is indicated by the type of reaction $A \leftrightharpoons B$, the molar free energy change is given by

$$\Delta G = \Delta G^\circ + RT \ln \left(\frac{[B]}{[A]} \right) \tag{1}$$

and the fractional charge (mole fraction of the more energetic state) by

$$\text{Fractional charge} = \frac{[B]}{[A] + [B]} \tag{2}$$

In the case of a lead storage battery, A is ($2Pb(SO_4) + 2H_2O$) and B is ($Pb + PbO_2 + 2H_2SO_4$). For the metabolic adenylate system, A is ($ADP + P_i$) and B is (ATP).

A system is fully discharged when only A is present and fully charged when it consists of B alone. For intermediate states, the stoichiometrically linear charge function indicates how much work is available as a fraction of that of a totally charged system. [This metabolic use of the term "work" is slightly nonstandard. In thermodynamic terms, the maximum work available is the integrated product of the charge multiplied by the changing value of the Gibbs free energy as the system goes to equilibrium. But the energy of the adenylate system is used stoichiometrically—for example, to affect chemical change or mechanical movement—and charge is therefore proportional to available work, defined in terms of biological effect.] It is because of its stoichiometric nature that the charge function is more relevant in most contexts than the molar free energy change for both storage batteries and the metabolic adenylate system.

If the adenylate system merely alternated between ADP and ATP, the charge function would be the simple ATP mole fraction, [ATP]/([ATP] + [ADP]). Some enzymes, however, couple the use of ATP to synthetic reactions by converting ATP to AMP and pyrophospate, and so the concentration of AMP must also be taken into account.

$$\mathrm{ATP} + \mathrm{H_2O} \leftrightharpoons \mathrm{AMP} + \mathrm{PP_i} \qquad (3)$$

The pyrophosphate is rapidly hydrolyzed enzymically by pyrophosphatase, and this removal of product pulls the reaction forward (increases the numerical value of the negative free energy change).

Accumulation of AMP as a consequence of such reactions would deplete the cell's stores of ATP and ADP and so would be rapidly lethal. That outcome is prevented by the action of adenylate kinase, which catalyzes the phosphorylation of AMP:

$$\mathrm{ATP} + \mathrm{AMP} \leftrightharpoons 2\mathrm{ADP} \qquad (4)$$

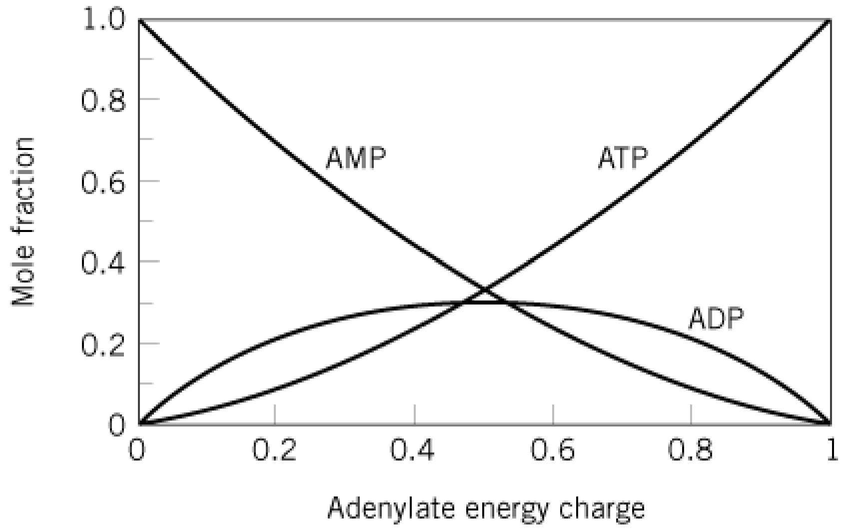
The sum of reactions (2) and (3) is conversion of two molecules of ATP to two of ADP. In such cases, a single molecule of ATP, in effect, supplies twice as much metabolic energy to a metabolic reaction as is obtained from action of an ordinary kinase that converts ATP to ADP, but a second molecule of ATP is required to make good the energy balance.

Because of the participation of AMP in metabolic energy transduction, the simple mole fraction of ATP is not an adequate measure of the energy status of the adenylate system. Reaction (3) shows that two molecules of ADP are energetically equivalent to one of ATP. Thus, the linear charge function for the adenylate system (the effective mole fraction of ATP) is seen to be

$$\text{Adenylate charge} = \frac{[\mathrm{ATP}] + 0.5[\mathrm{ADP}]}{[\mathrm{ATP}] + [\mathrm{ADP}] + [\mathrm{AMP}]} \qquad (5)$$

The adenylate charge is the linear measure of the metabolic work available. A system containing only ATP is fully charged, with an adenylate charge value of 1.0, and one containing only AMP is fully discharged, with an adenylate charge of 0. The charge value would be 0.5 if only ADP were present. If reaction (3) catalyzed by adenylate kinase is at equilibrium, the concentrations of ATP, ADP, and AMP are fixed for any particular value of the adenylate charge (Figure 1).

Figure 1. Mole fractions of the components of the adenylate nucleotide system as a function of the adenylate charge. The reaction catalyzed by adenylate kinase is assumed to be near equilibrium, with an apparent equilibrium constant irrespective of differential ionization and magnesium binding) of 0.8.



2. Regeneration and utilization of ATP

In aerobic organisms, ATP is regenerated mostly by oxidation of foods or storage compounds to carbon dioxide (see ATP Synthase). In anaerobic organisms, substrates undergo other energy-yielding conversions—for example, fermentation of glucose to ethanol and carbon dioxide—rather than oxidation. Carbohydrates are converted to pyruvate by way of the glycolytic pathway. The pyruvate is oxidized to a derivative of acetic acid, acetyl coenzyme A, which is oxidized to carbon dioxide in the reactions of the citrate cycle, or Krebs cycle. The electrons lost in those oxidations are passed on to oxygen by mediation of a series of membrane-associated enzymes. Those electron transfers are coupled to the conversion of ADP to ATP, thus supplying metabolically available energy to the adenylate system. The routes by which other classes of foods are metabolized feed into this central pathway. Fats are broken down to produce acetyl coenzyme A, which joins the carbohydrate pathway at that point. Amino acids derived from **protein degradation** are metabolized by individual pathways to produce various intermediates of glycolysis or the citrate cycle. Thus, the same central pathways are taken in the utilization of all foods.

Glycolysis and the citrate cycle are also centrally involved in biosynthesis. The biosynthetic pathways leading to the many components of a cell all begin with intermediates of glycolysis or the citrate cycle. That is, 10 or 12 intermediates of these degradative pathways are also the starting points for all synthetic sequences. Each such intermediate occupying a metabolic branchpoint must be partitioned between two competing pathways, one leading to oxidation to carbon dioxide and the other to synthesis of one or more components of the cell. The adenylate system provides energy for the chemical activities of the cell, including biosynthesis, for **active transport** of nutrients and ions across membranes against chemical potential gradients, and for most other biological requirements, including mechanical movement. All those functions are catalyzed or affected by proteins. Proteins involved in those functions have evolved affinities for ATP and ADP (or AMP) that maximize their functional usefulness to the organism. Thus, it is essential that the ratio of ATP to ADP remain virtually constant. The problem would be equivalent to the regulation of voltage by the power supply of a complex electronic device, if it were not so much more complicated.

3. Regulation of the Regeneration and Utilization of ATP

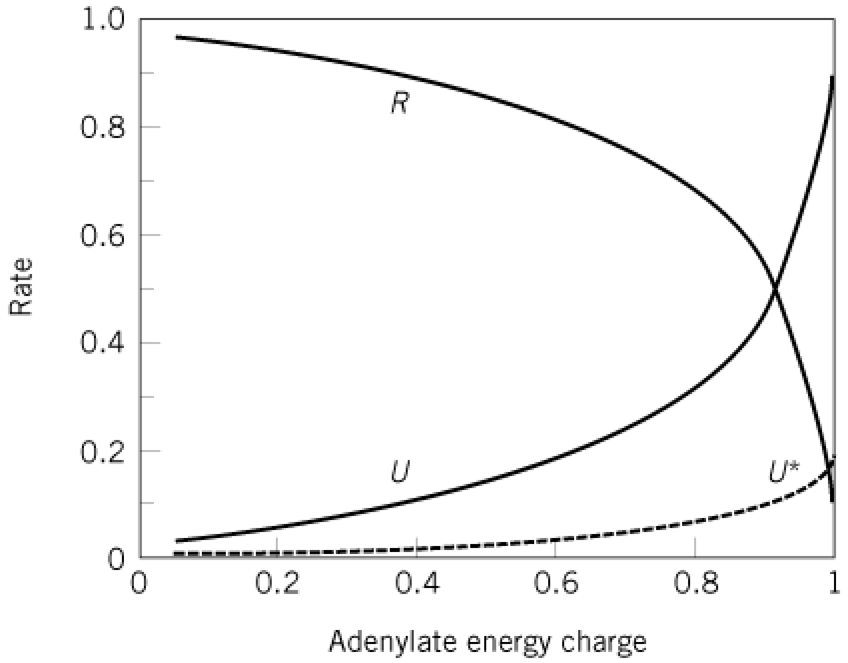
The rate of regeneration of ATP from ADP is regulated in large part by controlling the rate at which substrate is made available to the electron transport phosphorylation system. At least five enzymes that catalyze reactions in glycolysis or the citrate cycle respond sensitively to the status of the adenylate pool and adjust the properties of the catalytic site accordingly. An increase in the energy charge causes a decrease in the rate of the reaction catalyzed by the enzyme, and a decrease in charge causes an increase in rate. This **feedback inhibition** system acts to adjust the rate of regeneration of ATP to meet momentary requirements and thus to stabilize the value of the charge. The multiplicity of control sites may be surprising; a single throttle point would seem to be sufficient to regulate the rate of supply of substrate to the electron transport system. The regulatory requirements are, however, much more complex because the central pathways also supply starting materials for synthesis.

Core metabolism consists of the central pathways by which foodstuffs or storage materials of all types are prepared for oxidation and of branches from those pathways that lead to synthesis of one or more products. The primary function of oxidative pathways is regeneration of ATP from ADP, which puts energy into the adenylate system. Biosynthesis is powered by conversion of ATP to ADP, which removes energy from the adenylate system. Adjustment of the partitioning of resources between these oppositely directed pathways to meet the momentary metabolic needs of the cell or organism is the most central of the regulatory requirements that underlie cellular function and survival. At each branchpoint, the partitioning of resources must respond at least to the energy status of the cell as reflected in the ATP/ADP system and to the momentary need for the end products of the synthetic branch.

At such branchpoints, the next enzyme in the degradative pathway and the first enzyme in the biosynthetic branch compete for the branchpoint metabolite, their common substrate. Maintenance of an appropriate balance between oxidation and biosynthesis requires that both enzymes must be regulated. As well as decreasing the rate of the degradative reaction, an increase in the value of the charge leads to an increase in the rate of the competing reaction that channels the branchpoint metabolite into biosynthesis. Thus, enough substrate is oxidized to maintain the normal status of the adenylate system, and biosynthesis is allowed to the extent that the products are needed and the supply of resources allows.

This partitioning is not affected by turning enzymes on and off but by changing the affinities of the competing enzymes for the substrate, which allows for much more sensitive control. Affinity is usually expressed in terms of the Michaelis constant, $\boldsymbol{K_m}$, the concentration of substrate at which half the catalytic sites bind substrate, leading to a reaction velocity half the maximal rate. Thus, competition between the enzymes is regulated in the most direct and effective way—by modulating their relative abilities to capture the common substrate. The competition is shown generically in Figure 2. Reactions in pathways that lead to degradation of substrate and the regeneration of ATP respond to variation in the energy status of the adenylate pool as indicated by curve *R*, and reactions that direct substrate into biosynthetic pathways that utilize ATP respond as shown by curve *U*. The result is that the value of the energy charge is maintained within a narrow range of values near the intersection of the curves. If the charge drifts upward slightly, the rate of use of ATP in biosynthesis tends to increase and the rate of regeneration of ATP decreases, counteracting the drift. A downward drift has the opposite effect.

Figure 2. Generalized illustration of the effects of the adenylate charge on the rates of reactions in which ATP is regenerated (*R*) and in which ATP is utilized (*U*). Curve *U* was calculated for an enzyme for which the K_m for ATP at the catalytic site is six times that of ADP. Curve U^* represents 80% depression of rate as a consequence of feedback inhibition of the enzyme by the end product of the biosynthetic sequence.



The regulatory interactions illustrated by curves *R* and *U* are necessary but not adequate. By themselves, they would adjust the rate of all biosynthetic sequences similarly and only on the basis of the availability of energy, without regard to the need for the individual products. Those controls are supplemented by product feedback inhibition. The first enzyme in nearly every biosynthetic sequence that has been studied bears a regulatory site that binds the end product of the sequence. When that site is occupied, the conformation of the enzyme changes so as to decrease the affinity for substrate at the catalytic site (increase the K_m) (see Allostery). Thus, as the concentration of end product rises, the fraction of enzyme molecules that bind it increases, the affinity of enzyme for substrate decreases, and the enzyme competes less vigorously for substrate. When the concentration of end product falls—for example, when an amino acid is being used more rapidly for protein synthesis—a smaller fraction of the regulatory sites of the first enzyme involved in its synthesis is occupied by end product. The resulting decrease in K_m causes the substrate to be more successful in its competition with the enzyme that catalyzes the next step in the degradative pathway, and the rate of synthesis increases. Such interactions adjust synthetic rates to meet changing metabolic needs. Curve U^* in Figure 2 illustrates the response of an enzyme when the end product of its sequence is available in adequate amount from external sources. Any response between curve U^* and somewhat above curve *U* is possible. Under ordinary conditions, the response will fluctuate in the vicinity of curve *U* to adjust production to meet metabolic demand. These interactions stabilize the pools of amino acids, assuring that they will neither be depleted when demand for protein is high nor build up to unnecessary or injurious levels when demand is small. Pool levels of other metabolites are regulated similarly.

The curves of Figure 2 thus provide a general overview of the regulation of the central pathways in their roles of regenerating ATP and providing starting materials for biosynthesis (1). The interaction of curves *R* and *U* adjust degradative metabolism and overall biosynthetic rates so as to maintain a nearly constant value of energy charge and, in the process, necessarily cause an appropriate partitioning of resources between degradation and synthesis. Superposition of product feedback inhibition, illustrated by curve U^*, adjusts the rate of each individual synthetic sequence to meet the momentary needs of the organism or cell. Even when the overall rate of biosynthesis is high, the synthetic pathway leading to any given metabolite will be suppressed when that product is in good supply. Thus, the components of this control system act together to assure that the adenylate system, the immediate energy source for nearly all cell activities, is maintained at a high and constant charge, near 0.9 (2), and that the rate of production of each biosynthetic product is determined by interaction between the overall availability of resources and the cell's need for the individual product. Regulation of biosynthetic rates is roughly equivalent to the decisions made by a human consumer who must balance how strongly an item is desired and how readily it can be afforded.

4. Regulatory Properties of Enzymes

Enzymes that show *R*-type responses (see Allostery) catalyze reactions in the pathways that supply substrates for electron transport–linked regeneration of ATP but usually do not involve ATP or ADP directly. Such enzymes have, therefore, evolved regulatory, allosteric sites, distinct from the catalytic site, where ADP or AMP can bind, causing conformational changes that increase the binding affinity for the substrate at the catalytic site. Some such enzymes decrease substrate affinity when ATP binds at a regulatory site. Typically, the nucleotide binds cooperatively to two or more sites, and the effect on K_m is related to the square or higher power of the nucleotide concentration. Such interactions underlie the sensitive response of *R*-type enzymes to variation in the value of the charge (3).

In contrast, ATP and ADP are directly involved in most of the reactions at branchpoints that direct substrate into synthetic sequences. Thus, separate nucleotide-binding regulatory sites are not required. The *U*-type response is a consequence of higher affinity at the catalytic site for ADP, a product of the reaction, than for ATP, a reactant. This reversal of the usual pattern of higher affinity for reactants than for products results in pronounced inhibition by ADP across most of the energy charge range. At a charge of 0.5, for example, when the concentrations of ATP and ADP are approximately equal, ATP would be excluded from most of the catalytic sites because of competition by ADP. The result would be that most of the kinetic response to variation in the ATP/ADP ratio would occur in a rather narrow range near the high end of the energy charge scale. Curve *U* of Figure 2 is calculated for an enzyme for which the value of K_m for ATP is six times that for ADP.

The regulatory stability illustrated by Figure 2 depends on (1) precise evolutionary adjustment of the affinities for adenylates at regulatory sites of *R*-type enzymes and at catalytic sites of *U*-type enzymes and of the conformational links by which binding at those sites causes conformational changes that modulate affinity for substrate at catalytic sites and (2) the relative affinity at catalytic sites of *U*-type enzymes for ATP and ADP. As a consequence of such interactions, the ATP/ADP ratio, or the energy charge, affects reaction rates more strongly than do the absolute concentrations of the adenylate nucleotides. A mutant strain of *Escherichia coli* unable to synthesize adenylate nucleotides grew on adenine-limiting media at essentially normal rates when the intracellular concentrations of ATP, ADP, and AMP were half the normal levels. The energy charge and the ATP/ADP ratio retained their normal values. That mutant, like other organisms that have been studied, did not grow if the energy charge fell slightly below its usual value of about 0.9 (4).

The controls illustrated in Figure 2 should not be confused with thermodynamic or mass-action effects; they are strictly kinetic. The value of the Gibbs free energy change is high and negative for *U*-type reactions under all physiological conditions, as is also true for *R*-type reactions. Thus, degradation of fuels and synthesis of products are both thermodynamically favorable at all times, and evolved kinetic control mechanisms determine which conversions actually occur. The adenylate energy transduction system, which links metabolic sequences and nearly all other cell activities energetically, is ideally placed for the additional role of mediating the regulatory interactions that underlie the integrated activities of cells and organisms.

Adenylate Cyclases

The ubiquity of cyclic AMP (cAMP) in regulating **enzymatic** activity and/or **genetic expression** in all kingdoms of life, except for the **archaea** (but see later), accounts for the interest displayed in its mode of synthesis and the vast amount of literature devoted to the enzymes that produce it, the adenylate cyclases. These enzymes, which catalyze synthesis of cAMP from ATP and yield pyrophosphate as a by-product, can be classified into four different classes according to their common features: (1) cyclases related to enterobacterial adenylate cyclases; (2) toxic adenylate cyclases isolated from bacterial pathogens; (3) a large and probably ancient class that comprises cyclases from both eukaryotes and prokaryotes and is strongly related to guanylate cyclases; and (4) one example, presently known only from the eubacteria *Aeromonas hydrophila* and *yersinia pestis*, that differs entirely from all other classes.

0.1. Class I: The Enterobacterial Type

The first complete adenylate cyclase gene, *cya*, was cloned and sequenced from *Escherichia coli*. Work on other enterobacteria, such as *Erwinia chrysanthemi*, *Proteus mirabilis*, *Salmonella typhimurium*, *Yersinia intermedia*, and *Yersinia pestis* demonstrates that both the environment of the genes and the proteins specified are similar in size and overall organization to those of *E. coli* at the corresponding locus (1). Analysis of the *cya* gene from other bacterial species, related to enterobacteria but distinct from them, using genetic complementation of appropriate *cya* defective strains of *E. coli* (and more recently by direct sequencing of whole genomes) reveals that the genes from many other bacteria, in particular *Aeromonas caviae*, *Aeromonas hydrophila*, *Haemophilus influenzae*, *Pasteurella multocida*, and *Vibrio cholerae*, directly synthesize a protein structurally and phylogenetically related to the *E. coli* cyclase (1, 2) (see also the database at `http://www.tigr.org`).

No long stretch of **hydrophobic** amino acid residues is present to explain the membrane-bound localization of the adenylate cyclases. In all cases, the proteins are very rich in cysteine residues, an uncommon feature for proteins located in the cytoplasm or at the cytoplasmic border of the membrane. This might account for the extreme difficulty in purifying the enzymes. In addition, they are also rich in histidine residues, which could indicate that metal ions take part in the folding and/or activity of the polypeptide chain, but no experimental data support this hypothesis. Finally, the protein is made of two functionally well-defined **domains**. The catalytic domain is NH_2-terminal, whereas the glucose-sensitive regulatory domain is COOH-terminal. Comparison of the polypeptide sequence of the catalytic domain of the *E. coli* enzyme with sequences in the protein data libraries do not reveal significant identities with other known proteins. The catalytic domain sequence has been experimentally identified to be about 420 residues. Differences in the amino acid sequence of the *E. chrysanthemi* enzyme often result from the presence of complementary charged residues in place of neutral ones. This suggests that there are more electrostatic interactions (including salt bridges) that stabilize the protein at the lower growth temperature of this bacterium. This observation might be helpful when trying to understand the tertiary structure of the protein, which is still not known.

The carboxy-terminal domain of the protein is involved in regulating of the enzymatic activity, in particular its inhibition by glucose. A component of the phosphorylation cascade that mediates import of glucose in the cell, enzyme IIAGlc, is involved in this regulation, but in a way not yet understood. An aspartate residue (Asp414 in the *E. coli* enzyme) is involved in the process in an unknown way. Tonic inhibition of the catalytic domain by the regulatory domain could be relieved by phosphorylation of this residue, although such phosphorylation has never been demonstrated (3).

0.2. Class II: The Calmodulin-Activated Toxic Class

Whooping cough is caused by the **gram-negative** bacterium *Bordetella pertussis*, which secretes many toxic proteins into the medium, including an adenylate cyclase. In 1980 it was discovered that this enzyme is activated by a host protein, calmodulin, which does not occur in bacteria (4). Two years later, Leppla (5) demonstrated that another toxic adenylate cyclase, secreted by a gram-positive bacterium, *Bacillus anthracis*, the etiological agent of anthrax, is also activated by host calmodulin. These observations stimulated intense efforts, but several years were required before the *cya* genes from either organisms could be cloned. However, in 1988 a simple idea, predating its generalization under the name "two-hybrid system," *in vivo* complementation by a **plasmid** encoding an activator of the function (in this case, calmodulin), permitted the cloning of adenylate cyclase genes coding for the calmodulin-dependent cyclases (6).

Bordetella pertussis adenylate cyclase is synthesized as a large bifunctional polypeptide chain of 1706 amino acid residues. This contrasts with the various low values reported for the molecular weight of the purified protein (from 43 to 70 kDa). The explanation became apparent when it was demonstrated that the N-terminal segment of the protein (400 residues) alone displays calmodulin-activated adenylate cyclase activity, whereas the rest of the molecule is responsible for hemolytic activity and for transporting the toxin. Sequence, molecular genetic, and physiological studies indicate that the adenylate cyclase domain is fused to a polypeptide chain similar to that of the *E. coli* hemolysin toxin. Therefore the name cyclolysin was coined for the toxic adenylate cyclase from *B. pertussis*.

The adenylate cyclase of *B. anthracis* has been named after the symptom it triggers in the infected host, edema factor. It is encoded in a plasmid, together with another toxin, the lethal factor and a carrier protein, the protective antigen, necessary to internalize both the edema factor and the lethal factor into host target cells. The adenylate cyclase (edema factor) protein, 800 amino acid residues long, comprises four regions of different function. The first region is a signal peptide, permits secretion of the protein. The second region corresponds to the domain that binds with the protective antigen. The third region encodes the adenylate cyclase function. It is followed by the fourth region of unknown function. These toxic adenylate cyclases have been subjected to a most thorough biochemical analysis, but they have not yet been crystallized.

In spite of several attempts to isolate other members of this class, until 1998, we knew only three examples of such proteins, isolated from extremely distant bacteria, one gram-positive and two gram-negative (the adenylate cyclase from *B. bronchiseptica* is very similar to the *B. pertussis* enzyme) (7). Several examples of similar proteins have now been discovered in *Pseudomonas aeruginosa*, and in *Yersinia* species. Comparison of the catalytic regions of the *B. pertussis* and *B. anthracis* adenylate cyclases identified four conserved regions that are involved in catalysis, calmodulin binding and activation. The first region comprises a sequence, Gly-XXXX-Gly(Ala)-Lys-Ser, similar to the nucleotide-binding motif found in many ATP- or GTP-binding proteins.

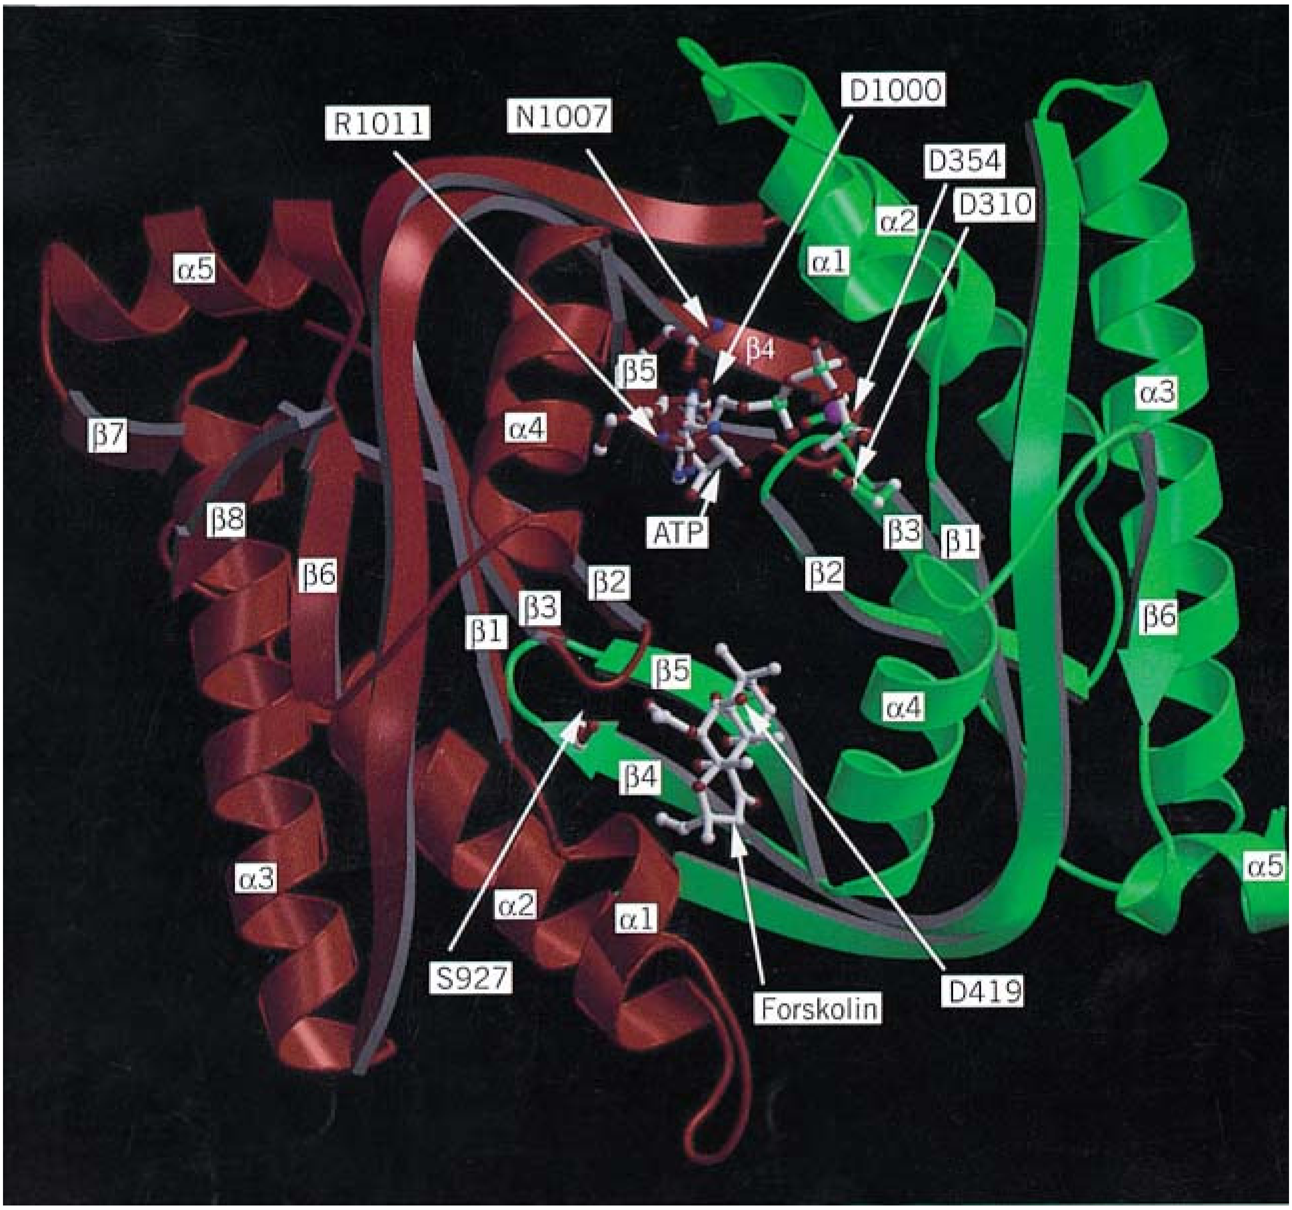
Therefore it was proposed as part of the catalytic site, and *in vitro* mutagenesis substantiated this interpretation. A second region, with the sequence Pro-Leu-Thr-Ala-Asp-Ile-Asp having some similarity in 6-**phosphofructokinase**, is also involved in catalysis, and it was proposed that the aspartate residues present in this region are involved in binding ribose and magnesium-phosphate. Although it is strongly conserved, however, the first proline residue does not seem very important because it could be replaced by a leucine residue without any measurable influence on the activity or calmodulin activation of the wild-type enzyme.

Although many calmodulin-dependent enzymes have been identified, the mechanism of activation by calmodulin is still poorly understood (see Calmodulin). In several cases, limited **proteolysis** releases active, calmodulin-independent forms of the enzymes. Accordingly, it was proposed that the calmodulin-binding domain of these enzymes blocks access of substrates to the active site and that activation results because an inhibitory domain is removed upon binding calmodulin. The most original feature of the *B. pertussis* protein is that it can be split into two separate domains which recover most of the initial activity when combined. This observation, together the with analysis of mutants in the region conserved between the *B. anthracis* and *B. pertussis* enzymes, indicates that these proteins may form a catalytic center from the cooperation of two halves. The function of calmodulin may be to trigger the appropriate conformational movement necessary to form an active catalytic center (3).

0.3. Class III: The “Universal” Class

Adenylate cyclases from multicellular eukaryotes have long remained elusive because purifying the corresponding catalytic subunit is extremely difficult. Following intense work all over the world, however, they have been the first adenylate cyclases to be crystallized and analyzed by X-ray crystallography (see Fig. 1). The activity of these enzymes is subject to a complex regulatory pattern, in particular by GTP-binding proteins. Class III enzymes were first discovered in yeast, but, for convenience, we start with the eubacterial enzymes.

Figure 1. Three-dimensional model of the C1 and C2 domains of the catalytic core of type I adenylate cyclase derived fr the X-ray crystallographic structure of the C2 homodimer of the type II enzyme (19). The polypeptide backbone of the C domain is green and that of C2 is red. The C-terminal nonhomologous segment of C1 is truncated after the a-helix 5 (low right). Only a few side chains in the active site are shown, designated by one-letter abbreviations. When they differed frc the residues in the crystal structure, they were placed according to Liu *et al*. [*Proc. Natl. Acad. Sci.* (1997) **94**, 13414–13419.] ATP was placed as described by Liu *et al*. and modified according to the interactions reported by Tesmer *et al*. [*Science* (1997) **278**, 1907–1916.] The ligand atoms are indicated by C, white; N, blue; O, red; P, green, and Mg, purple. figure is kindly provided by James Hurley. See color insert.



0.3.1. Eubacteria

Class III adenylate cyclases form a very diverse collection in eubacteria, both in length and in regulation. Gram-positive bacteria such as *Corynebacterium liquefaciens* secrete large amounts of cAMP because they have a very active class III adenylate cyclase, which is activated by pyruvate. *S. coelicolor* synthesizes a much less active adenylate cyclase involved in aeromycelium formation. Gram-negative bacteria, such as *Rhizobium meliloti*, synthesize at least two different adenylate cyclases. Disruption of both genes simultaneously does not alter cAMP production and suggests the presence of further enzymes. The gram-negative sliding myxobacterium *Stigmatella aurantiaca*, that exhibits an elaborated differentiation pattern, harbors at least two adenylate cyclase genes, each of them corresponding to class III enzymes. They have been partially purified and are inhibited by adenosine, as are the mammalian enzymes (see later). They comprise two domains. The catalytic domain is carboxy-terminal and the regulatory domain is a likely ion transporter in one case and the phosphorylated moiety of a two-component regulatory system in the other. Many other bacteria possess class III cyclases, in particular **cyanobacteria** (8, 9). These enzymes generally comprise two domains. The catalytic domain is carboxy-terminal. There are no indications that they must oligomerize to be active.

0.3.2. Lower Eukaryotes

Saccharomyces cerevisiae was the first organism from which class III adenylate cyclase genes were cloned and sequenced. The enzyme is activated by the *RAS* gene product (10, 11). Two forms of the enzyme may exist. A long form contains repetitions of a leucine-rich motif that plays a regulatory role and whose significance was recently substantiated and extended. Then it became clear that this eukaryotic adenylate cyclase is completely different from the enterobacterial class because of sequence differences in the catalytic center and also because the organization of the gene is different. The catalytic domain is located at the COOH-terminus in *S. cerevisiae* cyclase, whereas it is found at the NH_2-terminus in *E. coli*. The yeast enzyme remained the only example of its class until Garbers, Goeddel and co-workers (12) recognized that the genes encoding guanylate cyclases that had been cloned from several metazoans were derived from an ancestor common to the yeast adenylate cyclase. Another member of class III was subsequently discovered by Young *et al.* (13), who cloned the adenylate cyclase gene from *Schizosaccharomyces pombe* by hybridization using the catalytic domain gene sequence from *S. cerevisiae* as a probe. Finally, the first higher eukaryote adenylate cyclase gene isolated in Gilman's laboratory (14) from bovine brain displayed features clearly reminiscent of this class. Since then, many other genes or cDNA for adenylate cyclases belonging to this class have been isolated and sequenced from lower eukaryotes: *Saccharomyces kluyveri*, *Trypanosoma brucei* and *T. equiperdum*, *Plasmodium falciparum*, *Neurospora crassa*, and *Dictyostelium discoideum* (3).

0.3.3. Higher Eukaryotes: Nine Types

Many class III adenylate cyclases have been identified in higher eukaryotes, in particular in vertebrates, but the most thorough study is in mammals, where several types differing in their regulatory properties have been identified (15). All are regulated in more or less complex ways by **G-proteins** (16). Mammalian adenylate cyclases are informally grouped into nine types according to their tissue location and activity regulation. All but type 9 are activated by the diterpene forskolin, and some are activated by protein kinase C and/or other regulators. Type 1 enzymes were described as calmodulin-activated enzymes from brain. Type 2 proteins are found in brain, lung and other tissues. Type 3 are abundant in olfactory tissue, and the smaller type 4 enzymes are present in testicular tissue. Adenylate cyclase 1, 2, and 8 are positively regulated by calcium/calmodulin, whereas types 5 and 6 are directly inhibited by calcium. Adenylate cyclase 2 and 4 are sensitive to multiple regulatory effects from diverse receptors (3, 15). Adenylate cyclase 9 mRNA, found in rat brain, is particularly abundant in the hippocampus, cerebellum, and neocortex (17). However, the classification into types is somewhat arbitrary (for example, type 4 can also be calmodulin-activated). They all have overall similar structures. Two phylogenetically related cytoplasmic domains are required for catalysis. All types are connected by an integral membrane domain and have variable integral membrane domains at the NH_2 terminus of the protein. Among their many functions, their role in synaptic plasticity and memory is particularly interesting (18) and will certainly make adenylate cyclases extremely fashionable again.

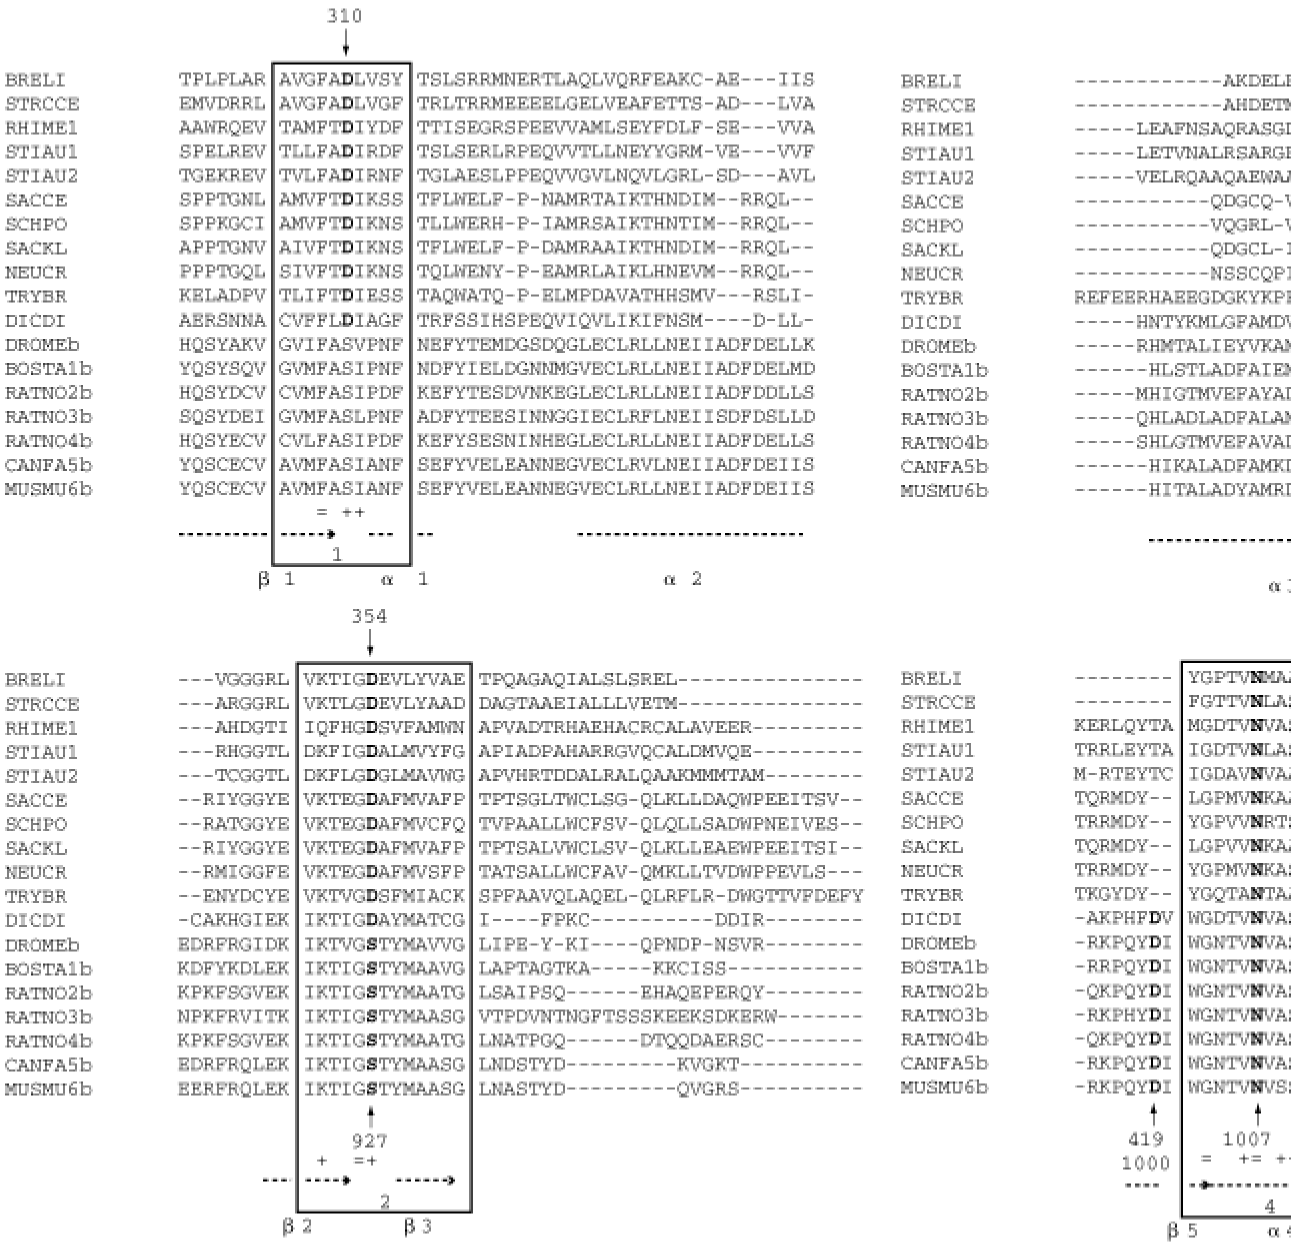
0.3.4. Three-Dimensional Structure

The diverse origins of class III adenylate cyclases are reflected in the wide variation in their general organizations and molecular weights. The smallest protein is the *R. meliloti* enzyme, which contains only a catalytic domain, although some data suggest that an upstream sequence may yield a much longer protein that has a complex regulatory pattern. The next shortest protein, also bacterial, is the enzyme from *C. liquifaciens*. The yeasts produce long proteins, as do higher eukaryotes (except in the case of the testicular enzyme). In all cases, the catalytic domain is located at the COOH-terminus. The mammalian enzymes consist of twelve hydrophobic membrane-spanning regions that form two distinct domains, two cytoplasmic regions that contain both variable and conserved regions, and, in particular, two well-conserved domains that are responsible for catalysis.

Comparison of the catalytic domain sequences of the class III proteins shows that four amino acid stretches are strongly conserved: (1) (Met/Leu/Ile/Val)-(Met/Leu/Ile/Val)-Phe-(Ala/Thr)-(Asp/Ser)-(Leu/Ile)-X-(Asn/Asp)-(Phe/Ser); (2) (Ile/Val)-Lys-Thr-X-Gly-(Ser/Asp)-(Ala/Ser/Thr)-(Tyr/Phe)-

Met; (3) (Met/Leu/Ile/Val)-(Arg/Lys)-(Met/Leu/Ile/Val)-Gly-(Met/Leu/Ile/Val)-(His/Asn)-X-Gly-X-(Val/Ala)-(Val/Leu)-(Ala/Ser)-Gly; and (4) (Trp/Tyr/Phe)-Gly-(Asn/Asp/Pro)-Thr-Val-Asn-X-Ala-Ser-Arg-(Met/Leu/Ile/Val) (see Fig. 2). Crystallization of the catalytic core of one protein and determination of its structure by X-ray diffraction (19) showed that these regions are part of the organization of the structure (Fig. 1). The crystal structure contains the forskolin-binding site but unfortunately not the nucleotide binding site. As a step toward understanding the evolution and function of class III cyclases, enzymes displaying significant guanylyl cyclase activity that have evolved from an adenylyl cyclase ancestor were isolated. A single amino acid residue change (Gly-Asp-Thr-Val-Asn to Gly-Asp-Thr-Ile-Asn in the region of the fourth a-helix of the catalytic core) alters the nucleotide specificity of the enzyme (20). This corresponds to a pocket situated in a region of the protein that might accommodate the heterocyclic base (19).

Figure 2. Alignment of the amino acid sequences of Class III adenylate cyclases from various organisms. The four regio text are enclosed in the four boxes. Secondary structural elements found in the crystal structure of Fig. 1 are displayed ur corresponding residues of the active site depicted in Fig. 1 are indicated.



0.4. Class IV Adenylate Cyclases

The preceding three classes of structurally unrelated adenylate cyclases already pose a challenging problem. So it was a surprise that *Aeromonas hydrophila* synthesizes another enzyme, a very small cyclase of 193 residues, which has an optimal temperature for activity of 65°C and is at least ten times more active than the class I adenylate cyclase in the same organism (21). No function has yet been discovered for this protein. As yet, it has been found only in various isolates of *A. hydrophila* and in *Y. pestis* (unpublished). There was one report of the presence of cAMP in Archaea, but this was later proven to be the result of an artifact of the growth culture. Therefore it was interesting to see that the sequence of adenylate cyclase from *A. hydrophila* is significantly similar to a gene product of the archaebacterium *Methanococcus jannaschii*. The gene is expressed in *E. coli*, where it is toxic, but it does not restore cAMP synthesis. Therefore, nothing is yet known about the nature of adenylate cyclases, if they exist, in Archaea, but we may expect that, at some point, they might be discovered and that they would belong to this new class.

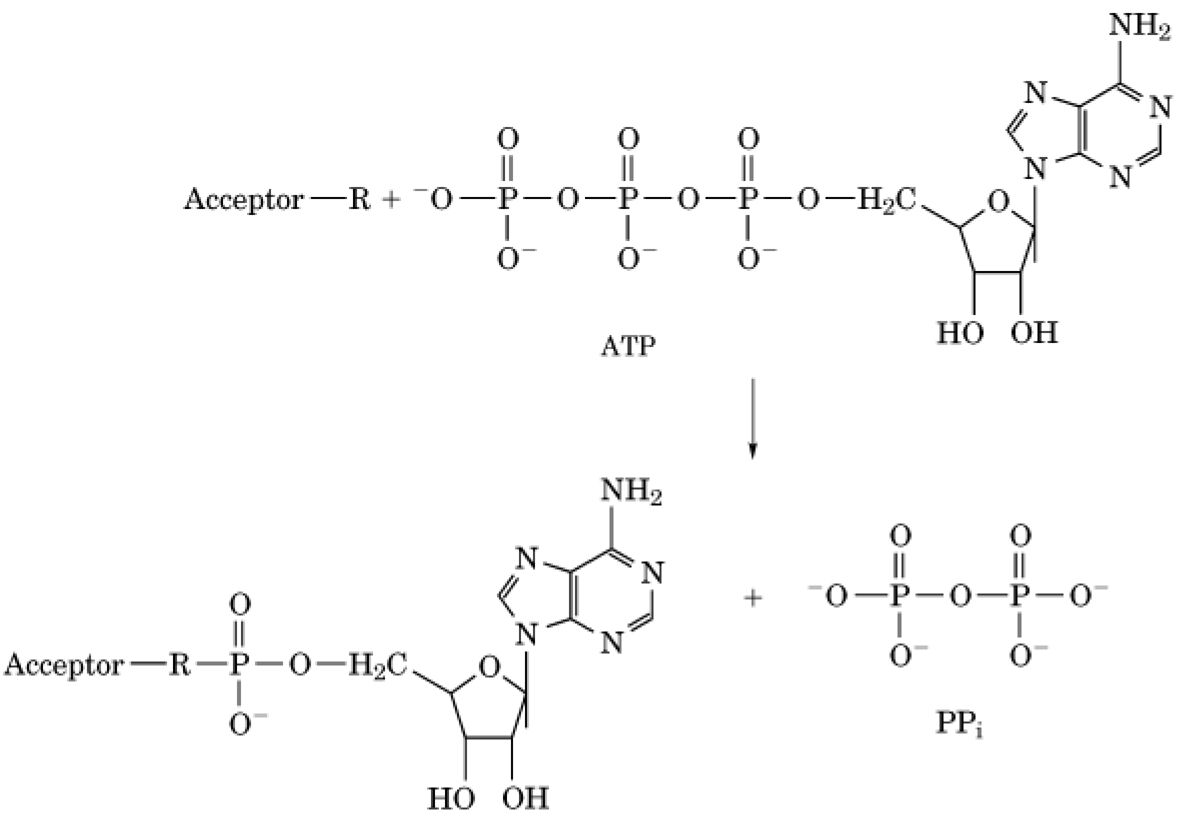
Adenylylation

Adenylylation is the process in which adenosine-5′-monophosphate (AMP) is covalently attached to a protein, nucleic acid, or small molecule via a phosphodiester or phosphoramidate linkage. Most often, the AMP is derived from ATP, but in some bacterial adenylylation reactions $NADP^+$ is the source. Similarly, deadenylylation is the process in which AMP is removed from the adenylylated molecule. The adenylylation/deadenylylation processes may provide regulatory control of enzyme activity, contribute to intermediate steps in individual enzymatic reaction mechanisms, or occur as intermediate steps along the biosynthetic pathway of cofactors. In this sense, adenylylation is analogous to **phosphorylation**, sulfation, **methylation**, and other intracellular covalent modification reactions for which multiple functions exist. Adenylylation occurs in a wide range of organisms, including bacteria, yeast, and mammals, although it is less common than many other post-translational modification reactions as a source of enzyme regulation. The general chemical reaction for ATP-dependent adenylylation is shown in Figure 1.

Figure 1. General reaction scheme for ATP-dependent adenylylation. R = O or N. The a, b, and g phosphorous atoms are labeled.



It is important to distinguish adenylylation from the related processes of phosphorylation, adenylation, and **ADP-ribosylation**:

1. Phosphorylation is readily distinguished from each of the other processes by the lack of

incorporation of sugar or adenine in the acceptor.

2. Adenylation results in covalent attachment of ADP via the b-phosphoryl group. Relatively few examples of adenylation are known, and they appear to be limited to adenylation of carbohydrates to yield, for example, glucose-1-ADP.
3. ADP-ribosylation results in a covalent bond between the ribose moiety of NADPH and an acceptor.

These covalent modification reactions also contribute to multiple biological functions, including regulation of enzymatic activity. Analytically, adenylation may be distinguished from adenylylation with the appropriate radiolabeled substrates. Specifically, a-^{32}P-ATP, but not b-^{32}P-ATP or g-^{32}P-ATP, will yield radiolabeled acceptor if adenylylation occurs. Typically, ATP that is radiolabeled with ^{3}H or ^{13}C in the adenine moiety is also used, in separate experiments, to confirm that label incorporated into the acceptor is not a result of phosphorylation, without adenylylation. An additional criterion that is often applied to distinguish adenylylation from phosphorylation is its sensitivity to phosphodiesterases. Phosphodiesterases will cleave the AMP from an adenylylated substrate, but they will not hydrolyze phosphate from phosphorylated protein. Specific examples of molecules that are adenylylated are discussed separately below.

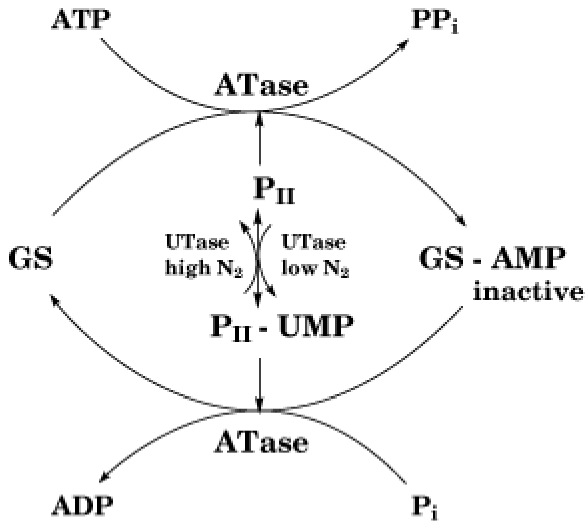
1. Glutamine Synthetase

In all organisms, glutamine synthetase (GS) plays a critical role in intermediary metabolism by catalyzing the ATP-dependent condensation of ammonia with glutamate, to yield glutamine. It was discovered by Stadtman and co-workers (1, 2) that *Escherichia coli* glutamine synthetase exhibited dramatically different kinetic properties when isolated from cultures grown in nitrogen-rich vs. nitrogen-starved media. They demonstrated that the differences in enzymatic activity of GS corresponded to the presence or absence of covalently attached adenylyl groups. Since their initial findings, bacterial GS and associated regulatory enzymes have provided a paradigm for understanding biological regulation of nitrogen assimilation in some prokaryotic organisms. Comparison of the molecular details of adenylylation-dependent regulation of prokaryotic GS remains an active research area. Mammalian and plant GS, in contrast, are not regulated by adenylylation.

Regulation of glutamine biosynthesis is characterized most thoroughly for *E. coli* and includes a complex bicyclic cascade that controls the adenylylation of Tyr397 on the surface of GS. Bacterial GS are dodecameric oligomers with two face-to-face hexameric rings. In the subset of bacterial strains that regulate GS activity via adenylylation, the adenylylation state of GS may vary from 0 to 12 AMPs/GS dodecamer, and the enzymatic activity decreases with increasing extent of adenylylation. The regulatory cascade is summarized in Figure 2. It includes the adenylyl transferase (ATase), a signal transduction enzyme (P_{II}), and a uridylyl transferase (UTase) enzyme that responds directly to nitrogen levels. When the nitrogen levels are low, UTase uridylylates P_{II} at Tyr51 to form P_{II}-UMP. P_{II}-UMP stimulates the deadenylylation activity of ATase, to decrease the proportion of GS in the adenylylated form and thus to increase the rate at which nitrogen is "fixed" in the amino acid glutamine, derived from glutamate by GS. When nitrogen levels are high, the UTase cleaves the UMP from P_{II}-UMP to generate P_{II}. Unmodified P_{II} stimulates the adenylylation activity of ATase, to increase the adenylylation state of GS and reduce its efficiency in converting glutamate to glutamine. The complexity of these regulatory cascades underscores the importance of adenylylation as a mechanism for controlling nitrogen metabolism in some prokaryotes.

Figure 2. Bicyclic cascade for regulation of *E. coli* glutamine synthetase (GS). ATase catalyzes the

adenylylation/deadenylylation of GS; P_{II} stimulates the adenylylation activity, and uridylylated P_{II} (P_{II}-UMP) stimulates the deadenylylation activity. Uridylylation of P_{II} is catalyzed by UTase. UTase uridylylates P_{II} when nitrogen levels are low, and it hydrolyzes the uridylyl group from P_{II}-UMP when nitrogen levels are high.



The structural basis for the decrease in enzymatic activity of *E. coli* GS upon adenylylation is not known. Although X-ray crystallography structures are available for the unadenylylated GS from *Salmonella typhimurium* (3, 4), no structure for an adenylylated GS has been determined. Spectroscopic and kinetic analyses indicate that adenylylation causes an increase in the Km (Michaelis constant) for substrates and for the metal cofactors (Mg^{2+} or Mn^{2+}) that are required at each GS active site, although no specific interactions between the adenylyl group and protein residues have been identified (5-7). On the basis of many biophysical criteria and hydrodynamic volume properties, the adenylylated and unadenylylated forms of GS do not differ greatly in conformation (8, 9). Presumably, adenylyl groups attached at Tyr397 of each subunit in dodecameric GS induce subtle changes in the local conformation of the active sites to which they are adjacent. Spectroscopic methods have suggested that the adenine moiety of AMP attached to each subunit within the hexameric ring structure is highly dynamic, and it collides by diffusion with the subunit adjacent to it (10, 11). Thus, specific hydrogen bonds or electrostatic interactions between the adenylyl groups and protein residues may be limited to the phosphate and ribose moieties of AMP. Alternatively, AMP may simply block the enzyme active sites sterically.

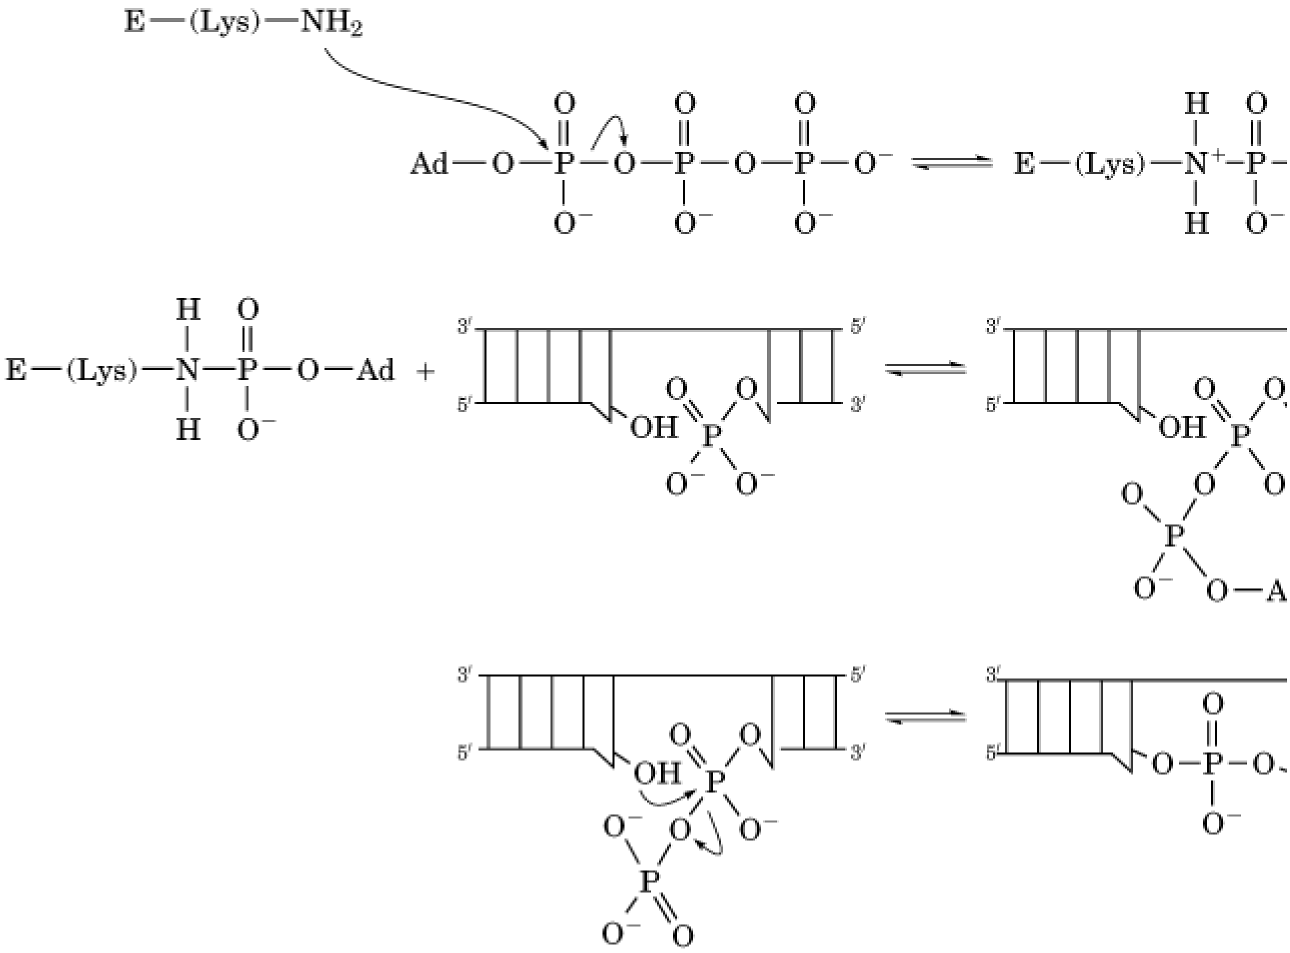
Based on sequence comparisons of GS from numerous prokaryotes, and on mutational analysis of the *E. coli* and *Anabaena 7120* GS, a minimal **consensus sequence** including the Tyr 397 to be adenylylated and a properly positioned proline residue are required for efficient adenylylation by ATase. These two residues are indicated in bold in the local sequence of *E. coli* GS: Met-Asp-Lys-Asn-Leu-**Tyr**-Asp-Leu-**Pro**-Pro-Glu-Glu-Ser-Lys. Individual mutation of several residues in this sequence has negligible or modest effects on the rate of adenylylation by ATase. In contrast, replacement of the bold proline nearly abolishes the ATase-catalyzed adenylylation, and substitution of serine by proline at the analogous position in the *Anabaena 7120* is sufficient to make this GS a substrate for ATase from *E. coli* (12, 13).

The *E. coli* Atase has been characterized genetically and biochemically; it is a constitutively expressed 945 amino acid residue protein (~115 kDa) that contains two highly homologous **domains** (8, 14). Genetically engineered N- and 3C-terminal domains that have been expressed separately and purified are both catalytically active. However, the two nonoverlapping constructs exhibit different catalytic activities. The N-terminal domain (residues 1 to 423) catalyzes deadenylylation of GS, requires P_{II}-UMP, and is inhibited by P_{II}. In contrast, the C-terminal domain (residues 425 to 945) catalyzes the adenylylation of GS and is not regulated by P_{II} or P_{II}-UMP. It is striking that P_{II} is required for the adenylylation activity of the full-length ATase, whereas the C-terminal domain by itself is unresponsive to P_{II} or P_{II}-UMP. Presumably, P_{II} and P_{II}-UMP regulate the adenylylation reaction of the C-terminal domain by interacting with the N-terminal domain, or the full-length construct is required to maintain the structural integrity of this regulatory site. In addition, glutamine activates the adenylylation reaction of the C-terminal domain. It also is noteworthy that the adenylylation and deadenylylation reactions catalyzed by ATase are not the reverse of each other. Deadenylylation requires inorganic phosphate (P_i) rather than PP_i, and the reaction product is ADP rather than ATP. In effect, this deadenylylation reaction may be considered formally as transfer of an adenylyl group from GS to P_i, or the adenylylation of phosphate anion. Although the two functional domains of ATase exhibit significant homology at the amino acid level, they have clearly distinct functional properties. The structural basis for these differences remains unknown.

2. DNA Ligases, RNA Ligases, and Related Enzymes

DNA ligases and RNA ligases catalyze the formation of phosphodiester bonds at single strand breaks with adjacent 3′-hydroxyl and 5′-phosphate termini in DNA or RNA, respectively. For bacterial, mammalian, and virus ligases, the first step in the catalytic cycle is the adenylylation of an active-site e-amino group of a lysine side chain (Fig. 3). Mammalian and virally encoded ligases utilize ATP to adenylylate the lysine, whereas bacterial ligases exploit $NADP^+$. A consensus sequence found in ligases from each of these sources that includes the adenylylated Lys, in bold, is -**Lys**-X-(Asp/Asn)-Gly- (15, 16). The phosporamidate bond formed upon adenylylation of the lysine residue is more stable toward hydrolysis than is the phosphoester bond formed upon adenylylation of tyrosine residues or hydroxyl groups of aminoglycosides. Interestingly, a similar consensus sequence is found in messenger RNA-capping enzymes that transfer guanylylate to the 5′-terminus of mRNA, followed by methylation to generate the mature RNA message.

Figure 3. Mechanism for DNA and RNA ligases. The catalytic reaction begins with ATP-dependent adenylylation of the
adenine; E, a ligase.



Functionally related RNA 3′-phospho-cyclases have been identified, and they appear to be present in mammals, yeast, enteric bacteria, and archaebacteria. This wide distribution suggests that these enzymes have a critical role, but no physiological function has been determined. As part of the catalytic cycle, the 3′-phosphoryl group on the terminal nucleotide of transfer RNA or **small nuclear RNA** (snRNA) undergoes ATP-dependent adenylylation, to generate a phosphodiester bond. This intermediate is attacked subsequently by the 2′-hydroxyl group to release AMP and produce a terminal cyclic phosphate (17). As with the ligase-catalyzed reactions, this cyclization proceeds via an initial adenylylation reaction.

3. Other Mammalian Proteins

On the basis of radiolabeling experiments, it has been suggested that plasma membrane proteins from liver or parotid glands of rats are adenylylated (18, 19). No function has been ascribed to any of these proteins. The hepatic proteins are glycosylated, and their adenylylation is inhibited by lectins (20). An interesting possibility is that the adenylyl group is attached to these proteins via their carbohydrates. The same proteins are phosphorylated, and it has been suggested that some protein kinases may be capable of catalyzing adenylylation, in addition to phosphorylation. Further studies that demonstrate covalent attachment of adenylyl groups unambiguously are required, and the physiological function for adenylylation of these proteins remains unclear.

4. Aminoglycoside Antibiotics

Several aminoglycoside antibiotics, including tobramycin, gentamycin, and kanamycin, are adenylylated by bacterial nucleotidyl transferases, and this contributes to antibiotic resistance in some strains. The enzymes responsible are not specific for ATP, and they also utilize GTP or UTP, thus resulting in guanylylation or uridylylation as well. These nucleotidyl transferases are **plasmid**-encoded. The adenylylation (nucleotidylylation) site on various aminoglycoside antibiotics differs, but it is most frequently either (a) the 2′- or the 3′-hydroxyl of the 3-aminoglucose ring or (b) the 4′-hydroxyl of the 6-aminoglucose ring. Based on the X-ray crystallography structure of kanamycin nucleotidyl transferase (21), the catalytic mechanism has been proposed to be an in-line displacement of PP_i by the hydroxyl group of the aminoglycoside, with an active-site glutamate residue acting as a general base. The presence of only a few contacts between the adenine ring of ATP and the nucleotidyl transferase active site is consistent with the lack of specificity for the nucleotide substrate.

5. Adenosine-5-Phosphosulfate

An additional example of adenylylation is provided by the biosynthetic pathway of the cofactor 3′-phospho-adenosine-5′-phosphosulfate (PAPS), which is summarized in Figure 4. This cofactor is used by several sulfotransferases in the sulfation of catechols, phenols, and other alcohols. An intermediate formed en route to PAPS is adenosine-5′-phosphosulfate (APS). APS is formed by ATP sulfurylase, in an adenylylation reaction that requires ATP and sulfate ion, SO_4^{2-}, to yield APS and PP_i. The formation of APS is partially rate-limiting in PAPS biosynthesis, and deficiency of ATP-sulfurylase may cause impaired sulfation of proteoglycans required for maintenance of extracellular matrix, cartilage, and connective tissues. Thus, the adenylylation reaction catalyzed by this enzyme may have direct clinical impact, manifested as chondrodysplasias, if it operates inadequately (22).

Figure 4. Biosynthesis of 3′-phospho-adenosine-5′-phosphosulfate (PAPS). The first step in the biosynthetic pathway is adenylylation of sulfate to generate adenosine-5′-phosphosulfate (APS).

Adjuvants

The term *adjuvant* designates substances that enhance the immune response without affecting the specificity of recognition. "Adjuvanticity" was first described in the 1920 by Ramon, who made the observation that mineral substances (such as metal salts and aluminum) or crude materials (such as tapioca) considerably augment the immune response to various vaccines. He then invented the name of "substances stimulantes et adjuvantes de l'immunité." When an immune response is monitored by the kinetics of occurrence of circulating antibodies, it can easily be shown that, in the presence of adjuvants, the antibody titer is considerably higher and is maintained for a much longer period of time. Although first discovered over 70 years ago, very little progress has been made in this area, and the mode of action of adjuvants remains somewhat elusive. It is generally accepted that they act essentially in two ways: (*1*) retain the antigen in emulsion or aggregates, depending on the nature of the adjuvant, ensuring a slow but relatively constant release of antigen that may continuously restimulate the immune system; and (*2*) behave as a nonspecific activator of some partners of the immune response, like mobilizing macrophages that are acting as **antigen-presenting** cells or by exerting a polyclonal activation of lymphocytes, which is the case for the bacterial lipopolysaccharide (LPS), a potent polyclonal activator of B cells.

To date, the best and universally used substance is the so-called Freund's complete adjuvant, which is an emulsion prepared with a suspension of killed mycobacteria in mineral oil. Unfortunately, it cannot be used for human purposes and must be strictly confined to laboratory animals. Attempts have been made to isolate active molecules from mycobacteria (and also from many other microorganisms). This resulted in a long list of molecules, from which the muramyl dipeptide (*N*-acetylmuramyl-L-alanyl-D-isoglutamine, or MDP) was the most extensively studied. Endowed with good adjuvant properties, it is still too toxic for human use; and many attempts have been made, and are still being made, to define nontoxic homologues. For vaccination purposes in humans thus far, the old recipes, among which are aluminum hydroxide, aluminum phosphate, or alum precipitate, are still the most widely used.

An interesting advance was made with ISCOM (which stand for immuno-stimulating complex), proposed by Morein et al. (1) ISCOM is a cage-like matrix made up of cholesterol and Quil A, which is a substance extracted from the bark of a tree, *Quillaja saponaria*, that contains, after partial purification, five main components with triterpenoid structures. The matrix spontaneously organizes in the presence of antigen, most often protein isolated from a viral coat envelope. The construction ensures high immunogenicity and is used in a number of animal vaccines.

It is likely that one key event played by adjuvants is at the steps of antigen uptake and processing by antigen-presenting cells. Supporting this idea is the fact that bacterial, or more generally particulate antigens, are far better immunogens than the purified molecules isolated from cells. This constitutes an obvious difficulty for designing sophisticated "pure" vaccines, which would at first sight appear advantageous over using complete bacteria that usually contain toxic components, but that also serve as carrier with an adjuvant effect for the desired antigen. To date, an ideal vaccine would have to reconcile the purity of a recombinant protein with a well-characterized potent adjuvant. We know much about making recombinant proteins, but have at present no convincing pure adjuvant. One interesting approach is to use a living vector, such as vaccinia virus, that has been genetically modified to express a given antigen at the surface of the microorganism. One may also couple a gene expressing the antigen with a gene encoding a **cytokine** that would specifically favor the amplification of a helper T cell compartment. Another possibility is to embed the antigen in liposomes that could be eventually targeted to well-defined cells of the immune system.

All these approaches have been attempted with variable success. To date, one must unfortunately admit that, despite the fantastic progress made in recent years in the understanding of the basic mechanisms that operate in the immune system, no really significant advances have been made in defining more efficient and more rational vaccines.

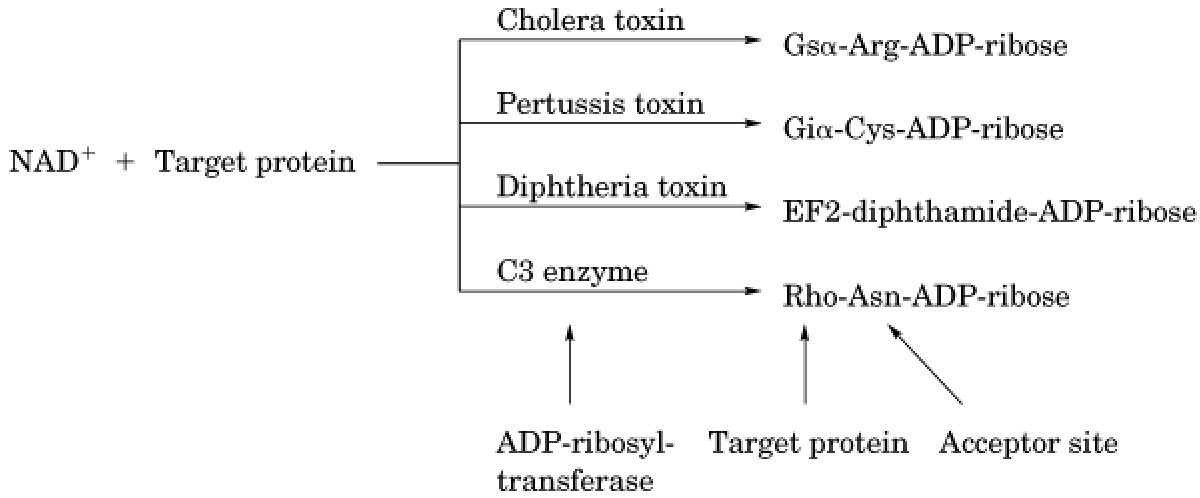
ADP-Ribosylation, Mono

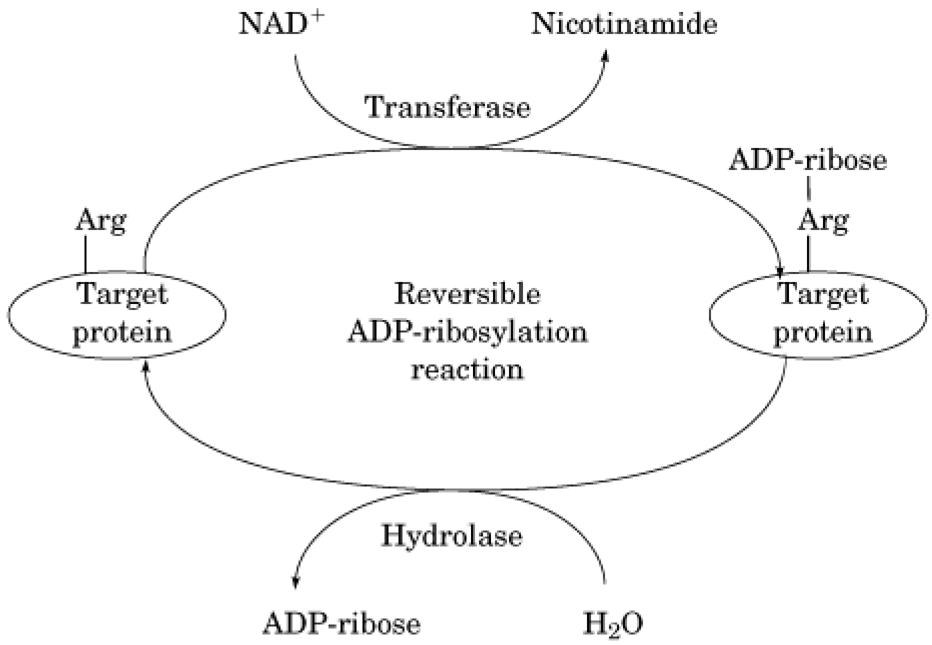
MonoADP-ribosylation is a post-translational modification, catalyzed by ADP-ribosyltransferase (ADPRT), that transfers the ADP-ribose moiety from NAD^+ to a specific amino acid residue of target protein and releases the nicotinamide moiety. To date, four amino acid-specific ADPRT have been reported, specific for arginine, cysteine, diphthamide (a modified form of histidine), and asparagine residues. These transferases were originally discovered as the **cholera**, **pertussis**, and diphtheria toxins and the *Clostridium botulinum* C3 enzyme (1, 2), in the order of amino acid-specificity described above. The native form of such ADP-ribosylating toxins is a heteromultimer, and one of the subunits has ADP-ribosyltransferase activity (1). The catalytic subunit penetrates the host cell with the assistance of the other subunits. The prokaryotic ADPRT modify target proteins, including a variety of GTP-binding proteins, in eukaryotic cells (Fig. 1). This modification leads to alterations in the target protein, and consequently in cell functions (1). The bacterial toxins and C3 enzyme have proven extremely useful in studies on signal transduction pathways in various cell types of eukaryotes. MonoADP-ribosylation must be distinguished from poly-ADP ribosylation.

Figure 1. Target protein and acceptor site for ADP-ribosylation in eukaryotic cells by prokaryotic toxins and C3 enzyme.



The reversible Arg-specific ADP-ribosylation (Fig. 2), like protein **phosphorylation**, was initially documented as a regulatory mechanism for control of nitrogen fixation in the **photosynthetic** bacteria *Rhodospirillum rubrum* and *Azospirillum braziliense* (3). Endogenous dinitrogenase reductase-ADPRT modifies Arg101 on the target protein, dinitrogenase reductase, resulting in inactivation of the reductase. Recovery from the inactive form is achieved through cleavage of the Arg-ADP-ribose linkage by dinitrogenase reductase-activating glycohydrolase. This is the only example of metabolic regulation through endogenous ADP-ribosylation. Purification, characterization, and molecular cloning of eukaryotic Arg-specific ADP-ribosyltransferase (4-7) and of ADP-ribosyl-Arg hydrolase (8) were reported. By analogy to prokaryotes, metabolic regulation through reversible ADP-ribosylation in eukaryotes has been postulated.

Figure 2. Arg-specific ADP-ribosylation and de-ADP-ribosylation reactions.



Among the eukaryotic ADPRTs detected, the best-defined one is Arg-specific. Purification and characterization of the ADPRT from turkey erythrocytes (4), rabbit skeletal muscle (9), and chicken peripheral heterophils (polymorphonuclear leukocytes) (5) revealed that these enzymes exhibit different physical and regulatory properties, kinetics, and intracellular localization. Guanidino compounds, such as arginine and agmatine, function *in vitro* as acceptors for Arg-specific ADPRT (4). With b-NAD^+ and arginine as substrate, a-ADP-ribosylated arginine is formed by Arg-specific ADP-ribosyltransferase; and the a anomer, but not the b anomer, is utilized as substrate by ADP-ribosyl-Arg hydrolase (10).

Some of the ADPRTs catalyze NAD glycohydrolysis or auto-Arg-specific ADP-ribosylation, when either water or the enzyme itself serve as acceptor for ADP-ribose (1, 2). Upon incubation of intact cells or cell lysates with [^{32}P]NAD^+, it would appear that the ADP-ribose released from NAD^+ by cellular NAD glycohydrolase is attached to some proteins nonenzymatically (11, 12). Thus, enzymatic and non-enzymatic ADP-ribosylations should be differentiated.

Molecular cloning and expression studies of complementary DNA for Arg-specific ADPRT revealed that the rabbit and human skeletal muscle transferases are glycosylphosphatidylinositol-anchored (GPI-anchored) (6) and that two forms of transferases from chicken bone marrow cells are secreted (7).

The previously known rat and mouse T-cell marker RT6 have significant sequence Homology to the ADPRT. It is now accepted that these proteins are GPI-anchored and possess transferase and/or NAD glycohydrolase activities (13-15).

A common feature of the vertebrate Arg-specific ADP-ribosyltransferase is their resemblance to the transferase from cholera toxin and to *Escherichia coli* heat-labile enterotoxin. Strictly conserved regions around the active site containing two Glu residues (E207 and E209, indicated with an asterisk in Fig. 3) are seen in all Arg-specific ADPRT detected in vertebrates, bacteria, and viruses. On the other hand, RT6.1 and RT6.2 (rat), which have NAD glycohydrolase activity, but not Arg-specific ADPRT, contain Gln in place of Glu207. The recombinant protein of a mutant Gln207Glu-RT6.1 possesses Arg-specific ADPRT activity (16, 17), but alterations in the kinetic parameters of the NAD glycohydrolase reaction are slight (17). Furthermore, the mouse homologues of rat RT6, Rt6.1, and Rt6.2 have Glu207 and ADPRT activity. When the Glu is replaced with Gln, Rt6.1 loses the activity (17).

Figure 3. Comparison of the amino acid sequences of a Glu-rich motif in eukaryotic, prokaryotic, and viral Arg-specific ADP-ribosyltransferases and T-cell antigen RT6. References are cited by the numbers in parentheses. ADPRT: arginine-specific ADP-ribosyltransferase.

It has been reported that defects in RT6 expression are associated in various animal models with the pathogenesis of autoimmune insulin-dependent diabetes and systemic lupus erythematosus (18, 19), although a possible mechanism for RT6-mediated protection from these autoimmune diseases is unknown. Definite physiological functions of monoADP-ribosylation in eukaryotes must be established by further investigation.

Adriamycin

1. Introduction

Adriamycin is the trade name for an anthraquinone-containing antibiotic which also has the international nonproprietary name (INN) of doxorubicin (1) and the NCI internal identification number NSC 123127. It is a member of the anthracycline group of compounds that contain an anthraquinone chromophore and a polycyclic ring system (1). It has good anticancer activity against a wide spectrum of tumors (and still remains as the antitumor agent that has the widest spectrum of anticancer activity) and is one of the most extensively used of the fifty or so chemotherapeutic compounds currently in clinical use (2-4). Its full potential as an anticancer agent has not been reached because of a dose-limiting cardiotoxicity (1-4). Despite enormous effort during the last 30 years to develop more effective and less cardiotoxic derivatives, it remains one of the best, proven anticancer drugs. It also exhibits good antibacterial activity.

2. Structure and Chemistry

Adriamycin consists of a planar tetracyclic ring system linked by a glycosidic bond to daunosamine, an amino sugar (Fig. 1). It is a bright red compound that is normally isolated as the hydrochloride salt, has the chemical composition $C_{27}H_{29}O_{11}\cdot HCl$, a molecular weight of 579.98, and is soluble in water, physiological saline, and methanol (5, 6). The p*K*a of the amino group is 8.2 (5, 6). In neutral aqueous buffers, it self-associates (7), has absorbance maxima at 233, 480, and 530 nm, and at concentrations less than 25 µM has an extinction coefficient of 11,500 $M^{-1}cm^{-1}$ at 480 nm (7). It is fluorescent and can be quantitated in aqueous solutions using excitation and emission wavelengths of 480 and 595 nm, respectively. The solid compound is quite stable if kept in the dark at 4°C and free of moisture. It is photosensitive and therefore solutions must also be kept in the dark at 4°C; even under these conditions, some decomposition will occur in a week or so. It chelates Fe^{3+} with exceedingly high affinity and readily forms the $Fe(Adriamycin)_3$ complex (8).

3. History

In 1958 a new species of *Streptomyces* was identified in a soil sample taken from southern Italy. A red antibiotic, daunomycin was isolated from this microorganism and exhibited good activity against a range of murine tumors (1). In a search for other potentially more active derivatives of daunomycin, the soil microorganism was subjected to the mutagen *N*-nitroso-*N*-methyl urethane and produced a mutant strain that yielded a modified form of the antibiotic. This new antibiotic (named Adriamycin because of the closeness of the original soil sample to the Adriatic Sea) exhibited both a wider spectrum of activity and an improved anticancer response against animal tumors than daunomycin (1) and was also remarkably successful in treating human tumors. Adriamycin was rapidly introduced into clinical trials in Italy and the United States and was approved for clinical use in the United States in 1974 (1).

4. Clinical Use

4.1. Tumors

Adriamycin is particularly useful for treating solid tumors such as breast, lung, ovarian, and thyroid carcinomas, as well as soft tissue sarcomas (2-4). It is also active against lymphoid and myelogenous leukemia (2-4).

4.2. Dose and Administration

It is normally administered as a bolus at a dosage of 45–75 mg/m^2 every 3–4 weeks, or more recently as a continuous intravenous infusion during 4–5 days (2, 3). It is inactive if administered orally because the glycosidic bond is hydrolyzed in the gastrointestinal tract. For most treatment regimes it is administered as one component of a combination of drugs (2).

4.3. Side Effects

The most significant problem is a cumulative, dose-dependent cardiomyopathy that can lead to heart failure in up to 10% of patients who receive the maximum recommended dose of 550 mg/m^2(2, 3). This cardiotoxicity can be acute (hours to days following treatment) or more commonly, can be delayed by months or even years. The cardiotoxicity appears to be due to the redox activity of the drug (9): Adriamycin can undergo a one electron reduction [catalyzed by a range of enzymes such as microsomal cytochrome P450 reductase, mitochondrial NADH dehydrogenase, cytochrome b5 reductase, and xanthine reductase (10)] leading to production of the semiquinone that generates superoxide in the presence of molecular oxygen, then hydrogen peroxide, and ultimately the extremely reactive and highly toxic hydroxyl radical. These hydroxyl radicals react with any nearby molecule, and hence lead to oxidative damage of critical targets such as DNA and membrane lipids. In most tissues this lethal process is minimized by superoxide dismutase (which converts superoxide to hydrogen peroxide) and catalase (which subsequently converts hydrogen peroxide to water), as well as glutathione peroxidase (which also converts hydrogen peroxide to water). Heart tissues are particularly sensitive to Adriamycin because of their greatly compromised capacity for protection against hydroxyl radicals due to the lack of the bulk hydrogen peroxide detoxifying enzyme catalase and also because Adriamycin inhibits gutathione peroxidase activity (10). Other side effects of Adriamycin therapy are hair loss (alopecia) which usually starts after the first dose of Adriamycin, nausea and vomiting (usually overcome nowadays by appropriate antinausea drugs), and reduction in bone marrow function (with maximum suppression 10–14 days following treatment).

4.4. Pharmacokinetics

The disappearance of Adriamycin in plasma is adequately described by a three-compartment model whose half-lives are approximately 10 min, 3 h, and 30 h (11). The plasma level is rapidly depleted and only 0.2 mM remains (average of nine patients) several hours after administration of a 30 mg/m^2 bolus dose of Adriamycin (12); 0.02 μM remains several hours following a 75 mg dose (either as a bolus or 4 h infusion) to a single patient (13). In contrast, the intracellular concentration of drug was approximately 4 μM and 6 μM, respectively, for these two studies (12, 13). The striking features of these results are that the intracellular concentration of drug is typically 100–1000 times greater than that in plasma (14), and that the intracellular drug pool has an extremely long half-life of 4–5 days (13). The uptake into solid tumors is similar to that of normal tissues (12).

Pharmacology. The major metabolite of Adriamycin involves metabolism of the C9 side chain alcohol to adriamycinol, where the conversion is catalyzed by the ubiquitous cytoplasmic NADPH-dependent aldo-keto reductase (15). Subsequent microsomal glycosidases that are present in most tissues convert adriamycinol into the inactive deoxyadriamycinol aglycon and daunosamine. The aglycon is then demethylated and conjugated to polar groups to yield more hydrophilic metabolites that are excreted mainly in the bile (15).

The drug distribution has been examined in 20 cancer patients where tissue uptake decreased in the following order: liver > lymph nodes > muscle and bone marrow > fat and skin (12). It has long been known that Adriamycin localizes in the nucleus at the subcellular level (16). This has been confirmed recently in single squamous carcinoma cells by quantitative confocal laser scanning microscopy, where the nuclear level was twice that of the cytoplasm 30 minutes after exposure to 1 μg/mL of Adriamycin, and increased even more with time (17). Interestingly, the cytoplasmic drug level was also higher than that of the medium (17), and this is surprising because Adriamycin is taken up into cells by passive diffusion (18). Nuclear localization is readily attributed to the known high affinity of Adriamycin for DNA (see below). The nature of cytoplasmic localization is less clear, but the distribution as a multitude of small patches of fluorescence throughout the cytoplasm (19) is consistent with some degree of mitochondrial localization (because the drug binds to mitochondrial membranes and, to a lesser extent, also to mitochondrial DNA); it is known that there are as many as a thousand mitochondria per cell (20).

4.5. Resistance

When cells in culture are exposed to Adriamycin for an extended period of time, the cells gradually become resistant to the drug. This type of resistance is due primarily to amplification of the multidrug transporter gene *mdr1* that leads to overexpression of a 170-kDa glycoprotein now known as P-glycoprotein (21). This protein forms a pore in the cell membrane and actively pumps Adriamycin (and many other drugs) out of the cell, using ATP as an energy source. In patients treated with Adriamycin, much of the resistance that develops over several months (and diminishes the antitumor effect of the drug) and appears to derive from overexpression of P-glycoprotein. To enhance the usefulness of Adriamycin, there have been some attempts to develop specific inhibitors of this protein. This approach is no longer considered viable because of the multitude of other drug efflux pumps that have been identified in recent times (22).

In addition to the phenomenon of multidrug resistance, other mechanisms of resistance have been identified for Adriamycin, including elevated levels of glutathione and decreased levels of topoisomerase II in cells in culture (although not yet demonstrated in tumors) (21).

5. Interactions with DNA

Numerous studies have shown that Adriamycin binds to DNA with high affinity by intercalating between adjacent base pairs of DNA. In this process the DNA unwinds to accommodate the drug. This is reflected by an increase in the length of small linear fragments of DNA (hence an increase in the viscosity of the solution) or in the loss of a number of negative supercoils for supercoiled DNA such as a plasmid (that results in an initial increase of viscosity and a decrease of the sedimentation coefficient). These processes have been summarized previously (3, 23). The structure of the intercalated species has been fully characterized by X-ray crystal studies of the drug–oligonucleotide complex. The dominant features are that the drug chromophore lies virtually at right angles to the adjoining base pairs and the amino sugar fits snugly into the minor groove of DNA (24, 25).

Earlier binding studies (before about 1980) misinterpreted curved Scatchard plots as indicating more than one class of DNA binding site. It is now known that this curvature which results from the extreme form of negative cooperativity is displayed when the drug binds to DNA, and is fully described by the neighbor-exclusion principle; values for the intrinsic association constant and the number of occluded base pairs are approximately $2 \cdot 10^6\ M^{-1}$ and 3.0 bp, respectively, at near physiological ionic strengths (26, 27). Although this interpretation assumes that the drug intercalates randomly between all possible base pair combinations, this is not strictly correct because there is a slight selectivity of sequence for some sites. Theoretical quantum mechanical calculations indicated the requirement for a three base pair site, and ACG is likely to be the preferred site (28, 29). *In vitro* transcription footprinting studies confirmed the requirement for a triplet site, but showed that the preferred consensus sequence is TCA (where the drug intercalates between C and A) (30), although there was clearly only small energetic differences between this and other triplet sites.

Adriamycin is in rapid equilibrium with DNA. The on-rate is diffusion controlled, and the off-rate is also fast and usually measured by stopped-flow detergent sequestration. This has revealed that Adriamycin has an overall half-life on DNA of approximately 0.5 s at room temperature (31), although by analogy with the structurally similar drug daunomycin, the kinetic processes are likely to be much more complex, especially for longer dissociation times (32).

6. Mechanism of Action

The exact molecular events involved in the mechanism of action of Adriamycin have not yet been resolved. Although many possible mechanisms have been proposed and the problems in identifying the critical factors have been well summarized (33, 34), many potential mechanisms have been identified, including impairment of topoisomerase II activity, bioreductive action of the drug, free radical effects, membrane related effects (33, 34). There is a convincing body of evidence to show that the primary target is DNA (33-35). Some of this evidence is that almost all of the drug in the nucleus (>99.8% of single, living cells is associated with DNA (36); more than 80% of all of the drug present in human tumor biopsies is associated with DNA (37); and increasing drug activity (over three orders of magnitude) correlates with increasing DNA binding, damage, or impairment of DNA template activity (38). Therefore DNA binding appears to be related in some way to the anticancer properties, and at present there are two types of interactions with DNA that appear to relate to the drug action: impairment of topoisomerase II activity and formation of drug–DNA adducts.

6.1. Impairment of Topoisomerase II

When Adriamycin is added to tumor cells in culture, protein-associated double- and single-strand

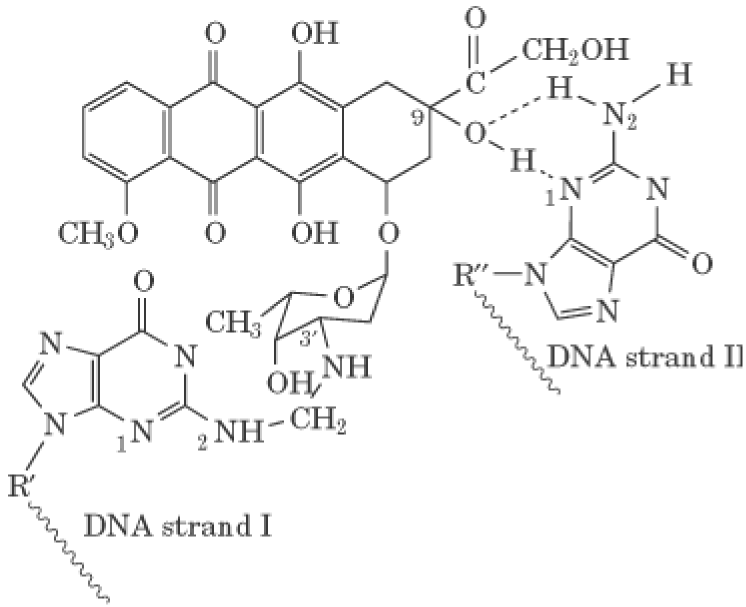
DNA breaks occur close to nuclear matrix attachment sites where topoisomerase II is localized. This enzyme regulates the topological state of DNA, and the DNA breaks appear to arise from intercalation of the drug at that site, which results in structural distortions that interfere with the re-ligation step of topoisomerase II (2, 39, 40). There are several reasons why this appears to be a major contribution to the mechanism of action of Adriamycin: the activity of the enzyme is reduced in tumor cells which are resistant to Adriamycin (39, 40); a correlation has been shown between the induction of double-strand DNA breaks and the cytotoxicity of Adriamycin in P388 leukemia cells (41); and this type of DNA damage occurs at clinical levels of the drug (39, 40). However, there is also evidence that other factors contribute to the mechanism of action of Adriamycin and that the activity cannot be accounted for solely by impairment of topoisomerase II: some studies failed to detect DNA strand breaks in cell cultures at Adriamycin concentrations where cytotoxic responses were observed (42); topoisomerase II mediated damage is rapidly reversible following removal of the drug (39), whereas it is known that DNA double- strand breaks increase long after removal of the drug (43); some derivatives that induce a high level of double-strand breaks exhibit a low level of cytotoxicity (44); and there is little evidence that topoisomerase II is involved in some tumors (10).

6.2. Adriamycin–DNA Adducts

There have been many reports of Adriamycin–DNA adducts formed by enzymatic, microsomal, or cellular activation of the drug (33, 45, 46), but it was not until 1990 that it became clear from *in vitro* transcription footprinting studies that these adducts formed predominantly at 5′-GC-3′ sequences (47). It was subsequently shown that adducts at these sites behave as an interstrand cross-link (48, 49), although with limited stability [half-life of 5 –40 h depending on the DNA sequence and fragment length (49, 50)]. It is now clear that adducts at GC sequences and interstrand cross-links at GC sequences are one and the same lesion and that the adducts stabilize DNA sufficiently so that they function as “virtual interstrand cross-links” (51-53). The adducts have been well characterized in the solid state by X-ray crystal diffraction (54) and in solution by 2-D NMR (55).

Surprisingly, it has been shown that the adducts are mediated by formaldehyde and involve a characteristically unstable aminal linkage to the N-2 of guanine on one strand of DNA (51-55) (Fig. 2). This unusual adduct exhibits some of the characteristics of an interstrand cross-link because of the additional stability that arises from the intercalated chromophore and from additional hydrogen bonds that are formed to the second DNA strand (51-55). The cross-linkage is unstable to heat and to alkali, and this explains why it has proven so difficult to find this lesion in cells in the past (50). Conditions have been established to isolate these lesions from tumor cells (56-59), and this led to a resurgence in cellular studies of this drug. There is now good evidence that these adducts contribute to the mechanism of action of Adriamycin: the capacity of different derivatives of Adriamycin to form adducts (virtual cross-links) correlates well with their cytotoxicity (57), and gene-specific cross-linking assays have detected sufficient lesions in both the nuclear and mitochondrial genomes to show that this lesion is cytotoxic at clinical levels of the drug (58). Total cellular DNA adducts have also been quantitated directly using $[^{14}C]$Adriamycin (58). Because of the formaldehyde-dependent activation of Adriamycin, formaldehyde-releasing prodrugs that have been examined in combination with Adriamycin lead to as much as a 20-fold increase of Adriamycin–DNA adduct levels and a synergistic cytotoxic response (59).

Figure 2. Structure of Adriamycin–DNA adducts (52, 54, 55). The exact location of H bonds has not been defined and will depend upon the DNA sequence flanking the 5′-[GC-drug-N]3′ binding site (55).



6.3. Other Possible DNA-Related Effects

Two additional DNA-related effects also occur at low drug levels *in vitro*, but at this stage the contribution to the mechanism of action of Adriamycin under clinical conditions is unknown (34): impairment of DNA ligase activity (60): impairment of helicase activity (61).

6.4. Current Status

The evidence at present indicates that there is no single mechanism of action of Adriamycin. Both impairment of topoisomerase II activity (resulting in protein associated double-strand breaks) and formation of interstrand cross-links occur at clinical levels of the drug. It is known that Adriamycin activates the general cellular response to DNA damage in which the tumor suppressor protein p53 is induced, resulting in arrest of the cell cycle and the induction of apoptosis (62). Although it is known that apoptosis occurs at submicromolar concentrations of the drug (63), this response is yet to be fully understood in the context of drug-induced cytotoxicity (64). The development of new derivatives of Adriamycin in the future is likely to rely heavily on an even more detailed understanding of the molecular consequences of the DNA damage induced by this drug.

7. The Search for New Derivatives

Because of the dose-limiting toxicity of Adriamycin, there has been an intense international effort in the past three decades to find new derivatives that have improved anticancer activity and/or reduced cardiotoxicity. This endeavor has been extremely well summarized by Weiss (1). Unfortunately, the outcome from this search has been disappointing. From more than 2000 derivatives tested by 1992 (and perhaps as many as 2500 tested to date), none is substantially superior to Adriamycin for proven clinical anticancer activity. However, several offer advantages for clinical use: idarubicin (lacking the methoxy group at the C4 position) is more amenable to oral administration than Adriamycin; epirubicin is less cardiotoxic and results in less nausea and vomiting than Adriamycin at equimolar doses—it has anticancer activity similar to that of Adriamycin, but reduced side effects have facilitated its wide use as an alternative to Adriamycin. High-dose clinical trials are still in progress with this derivative. One new and encouraging approach that is emerging is the development of “preactivated” forms of the anthracyclines; these formaldehyde-activated derivatives (doxoform, epidoxoform) exhibit increased toxicity to tumor cells, especially to anthracycline-resistant cells (65).

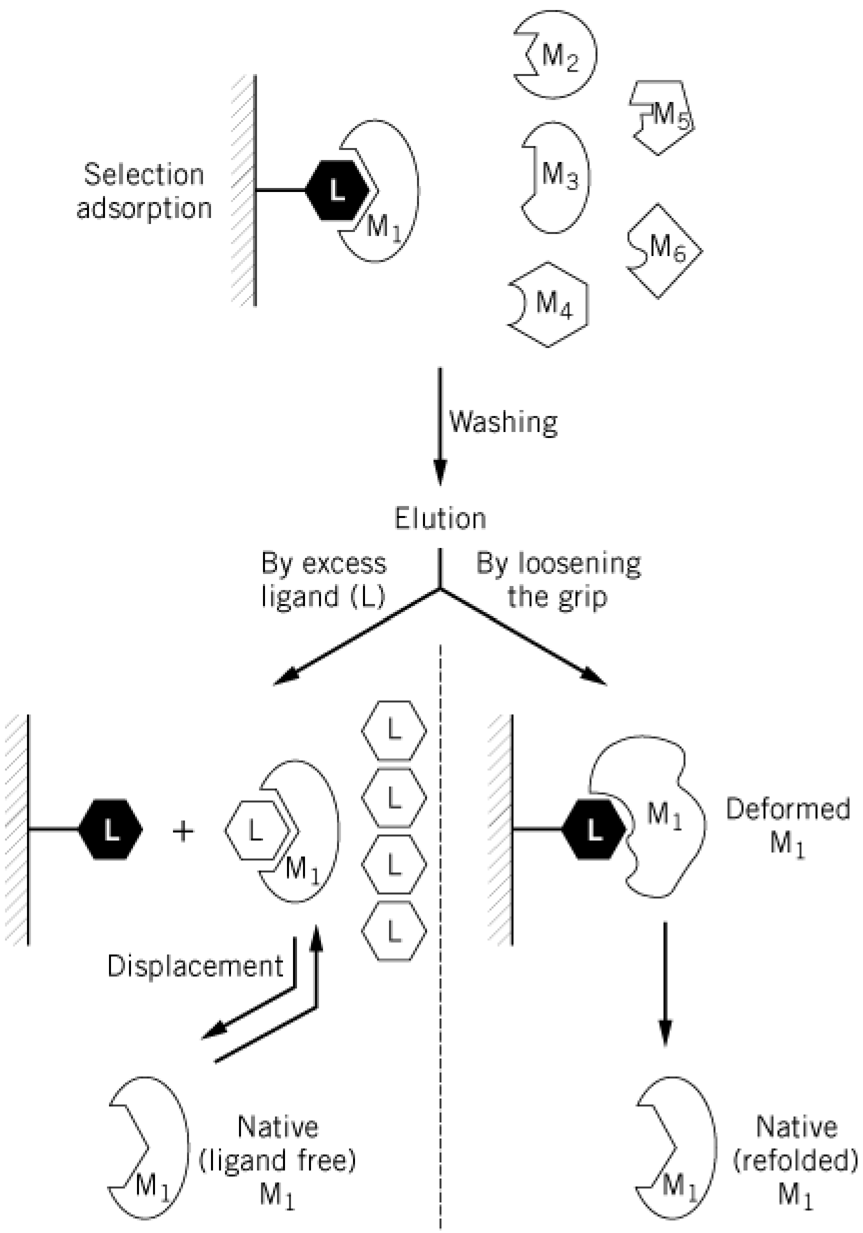
Affinity Chromatography

1. The Basic Principle

Affinity chromatography (AC) is a general **chromatographic** method for the selective extraction and purification of biological macromolecules on the basis of their biorecognition (1-3). The method makes use of the specific physiological affinity between a desired macromolecule (M) and one of its physiological ligands (L). The ligand, or its analogue (L′), actually acts as a "bait" and is used to extract or "fish out" a desired macromolecule (M_1) (Fig. 1) from a mixture of macromolecules (M_1; M_2; M_3; M_4; M_5; M_6¼). The other macromolecules have a very low (if any) affinity for L, presumably because they are designed to refrain from interfering *in vivo* with the physiological recognition of L by M.

Figure 1. Schematic representation of the general procedure for an AC purification. For further details, see text.

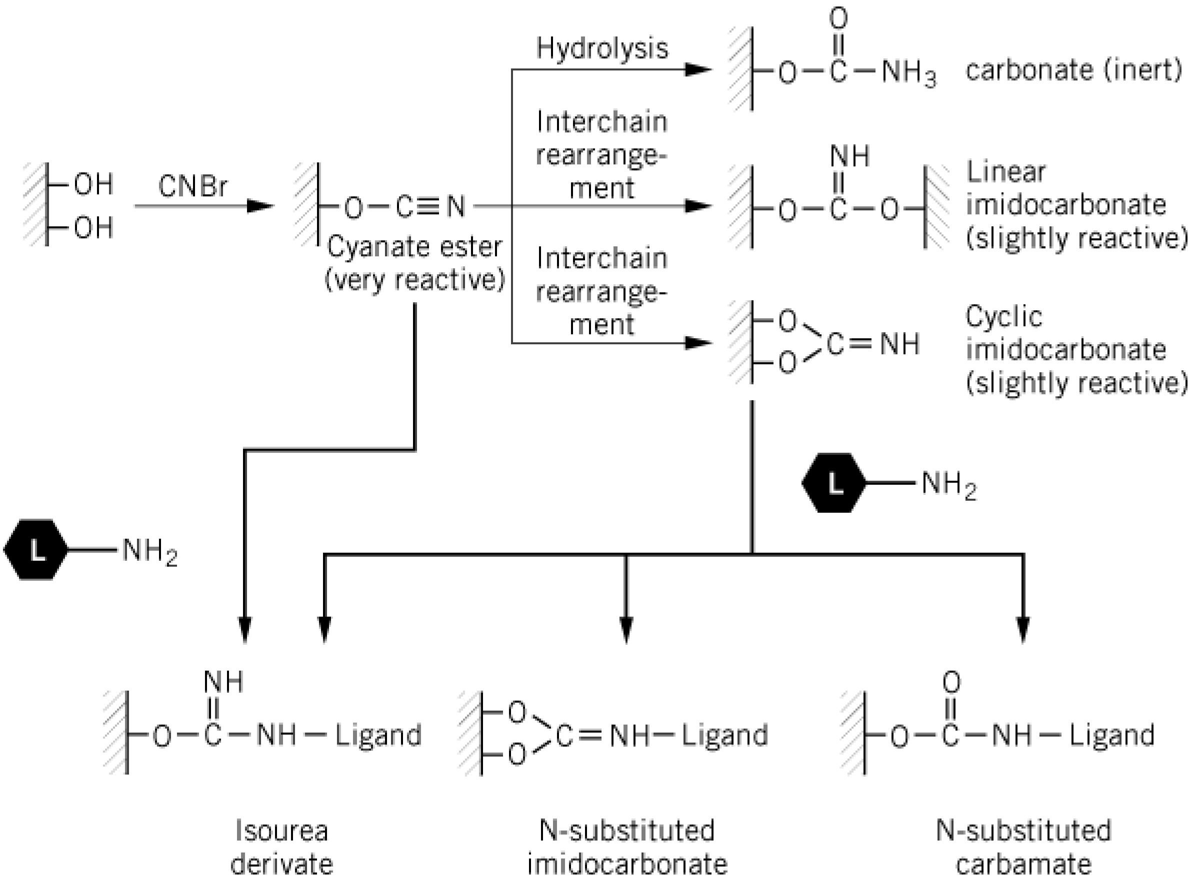


2. General Procedure for an AC Purification: Key Steps

1. *Immobilization (anchoring) of the ligand on an inert carrier*: L is anchored on a carrier to yield an insoluble material, usually in a beaded form. This carrier should be as inert as possible (eg, beaded agarose) to achieve true **active-site**-mediated AC. Also, the attachment point of the ligand should not involve groups that are involved in binding to the macromolecule. Over the years, different carriers and various methods for ligand immobilization were developed. These were reviewed and evaluated by Wilchek et al. (3). In general, the anchoring of L onto an inert carrier involves (i) the introduction of chemically reactive groups to the inert carrier, (ii) the covalent attachment of L to the activated carrier, and (iii) inactivation of the excess of reactive groups (if any) that may remain on the activated carrier after completion of the ligand anchoring step. The immobilized ligand can be used either batchwise or as a column. It may also find other uses—for example, to detect or demonstrate specific protein–protein interactions by the binding of a specific protein. Furthermore, it may use the resulting column material to bind and fish out another protein that interacts with it. Such immobilized ligands have been used also for labeling of cells, for the localization of proteins on cell surfaces, for the demonstration of leakage of enzymes or specific proteins from damaged tissues, and so on.

Historically, the pioneering work of Axén et al. (4) on the CNBr activation of beaded agarose had a great influence on the development of AC and the conversion of this methodology into a most widely used tool in separation science. To this day, beaded agarose continues to be the inert carrier of choice, and its activation with CNBr for ligand binding is still an activation method of choice. A thorough analytical study of the mechanism of activation of agarose by CNBr (5) showed that three major products are formed: a carbamate (chemically inert), a linear or a cyclic imidocarbonate (slightly reactive), and a cyanate ester (chemically very reactive). Analysis of freshly activated agarose showed that 60% to 85% of the total coupling capacity of the agarose is due to the formation of the cyanate esters. They are the ones that actually react and immobilize the ligand (Fig. 2). On the basis of this mechanism of activation by CNBr, it became possible to develop more efficient activation procedures, which are reviewed in Refs. 3 and 6.

Figure 2. The mechanism of the CNBr activation of agarose. (Modified from Ref. 3.)



2. *Selective adsorption*. The key selective step in AC is obviously the extraction of the desired macromolecule M, which is singled out and removed by the immobilized L, from the mixture in which it is present. The macromolecule—be it an enzyme, an antibody, a receptor, a hormone, a growth factor, or the like—is selectively bound by the biospecific ligand L, which can be another protein, a peptide, a polynucleotide or a nucleotide, a polysacharide or a carbohydrate, a lipid, a vitamin, or just a metal ion. Functionally, L may be a substrate, a substrate analogue, an inhibitor, an antigen, a coenzyme, a cofactor, or a regulatory metabolite. In many cases, the biospecific ligand used for the immobilization is a structural analogue of the physiological ligand (L′). It is imperative, however, to ensure that it still retains the property of selective binding to M, and ideally to M only. In choosing the ligand for an affinity chromatography column, it is often possible to adjust the grip

of M onto the anchored L, and thus to optimize both the adsorption and the elution steps. It should be noted that the adsorption conditions used (buffer, pH, ionic strength, temperature) should also be carefully chosen to secure an optimal and selective adsorption.

3. *Washing out nonspecifically bound impurities*. This is usually carried out with an excess of the buffer used for selective adsorption.

4. *Elution of the desired macromolecule*. The detachment of M from the column (elution) is one of the most important steps in purification by AC. Obviously, the ideal elution is by a specific displacement of M with an excess of its biospecific ligand (Fig. 1). This procedure preserves the native structure of M by forming the more stable complex of M with its biospecific ligand L. When such elution is achieved, it strongly suggests that true **active-site**-mediated AC is involved. However, very often biospecific ligands fail to elute the desired protein, and nonspecific means have to be applied. These usually include a change in solvent or buffer composition, a change in pH or in ionic strength, the addition of a **chaotropic** or a "deforming" buffer, a change in temperature, or a change in the electric field (**electrophoretic** desorption) (3). All these bring about a deformation of the protein (7, 8), a concomitant loosening of the grip of M for L, and consequently elution. In some cases, the binding of M to the L column is so tight that it is not possible to recover M in a fully active form. If M is an enzyme, this may yield a less active preparation (part of the M molecules may be totally inactive, or all molecules may have a lower affinity for the substrate or a lower turnover number). In some instances, the purified enzyme is fully active, but it may lose its ability to be regulated—for example, if the regulatory domain of M loses its affinity for a regulatory metabolite. Under such circumstances, immobilized ligands with lower affinity for M must be tried. Among the remedies that can be used to improve the elution step, one should note the possibility of binding the ligand to the matrix by means of an easily cleavable form—for example, through an ester bond (9, 10), which can be readily hydrolyzed with a mild base; through a link that includes vicinal hydroxyl groups, which can be readily cleaved with periodate; or through diazo bonds, which can be readily reduced with dithionates (11). It should be remembered, however, that such columns are of limited value, because they can be used only once. Electrophoresis has also been used for elution (12). Because proteins are charged, they will detach from the column and migrate toward the appropriate electrode, if the column with the adsorbed M is exposed to a strong enough electric field. This mild method of elution was successfully applied with high yields in immunoaffinity chromatography and in some AC systems.

3. Interposing an "Arm" Between the Ligand and the Matrix Backbone

While developing the basic principles of AC, it was observed that the purification of M is often improved by interposing a hydrocarbon chain (an "arm" or a "spacer") between L and the matrix backbone (1). It was presumed that such an arm relieves the steric restrictions imposed by the backbone on the ligand, thereby increasing its flexibility and its availability to the protein (13). Such arms were found to improve significantly the extraction of proteins and the efficacy of the purification by AC. Initially, it was assumed that such hydrocarbon arms do not alter the inert nature of the matrix, a condition that obviously has to be ensured to preserve an active-site mediated adsorption of the extracted protein. This assumption seemed reasonable at the time because it had just been shown that at least some water-soluble proteins are quite well described as "an oil drop with a polar coat" (14), implying that the surface of water-soluble proteins is polar and thus not attracted to lipophilic "baits." We now know that such arms, in and of themselves, may bind proteins. In fact, this observation led to the discovery of hydrophobic chromatography.

4. The Limitations of Biospecificity—Interactions that are not Active Site-Mediated

Proteins and their physiological ligands are multifunctional molecules whose functions involve a variety of physical interactions: hydrophobic, **electrostatic**, ion-dipole, and so on. Therefore, it is reasonable to assume that a protein might interact with a column coated with a ligand (very often anchored to the beads at a local concentration much higher than its concentration *in vivo*) not only by means of its active site. While it is sometimes possible to minimize these nonspecific interactions, it is not always possible to avoid such interfering effects, because they may be an intrinsic property of the system. For example, if ATP is linked to a matrix through its amino group or its ribose moiety; the column thus obtained may retain an enzyme having a biospecific site for ATP; but at the same time, this very column would be negatively charged due to its triphosphate groups, and it would have hydrophobic loci due to its adenine residues. Other proteins, in addition to the desired one, may therefore "regard" the column material as an **ion exchanger** by virtue of its triphosphate groups, or as a hydrophobic column by virtue of its adenine moieties. The efficiency of resolution will then depend on the magnitude of the affinity produced by charge–charge or hydrophobic interactions, as compared to the affinity between the active site of the desired macromolecule and its immobilized substrate or effector analogue. With columns of macromolecular ligands (eg, enzyme subunits, antibodies, lectins), the probability of encountering such built-in interfering effects is considerably higher, because their immobilization usually involves different anchoring points. This leads to a heterogeneous presentation of the various regions of the ligand macromolecule. In some of these presentations, the biospecific active site is available for interaction, while in other presentations the active site itself is inaccessible or sterically hindered. Hydrophobic patches in such ligands may be available for interaction not only in the biospecifically functional presentation, but also in other presentations. In fact, the tendency of a lectin such as concanavalin A to adsorb onto hydrophobic substances, in addition to its binding to sugars of the mannosyl configuration, was observed in several laboratories.

5. The Relativity of Biological Recognition: Different Proteins may Share a Taste for a Biorecognition Elements

The occurrence of common biorecognition sites in different enzymes is obvious when they are functionally similar, acting on the same substrate (eg, ATP), or utilizing the same cofactor (eg, NAD). This actually forms the basis for general ligand-affinity chromatography (15). However, common biorecognition elements may also be found with proteins having no apparent functional similarity. For example, the free catalytic subunit of cAMP-dependent protein kinase (**protein kinase A**) is preferentially retarded on immobilized soybean trypsin inhibitor (16). Though initially unexpected, this is actually not surprising; in spite of the fact that **trypsin** and this kinase catalyze two different chemical reactions (hydrolysis of peptide bonds versus a phosphotransferase reaction), these two enzymes do have similar biorecognition elements (or subsites) at their active site: trypsin cleaves peptide bonds adjacent to positively charged amino acid residues (arginine and lysine), while cAMP-dependent protein kinase phosphorylates serine residues that are vicinal (in the sequence of amino acids) to the same positively charged arginine and lysine residues (17-20). Similarly, it was shown (21) that TLCK (a-*N*-tosyl-L-lysine chloromethyl ketone), an affinity labeling reagent originally designed for labeling the active site of trypsin, specifically attacks a thiol group at the active site of the catalytic subunit of cAMP-dependent protein kinase. It seems, therefore, that the retardation of the free catalytic subunit on the immobilized inhibitor is due (at least in part) to an affinity between the inhibitor and recognition subsites at the active site of the enzyme.

Affinity Electrophoresis

By analogy to affinity chromatography, it is possible to introduce specific **ligands** for a macromolecule into the gels of gel electrophoresis and to measure the specific retardation of the macromolecule due to its interaction with such a reagent. The advantage of such affinity methods lies in the augmented resolving power conferred by the specificity of the binding interaction.

The procedures used to introduce affinity reagents into gels have varied. In cross electrophoresis, a ligand with a net charge opposite to the species of interest migrates electrophoretically into the gel in the opposite direction. Alternatively, uncharged ligands can simply be added to the gelation mixture. Macromolecular substrates within a gel may serve as immobilized affinity reagents, either by themselves or as carriers of covalently attached affinity groups. The magnitude of the electrophoretic retardation depends on the concentration of the affinity reagent in the gel; quantitative determination of this relationship makes it possible to estimate the apparent association constant for binding of the ligand to the sample. Further information concerning the interaction can be gained from affinity electrophoresis by variation of the buffer composition (eg, the addition of metal ions to the buffer), the pH, or the temperature.

Affinity Labeling

Affinity labeling is a strategy to modify chemically an amino acid residue within a specific **ligand-binding** site of an enzyme, either at the active site or at a regulatory, **allosteric** site. In this approach, a reagent is designed that resembles structurally the natural ligand of the enzyme but features in addition a functional group capable of reacting covalently and indiscriminately with many different amino acid residues. The designed reagent is intended to mimic the natural ligand in forming a reversible enzyme-reagent complex analogous to the enzyme-substrate complex and, once directed to that specific site, to react irreversibly with an amino acid residue accessible from that site. In the case of a purified enzyme, such a reagent allows identification of a particular ligand binding site or **domain**, which can be an experimental evaluation of a predicted binding site location based on recognition of a protein motif from its amino acid sequence. Affinity labeling constitutes a valuable starting point for selecting appropriate target sites for subsequent site-directed mutagenesis experiments and is an important tool in probing structure–function relationships in enzymes. If the synthesized reagent has a characteristic absorbance or fluorescence spectrum, affinity labeling offers a means of introducing a chromophore at a specific substrate site to report on the enzyme conformation or on distances between designated sites in the enzyme. For medicinal chemistry, affinity labeling permits mapping of the substrate binding site and establishment of its size, so that inhibitory drugs directed toward that site can be designed more rationally. In the case of a heterogeneous cell preparation or of a complex protein mixture, a specific affinity label can be used to identify a **receptor** protein or to tag a class of macromolecules, such as **nucleotide binding** proteins.

One characteristic of affinity labeling is the initial formation of a reversible enzyme–reagent complex (ER), as indicated below.

$$E + R \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ER \xrightarrow{k_{max}} ER' \tag{1}$$

where E and R represent the free enzyme and reagent, respectively, and ER' is the covalently modified enzyme. The formation of a reversible ER complex is often indicated by a "rate saturation effect" in which the rate constant for modification (k_{obs}) increases as the reagent concentration is elevated until the enzyme site is saturated with reagent; subsequently, the rate constant (k_{max}) is not changed by further increases in reagent concentration (see Kinetics). This kinetic pattern contrasts with the linear dependence on reagent concentration of the rate of a direct bimolecular chemical modification. For an affinity label, k_{obs} can be described by the equation

$$k_{obs} = \frac{k_{max}}{1 + \frac{K_R}{[R]}} \tag{2}$$

where the apparent dissociation constant for the enzyme–reagent complex K_R, is given by $(k_{-1} + k_{max})/k_1$ and where k_{max} is the maximum rate of modification at saturating concentrations of reagent. This type of kinetic behavior is often presented as a double reciprocal plot of $1/k_{obs}$ versus $1/[R]$, based on the equation

$$\frac{1}{k_{obs}} = \frac{1}{k_{max}} + \left(\frac{K_R}{k_{max}}\right)\left(\frac{1}{[R]}\right) \tag{3}$$

Examples of **purine** nucleotide-based affinity labels are shown in Figures 1 and 2. Experiences with their use illustrate the possibilities of affinity labeling.

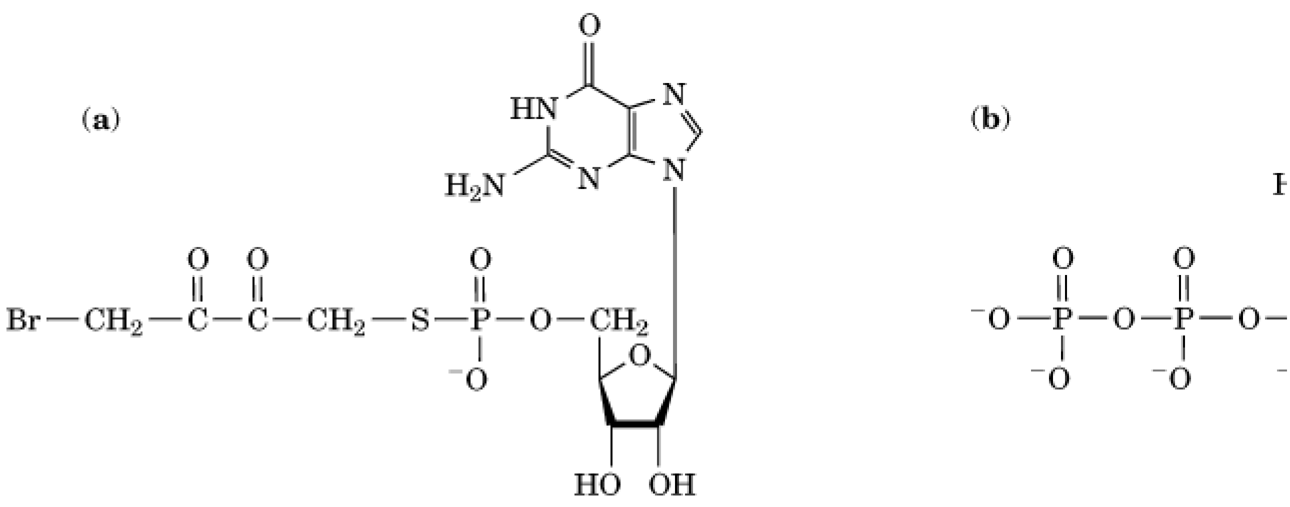
(**b**) the natural ligand GTP.



GMPS-BDB

GTP

1. BDB-TAMP

The compound 6-(4-bromo-2,3-dioxobutyl)thioadenosine 5′-monophosphate (6-BDB-TAMP) shown in Figure 1 was synthesized as a reactive nucleotide analogue to target nucleotide binding sites in enzymes (1). The bromoketo group, adjacent to the 6-position of the purine ring, can potentially react with several nucleophiles found in proteins, including those of the side chains of cysteine, histidine, tyrosine, lysine, methionine, **glutamate**, and **aspartate** residues. In addition, the dioxo group provides the possibility of reaction with arginine residues.

As shown in Figure 1, the structure of 6-BDB-TAMP also exhibits a remarkable resemblance to that of adenylosuccinate, a key metabolic intermediate in the conversion of inosine monophosphate to adenosine monophosphate. The last step in that pathway is catalyzed by adenylosuccinate lyase, an enzyme proposed to initiate the cleavage reaction to AMP by attack of an enzymic general base on the b hydrogen of adenylosuccinate. Elimination of the amino group is then facilitated by protonation of the leaving group by an enzymic general acid. Despite this proposal, the key general base and acid of the enzyme had not been identified. The similarity between the structures of adenylosuccinate and 6-BDB-TAMP suggested that the latter would bind irreversibly to the adenylosuccinate site of adenylosuccinate lyase, where the bromodioxobutyl group would be likely to occupy the succinyl subsite at which the critical catalytic steps should occur.

6-BDB-TAMP has recently been confirmed to function as an affinity label of *Bacillus subtilis* adenylosuccinate lyase (2). The initial inactivation rate constant exhibits nonlinear dependence on the concentration of 6-BDB-TAMP, with an apparent reversible K_R = 30 μM prior to irreversible inactivation at pH 7.0 and 25°C. The tetrameric enzyme incorporates about 1 mol of 6-BDB-[^{32}P] TAMP per mol of enzyme subunit on complete inactivation. The substrate adenylosuccinate or the products AMP plus fumarate protect against inactivation and incorporation of radioactive reagent, indicating that 6-BDB-TAMP targets the adenylosuccinate binding site. Purification of the only radioactive peptide labeled by 6-BDB-TAMP led to the identification of His^{141} as the modified amino acid (2). These results indicated that 6-BDB-TAMP is an affinity label of His^{141} in the substrate binding site of adenylosuccinate lyase, where it may serve as a general base accepting a proton from the succinyl group during catalysis (2) (see Histidine (His, H) residues). This study illustrates many of the desirable characteristics of affinity labeling: binding of the reagent by the enzyme prior to modification of a single site under mild conditions, competition between the reagent and the natural ligand (adenylosuccinate), and identification of the modified residue within a protein of known amino acid sequence.

2. GMPS-BDB

A reactive guanine derivative is shown in Figure 2, guanosine 5′-0-[S-4-bromo-2,3-dioxobutylthio] phosphate (GMPS-BDB), which represents a novel class of compounds containing a bromodioxobutyl group linked to the sulfur of a purine nucleotide thiophosphate (3, 4). The reactive moiety of GMPS-BDB is located at a position equivalent to that of the pyrophosphate region of GTP, as illustrated in Figure 2. Thus, it might be expected that GMPS-BDB would act as an affinity label for GTP sites in proteins (see GTP-Binding Proteins).

Adenylosuccinate synthetase catalyzes the first of the two enzymatic reactions in the conversion of IMP: the condensation of IMP and aspartate to form adenylosuccinate, as GTP is hydrolyzed to GDP and inorganic phosphate. The phosphoryl group has been proposed to be transferred to IMP from the terminal phosphate of GTP to form a 6-phosphoryl-IMP intermediate.

GMPS-BDB has been used as an affinity label of adenylosuccinate synthetase from *Escherichia coli*, and it has been demonstrated that inactivation occurs concomitantly with the modification of Arg^{143} of each subunit of the dimeric enzyme (5). The modification of Arg^{143} and the inactivation by GMPS-BDB is prevented by adenylosuccinate or by IMP plus GTP, implying that the reaction target is in the region of the active site. This result pointed to Arg^{143} as a logical target for site-directed mutagenesis; when the positively charged arginine was replaced by the neutral leucine, the expressed mutant enzyme exhibited a significant decrease in its affinity for nucleotides (5).

The crystal structure of *E. coli* adenylosuccinate synthetase has been determined, allowing a comparison to be made between the substrate sites identified by affinity labeling of the enzyme in solution and those assigned within the crystalline form by X-ray crystallography. Arg^{143} from one subunit projects into the putative active site of the second subunit, indicating that both subunits of dimeric adenylosuccinate synthetase contribute to each active site and that Arg^{143} plays an important role in nucleotide binding.

3. AMPS-BDB

The adenosine analogue of GMPS-BDB has also been synthesized: adenosine 5′-0-[S-(4-bromo-2,3-dioxobutyl)thiophosphate] (AMPS-BDB) (4) and can be considered as a reasonable mimic of ADP or ATP. Bovine liver glutamate dehydrogenase is an allosteric enzyme that is reversibly activated by ADP. On incubation of AMPS-BDB with glutamate dehydrogenase, the enzyme reacts covalently, resulting in an irreversibly *activated* enzyme that is no longer responsive to externally added ADP (6). AMPS-BDB appears to function as an ADP substitute that is covalently bound to Arg^{459} within the activator site of the allosteric bovine liver glutamate dehydrogenase (6).

The above are representative examples of enzymes that have been studied using the strategy of affinity labeling. They illustrate how affinity labeling, X-ray crystallography and site-directed mutagenesis can be used as complementary approaches in evaluating the functional role of particular amino acids in a protein.

Affinity Maturation

It was observed long ago that the affinities of antibodies increase with time during immunization with a T-dependent antigen. When such an antigen is injected for the first time, it induces the occurrence of low-affinity IgM antibodies, which are rapidly replaced by IgG. This takes place in the first two weeks of the primary response. At the same time, an increase of the average affinity is usually observed. If the same antigen is given a second time, IgG antibodies are subsequently produced at a higher yield, and with an average affinity that is still increasing. This is characteristic of the secondary response, a phenomenon that may be repeated and amplified by multiple administrations of the antigen. This is why long-term immunization schedules are used whenever both high titers and high affinity are wanted. Affinity maturation, which is a unique property of B cells stimulated by T-dependent antigens, is the consequence of (*1*) the clonal organization of lymphocytes, (*2*) the expansion of clones that have been stimulated specifically by the antigen, and (*3*) the presence of a very peculiar mechanism that generates somatic mutations at each cellular division of stimulated B cells.

1. Antibody specificities are spread randomly in the huge collection of clones that represent at any given time the repertoire expressed by B lymphocytes that have rearranged their immunoglobulin genes and thus have IgM at their surface. Clones that are potentially reactive to the antigen proliferate, as the result of the cooperation between T cells and B cells and the phenomenon of **antigen processing** and presentation. This ensures that the first wave of antibodies are generally of low or moderate affinity.

2. As the immunization proceeds, expansion of the B-reactive cell population takes place, giving rapidly growing colonies, termed *germinal centers*, in secondary lymphoid organs (lymph nodes, tonsils, spleen). Germinal centers are highly organized structures that favor cell–cell interactions that will amplify local B-cell division and expansion.

3. At the same time, somatic mutations will be triggered by a mechanism that is **probably** enzyme-driven, but still not completely elucidated. The rate of the mutations that are introduced is of the order of 1×10^3 per base pair and per generation, which is excessively high. As a result of these mutations, some clones will gain affinity, whereas others will lose. One therefore needs mechanisms to select clones of high affinity and eliminate those of lower affinity; otherwise the system would expand indefinitely and explode. Stimulation by antigen will favor the saving and expansion of clones with the highest affinity, whereas apoptosis will operate on cells that did not receive stimuli as they lost recognition ability.

PCR and DNA sequencing at the level of single cells allowed the group of Rajewsky to trace the successive mutations that occurred at each cell division, so that it was possible to reconstruct a genealogical tree of these mutations within the germinal center. Interestingly, hypermutated cells can ultimately follow two types of differentiation: One leads to the terminal plasma cells, which will secrete circulating antibodies, and the other leads to the so-called memory cells that may persist for long periods of time and may be restimulated with great efficiency in the course of another run of immunization.

The extraordinary plasticity and adaptability of the immune system are thus quite remarkable and allow it to respond efficiently to pathogens. Raising memory cells endowed with the ability to produce rapidly high-affinity antibodies is an obvious goal of vaccination.

Affinity Selection

A key requirement of combinatorial library approaches is that desirable molecules must be segregated from the remaining library population. Segregation is most often accomplished by affinity partitioning, in which an immobilized target is used to capture interacting molecules from a solution-phase library. Target proteins can be immobilized either using antibodies bound to *Staphylococcus* protein A, using absorption of targets onto wells of plastic microtiter plates, or covalent attachment to a variety of polymeric supports. Alternatively, combinatorial libraries attached to solid supports—for example, one-bead, one-compound (OBOC) libraries—can be used to bind soluble targets. Solid-phase libraries have also been used to screen highly complex targets, such as living cells on which a variety of receptors are expressed (1). In all cases, unbound material is removed by washing, and the bound material is recovered for amplification or identification, depending on the nature of the library.

Plastic pins were used to develop the first peptide-based combinatorial libraries. The pins are arranged such that they fit neatly into a single well of a microtiter plate. Thus, the pin system provides a convenient format for both synthesis and screening. The power of this method derives largely in the ease of handling large numbers of discrete syntheses in parallel. Sequential steps of the synthesis can be carried out by transferring the pin arrays through various microtiter reaction chambers. The peptides are then directly available for affinity screening, either on the solid phase or following cleavage from the solid support.

Lam et al. (2) developed another approach for peptide affinity selection involving split synthesis of peptides on solid support beads (OBOC libraries: see Combinatorial Synthesis). From a pool of millions of beads, a binding reaction is performed using a target molecule such as an antibody, receptor, enzyme, or even whole cells. Beads displaying affinity for the target are isolated, and the peptide on the bead can be microsequenced.

Fodor et al. (3) have developed immobilized combinatorial libraries on silicon microchips. Chip-based addressable libraries of peptides, oligonucleotides, and small organic molecules can be readily prepared. These methods use photolithography to control regions accessible for subsequent chemical modification. This method enables a miniaturized, fully addressable library to be generated on the surface of a silicon chip. The resulting arrays can be screened using standard affinity methods.

The affinity selection methods described above are extremely broad in their applications. Although classical nucleic acid libraries have been screened by **hybridization**, which is a highly specialized type of affinity partitioning, modern DNA and RNA aptamer libraries are screened in identical fashion to other combinatorial libraries by affinity selection over immobilized targets. Although selection strategies have been introduced that are based on properties other than affinity, such methods are highly specialized and are not likely to displace the current reliance on affinity methods for combinatorial screening.

Agarose

Agarose is one of the two most popular materials used to prepare gels for use in gel electrophoresis, the other being polyacrylamide. Agarose is primarily a polymer of molecular weight approximately 120 kDa of agarobiose (an anhydrogalactose-galactose disaccharide). At sufficiently high concentrations and low temperatures, the polymer forms b-helical strands, which interact by **hydrogen bonding** to form the agarose gel; they dissociate at higher temperatures to form agarose solutions. Such thermally controlled gelation is the unique feature of agarose, which provides both a high reproducibility and simplicity of preparing the gel. Since gelation requires noncovalent interactions between the copolymer strands, denaturing agents, such as solutions of urea, prevent gelation.

Agarose is derived from a natural product of oceanic algae, agar. It is processed to reduce the content of acidic groups, primarily sulfate, so as to reduce the degree of electroendosmosis that occurs during electrophoresis. Further industrial processing produces a large number of commercially available agarose fractions distinguished by (1) the degree of electroendosmosis in an electric field, determined by the number of acidic groups; (2) the degree of covalent substitution of the acidic groups with chemical groupings such as hydroxyethyl or vinyl (allyl) groups, which tends to lower the melting point in proportion to the degree of substitution; (3) the addition of linear carbohydrate polymers, such as clarified locust bean gum, to increase the viscosity of the gel and thereby eliminate measurable electroendosmosis.

Most agaroses at concentrations greater than about 0.4% (w/v) form gels at room temperature. Agaroses with unusually high gel strengths can gel at concentrations as low as about 0.05%. The pore sizes of such agarose gels make them ideal for separating **DNA** molecules and **oligonucleotides**; their mobility is determined primarily by their size, as nucleic acids of the same class have the same charge density per nucleotide. The least concentrated gels exhibit mean pore sizes of up to 500 to 1,000 nm, sufficiently large for the penetration of large particles or small viruses (see Particle Electrophoresis). Highly soluble agarose species substituted to a maximum extent by hydroxyethyl groups can be used to prepare gels with concentrations of up to 9 to 10%. Such gels have pores of similar size to those of 3 to 6% polyacrylamide gels, and with greater resolving power for native proteins. Agarose can also be used as a copolymer with polyacrylamide, which provides larger pore sizes than polyacrylamide by itself. The copolymer is produced by adding agarose to the mixture of acrylamide monomers before its polymerization. For the separation by size of DNA fragments, or of other large particles, by capillary zone electrophoresis, solutions of agarose can be used.

The adherence of agarose gels to glass or plastic apparatus walls is very weak, and only horizontally oriented gel electrophoresis apparatus can normally be used. The adherence of agarose to vertical glass surfaces may, however, be strengthened by drying a thin film of agarose onto glass walls; this can permit electrophoresis in vertical glass slabs or tubes. Horizontal thin-layer agarose gels with high Joule heat dissipation capacity, which are therefore amenable to electrophoresis at high field strength without melting, can be formed on hydrophilic surfaces of thin plastic sheets (eg, "Gel-Bond").

For preparative purposes, bands of a macromolecular sample in agarose gels may be recovered by solubilizing the agarose at increased temperature or adding the enzyme agarase. The macromolecule of interest is subsequently separated from the low-molecular-weight agarose fragments by filtration or precipitation methods.

Agglutination

"Agglutinin" is an obsolete term for an antibody capable of causing cells to come together in macroscopic clumps. Agglutination (clumping) of bacteria by serum was perhaps the earliest observed manifestation of *in vitro* immune reactions. The phenomenon is due to crosslinking of cells through the reaction of multivalent antibody molecules with cell-surface antigens. The quantity of antibody necessary for crosslinking is generally very small, yet the cell masses involved in agglutination generate a response visible to the naked eye. Because of these characteristics, this oldest of techniques remains one of the most sensitive and widely used types of immunoassay.

Agglutination immunoassays can employ cells or synthetic particles. The two broad categories of cell-based agglutination assay are termed "direct" and "passive". In the direct assay, antibodies cause clumping of microbes or blood cells by reaction with surface antigens endogenous to those cells. Typically, the immune status of serum in a test sample will be assessed, based on the highest dilution that will still agglutinate target cells. Direct agglutination assays are widely used to diagnose infectious disease by the presence of specific antibodies in acute or convalescent serum. The "monospot" assay for infectious mononucleosis is an example of this application (1). In passive agglutination immunoassays, the target antigen is exogenous, and is coated covalently or by adsorbtion onto the cells used for the assay. Test samples are then assayed as for the direct agglutination method. Many variants of direct and passive agglutination are in use for research or diagnostic procedures. For example, the test for Rh blood type is a two-step method in which antibodies in the test sample react with endogenous Rh antigen on erythrocytes, then addition of anti-human IgG induces agglutination (2).

Availability of uniformly sized latex particles allowed development of a chemically defined substrate on which to attach antigen or antibody (3). The role of the particles was precisely analogous to that of cells, in that their aggregation in response to antibody–antigen crosslinking generated an optically detectable signal. The advantage of inert particles was in their stability, compared to cells, and in interassay reproducibility. Measurement of agglutination was at first by turbidometry. Development of laser light-scattering techniques have greatly improved the sensitivity of detection (4) and have led to development of automated instruments for quantitation of agglutination reactions.

Agrobacterium

Agrobacterium tumefaciens and *Agrobacterium rhizogenes* are members of the *Agrobacterium* genus of soil **bacteria** responsible, respectively, for tumor formation and hairy root disease in dicotyledenous **plants**. The molecular basis of inducting neoplastic growth in plants has been one of the most intriguing areas of research in plant pathology for more than 50 years. Advances in understanding the molecular basis of tumor formation has led to the development of **vector** systems based on *Agrobacterium* to carry out plant genetic engineering.

Agrobacterium belongs to the *Rhizobiacae* family. Classification of the bacterium has been based on physiological and biochemical criteria, although increasingly the taxonomic structure of the genus has been based on **DNA** analysis of **chromosomal** groups of the differing biovars (1). The best studied members of the genus are *A. tumefaciens* and *A. rhizogenes*. *A. tumefaciens* is the causative agent of crown gall disease. It has a wide, obvious host range, including the majority of dicotyledonous plants and some monocotyledonous plants (2). Practically, crown gall can be a serious disease of fruit crops, including grape vines. The physical basis of crown gall disease is the transfer of a defined region of DNA, transferred or T-DNA, from a **plasmid** maintained in the bacteria, known as the Ti or tumor-inducing plasmid (see Ti Plasmid) to the genome of the infected plant cell. *A. rhizogenes* induces hairy root disease analogously. A T-DNA is transferred from the Ri, or root-inducing, plasmid to the genome of the infected plant cell (see Ri Plasmid). This natural form of plant cell transformation has been adapted and used extensively in creating **transgenic** plants (see Plant Genetic Engineering).

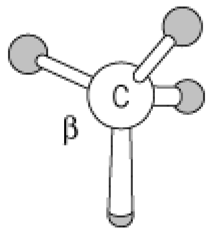
Alanine (Ala, A)

The amino acid alanine is incorporated into the nascent polypeptide chain during **protein biosynthesis** in response to four **codons**—GCU, GCC, GCA, and GCG—and represents approximately 8.3% of the residues of the proteins that have been characterized. The alanyl residue incorporated has a mass of 71.09 Da, a **van der Waals volume** of 67 Å^3, and an accessible surface area of 113 Å^2. Ala residues are usually relatively variable during divergent evolution, as they are frequently interchanged in **homologous** proteins with serine, threonine, valine, glutamic acid and proline residues.

The Ala side chain is simply a methyl group:



This nonpolar side chain makes Ala residues unreactive chemically, relatively **hydrophobic**, and not very hydrophilic; consequently, 38% of the Ala residues are fully buried in the folded conformations of proteins. There, the methyl side chain undergoes rapid rotations about the C_a–C_b single bond. Ala has the greatest tendency of all the normal amino acid residues to adopt the **alpha-helical** conformation in model **peptides**. It occurs frequently in that conformation in folded protein structures, but at about only half that frequency in beta-sheets and in reverse turns.

Albumins

Albumins are operationally defined as proteins that (1) remain soluble in pure water after dialysis of protein samples such as egg white or blood serum against distilled water and (2) are not precipitated in 50% saturated ammonium **sulfate**. This contrasts with another group of proteins, called globulins, which are precipitated in both distilled water and 50% saturated ammonium sulfate. This operational classification is rather obsolete today, but names like serum albumin, ovalbumin, and lactalbumin have remained. Other albumins include muscle albumin and plant albumins (1).

1. Blood Albumins

Serum albumin and other plasma proteins have been most closely studied, mainly for their medical interest. After the cells have been removed from blood by light centrifugation in the presence of chelating agents such as EDTA, a yellowish fluid called plasma remains. By the addition of Ca^{++}, fibrinogen is converted to fibrin and the clotting process produces a soft gel. Removal of this gel by centrifugation or other methods will leave a clear fluid called serum. Serum thus obtained contains 70 to 80 g/L of total protein, consisting of more than 150 different kinds of proteins. Dialysis of serum against distilled water will precipitate the globulins, while albumins stay in solution. The albumin fraction contains serum albumin as the major protein (2, 3). (see Serum Albumin).

2. Egg Albumins

Egg proteins are first classified into yolk proteins and egg white proteins. Yolk contains proteins called vitellogenin, phosvitin, and lipovitellin, all in association with yolk lipid. Egg white is a reservoir of several kinds of proteins as a protective and nutritious environment for the fetus. Egg white proteins are further divided into albumins and globulins, as for serum proteins. The following is a list of egg white proteins that are not globulins. Descriptions of egg white globulins are found under Globulins.

2.1. Ovalbumin

This is the major **glycoprotein** in the white of eggs, comprising 65% of the total egg white protein, with a molecular weight of 43,000 and isoelectric point (pI) of 4.7. The N-terminal glycine residue is acetylated. Two species containing one or two sites of **phosphorylation** can be separated by electrophoresis. Oligosaccharide containing three moles of N-acetylglucosamine and five moles of mannose is linked to an asparagine residue through an **N-glycosidic** linkage. Treatment of ovalbumin with subtilisin yields a readily crystallizable plakalbumin, named after the platelike appearance of the resulting crystals. Ovalbumin is often used as an effective antigen in immunological studies. The protein has recently been found to have a similar amino acid sequence and three-dimensional structure to a1-antitrypsin of the serpin family (4) (see Ovalbumin).

2.2. Ovotransferrin (or *conalbumin*)

This protein binds ferric ions and is the same as apo-transferrin, but differing in the carbohydrate moiety. In egg white, the protein is present in an almost iron-free form. This protein constitutes about 10% of the egg protein.

2.3. Ovomucoid

Ovomucoid is a glycoprotein (carbohydrate content about 25% by weight) with a molecular weight of 28,000 and constitutes 1.5% of the total egg white protein. It inhibits **trypsin** and **chymotrypsin** but not **plasmin**, thrombin, elastase, or collagenase. Its pI falls in the range 3.9 to 4.5. It remains active in the supernatant after egg white has been coagulated by heat. It has three **homologous** domains connected by linking peptides, each domain being homologous to bovine pancreatic trypsin inhibitor (BPTI). Thus, it is speculated that ovomucoid has evolved by two tandem repeats of the BPTI gene. Carbohydrates are linked to asparagine residues at residue numbers 10, 53, 69, 75, and 175. Similar inhibitors can be purified from the egg white of the quail, goose, and turkey.

2.4. Ovoinhibitor
This is a 48-kDa multiheaded proteinase inhibitor that can simultaneously inhibit trypsin, chymotrypsin, and elastase. Unlike ovomucoid, it also inhibits the proteinases of bacterial origins. It is a glycoprotein with 5 to 10% content of carbohydrate.

2.5. Avidin
This protein occupies a special position in biochemistry in that it is widely used as a probe based on its strong affinity for biotin. Their binding constant reaches $10^{14}\ M^{-1}$ under optimal conditions. Avidin-biotin systems are widely used for labeling macromolecular interacting systems, not only protein–protein interactions, but also systems based on DNA and other macromolecules. Avidin can be substituted by streptavidin, which is of bacterial origin but with a similar activity. Avidin in the egg white is largely free of biotin, and feeding rats with purified avidin as the sole protein source will cause various symptoms known to accompany biotin (vitamin H) deficiency.

2.6. Ovomucin
This is a glycoprotein of high molecular weight responsible for the mucous character of egg white. The treatment of ovomucin with reagents that react with thiol groups reduces the viscous nature of egg white.

3. Plant Albumin

Ricin is an example of plant albumins (from *Ricinus communis*) and has an interesting toxic function. It consists of an A subunit, of 32 kDa, pI of 7.5, and 2.4% carbohydrate, and a B subunit, of 34 kDa, pI of 4.8, and 6.5% carbohydrate. It inactivates the 60S subunit of ribosomes after being internalized into the cell and thus inhibits a peptide elongation step (see Translation). The A subunit carries out the inactivation reaction, while the B subunit, which binds to cell-surface galactose residues, helps the A subunit to be internalized into the cell. Plant albumins are more readily precipitable in 50% ammonium sulfate than animal albumins.

4. Milk Albumins

4.1. a-Lactalbumin
This is a single-chain 14-kDa protein that is the same as the B chain of lactose synthetase in lactating granules. The A chain of lactose synthetase alone catalyzes the synthesis of N-acetylgalactosamine from N-acetylglucosamine and UDP-galactose, but when in association with a-lactalbumin, it uses glucose as a substrate and synthesizes lactose. The amino acid sequence of a-lactalbumin with 143 amino acids (human, bovine, guinea pig) is homologous to that of lysozyme, and its three-dimensional structure is also similar. A recent review of the relationship between lysozyme and lactalbumin is recommended (5) (see also Alpha-Lactalbumin and Lysozymes).

4.2. Lactoferrin
This is an iron-binding protein of 88,000 in humans and 86,000 in cows. It is similar in functional properties to serum transferrin, but immunologically and structurally distinguishable (6).

Alcohol Dehydrogenase (ADH)

ADH is a type of enzyme that catalyzes the reversible interconversion of an alcohol to an aldehyde/ketone [EC 1.1.1.1]. The substrate specificity is often wide, but it typically includes at least some activity with ethanol. The **coenzyme** is often **NAD$^+$**. ADH was initially purified from yeast (YADH) and from horse liver (LADH), sources from which it is commercially available. It is, however, now known to be widespread, with at least some forms present in **eukaryotes**, **prokaryotes** and **archaeabacteria** in general. It has been well studied at the protein and **DNA** levels from many sources. The "classical" forms of ADH are Zn-containing metalloproteins with subunits of ~40 kDa (~350 to 390 residues) (1). They are now considered part of a larger protein family (see Protein Evolution), known as medium-chain dehydrogenases/reductases (**MDR**) (2).

Although ADH is frequently regarded as well understood, much is still unknown, and novel findings of general interest are constantly obtained:

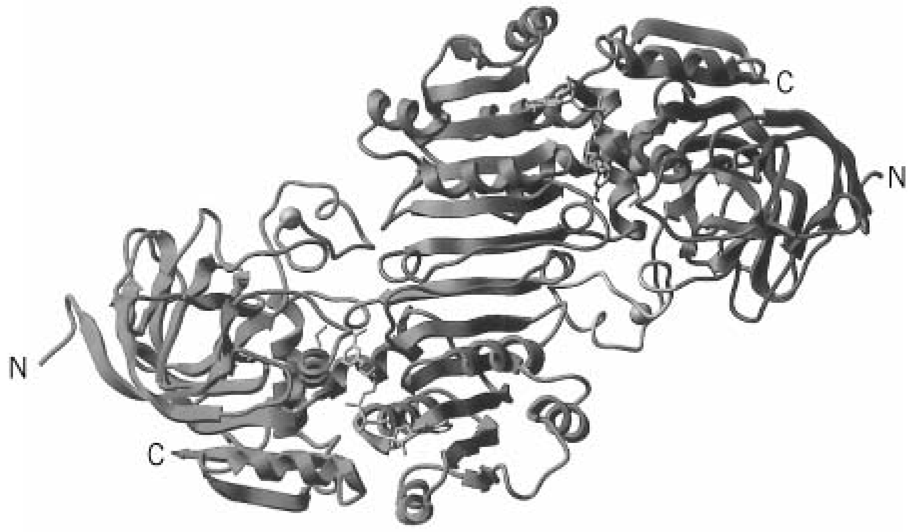
1. ADH is no longer just an enzyme, but a whole system of great complexity, involving other protein families and a multiplicity of MDR forms.
2. another such family is (short-chain dehydrogenases/reductases) SDR (3). The major ADH of insects is this type, and SDR enzymes are numerous, including **hormone**-converting and regulatory enzymes in humans and all living forms.
3. MDR-ADH occur as different classes (4) and **isozymes**. They exhibit distinct evolutionary patterns, repeated evolutionary origins, and varying properties. At least six classes and eight genes have been discerned in mammals, but these numbers are likely to grow; they differ among species because of recent gene duplications. Expressions differ with organ, tissue, and age, including special fetal forms.
4. Functionally, the ADH system has long been an enigma, but recent results suggest that it has important roles. Metabolically, ADH is associated with aldehyde dehydrogenase, which is part of another large family. Medically, both activities are important in alcohol metabolism and in several disease states but also in vision and in cellular regulation and differentiation (5, 6).

1. MDR-ADH

1.1. Classes in Vertebrates

Mammals and most vertebrates contain different classes of MDR Zn-containing ADH enzymes. These classes differ substantially in substrate specificity and in their immunological, chromatographic, and electrophoretic properties (4). They constitute separate forms that are intermediate in their properties between isozymes and distinctly different enzymes, and they differ in primary structures by about 30% but have closely related conformations (Fig. 1). The classes reflect a series of gene duplications, which occurred largely at early vertebrate times (8). Later duplications in individual lines have given rise to intraclass isozymes. The subunits of isozymes can hybridize into mixed dimers that reflect the subunit mixture, but those of different classes do not.

Figure 1. Structure of human ADH class I (7). The diagram and the modeling of ethanol were made with the program ICM (Molsoft, Metuchen, NJ) from coordinates in the data bank.



Class I contains the classical ADH enzyme, which is present in large amounts in liver but in lower amounts in many other organs. It is involved in ethanol metabolism and in liver function. It has good enzymatic activity with primary alcohols, cyclohexanol, retinols, and many other alcohols, plus their corresponding aldehydes. Isozymes occur and are largely species specific. The horse ADH subunits E and S derive from two separate genes and the human subunits a, b, and g from three genes. The a subunit is expressed in the fetus and b and g in the adult. The b and g types also exhibit further variability from alleles that have different population distributions in Caucasians and Orientals. This population variation, together with other alleles of the next enzyme of alcohol metabolism (aldehyde dehydrogenase), explains the different sensitivity to ethanol consumption of Caucasians and Orientals.

Class II ADH is highly variable. It is also expressed in the liver but in lower amounts. Thus far it is without a recognized functional role, but in humans it has a higher K_m for ethanol, and hence is of little importance in ethanol metabolism.

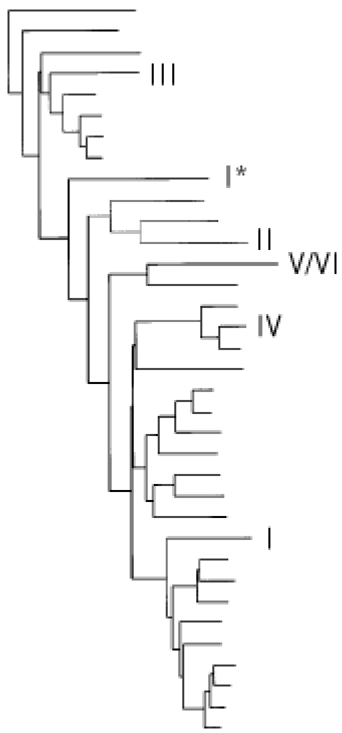
Class III ADH is expressed universally in cells and organs, and is identical to glutathione (GSH)-dependent formaldehyde dehydrogenase (EC 1.2.1.1). In the absence of GSH, it is a dehydrogenase toward long-chain alcohols and is largely inactive with ethanol. The $\boldsymbol{K_m}$ for ethanol is >3 M , so there is activity only at high ethanol concentrations. In the presence of GSH, class III ADH is active with the GSH/formaldehyde adduct, hydroxymethyl-GSH, when it functions as a formaldehyde dehydrogenase, producing formic acid.

Class IV ADH is present in the stomach and in skin (epithelia). It is the most ethanol-active form and has been discussed in relation to first-pass ethanol metabolism and to retinol dehydrogenase function. Both roles, however, are far from established.

Little is known about the remaining enzyme classes in vertebrates.

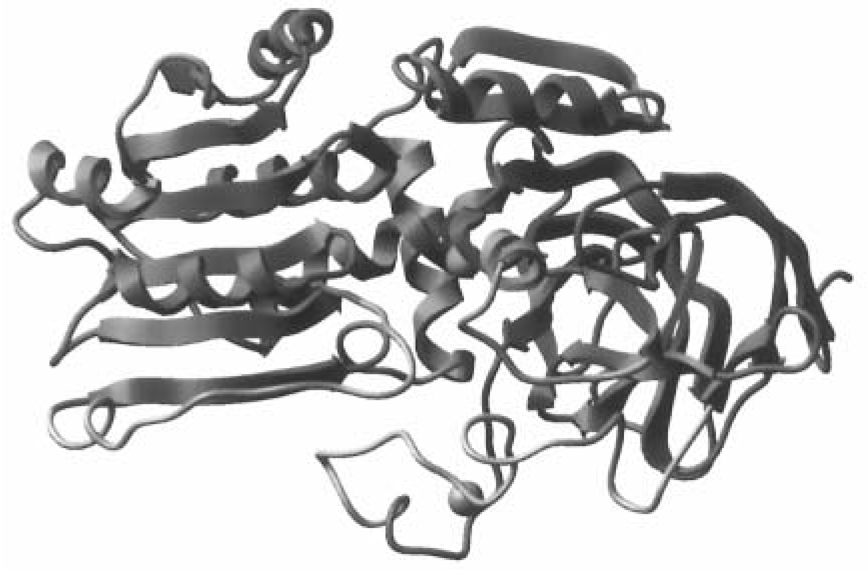
Class III is the evolutionary ancestor, which is apparent from phylogenetic trees (Fig. 2), the rates of change in present forms, and in apparently being the only MDR-ADH in invertebrates. However, final judgment of the phylogeny must await characterization of further forms. Additional gene duplications probably remain to be discovered, and the true evolutionary relationships may be complex, involving both extant and extinct forms.

Figure 2. Evolutionary tree of animal ADH. The deviating class I form of bony fish is indicated by a star. The tree was calculated using ClustalW (2) with corrections for multiple substitutions.



In molecular terms, the classes exhibit different evolutionary patterns. Class III is like an enzyme of basic metabolism, and has relatively constant functional properties among species and variation primarily in the nonfunctional parts of the protein (Fig. 3). Class I is the result of an early gene duplication from class III, whereas class IV in turn diverged from the class I line. Special hybrid forms of class I/III (in fish), II/I (in birds) and IV/I (in amphibians) have been traced and may reflect either the phylogeny or simply additional gene duplications. In short, the ADH system has many interesting evolutionary features (8).

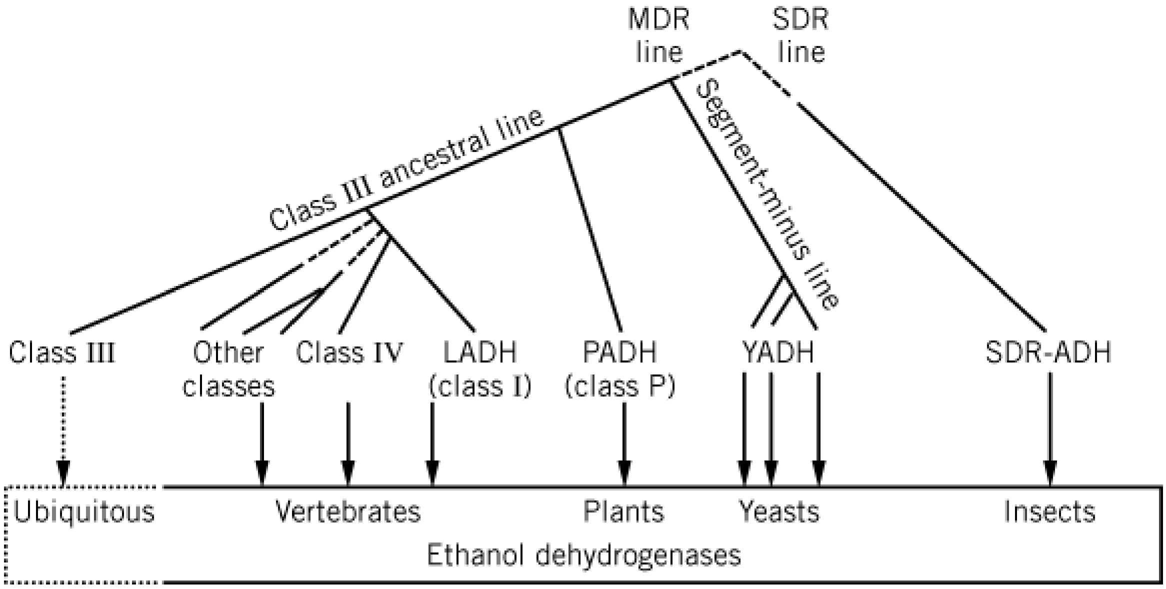
Figure 3. Variable segments in subunits of ADH. Those subunits that vary between class I enzymes affect functional segments, typical of a functionally variable protein. Those subunits variable between class III enzymes affect superficial segments, typical of a functionally constant protein (3).



1.2. Yeast, Plants, Other Nonvertebrate Forms

Nonvertebrate MDR-ADH are also frequent and have at least two classes. One is the class III enzyme, which has GSH-dependent formaldehyde dehydrogenase activity, as expected from the ancestral properties noted previously. The other is ethanol-active MDR-ADH: yeast ADH (YADH, from at least three genes) and plant ADH (PADH). YADH has greater ADH activity than LADH because of weaker **coenzyme** binding and consequently a greater turnover rate, because coenzyme dissociation is the rate-limiting step. Although YADH and PADH are related to LADH structurally and functionally, they are products of gene duplications separate from that leading to class I ADH. Combined, all of these ethanol-active forms suggest that ADHs active with alcohol have arisen several times during evolution, probably by functional **convergence**. Presumably all or many of these ethanol-active forms are derived from the ancestral class III line (Fig. 4), but they can differ in quaternary structure. Ethanol-active YADH is a tetramer, whereas yeast class III ADH is a dimer.

Figure 4. Functional convergence toward ethanol dehydrogenases in different lines of living organisms, emphasizing the repeated appearance of ethanol-activity, many separate gene duplications, and an apparent MDR-ancestral nature of class III. Dashed lines indicate unknown relationships, and dotted lines low activity with ethanol. Segment-minus forms lack internal segments (Fig. 1) and are tetrameric. The remaining forms are dimers. Apart from the gene duplications shown, which lead to ethanol-active dehydrogenases, additional branchings lead to cinnamyl ADH (in plants), sorbitol dehydrogenase (in animals), threonine dehydrogenase (in prokaryotes), several reductases (in prokaryotes and eukaryotes), and additional enzymes.



1.3. Function

Liver ADH (class I) is the major metabolic enzyme for ethanol, either ingested or produced in the intestine, and for other alcohols. Overall, the formaldehyde specificity of the ancestral form (class III), the multiplicity of all ADH systems, and the gradual changes in substrate specificity suggest that the whole ADH system is a basic enzyme, together with aldehyde dehydrogenase, in cellular defense reactions against alcohols and aldehydes, converting them to acidic end products. The validity of this general role of ADH is supported by the fact that the only animals apparently lacking ADH (except for formaldehyde-active class III) are marine invertebrates (10), whose environment is low in alcohol and aldehyde levels. The formaldehyde dehydrogenase activity of class III ADH is universal and constant throughout the living world, although the K_m and enzymatic efficiencies are increased in microorganisms. This permits life at higher aldehyde concentrations (11) and suggests a general defense function for the ADH system.

Additional functions of individual classes are likely. Class IV has been discussed relative to its possible role in retinal formation important for rhodopsin and vision (6) and in retinoic acid formation, which important for vertebrate growth and differentiation (5). Similarly, special forms of ADH and aldehyde dehydrogenase are involved in the fatty acid cycle in dermal wax and plasmalogen formation in the central nervous system and are associated with an inborn error of metabolism (Sjögren-Larsson syndrome) affecting the corresponding genes (12).

1.4. Other MDR Enzymes

Many enzymes active on other alcohols or polyols are related to MDR-ADH in structure and origin. Among these are sorbitol dehydrogenase, threonine dehydrogenase, quinone oxidoreductase, the enoyl reductase component of the fatty acid synthesis machinery, and enzymes with undefined functions, like VAT-1 of synaptic membranes (2). These enzymes are similar conformationally and in their overall active-site relationships. But they also differ markedly, including functionally, in that all do not have the active-site zinc typical of MDR-ADH. This suggests that they have different enzymatic mechanisms. Zinc is also absent in quinone oxidoreductase, which is a crystallin in ocular lenses of some animals.

2. SDR-ADH

Insect ADH is the only well known SDR-ADH, but hundreds of other SDR enzymes are known. These enzymes work on hydroxyl groups of a multitude of sugar, steroid, prostaglandin, and other compounds. They also include reductases, with other activities (like double-bond saturation), and enzymes of no less than three of the enzyme classes in general (oxidoreductases, lyases, and isomerases (3)).

3. Other ADH Forms

ADH activity is also known in enzymes other than the MDR and SDR forms, including iron-activated forms (13). Prokaryotes have several different forms, including long-chain alcohol dehydrogenases (14) and methanol dehydrogenases. They may even have MDR relationships, and this definitely applies to other special prokaryotic forms, such as factor-dependent formaldehyde DH (15), which is apparently the equivalent of class III MDR-ADH in **Gram-positive** bacteria.

Aligning Sequences

The most basic activity in sequence analysis involves aligning protein or nucleotide sequences together. This need arises due to the processes of molecular evolution: gene duplication followed by continual **divergence** of the sequences through the accumulation of mutations over time. Comparative biological analysis, which has long been such a powerful tool for biologists (as exemplified by Linnaeus and Darwin), is arguably even more applicable in sequence analysis than in any other branch of biology, because it can be applied to an enormous number of character states at the level of individual residues in nucleic acid or protein sequences. First, however, related sequences must be correctly aligned before the power of comparative analysis can be brought to bear. Because of the difficulty of aligning highly diverged sequences, and the many applications of sequence alignment, this is one of the most active areas for method development in computational biology.

Alignment tasks generally divide into pairwise sequence alignment and multiple sequence alignment, although the underlying algorithms may share many details. The most sensitive methods for aligning sequences belong to the class of algorithms known as dynamic programming (or minimum string edit) that were initially developed for applications in text comparison. Two of the dynamic programming algorithms most used in biology are usually known as Needleman–Wunsch (1) and Smith–Waterman (2), after the researchers who first applied them to biological sequences. Because these algorithms allow gaps to be inserted at any position in the sequences, they are computationally slow. By contrast, word comparison algorithms, which do not allow gaps, are much faster, but at the expense of accuracy and sensitivity in aligning sequences.

1. Pairwise Sequence Alignment Algorithms

1.1. Dynamic Programming

The basic algorithm works through a two-dimensional matrix in which every residue in one sequence is scored against every residue in the other sequence (1). The algorithm begins in one corner (eg, top left) of the matrix and ends in the opposite corner (bottom right). At each point in the matrix, the algorithm iterates the same set of choices. Typically, it chooses which of three existing paths scores best when extended into the current point: (i) match the residues and continue aligning from the previously aligned residue pair, or (ii) pay the penalty and insert a one-residue gap into sequence X, or (iii) pay the penalty and insert a one-residue gap into sequence Y (see Gap Penalty). The algorithm is guaranteed to find the best path through the matrix, allowing for gaps at any position in either sequence. Scores for matching the residues are taken from residue exchange, or mutation, matrices. For nucleotide sequences, these are usually quite simple: for example, +1 for an *identity*, 0 for a *transition*, and –1 for a *transversion*. For proteins, typical exchange matrices are the more complex 20 * 20 *PAM* (point accepted mutation) matrices introduced by Margaret Dayhoff (3), or subsequently derived PAM series derived from larger alignment datasets (4, 5). A PAM 250 matrix is shown in Figure 1. Gap penalties are used to control the frequency and length of gaps inserted in the sequences. Where appropriate, varying gap penalties in a position-specific manner can improve the alignment.

Residue Identity
Hydrophobic Similarity
Hydrophilic Similarity

Dynamic programming algorithms work through a two-dimensional matrix of area M*N in aligning sequences of lengths M and N. Therefore the computational requirement [usually symbolized as O(MN)] has a constant factor for the calculation, multiplied by the two sequence lengths. To obtain an alignment, the algorithm makes a first pass to determine the end of the highest scoring matched segment and then a second pass working back to obtain the alignment. If only the highest score, but not the actual path, is needed (as in a database search), then only the first pass need be done. Naive implementations that first plot the whole matrix to an array will also use O(MN) memory. Because the algorithm works through the array systematically, however, it is unnecessary to store the whole array in memory. Memory-efficient implementations of the first pass are straightforward, because the alignment is not being kept (6). The second pass, to obtain the alignment, is more complicated, but memory-efficient recursive methods have been developed that have allowed large alignment tasks to be ported to small personal computers, with a small but acceptable loss in calculation speed (7-9).

1.2. Global Alignment

The standard Needleman–Wunsch algorithm (1) finds the optimal full-length alignment for a pair of sequences. Global alignment is appropriate where sequences are known to be both **homologous** and collinear and is therefore often used for multiple alignment of sequence families.

1.3. Best Local Alignment

Variants of the Smith–Waterman algorithm (2) find the optimal alignment that has a positive value for the path for a given pair of sequences. Except for highly related sequences, the best local alignment is a partial match between the sequences. Residue exchanging mutation matrices, such as *PAM*250, provide log-odds scores for the likelihood that a pair of residues will exchange as a result of mutation: Similar residues that exchange easily have positive log scores, while dissimilar residues have negative log scores. The best local alignment is taken as the highest-scoring continuously positive path. This algorithm is appropriate under conditions where sequences are not known to be both fully homologous and collinear—for example, multi*domain* proteins, or DNA regions containing rearrangements. Smith–Waterman type algorithms underlie the most sensitive methods for database searching by sequence homology yet to be devised. Because of the computational cost, they are not applied as often as search methods using ungapped alignment algorithms.

The Waterman–Eggert (10) extension of the algorithm will return sets of suboptimal paths that do not intersect with the optimal path, and in this way it can find repeats in sequences.

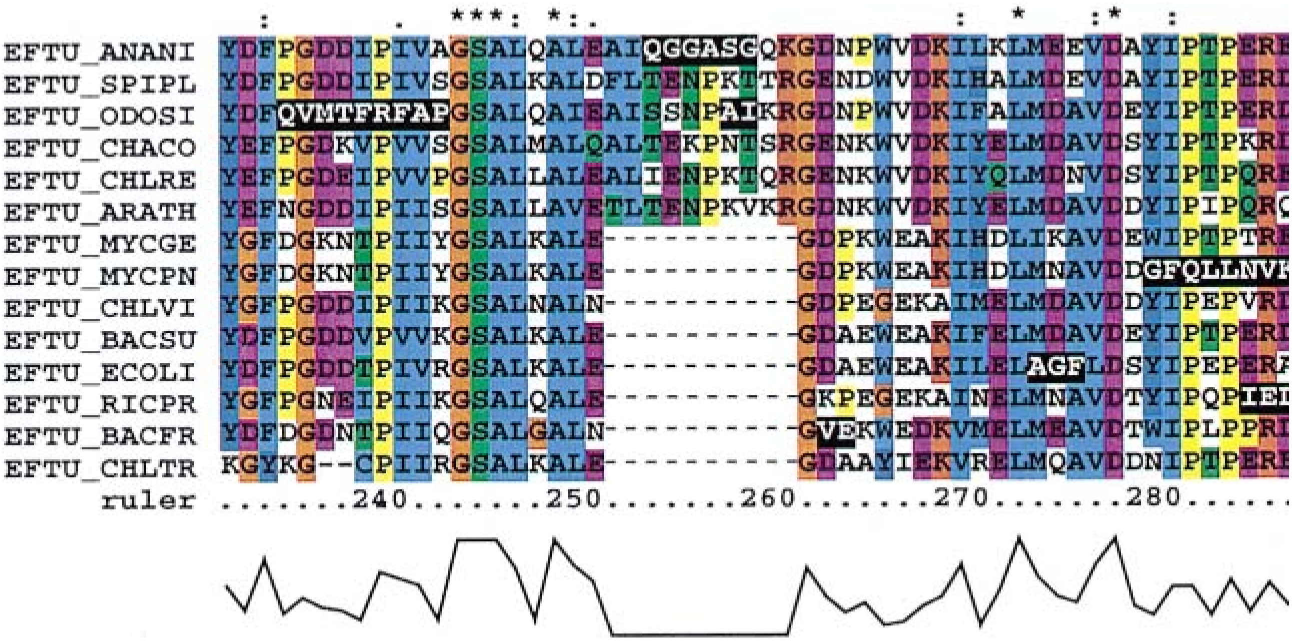
1.4. Best Local Ungapped Alignment

Widely used database search tools, such as BLAST (11) and FASTA (12), search for the highest scoring matched regions without allowing for gaps. Word searches and other ungapped alignment methods are much faster than dynamic programming approaches, but at the expense of sensitivity. Thus these methods are likely to miss homologous but divergent matches. To improve the results, FASTA does a second dynamic pass on the set of top hits. For a small reduction in search speed, BLAST2 examines the gap cost between the set of ungapped positive matches between two sequences and returns composite best locally aligned regions, including gaps whenever the score is still positive. The latter algorithm is likely to approach Smith–Waterman sensitivity except for the most unusual alignment circumstances.

2. Multiple-Sequence Alignment

This is a set of homologous protein or nucleotide sequences that have been correctly aligned, allowing for the presence of indels. Figure 2 shows an aligned region for some elongation factor TU sequences.

Figure 2. Part of a multiple alignment of 14 prokaryotic EFTU sequences using the one-letter code for amino acids. Gap
by asterisks are completely conserved, columns marked by colons are strongly conserved, and columns marked by perio
bottom shows the conservation in the columns. Color is an essential aid to sequence analysis and is used here to highligh
properties. Inverted characters indicate poorly matching regions of sequence. Some of these are due to natural sequence
sequence determination causing frameshifted regions: EFTUSPIPL 203–206, EFTUODOSI 234–243, EFTUMYCPN 27
errors may lead to false inferences: If R-285 were completely conserved, it would be a candidate functional residue, whil
incorrectly suggests a surface loop. See color insert.



2.1. Uses of Multiple Alignments

Multiple alignments are indispensable in computational biology. They are the basic dataset used to construct phylogenetic trees, which are themselves important computational tools (eg, for weighting sequences by divergence) as well as providing insight into past evolution. They reveal conserved residues that are likely to be structurally or functionally (eg, in catalysis) important and unconserved positions that either are unimportant or have acquired a change of function (Fig. 2). They improve the accuracy of many sequence analysis functions as compared to single sequences, such as **secondary structure prediction** (13), coiled-coil prediction (14), and **transmembrane helix** prediction (15). They are useful as the query input for the most sensitive homology searches (alignment profile (16) and hidden Markov model searches (17)) and can be used to detect divergent homologues that single-sequence queries cannot pick up. They are useful in the detection of **domains** and in defining their boundaries in modular, mosaic proteins (18). Multiple alignments of folded RNAs are a prime resource used in determining their secondary and tertiary structures, by mapping residue conservation and long-distance-coupled mutations (19, 20). DNA multiple alignments are used for identifying conserved signals, such as **promoter** elements and **RNA splice** sites (21).

2.2. Multiple-Alignment Algorithms

So far it has been necessary to adopt heuristic strategies to generate multiple alignments, because formally correct methods have been computationally impractical to implement. The ideal method to align N sequences would be N-dimensional dynamic programming, as this would be guaranteed to find the optimal path (ie, the optimal multiple alignment) in an N-dimensional matrix. Unfortunately the computer time required to align N sequences of length l is $O(l^N)$ and is impractical for more than three or four sequences, although by limiting the search space to likely regions, the MSA program can align up to eight sequences (22). Another broad class of methods, those that iterate toward an optimized score for the alignment, are still computationally intensive but are becoming practical with increasing computer power. These include a number of approaches, some of which may be used in combination, such as global minimization, genetic algorithms, and trained **neural networks** (23, 24). The goal is to harness a good model description of a multiple-sequence alignment with an effective iteration strategy, so as to get high-quality alignments in a practical timescale. In the meantime, widely used alignment programs such as Clustal W (25) follow the heuristical clustered alignment strategy.

2.3. Progressive Clustered Alignment

This two-step approach was introduced by Feng and Doolittle (26) in an attempt to minimize errors in the final multiple alignment, by aligning the most similar sequences first and the most divergent ones last. The set of unaligned sequences are first aligned in pairwise fashion to each other, so that a matrix of the approximate pairwise similarities may be obtained. A matrix-based tree construction method, such as Neighbor-Joining (27), is used to construct a dendrogram linking the sequences according to their observed similarities. Guided by the dendrogram branching order, the sequences are then sequentially aligned together using dynamic programming, beginning with the most closely related sequences and ending by merging the most divergent groups by profile alignment. This procedure minimizes alignment errors, which become more likely with increasing sequence divergence, becoming a problem for proteins less than 25% to 30% identical in sequence. The final alignment should always be examined for misalignment, especially of the more divergent sequences, because such errors are likely to be present in any but the most straightforward multiple alignment task.

The sensitivity of the basic clustered alignment strategy can be improved by several modifications, such as weighting the sequences by divergence and position-specific gap penalties (25). Where tertiary structure information is available, gap penalty masks can be employed to guide the gaps into regions of sequence that are expected to be tolerant of indels (28).

2.4. Profile Alignment

A set of aligned sequences can be aligned to one or more new sequences by treating the group much as a single sequence. The score for one alignment column can be obtained by summing the log-odds residue exchange scores for the observed set of amino acids (16), correcting for sequence relatedness by downweighting similar sequences (25). Conserved alignment columns score more highly than unconserved columns, where the log-odds scores tend to cancel each other. Gap penalties can be lowered at existing indels, because gaps in new sequences are more likely at these positions than at ungapped positions. The improvement in signal to noise provided by the extra information in the alignment means that a profile alignment is more accurate than independent pairwise alignment of the same set of sequences. As well as being used to merge aligned groups in the clustered alignment strategy, profiles provide a sensitive search strategy to find highly divergent homologues and are one of the main sequence analysis tools for identifying protein domain families (18).

2.5. Hidden Markov Model (HMM) Alignment

HMMs are a class of probabilistic models, applicable when the components of a complex linked system behave independently (a so-called Markov chain). Up to a point, this is valid for residue mutations in globular protein sequences, and HMMs are being applied increasingly in multiple-alignment algorithms and profile-type database searches (17, 29). The models are more complex than the widely used PAM model for protein evolution introduced by Margaret Dayhoff (3), providing both advantages and disadvantages. On the plus side, the models provide direct probabilities for evaluating database search matches, which can include multiple matches in a repeated sequence and can formally treat biological complexities such as splice junctions in genomic sequence. On the debit side, the extra parameters lead to more complex optimization problems at several levels. Thus, inexperienced users may set up poorly optimized HMMs while, for program developers, there is a problem as to whether the most appropriate HMMs are being applied to sequence evolution. It is important for the user not to be seduced by technical jargon, but to justify the use of newer methods such as these on the basis of convincing results.

3. Error in Sequence Alignments

Errors are very common and invalidate any conclusions obtained by methods based on sequence alignments (see Fig. 2). The three main sources of error are: the input sequences, mistakes by the user, or alignment algorithm failure. Causes and effects of error are manifold; some major ones are discussed below.

3.1. Errors in the Input Sequences

Experimental errors in determining sequences include double-insert cloning errors, truncated cDNA clones, base insertion or deletion causing translation **frameshifts**, and translation with inappropriate genetic code (eg, for plastid-encoded proteins). Figure 3 shows an example of a frameshift error in a database entry. Algorithm failure during alignment may be induced by sequence error, such as frameshifted regions, in which the sequences are no longer similar, and may induce incorrect gap placement (Fig. 2). Errors in sequences are very common and likely to be present in any sequence family (30, 31).

Figure 3. Frameshifted segment in the *Mycoplasma pneumoniae* EFTU sequence revealed by comparing the DNA to the closely related *Mycoplasma genitalium* EFTU using a dynamic programming three-frame comparison allowing shifts be translation frames (30). Exclamation points mark the frameshift sites. The first frameshift is caused by a base being drop and the second frameshift is caused by a base being added, thereby returning to the original translation frame. See Figure multiple alignment spanning this region.

Further errors can arise in preparing sequence database entries. These can affect any part of the entry and can have particularly unpredictable consequences. However, the most common annotation errors are undoubtedly in predicted translation products and are a consequence of the limited accuracy of current gene prediction algorithms; that is, despite high-quality DNA sequence, the predicted protein sequence might contain artificially translated **introns**, missed exons, or terminal truncations or might be an artificial fusion product of two independent genes. Protein sequence alignments can often help in identifying translation problems.

3.2. Mistakes by the User
Generally these are due to inadequate attention to detail. Erroneous inclusion of nonhomologous sequences in the input set is quite common, particularly if keyword searches are used to extract a set of sequences; there are many examples of unrelated proteins performing equivalent functions, as well as sequences that have functions incorrectly ascribed to them. Another source of error occurs during the alignment process, when parameters may be set poorly. Trial and error is usually needed to find the parameters that best suit a particular group of sequences. For example, insertion of too few or too many gaps may suggest that the gap penalties are not optimal. It is important to take the time to get a basic understanding of how a given program works, or it is unlikely to do the best job.

3.3. Algorithm Failure
Clustered alignment is a heuristic strategy that is not guaranteed to find the optimal multiple alignment. The alignment process is likely to compound errors introduced by the user or in the input sequences. Alignment mistakes will also be made in difficult alignment cases, even when there are no input errors. There are many instances of homologous proteins having diverged over long periods of time, so that they have apparently very little sequence similarity. The “twilight zone” where sequence similarity merges with sequence dissimilarity is in the range 20% to 25% identity. (Five percent identity would be a random match for protein sequence, neglecting residue biases. In practice, given residue biases and gap insertions to maximize the similarity, the expectation for random sequence matches approaches ~15% identity, but higher for short or biased sequences. There is, however, no *a priori* reason why correctly aligned but extremely divergent proteins should not be found with 0% pairwise identity.) Divergent nucleotide sequences are even harder to align, because random similarity is reached at ~25% identity before gaps are added. Wherever possible, alignments need to be checked against additional data available for a sequence family, such as known tertiary structures and whether invariant catalytic residues, or any other known conserved motifs, are correctly aligned.

3.4. Consequences of Errors in Aligned Sequences
Errors in multiple alignments can have disastrous consequences for **phylogenetic** inference on the basis of sequence trees. Sequences with misaligned segments or translation frameshifts are apparently more divergent than they should be from the other sequences. The branch leading to that

sequence will then have a longer length (which erroneously implies a more rapid molecular clock) and the branch point may migrate toward the centre of the tree, giving a false order of divergence. Such incorrect phylogenies may be quite exciting when they seem to refute established viewpoints. Two rules of thumb are useful: (i) Infinitely more wrong tree topologies can be generated than right ones, and (ii) wrong phylogenies are more interesting than right phylogenies. Incautious advocacy of a wrong phylogeny can waste many peoples' time.

Errors also disrupt evaluation of conserved sites in sequences (Fig. 2). Catalytic residues are often absolutely conserved, so a single misaligned sequence may lead to rejection of the correct site. Most conserved residues have a structural role: Structure prediction for protein uses conserved **hydrophobic** residues and, for RNA, conserved base-pairing residues. Misalignments disrupt the conservation periodicities, leading to rejection of the correct structures. Terminally truncated sequences of multidomain proteins can lead to false inferences for the domain boundaries, which are very usefully defined by coincidence with the protein *N*- or *C*-termini.

Alkaline Phosphatase

Alkaline phosphatases (E.C. 3.1.3.1) belong to a family of orthophosphoric monoester phosphohydrolases that have an alkaline pH optimum. Their genes are very frequently used as a **reporter** gene. Alkaline phosphatase activity is most commonly detected by the hydrolysis of 5-bromo-4-chloro-3-indolyl phosphate (BCIP), which, when coupled to the reduction of nitro blue tetrazolium (NBT), forms a formazan and an indigo dye that together form a strong black/purple precipitate (1). In addition, a number of fluorogenic substrates are also available (1). 4-Methylumbelliferyl phosphate (MUP) gives a blue **fluorescent** product upon hydrolysis, and 2-hydroxy-3-naphthoic acid-2-phenylanilide phosphate (HNPP/Fast Red TR) fluoresces with a broad emission peak between 540 and 590 nm and can be observed using either fluorescein or rhodamine filter sets. Molecular Probes Inc. have also developed a proprietary substrate called ELF-97 (Enzyme Linked Fluorescence-97), in which cleavage of the molecule converts it from a soluble phosphate to an insoluble alcohol, with an accompanying shift from weak blue fluorescence to a bright yellow fluorescence (2).

Human placental alkaline phosphatase (hpAP) is most commonly used as a reporter enzyme in nonradioactive detection systems, where the enzyme is linked to other molecular probes (eg, specific antibodies)—for example, for the detection of proteins and nucleic acids by **Western blot**, Southern blot, and **Northern blot** analysis, and most commonly in in situ hybridization. Elegant studies have also been performed in which hpAP is fused to soluble extracellular domains of receptor molecules, which are then used as probes to detect the sites of ligand production *in vivo* and facilitate the subsequent cloning of the ligand genes (3).

Although animals express a number of alkaline phosphatase genes, the human placental isoform has been developed as a reporter gene, because it can be distinguished from other endogenous isoforms through its high thermostability (4). Thus all background endogenous alkaline phosphatase activities, from embryonic, intestinal, and nonspecific genes, can be minimized by preheating tissue preparations up to 80°C for prolonged periods. hpAP also retains its activity following histological processing for wax imbedding and sectioning tissues. In addition, background from endogenous alkaline phosphatases can be further inhibited by the amino acids L-phenylalanine or L-homoarginine.

hpAP has been used in a wide range of applications, including *in vitro* transfection studies and transgenic studies *in vivo*. The sensitivity of hpAP in transient expression assays is equivalent to that of chloramphenicol acetyltransferase (CAT) (see Reporter Genes). A particularly useful variant of hpAP is a cDNA encoding a secreted form of the protein (5, 6) that allows hpAP activity to be assayed by sampling tissue culture medium, giving the benefit of monitoring changes in gene expression with time. In this system, background activities are further eliminated, because the endogenous isoforms are anchored to the cell membranes and do not contribute to the activity in the culture supernatants.

hpAP is also an effective reporter gene to analyze gene expression *in situ* in tissue preparations. hpAP was first used in retroviral vectors to infect small numbers of cells in developing embryos as a tool to study cell fate and lineage analysis; subsequently, hpAP has been used as a robust reporter gene in transgenic mice (7). Indeed, mice that express high levels of hpAP from a ubiquitously expressed **promoter** thrive with no adverse effects. hpAP is particularly useful to use in combination with a second reporter gene, such as *lacZ* (**beta-galactosidase**), in dual labeling studies, as the common substrates are quite distinct and give different colored products (8).

Alkylation

Alkyl groups have the general formula $C_n H_{2n+1}$–. Alkylation is a reaction that introduces an alkyl group into a compound. Commonly used alkylating agents are olefins, alkyl halides, and alcohols. Biologically important alkylation occurs on nitrogen and oxygen atoms in polynucleotides. Alkylating agents that cause these reactions are mutagens and carcinogens and include methyl methanesulfonate, dimethyl sulfate, *N*-methyl-*N*-nitrosourea, dimethylnitrosourea, 1-methyl-3-nitro-1-nitrosoguanidine, etc. Some alkylating agents are used as anticancer drugs, including cyclophosphamide, nitrogen mustard and its oxide, and triethylenephosphoramide.

Alkylating agents easily alkylate nucleophiles in proteins such as those on cysteine (1), histidine (2), and methionine (3) residues, amino groups (4), and sometimes tyrosine residues and carboxyl groups (5). The most well-known alkylation is that for blocking free thiol groups of cysteine residues to prevent their oxidation, especially in the course of determining the primary structure of a protein (see Protein Sequencing).

1. Reduction and Alkylation of Proteins

The protein at a concentration of 2% (w/v) is dissolved in 0.5 M **Tris** buffer, pH 8.1, containing 6 M **guanidinium chloride** and 0.002 M EDTA and reduced with **dithiothreitol** (50 mol/mol of disulfide bond) at 30° to 40°C for 4 h under nitrogen (6). Then the solution is cooled to room temperature, and iodoacetamide (100 mol/mol of the original disulfide bond) is added, with the addition of NH_4OH as necessary to maintain a constant pH. Other alkylating agents that can be employed instead are iodoacetic acid, 4-vinylpyridine, N-ethylmaleimide, and ethyleneimine.

Allelic Exclusion

The clonal selection theory put forward by Burnet (1) and Jerne (2) proposes that each single lymphocyte expresses only one single type of antibody. This theory received its first structural confirmation when it was shown that patients with multiple myeloma, a proliferative disorder of plasma cells, had in their serum a highly elevated level of only one molecular species of immunoglobulin, originating from the corresponding malignant clone. Single-cell experiments performed by the Nossal group in Australia (3) indicated that each cell isolated from mouse **immunized** with *Salmonella* antigens produced only one antibody of one given specificity. These observations were in agreement with the clonal theory, but did not explain by which mechanism this was achieved. An elegant approach to that problem was made with the analysis of allotypes in heterozygous animals. Allotypes, as defined by Oudin (4), are antigenic specificities that are shared by a group of animals within a given species. These genetic markers are **allelic** variants of immunoglobulins that are found on both the heavy and light chains. They have been studied extensively in the rabbits, mice, and humans. In most cases, they are the result of a few amino acid substitutions that confer specific epitopes (or allotopes) that can be recognized by specific antibodies. In a rabbit heterozygous for H- and L-chain allotypes, Oudin showed that any given immunoglobulin molecule always had two identical heavy chains and two identical light chains with respect to the corresponding allotypes. This ensured that the Ig molecule was symmetrical and therefore had two identical antibody combining sites, an obvious prerequisite of the clonal theory. The next step was made at the intracellular level, when Pernis et al. (5) showed with specific anti-allotype antibodies that, in a heterozygous rabbit, any given cell always expressed only one allotype of each heavy or light chain. This suggested that a B cell, although **diploid**, had only one of its two alleles functional, and the phenomenon was termed “allelic exclusion.”

The molecular mechanisms that account for this phenomenon could be understood only when the complex mosaic structures of immunoglobulin (Ig) genes were deciphered. Each Ig heavy or light chain contains an NH_2-terminal variable and a COOH-terminal constant region, each encoded by a multiplicity of gene segments. Diversity of the variable regions, which is directly linked to the necessity to produce a very large number of different antibody molecules with a limited number of genes, is generated by specific mechanisms of gene rearrangements that take place exclusively in lymphocytes. The heavy-chain **variable region** is encoded after the rearrangement of three discrete sets of germline gene segments (V_H, D, J_H), and two for the light chain (V_L, J_L). Gene rearrangements take place sequentially during B-cell differentiation in the bone marrow, in a strictly regulated manner, as initially proposed by Alt and Baltimore. The heavy-chain gene segments rearrange D to J_H and V_H to D–J_H. The gene-segment joinings are random, so only one-third of the rearranged genes have an open reading frame. As soon as one rearrangement is in frame, the corresponding m chain is expressed. Whenever the first rearrangement is successful, the second allele remains in the germline configuration, which indicates that a regulatory mechanism has taken place. It was shown by transfection experiments and by making m transgenic mice that the negative feedback inhibition of the gene rearrangement of the second allele was controlled by the m chain itself, when expressed at the cell surface. It was also shown that, at this "preB stage," the m chain was associated with a surrogate light chain (YL), which is monomorphic and composed of two polypeptide chains encoded by the l5 and VpreB genes. Expression of m–YL has been shown to down-regulate the heavy-chain gene rearrangement, whereas rearrangement of the light chain locus is switched on, in the same random reading frames as above. The final result of this complex sequence of events is that, at each locus, only one allele is functional; the other one either remains in the germline configuration or has an out-of-frame rearranged gene, thereby accounting for the allelic exclusion phenomenon.

Alloantibody, Alloantigen

Alloantigens are **allelic** variants that can induce, when injected into animals of the same species but having a distinct genetic background, the production of the corresponding alloantibodies. The most commonly known example of alloantigens are the blood group substances, which define the basic ABO blood groups in humans. Blood group substances have long been identified as being derived from a polysaccharide core that is found in pneumococcus group XIV, onto which three genes encoding for glycosyl transferases will serially add units that will confer a specific antigenicity to the newly derived molecule. Three genes operate this system in humans: A, B, and H. The H gene is present in all individuals and will add one residue of fucose, leading to the so-called H substance. In individuals who possess the A gene, an additional GalNAC (*N*-acetylgalactosamine) will be added, providing the A substance, which is expressed at the red blood cell surface and confers the A group. In those who have the B gene, a galactose residue is added to H, making the B substance, which is also expressed at the cell surface of red cells in individuals of group B. The A and B genes are codominant, so an individual will express the A, the B, or both the A and B molecules at the red blood cell surface, depending upon what A and B genes are present. If neither the A nor B allele is present, the group will be O. There are many other blood groups in humans, with special reference to the Lewis groups, which are also derived from the same polysaccharide backbone by addition of different units. What is peculiar regarding the ABO blood group system is the fact that individuals who lack the A or the B specificity spontaneously produce alloantibodies directed against the missing substance. So an individual of group A will make anti-B alloantibodies, an individual of group B will produce anti-A, and one of group O will have both. Very severe accidents in blood transfusion would result from the agglutination of the donor red blood cells by the alloantibodies of the recipient. The reverse situation, agglutination of the host red blood cells by antibodies of an incompatible donor, should also be avoided, although accidents are less severe. Antigen compatibility between donor and recipient is therefore a must. ABO compatibility should also be observed in allografts.

Even if the genetic determinism of these alloantigens is straightforward, it still is not clear why the alloantibodies corresponding to the nonexpressed substance(s) are produced. The prevalent explanation is that blood groups cross-react with bacteria normally present in the intestinal flora, which would stimulate the immune system to produce the corresponding crossreacting antibodies. It should be stressed that these “natural” antibodies are of the IgM type, which may be directly related to the fact that they are the result of the stimulation by a T-independent polysaccharide antigen. The titer of alloantibodies varies greatly between individuals, but may be considerably elevated upon an incompatible transfusion.

Another famous case of alloantigen in the blood groups is the Rhesus factor, which was responsible for the dramatic hemolytic disease of the newborn, due to the immunization of an Rh mother against red blood cells of an Rh^+ fetus. This occurs during the delivery because some fetal red cells may enter the maternal circulation and induce the formation of IgG antibodies that will actively cross the placental barrier in a subsequent pregnancy and then provoke lysis of Rh^+ fetus red cells. Treatment involves complete transfusion of the newborn with Rh blood. It has now been generalized to prevent the immunization by injecting the Rh mother with anti-D (anti-Rhesus) antibodies immediately after delivery, to trap the red blood cells from the newborn that would have penetrated the maternal circulation at birth.

Many other alloantigens are known, but alloantibodies are generally not produced unless the antigen is given. This is the case of the major histocompatibility complex (MHC) molecules, which constitute a major problem in transplantation. The name of major histocompatibility complex indicates by itself how these molecules were first discovered as a major target for graft rejection, as the result of a very severe alloimmune response, characterized primarily by the production of cytotoxic T lymphocytes. Many other systems may behave as potential alloantigens, which simply reflects the existence of allelic variants. The case of allotypes of immunoglobulins has been studied particularly by immunologists and has provided remarkable genetic markers for the study of immunoglobulin biosynthesis and diversity at the time.

Allophenic

Allophenic individuals are composed of cells of two different genotypes (often called mosaics or chimeras). Allophenic mice are the basis of the revolution in mouse genetics, allowing mice with specific gene replacements to be generated and studied. Allophenic mice are made by mixing cells from two embryos of different genotypes (1). These new composite embryos are implanted into foster mothers and allowed to develop. The early embryos are able to compensate and form a single individual from the mixture of embryonic cells. The mosaic progeny that result from these manipulations have tissues that contain cells of the two different genotypes. The allophenic mice have also been called tetraparental mice. When the germ cells are also of mixed origin, progeny can be recovered from both genotypes.

The ability to make allophenic mice in the laboratory was first used to study the contributions of cells to individual tissues. The number of cells that give rise to a particular tissue can be estimated from the proportions of the two genotypes in a large number of allophenic mice. The cellular autonomy of mutant phenotypes can be determined by generating allophenic mice between mutant and wild-type mouse embryos. The two cell types usually differ both in the mutant of interest and in some marker genotype, such as an enzyme polymorphism.

Two advances in the technology of allophenic mice have contributed to a revolution in mouse genetics in the last few years. The first advance was the ability to use embryonic teratocarcinoma cells from cell culture as one of the two cell types used to make the allophenic mice (2). The cultured cells are injected into the interior of a normal mouse embryo and are incorporated into the embryo, to form an allophenic mouse. The teratocarcinoma cells are totipotent and can even form germ cells that give rise to the **gametes** for the next generation. The second major advance was the development of techniques for site-directed mutagenesis and gene replacement in mammalian cells in culture (3) (see Gene Targeting). A gene of interest is altered in a specific way in teratocarcinoma cells in culture. A clone of cells with the altered genotype is produced, and cells from the clone are injected into early mouse embryos to produce allophenic mice. These allophenic mice can be studied as mosaic individuals or can be allowed to develop to fertile adults. If some of the germ cells in the adult allophenic mice are derived from the genetically altered teratocarcinoma cells, progeny can be recovered from the gametes produced by the teratocarcinoma cells and used to found a mutant strain of the specific genotype desired. This has led to the production of hundreds of new mouse strains mutant for developmentally important genes. It has also made the construction of mouse models for human disease far easier than in the past. These technologies have been extended from mice to a variety of other mammals; and they could be used to alter the human genome genetically, with far-reaching consequences.

Allostery

Allostery is used to describe regulatory phenomena in biological systems. The term "allosteric" (other shape) was coined by Monod and coworkers to describe a particular type of regulatory behavior and marks an important synthesis in the development of biochemistry and molecular biology. Since its inception, the term has evolved to describe several related concepts and is used today to describe a variety of phenomena. To some, it is associated with a particular type of regulatory behavior, while to many it is used to describe several different aspects of regulation. The development of the concept, the meanings it has come to have, its application in describing regulatory properties of proteins and enzymes, and recent developments that indicate the need to use it in its original sense are described here.

The allosteric concept was conceived in the early 1960s by Monod and coworkers to describe the properties of regulatory enzymes. In the mid-1950s, several investigators described enzymes whose catalytic properties were dependent on effector molecules other than the substrate. The first well-characterized example of this behavior was the finding by Cori and colleagues that 5′-AMP is required for the *in vitro* catalytic activity of glycogen phosphorylase b from resting skeletal muscle (1). Studies of the regulation of biosynthetic pathways in bacteria showed that the catalytic properties of the first enzyme in a pathway are often modulated by the end product of the pathway, which has a structure different from that of the substrate—for example, isoleucine inhibition of threonine deaminase (see Threonine Operon) (2) and CTP inhibition of aspartate transcarbamoylase (3). The differences in the structures of the substrates and effectors were first noted by Monod and Jacob, who postulated in a seminal paper in 1961 that the effectors bind to separate and distinct sites (4). They coined the term *allosteric site* for the effector binding site to distinguish it from the active site and postulated that the effectors act indirectly by causing changes in the conformation of the enzyme that alter its catalytic site and kinetic properties. In 1963, Monod and coworkers compiled the available data on regulatory enzymes (5). These enzymes all contained more than one subunit per enzyme molecule–that is, dimers, tetramers, and dodecamers. For several of these enzymes, changes in quaternary structure (association–dissociation of the subunits) had been shown to occur upon addition of the effectors. Monod was also aware of unpublished crystallographic results showing that the oxygen-binding sites on hemoglobin are located far from one another and that the distances between the amino acid residues labeled by heavy atoms change upon binding of oxygen (Ref. 6, pp. 577–578). On this basis, the key elements of a general model for the functional structures of regulatory enzymes were formulated:

1. Each molecule of the native enzyme contains multiple subunits with binding sites for substrates and ligands, and the regulatory behavior depends on the relationships between the subunits.
2. No direct interactions between substrate(s) or effectors are required, that is, the effectors act indirectly on the catalytic site.
3. The actions of the effectors are due entirely to a reversible conformational change in the protein that is induced by effector binding.

Monod et al. postulated that protein conformational change is the basis for control and coordination of chemical events in living cells, and Monod considered this to be the "second secret of life" (Ref. 6, p. 576). Structural studies using X-ray crystallography methods support the concepts of this general model.

These concepts were used to develop the concerted model, a specific molecular model for describing regulatory behavior (7). This model was developed as a plausible explanation for the positive cooperativity in the binding of oxygen to hemoglobins. Because the apparent affinity for binding of oxygen changes as its concentration is varied, these are called *homotropic interactions*. The concerted model retains the aspects of the general model with respect to oligomeric structure of the protein, multiple binding sites located far from one another, and conformational changes upon binding of one ligand that are transmitted by protein conformational changes to the other ligand binding sites, thereby altering the binding affinities. This model defines the relations between the conformational changes and ligand binding. The word *concerted* refers to the all-or-none nature of the conformational transition. That is, only two conformations are allowed for the subunits in an oligomer and all of the subunits in a given oligomer have the same conformation. The conformations are denoted by the terms *R-state* and *T-state*, and they differ in affinity for binding ligands. The R-state has the higher affinity for ligands. Positive cooperativity in oxygen binding is explained by a large predominance of the unliganded protein in the T-state with a shift to the R-state upon binding of oxygen. The model was extended to enzymes by assuming that the interactions between the substrate and enzyme are in rapid equilibrium and that all forms of the enzyme have the same V_{max}. At this juncture, the term *allosteric* takes a different meaning. The conformational change between the two states is called an *allosteric transition*. So, in addition to referring to sites for molecules other than the substrate, it refers to interactions between substrate binding sites on different subunits. The concept of the "other shape" is extended to the enzymes, which are termed "allosteric enzymes."

This initial formulation of the concerted model describes homotropic interactions. The original considerations of the allosteric concept were developed to treat cases in which the behavior of one molecule, the substrate, depends on the concentration of another molecule. These are called *heterotropic interactions*. The regulatory enzymes whose properties were catalogued by Monod et al. showed both homotropic and heterotropic effects (5). The phenomenon of desensitization—that is, treatments that result in loss of substrate homotropic interactions and heterotropic interactions, but do not affect catalytic activity, had been described for some of these enzymes. Monod et al. postulated that desensitization means that the molecular basis might be the same for both homotropic and heterotropic interactions. They stated that if this were the case, the concerted model could also be used to describe heterotropic effects—that is, the original allostery. In the model, activating effectors have higher affinity for the R-state, while inhibitory effectors have higher affinity for the T-state. This issue has resulted in great confusion in the use of the model. All subsequent treatments presume that a single allosteric transition is the basis for both homotropic and heterotropic effects. This presumption is particularly evident in structural studies of regulatory proteins, where the terms R-state and T-state dominate discussions.

In the three cases of regulatory proteins that have been examined with care, it is clear that the concerted model fails. More than two states are involved in oxygen binding to hemoglobin (8, 9). Homotropic and heterotropic interactions are not due to the same transition in aspartate transcarbamoylase (10, 11). Although the same T-state is predicted for phosphofructokinase with different inhibitors, experimental results show that the properties of the inhibited forms are different (12). These results argue strongly that the term *allosteric* should be used in a stricter sense to refer to effects of one ligand on the binding of another, independently of assumptions about the mechanism of the interaction.

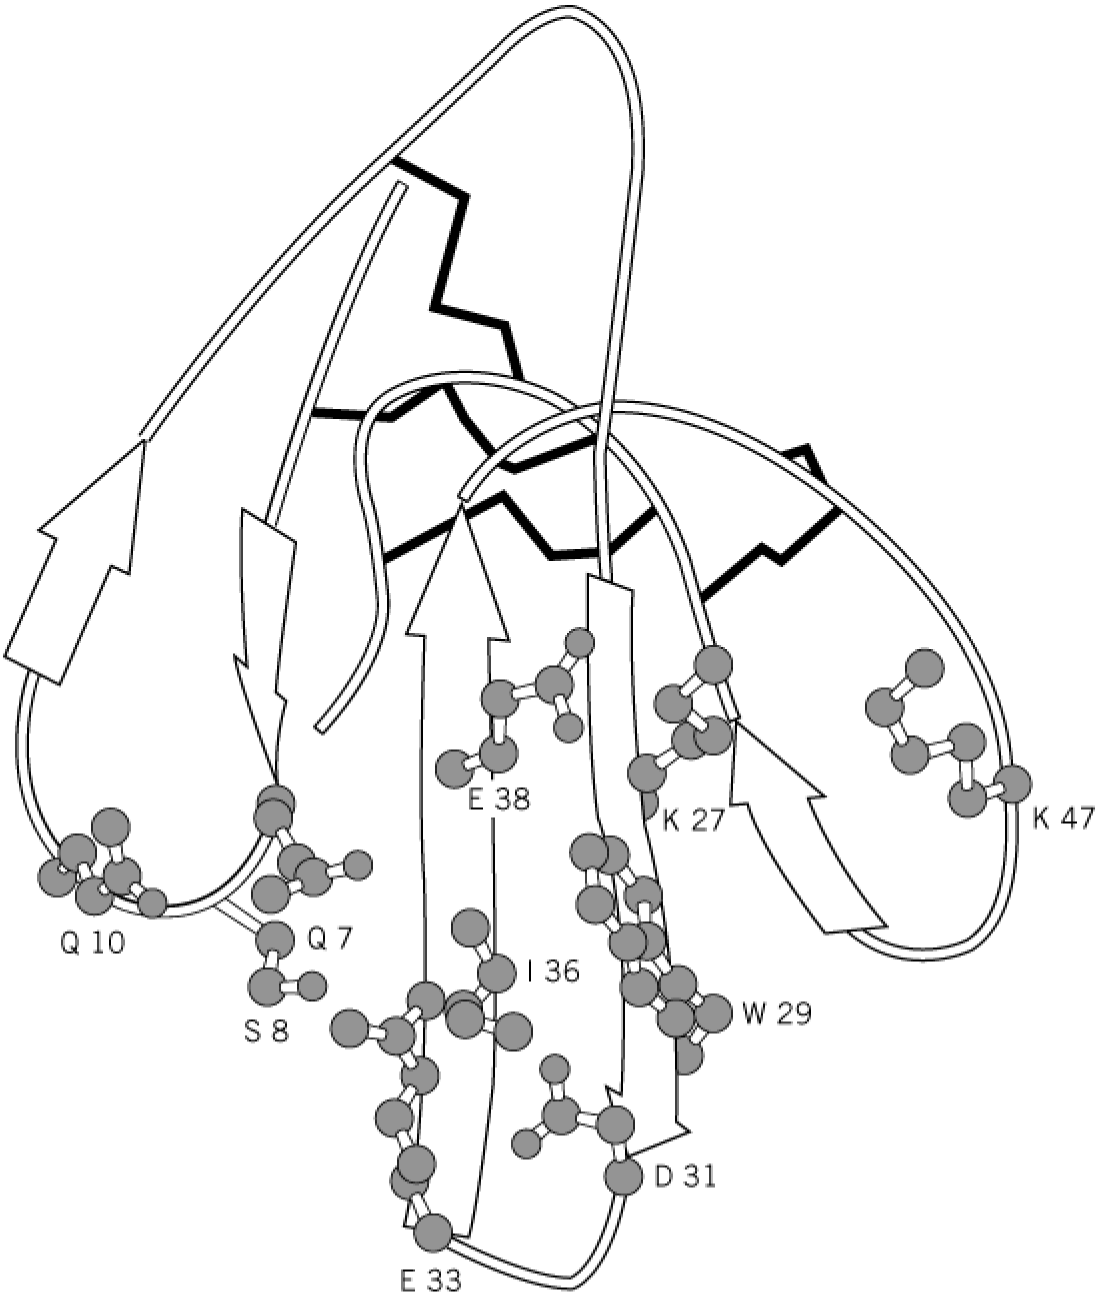
Alpha-Bungarotoxin and Curare-Mimetic Toxins

The venom of the banded krait snake (*Bungarus multicinctus*) contains a variety of protein toxins that are collectively called bungarotoxins. As is often the case, an animal venom is, in fact, a mixture of different toxins specific for different target molecules. The a-neurotoxins, or curare-mimetic toxins, bind specifically to the acetylcholine receptor with high affinities ($\boldsymbol{K}_d$ in the 10^{-9} to 10^{-12} M range for neuronal and muscular receptors of different species) and prevent the opening of the ion **channel** caused by acetylcholine binding (1, 2). Such inhibition of the transmission of the nerve-muscle impulse results in a flaccid paralysis, which may end in respiratory failure and death.

a-bungarotoxin is the prototype of a large group of monomeric toxins, produced by many snakes, including cobra and sea snakes, and composed of 66 to 74 amino acid residues with four or five disulfide bonds. Their three-dimensional structure is rather flat, with three adjacent b-sheet loops (3) that expose residues essential for receptor binding: Lys-27, Trp-29, Arg-39, and Lys-55 (numbering of erabutoxin) (Fig. 1) (4).

Figure 1. Erabutoxin, a snake toxin that binds to the acetylcholine receptor. Folding of the polypeptide chain shows the typical three-finger folding of curare-mimetic snake toxins. Several residues determine the specific binding and inhibition of the acetylcholine receptor with Lys-27, Trp-29, Arg-33, and Lys 47 playing a major role (4). Reproduced from (2) with permission.



Many species of snakes, including *B. multicinctus*, also produce a-neurotoxins of smaller size. Their polypeptide chains are 60 to 62 residues long but adopt the same three-finger b-sheet fold, stabilized by four disulfide bonds. At variance from the longer a-neurotoxins, these toxins are dimers, but the same three positively charged residues are essential for receptor binding. The corresponding area of the acetylcholine receptor involved in a-neurotoxin binding has not been mapped in detail, but the segment of residues 185 to 199 plays a major role, together with residues 128 to 142.

The various a-neurotoxins bind with a range of affinities and specificities to the multitude of muscular and neuronal acetylcholine receptors; fluorescent and **radiolabeled** toxin derivatives are invaluable tools for the study of the structure and function of such receptors (5).

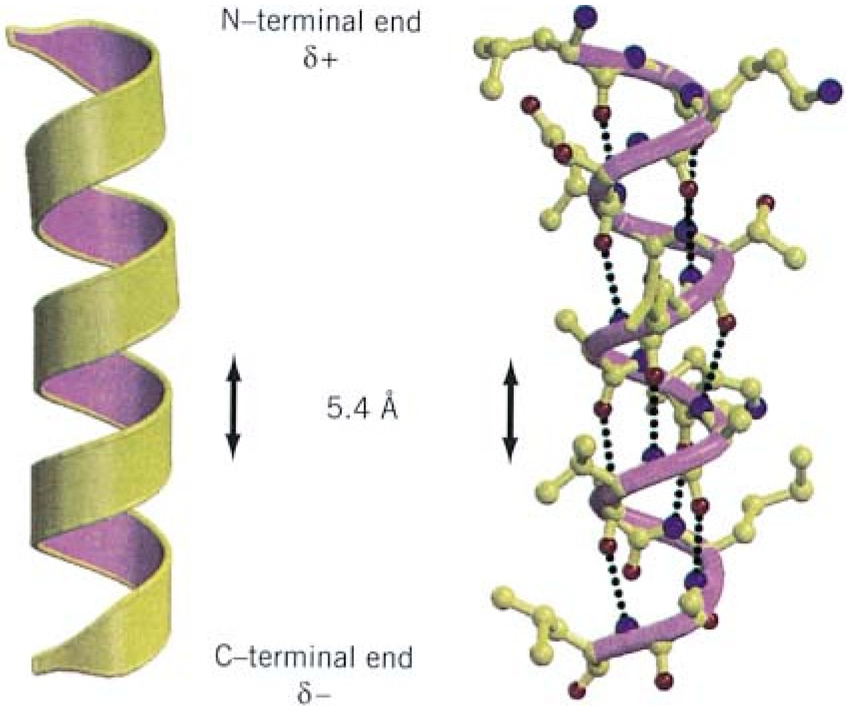
Alpha-Helix (3_{10}-Helix and Pi-Helix)

The right-handed a-helix is one of two regular types of protein **secondary structure**, the other being the b-strand that forms b-sheets. Helices are formed from consecutive stretches of **residues** of the polypeptide chain and are characterized by a right-handed coiled backbone and a regular repeating pattern of backbone hydrogen bonds. a-Helices are usually depicted as coils or cylinders in protein structure diagrams (Fig. 1). There are 3.6 residues in every turn of a-helix, and for each turn the backbone is translated by 5.4 Å (or 1.5 Å per residue). In protein structures, the average length of an a-helix is 10 residues, although much shorter and longer examples have been observed. The backbone angles are approximately –60° and –50° for f and Y, respectively, corresponding to the allowed region in the lower left of the Ramachandran Plot. The atoms of the polypeptide chain pack closely together in the a-helical conformation, making favorable van der Waals interactions. The side chains of each residue are oriented outward from the axis of the helix, with the Ca–Cb bond pointing toward the *N*-terminal end of the helix.

Figure 1. A typical protein a-helix. (**Left**) The helix is depicted schematically as a coil, and the *N*- and *C*-terminal ends, with their respective partial positive and negative charges, are indicated. (**Right**) The atomic detail of the a-helical structure is shown, with hydrogen bonds between backbone carbonyl oxygens (*i*) and backbone amide nitrogens of residue (*i* + 4) indicated by dotted lines. Nitrogen atoms are shown in blue and oxygen atoms are shown in red. This figure was generated using Molscript (3) and Raster3D (4, 5). See color insert.



A regular hydrogen bond pattern is formed in the a-helix, corresponding to bonds formed between the backbone carbonyl oxygen of residue (*i*) and the backbone amide of residue (i + 4) in the polypeptide chain, so that there are 13 atoms between each acceptor and donor pair. Thus, apart from the first few amide groups and last few carbonyl oxygen atoms, all the peptide bonds in an a-helix form hydrogen bond interactions. The hydrogen bonds are all oriented in the same direction, as are the dipoles of each of the peptide bonds. Therefore, the helix itself also has a significant dipole moment (a partial positive charge at the *N*-terminus and a partial negative charge at the *C*-terminus), and charged residues that interact with the dipole are often found in the sequence at the appropriate end of a helix (1). For example, the negatively charged Asp residue is highly favored at the *N*-terminus. The helix dipole has also been implicated in protein functions, such as substrate binding and catalysis.

Different amino acids have different tendencies for forming a-helices (2). The amide nitrogen of proline is cyclized with its backbone and thus cannot act as a hydrogen bond donor. Proline residues therefore are not found frequently in a-helices; when they are, they cause irregularities such as kinks and bends in the middle of helices. On the other hand, proline is a preferred residue at the *N*-terminus of the helix where other residues would have an unpaired backbone amide.

The staggered arrangement of side chains around the helix can be visualized in two dimensions through the use of a **helical wheel** (a projection down the axis of the helix). Helices in membrane proteins are often amphipathic, having polar or charged side chains arranged on one side and **hydrophobic** side chains on the opposite side of the helix.

There are several variations to the a-helix conformation of proteins. The 3_{10}-helix is more tightly wound than the a-helix with backbone hydrogen bonds formed between residues (*i*) and (i + 3). Its name is based on its structure, with three residues per turn and 10 atoms between hydrogen bond donor and acceptor (although in real protein structures this geometry may be somewhat distorted). The 3_{10}-helix is usually only observed at the ends of a-helices or in short stretches of 4 to 5 residues. The P-helix is more loosely wound than the a-helix with backbone hydrogen bonds formed between the (*i*) and (i + 5) residues and is very rarely observed in protein structures. The left-handed helix, having the same hydrogen bonding pattern as a-helices but backbone f and Y angles of +60° and

+50° (rather than the –60° and –50° angles of the right-handed a-helix), is not often observed, because this conformation results in steric clashes between backbone and side chain atoms. A glycine residue, however, having only a hydrogen atom as its side chain, can adopt this conformation. The poly(Pro)II helix, with no backbone hydrogen bonds, is also left-handed, with three residues per turn and a translation of 3.12 Å per residue. This helical structure is observed in polyproline and in proline-rich regions of proteins.

Alpha-Helix Formation

a-Helices are the most common type of **secondary structure** in globular proteins (see Alpha-Helix (310-Helix and Pi-Helix)). As such, there is intense interest in understanding the factors that contribute to a-helix formation in peptides and proteins (1-4).

All peptide helices unfold with increasing temperature. This indicates that helix formation is an enthalpically favorable process (it proceeds with the release of heat). The main feature of helical structure is the repeating pattern of intramolecular hydrogen bonds formed between atoms in the peptide backbone (> C=O · H—N <). These hydrogen bonds probably provide the main enthalpic stabilization to the helical conformation (5). Opposing this **enthalpy** is the conformational **entropy** of freezing the backbone conformation, because the process of change from a disordered conformation (unfolded peptide or protein) to an ordered one (helix) is unfavorable entropically. This unfavorable entropy is about the same magnitude as the favorable enthalpy; that is, in isolation the helices are at best marginally stable.

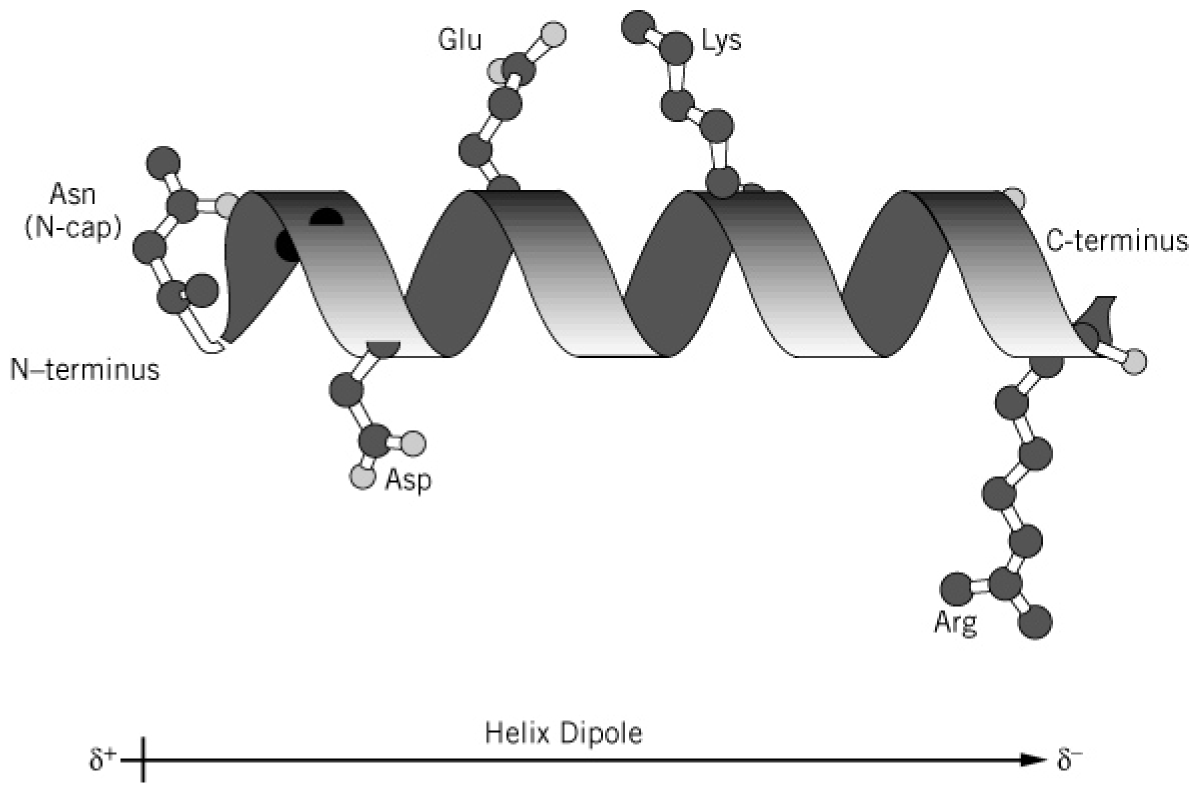
Because the a-helix has an (i, i + 4) backbone hydrogen bonding pattern, the first four > N—H and the last four >C=O groups of the helix will not be hydrogen-bonded to a backbone partner. Polar groups that do not form hydrogen bonds to water or other protein groups are destabilizing (see Protein Stability). Therefore it is important that these groups either be hydrated or have other intramolecular partners. The side chain of the first residue of the helix (the “*N*-cap”) often fills this role, if it is able to hydrogen-bond to one or two otherwise unsatisfied backbone >N—H groups. These "capping" hydrogen bonds have been proposed to be important factors in determining where helices begin and end in proteins (6, 7).

The helical conformation has the peptide groups and their associated dipoles aligned in the same direction, whereas in nonhelical forms the dipoles are distributed randomly. As the helix forms, the dipoles on adjacent peptide groups align in an unfavorable fashion (see Electrostatic Interactions). However, when a full turn of the helix is completed, the first hydrogen bond is formed and the peptide groups involved in the hydrogen bond align favorably. This adds to the **cooperativity** of helix formation: Once the first hydrogen bond is formed, it is easier to continue forming the helix. The alignment of the individual peptide group dipoles in a single direction gives rise to a helix *macrodipole* (simply the additive effects of the individual dipoles). The *N*-terminus of the helix has a partial positive charge, while the *C*-terminus carries a partial negative charge. Residues with charged side chains at the ends of a helix can interact favorably or unfavorably with the helix macrodipole, giving rise to an effect known as the *charge–dipole interaction*.

Different amino acid residues have different tendencies to form helices (see Helix–Coil Theory). For example, alanine is found in protein helices much more often than is glycine (8). The intrinsic preference to be in a helical conformation has been termed *helix propensity*. Since this is an intrinsic property, it should be characteristic of a given amino acid and independent of context. However, quantitative measurements of helix propensity in different systems have provided markedly different results (1, 2, 4). This reflects the difficulty of measuring intrinsic properties in complex molecules like proteins and peptides (however, see Ref. 9).

Interactions between side chains can also affect the stability of helices. Side chains three and four residues away from each other in the amino acid sequence will be close in space in a helical conformation. Therefore, electrostatic interactions, hydrogen bonds, or **hydrophobic** contacts between these side chains can contribute to helix stability. Likewise, if interactions are possible in the nonhelical form of the peptide or protein, this can alter the amount of a-helix observed in a peptide or protein. Figure 1 shows examples of various types of side-chain interactions possible in the helix, an estimate of the magnitudes of the contributions of the main factors contributing to helix stability, and comparison of these estimates with the **free energy** provided by typical interactions in proteins.

Figure 1. Interactions involving amino acid side chains that affect the stability of isolated a-helices. (**Top**) Ribbon model of an a-helix, with stabilizing interactions involving (i) hydrogen bonding of the *N*-cap side-chain at the *N*-terminus, indicated here as Asn, (ii) favorable electrostatic interactions of ionized side chains (Asp and Arg shown here) with the helix dipole, and (iii) electrostatic interactions between oppositely charged side chains on adjacent turns of the helix. (**Bottom**) Quantitative estimates of the net stabilizing interactions in an isolated a-helix and in folded globular proteins.



In addition to the stability of helices, their rates of folding and unfolding are of interest as well. The transition from helix to random coil occurs very rapidly, on the order of nanoseconds, two to three orders of magnitude faster than the fastest folding proteins (10).

Alpha-Lactalbumin

It requires patience to achieve quiet research. The investigation of properties of a-lactalbumin (a-LA) was not worthy of much notice until about 1965, especially from the standpoint of molecular biology. It is only a protein component of the complex enzyme "lactose synthase" and elucidation of its function had made little progress. However, the hidden connection to molecular biology was ferreted out in about 1967 and initiated the great explosion of activity in studying the molten globule (MG) conformation of proteins. These studies of the MG proteins opened a new area of structural biology connected to various physiological functions. Modern molecular biology sometimes requires the MG protein model to understand such physiological processes. The best-characterized MG is that formed by a-LA, and it can easily be prepared. a-LA is now one of the star proteins in molecular biology. The development of research into a-LA has been deeply affected by changing times.

One (a) of three peaks in the **sedimentation velocity** patterns of proteins in the non-casein fraction of skim milk was found responsible for a lactalbumin isolated from milk, which has subsequently been called a-lactalbumin. In the middle-1960s, it was confirmed that lactose is synthesized in the mammary gland UDP-galactose (UDP-Gal) and glucose (Glc) by an enzyme "lactose synthase," which can be resolved into two fractions. One of them is a-LA, and the other is galactosyltransferase (GT). Alone in the Golgi apparatus, but with metal ions such as Mn^{2+}, the latter catalyzes the transfer of Gal to GlcNAc on **glycoproteins**:

$$\text{UDP-GAL} + \text{GlcNAc} \rightarrow \text{Lactosamine-NAc} + \text{UDP} \qquad (1)$$

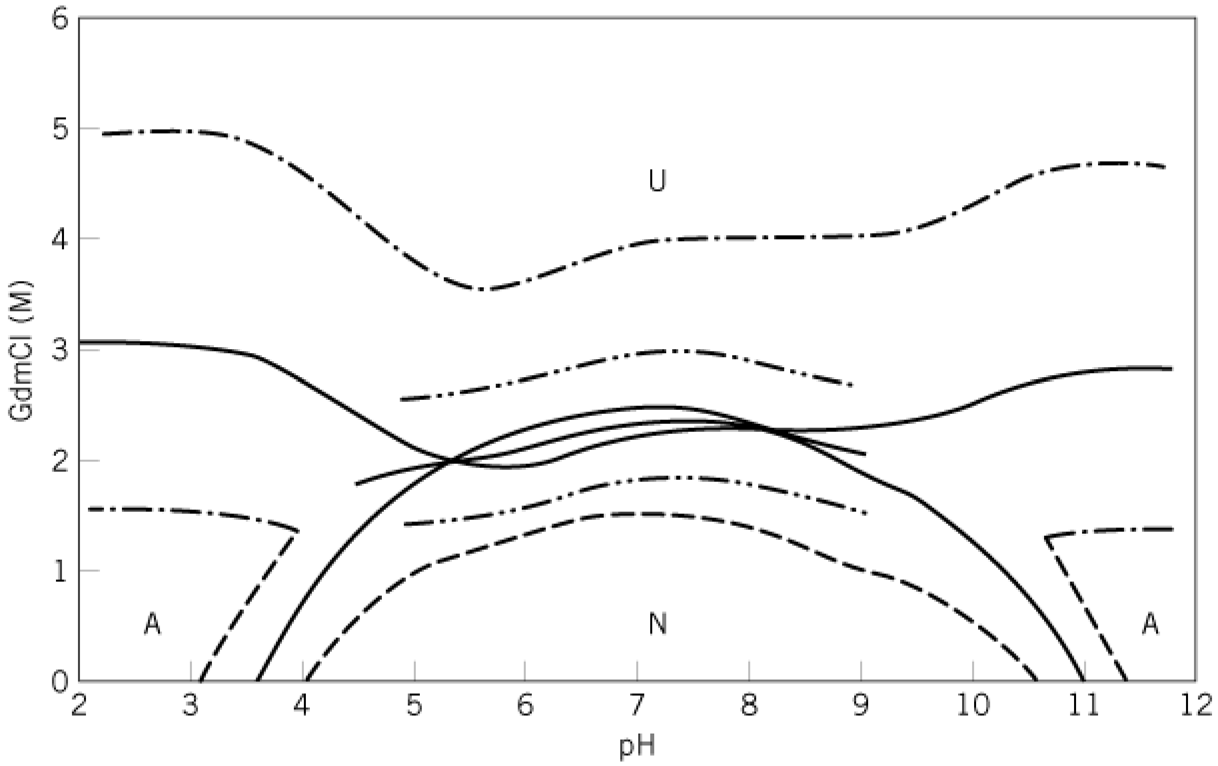
where NAc is the NAc is the N-acetyl group. a-LA is synthesized in the mammary gland during the lactation. It passes through the Golgi apparatus where it combines with GT and alters its substrate specificity to inhibit reaction 1. A decrease of three of magnitude in the K_m for Glc facilitates the synthesis of lactose instead:

$$\text{UDP-Gal} + \text{Glc} \rightarrow \text{Lactose} + \text{UDP} \qquad (2)$$

1. Structures

a-LA is normally a single polypeptide chain of 123 residues, four disulfide bonds, and a molecular weight of about 14,000 except for rat a-LA, which has 140 residues. About 1970, similarities were noted in the molecular weight and amino acid sequence between a-LA and hen egg white lysozyme (HEWL), a lytic enzyme. Subsequently, it was found that the exon-intron organization of the genes for both proteins are the same 1, 2. These suggested **divergent** evolution of the two proteins from a common ancestral gene, and a-LA was assumed to have a three-dimensional structure similar to that of HEWL, in spite of marked differences in their functions. **X-ray crystallographic** determination of the a-LA structure was not successful for a long time, but the conformations of both proteins in aqueous media were compared. Until 1980, significant differences in their physical behavior were observed:1) An intermediate conformation appears in the unfolding equilibrium of a-LA, but not of HEWL, at intermediate concentrations of **guanidinium chloride** (GdmCl) at a neutral pH, which is also stable at acid pH and is designated the "A-State"; 2) One Ca^{2+} ion is tightly bound to a-LA, but not to HEWL, and stabilizes the native (N) form. Removal of Ca^{2+} from a-LA induces the A-state near room temperature. Figure 1 shows a phase diagram of bovine a-LA for the N-, A-, and U- (unfolded) states in of GdmCl at 25°C, and the unfolding equilibrium has been explained in terms of the three states (3-5). Subsequently, it was shown that the kinetic intermediate of bovine a-LA captured at the early stage of refolding from U has properties similar to the equilibrium A-state. Later, it was reported that a number of proteins including HEWL assume the equilibrium and kinetic intermediate(s) similar to the A-state of a-LA in the molten globule (MG) form, and the MG was considered to be a third physical state of proteins (see Molten Globule). However, the conformational transition of the A to U of a-LA is nonco-operative, and then the folding of a-LA along the multipathway, which is apparently in the two-state type, is proposed (6-8). Also, recently, the kinetic intermediates of folding of a-LA with non-native secondary structures were shown, especially in the apo-form (9).

Figure 1. Phase diagram for the three states (N, A, and U) of bovine a-lactalbumin in a solution of GdmCl at any concentration and pH at 25°C.* The solid curves represent the pH and [GdmCl] where K_{eq}^{NU} K_{eq}^{AU}, or K_{eq}^{NU} is unit. K_{eq}^{ij} is for the conformational transition between *i* and *j*. The other curves represent the pH and [GdmCl] where K_{eq}^{NA} = 10 or 0.1 (---), K_{eq}^{AU} = 10 or 0.1 (-.-), and K_{eq}^{NU} = 10 or 0.1 (-. .-). *K. Kuwajima, Y. Ogawa, and S. Sugai (1983) *J. Biochemistry* (Tokyo) **89**, 759–770.



Since 1987, the crystal structures of a-LA from various species (baboon, human, goat, guinea pig, and bovine) and their recombinant and mutant forms have been determined at resolutions of 1.15 to 2.4Å 10-15. The overall features of the authentic forms are similar to those of HEWL. Both structures are divided into two (a and b) sub**domains** by a deep cleft, the a-domain comprises residues 1 to 34 and 86 to 123, and the b-domain includes residues 35 to 85. In baboon a-domain contains four a-helices, A (residues 5 to 11), B (23 to 34), C (86 to 99), and D (105 to 109), plus single turns of 3_{10}-helices (12 to 16,101 to 104, and 115 to 119). The b-domain consists of a three-stranded antiparallel b-sheet (41 to 56), a 3_{10}-helix (76 to 82), and loop regions (Fig. 2). In a-LA from other species, however, the D-helix is replaced by a loop. The C-terminal region is flexible. The conformation and the ligand coordination of a Ca^{2+}-binding site (K_a of 10^9 to $10^{10} M^{-1}$ in the N-state) are observed at the interface of both the domains in all of a-LA. The Ca^{2+}-binding site is composed of three Asp residues at 82, 87, and 88 and peptide carbonyl oxygens at residue 79 and 84 (the other two ligands are water molecules) and is in a slightly disordered, rigid pentagonal bipyramidal form (designated the “a-LA elbow”). The Asp residues are not found in the corresponding region of most lysozymes, but some have the Ca^{2+}-binding site in an a-LA elbow (Table 1), which bind a Ca^{2+} ion in the N-state and are important for studying the evolution of the a-LA family. A Zn^{2+}-binding site was also found in the human a-LA crystal, located at the entrance of the cleft between the two subdomains and coordinated with Glu 49, Glu 116, and two water molecules. Also, the Mn^{2+}-and weak Ca^{2+}-binding sites were also indicated. a-LA binds numerous other metal ions: Na^{+},K^{+},Ba^{2+},Mg^{2+},Co^{2+},Cu^{2+},Pb^{2+},Hg^{2+},Cd^{2+},Sr^{2+},Al^{3+},Tb^{3+},Eu^{3+},Sc^{3+}, and Y^{3}. However, elucidation of their locations and roles in lactose synthesis are awaited. Recently, binding of fatty acids to human a-LA is noted in connection with its function. The structures of a-LA determined by X-ray crystallography and by NMR in solution exhibit two **hydrophobic** clusters of aromatic residues: cluster I of Phe 31, His 32, Tyr 36, and Trp 118 and cluster II of Trp 26, Phe 53, Trp 60, and Trp 104 (16-19). These make up the cores in a-LA by combining with other hydrophobic parts in the a-domain.

Table 1. Comparison of “Equivalent Amino Acid Residues” in Some a-Lactalbumins and Lysozymes at the Calcium-Binding Sites

Protein	Source	Residue[a] 79	82	84	87	88
a-Lactalbumin	Baboon	Lys	Asp	Asp	Asp	Asp
	Human	Lys	Asp	Asp	Asp	Asp
	Bovine	Lys	Asp	Asp	Asp	Asp
	Equine	Lys	Asp	Asp	Asp	Asp
	Wallaby	Lys	Asp	Asp	Asp	Asp
	Guinea pig	Lys	Asp	Asp	Asp	Asp
	Goat	Lys	Asp	Asp	Asp	Asp
	Camel	Lys	Asp	Asp	Asp	Asp
	Rabbit	Asn	Asp	Asp	Asp	Asp
	Rat	Lys	Asp	Gly	Asp	Asp
Lysozyme	Human	Ala	Gln	Asn	Asp	Ala
	Bovine	Glu	Glu	Asp	Lys	Ala
	Hen egg	Ala	Ser	Asp	Ala	Ser
	Equine	Lys	Asp	Asn	Asp	Asp
	Pigeon	Lys	Asp	Asn	Asp	Asp
	Canine	Lys	Asp	Asn	Asp	Asp

[a] Residue numbers for lysozyme are equivalent numbers for human a-lactalbumin.

2. Molten Globule Intermediate

The molten globule of a-LA is compact (a radius of gyration only about 10% larger than that of the N-form) and has N-like secondary structures, but without the specific **tertiary structural** packing interactions. a-LA assumes the following stable MG forms in aqueous media: 1) An equilibrium unfolding state at intermediate concentrations of GdMCl or urea; 2) The acid state; 3) A partially unfolded state obtained by removing of the bound Ca^{2+} at neutral pH and low salt concentrations, and 4) After partial reduction of the disulfide bonds. NMR and amide hydrogen exchange show heterogeneous structures of the MG, an a-domain relatively structured by hydrophobic interactions, and a more unfolded b-domain. Hydrophobic clusters I and II in the native form are somewhat rearranged locally, and some form of the hydrophobic core persists in the MG form and play as nuclei for the folding. The disulfide bond between Cys 6 and Cys 120 in native a-LA can be reduced extremely quickly by thiol agents. The free thiol groups in the three-disulfide intermediate (3SS) of a-LA are easily modified by **iodoacetic acid** or iodoacetoamide and generate carboxymethylated or carboxyamidomethylated 3SS a-LA, respectively. These trapped derivatives of bovine a-LA retain the N-form, with slight changes in the local conformation very near Cys 6 and Cys 120, but they assume the MG form in the absence of Ca^{2+} or at acid pH (20-25). A two-disulfide species and its trapped derivatives can also be obtained by subsequently reducing the 28–111 disulfide bond. The 2SS derivatives have partial MG characteristics. These disulfide intermediates and their derivatives are frequently used as models of partly unfolded proteins in the molecular biology because they are well characterized and easily prepared (26-28).

3. Functions

Lactose synthase (reaction 2) has long been studied to determine the binding sites of the saccharides and of metal ions and the interaction site between GT and a-LA. The structure of a-LA-GT complex has not been determined, but it has been shown by indirect methods such as chemical modification and site-directed mutagenesis that Ca^{2+} and some residues of a-LA adjacent to the cleft including Phe 31, His 32, Ala 106, and Leu 110 are crucial for the function of lactose synthase. The flexible C-terminal region, part of the hydrophobic clusters, and the cleft are essential for the lactose synthase function. The binding sites of a-LA on GT have been tentatively identified. The difference in function between a-LA and lysozyme has been explained by roles of some residues such Tyr 103 in a-LA. Mutations of six residues in the cleft of a-LA to the corresponding ones of lysozyme created a catalytic site of lysozyme in a-LA and hydrolyzed the glycoside bond, as chicken lysozyme (29).

It has been confirmed that **molecular chaperones** bind the protein and assist it folding in the cell. Physicochemical studies *in vitro* indicate that the **chaperonin**GroEL binds apo- or disulfide-reduced a-LA in the MG form, although it scarcely interacts with the N-state of a-LA (30-34). GroEL recognizes the hydrophobic surface exposed on the MG-form. a-LA bound to GroEL is also in the MG-form. a-LA and its disulfide-reduced forms in the MG interact with other chaperones and are frequently used as model substances for studies of protein folding in the cell. The insertion of soluble proteins into membranes and the conformations of the membrane-bound protein have been topics of interest (35-38). The insertion of a-LA into model membranes occurs under conditions that favor formation of the MG with its hydrophobic surface. The inserted a-LA is also in the MG-form, and its association with a lipid bilayer affects the chain mobility of the lipids.

Recently, some multimers of human a-LA prepared from its milk casein fraction were indicated to induce **apoptosis** in cancer cells, leukoma (L210), and lung carcinoma (A549) but not in healthy cells, although the monomeric human a-LA did not induce apoptosis in any cell (39-42). The active **high oligomers** are folding variants of human a-LA, to which fatty acids are bound, and assume the MG form. They were shown to accumulate in the nuclei of sensitive cells and to induce DNA fragmentation. The latter process requires Ca^{2+} ions. a-LA has important biological functions in addition to lactose synthesis.

a-LA is a protein of interesting structure, properties, and functions, and it will be noted in molecular biology in the future.

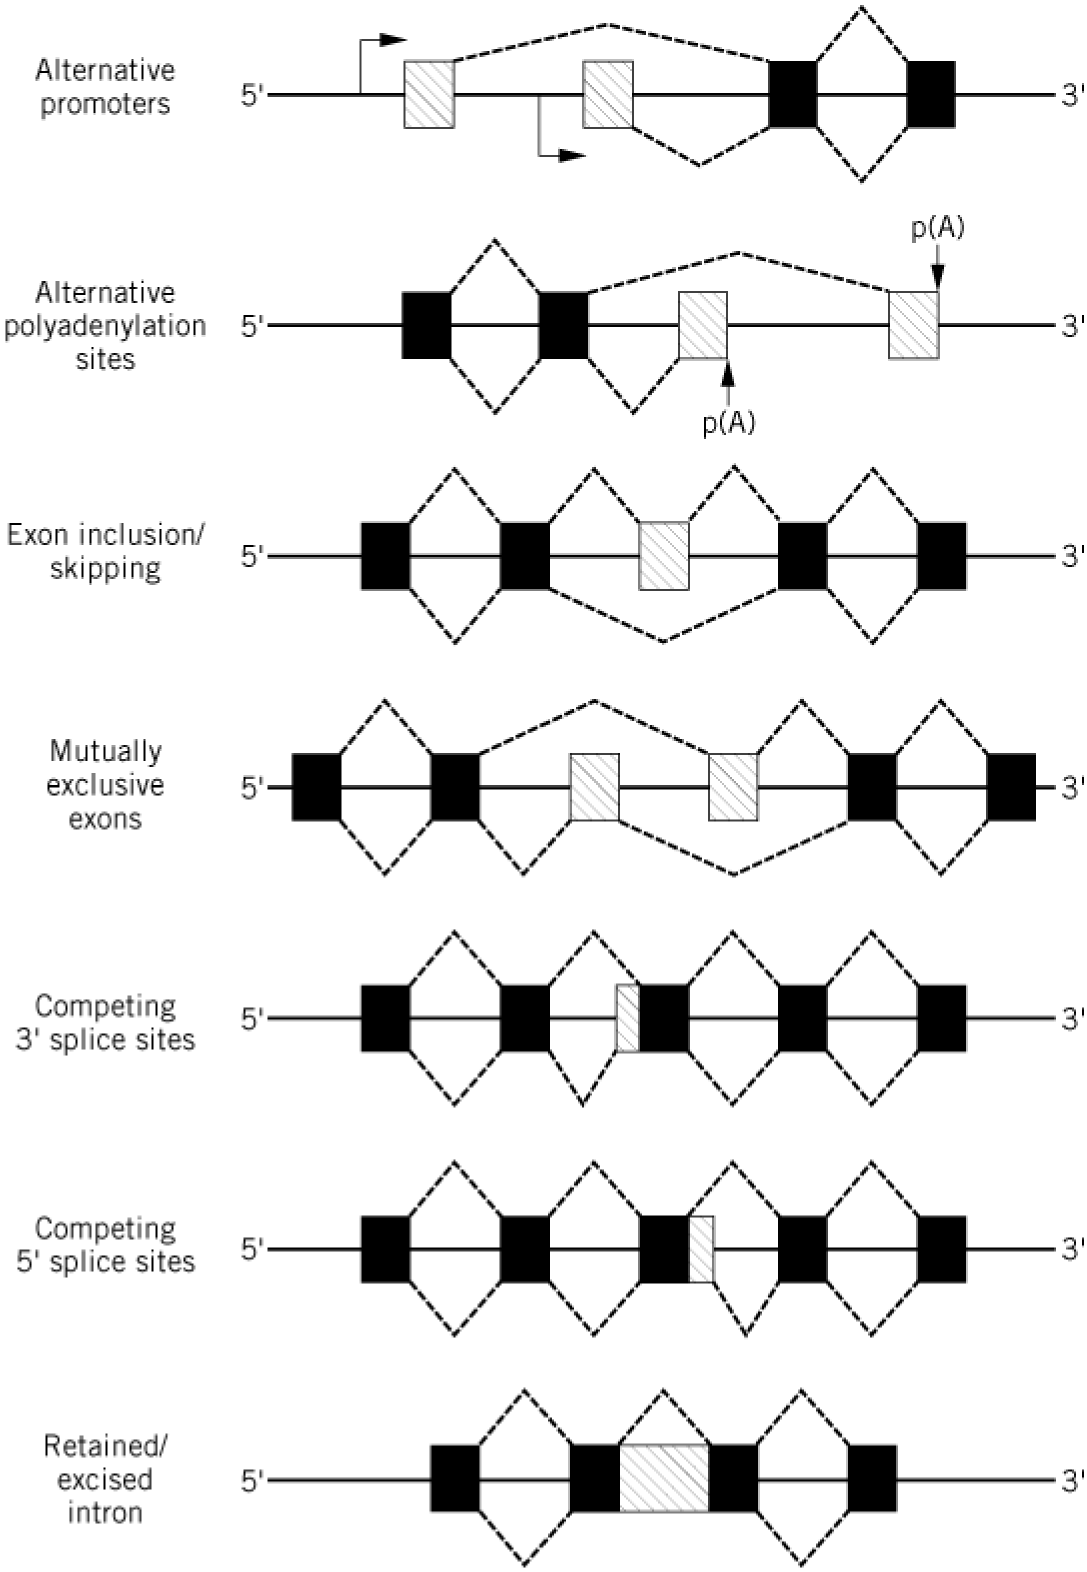
Alternative Splicing

Most eukaryotic **genes** that code for proteins contain noncoding sequences (**introns**) that are interspersed among the coding regions (exons). Transcription of these genes generates so-called pre-mRNA molecules, which are converted to mature mRNAs by a process termed RNA **splicing**. During this process, the introns are precisely excised and the exons are ligated together (see RNA Splicing). The majority of nuclear pre-mRNAs are spliced constitutively; that is, only one mature mRNA species is generated from a single pre-mRNA in all tissues. In some cases however, alternative 5′ and/or 3′ splice sites are used during splicing, resulting in the production of more than one mRNA species from a single pre-mRNA. Alternative splicing has been documented for many eukaryotic genes, and a variety of alternative splicing patterns have been observed, as depicted schematically in Figure 1. The utilization of alternative 5′ and/or 3′ splice sites (also referred to as donor and acceptor sites, respectively) can result in structurally distinct mRNAs by either excluding potential exon sequences or incorporating otherwise noncoding intron sequences. For some pre-mRNAs, alternative splicing is a nonregulated event such that two or more alternatively spliced mRNAs are produced at a given ratio to one another in all cell types. For others, the choice of alternative splice sites is regulated in a tissue-specific or developmental manner. This type of regulation is mediated by trans-acting factors that are differentially expressed in a particular tissue or at a specific time during development (see text below). These *trans*-acting factors may be positive or negative regulators that activate or repress the use of an alternative splice site either directly or indirectly, for example by modulating the affinity of general splicing factors.

Figure 1. Patterns of alternative splicing. Constitutively spliced exons are shown as black boxes, alternatively spliced exons are shown as shaded boxes, and introns are shown as a solid lines between the exons. Transcription start sites are indicated by an arrow, and polyadenylation sites are indicated by p(A). Splicing events are depicted by a dashed line.



Alternative splicing can lead to both quantitative and qualitative changes in gene expression. Quantitative changes can arise if the alternatively spliced mRNA contains a prematurely truncated open reading frame (ie, due to the presence of a stop codon) or exhibits an altered stability or translation efficiency. In many cases, alternative splicing leads to the production of so-called protein isoforms that are structurally identical in all but a specific region or domain (1). Such structural variants of a given protein often exhibit significant functional differences. Thus, through the generation of multiple protein isoforms, alternative splicing can enhance the phenotypic variability of a single gene.

A central question in both constitutive and alternative splicing that has yet to be clearly resolved is how the correct pairs of 5′ and 3′ splice sites are selected for cleavage and subsequent ligation (see also Splice Sites). Pre-mRNAs contain multiple authentic 5′ and 3′ splice sites, which must be properly paired in order to prevent the random skipping of one or more exon. Furthermore, these sites must be distinguished from other nonauthentic sites that are also repeatedly present in most pre-mRNAs. In the case of alternative splicing, several different factors appear to be responsible for the preferential selection of one splice site over another. Firstly, features of the pre-mRNA itself (so-called cis-acting elements) can influence splice-site utilization. For example, the conserved sequences found at the 5′ and 3′ splice sites and the branch site contribute to splice site selection (see Splice Sites). In recent years it has become clear that the relative strengths of competing splice sites is often a deciding factor in determining which site is used preferentially. The strength of a particular 5′ or 3′ splice site is generally a measure of how efficiently it binds spliceosomal components, such as the U1 and U2 snRNPs or the splicing factor U2AF, which play important roles during the early stages of spliceosome assembly. This in turn is often, but not always, a function of how closely its sequences match the 5′ and 3′ splice site consensus sequences, or a function of the length and uridine content of the polypyrimidine tract, which determines its affinity for U2AF. The selection of weak 5′ and 3′ splice sites, on the other hand, can be enhanced by splicing factors that promote U1 or U2 snRNP binding (eg, SR proteins; see text below). Some 5′ splice sites also activate usage of an upstream 3′ splice site (eg, in the preprotachykinin pre-mRNA); and, vice versa, some 3′ splice sites can promote the use of a downstream 5′ splice site (eg, in the B-tropomyosin pre-mRNA) (2, 3). In the former case, factors bound at the 5′ splice site (the U1 snRNP) enhance the interaction of U2AF with the upstream 3′ splice site via a network of molecular interactions across the exon (4, 5)

In some cases, regions of the pre-mRNA other than the 5′ and 3′ splice sites also contribute to alternative splice-site selection. Purine-rich sequences (so-called splicing enhancers), which are typically located in exons and often bind SR proteins, are known to enhance the use of adjacent 5′ or 3′ splice sites by stabilizing the interactions of spliceosomal components with them (reviewed in Ref. 6). In some instances, intron sequences or sequences in the 3′-untranslated region that regulate polyadenylation have also been shown to influence alternative splicing. Finally, pre-mRNA secondary structure (eg, stem-loop structures) can affect splice-site selection, for example by blocking the interaction of spliceosomal components with a particular splice site (7, 8).

Splice-site selection during alternative splicing is also regulated by *trans*-acting factors. Many of the currently identified *trans*-acting factors also function in constitutive pre-mRNA splicing. In this case, variations in their concentration, or the concentration of factors that compete with them, are thought to lead to tissue-specific modulation of splice-site usage. Foremost in this catagory of factors are members of the evolutionarily conserved SR protein family, which are characterized by an amino-terminal **RNA-binding domain** and a *C*-terminal domain rich in arginine–serine (RS) dipeptides (reviewed in Ref. 9). SR proteins (eg, SF2/ASF and SC35) play essential roles in constitutive nuclear pre-mRNA splicing, particularly at the earliest stages of spliceosome assembly (see Spliceosome). Moreover, in pre-mRNAs that contain multiple 5′ or 3′ splice sites (see Fig. 1), high concentrations of SR proteins generally enhance the use of the more proximal (downstream) 5′ splice site (so-called switching activity) or more proximal 3′ splice site (9, 10). However, apparently due to differences in the affinities of individual SR proteins for different pre-mRNAs, the effect of a particular SR protein on 5′ splice site selection can vary from one pre-mRNA to the next (11, 12). SR proteins appear to act by facilitating the interaction of the U1 snRNP with the 5′ splice site, an initial step for 5′ splice-site recognition, or by promoting the association of U2AF with the 3′ splice site (see Spliceosome). High concentrations of SR proteins can also inhibit exon skipping (Fig. 1), which likewise involves promoting the use of a proximal 5′ splice site. Interestingly, the activity of SR proteins such as SF2/ASF or SC35 in 5′ splice-site selection (but not in constitutive splicing) can be antagonized by the hnRNP proteins A/B (13, 14). High concentrations of these proteins generally favor the use of more distal 5′ splice sites, and the ratio of 5′ splice site usage is determined by the relative amounts of hnRNP A/B and SR protein. Thus, the amount of some alternatively spliced pre-mRNAs can be modulated by varying the cellular concentrations of these proteins (15). SR proteins are also involved in activating weak 5′ and 3′ splice sites that are located adjacent to purine-rich splicing enhancers (reviewed in Refs. 9 and 16). The binding of specific SR proteins to these exon enhancer sequences promotes the interaction of U2AF, and thus the U2 snRNP, with the 3′ splice site or the U1 snRNP with the 5′ splice site.

Trans-acting alternative splicing factors that are expressed in a tissue-, sex- or developmental-specific manner have also been identified. In mammals, concrete, well-understood examples of cell-specific regulators of alternative splicing are currently limited. The best-characterized factors are those responsible for alternative splicing events in the fruit fly *Drosophila melanogaster*. For example, sex determination in fruit flies involves a cascade of alternative splicing events that are regulated by sex-specific proteins (17) (see Fig. 2). In males, splicing of the Sex-lethal (Sxl), transformer (tra) and doublesex (dsx) pre-mRNAs are nonregulated events that appear to require only the general splicing machinery (ie, they represent the so-called default splicing patterns). In females, alternative splice sites are activated by female-specific factors, either directly or indirectly, through the inactivation of the male-specific site. The first of these factors known to act in this cascade is the female-specific Sxl protein, which regulates its own synthesis by an alternative splicing event. In females, Sxl is thought to block (by a currently unknown mechanism) use of the 3′ splice site of the third exon of the Sxl pre-mRNA, which leads to exon 3 skipping (18, 19). Because exon 3 contains a stop codon, functional Sxl protein is produced only from the female-specific Sxl mRNA (Fig. 2). In the next step of this cascade, the Sxl protein inhibits the use of the upstream 3′ splice site of exon 2 of the *tra* pre-mRNA, which in turn activates splicing at a weaker downstream 3′ splice site. Specifically, Sxl has been shown to bind to the stronger polypyrimidine tract of the upstream 3′ splice site and thereby to inhibit the binding of U2AF (20). This results in U2AF binding to the downstream site, for which it has a lower affinity. The resulting exclusion of exon 2, which also contains a stop codon, leads to the production of functional *tra* protein in females. In the last step, the tra protein, in conjunction with tra-2, directly activates use of the weak 3′ splice site of exon 4 of the doublesex pre-mRNA. Tra and Tra-2, both of which contain RS domains, interact with a purine-rich splicing enhancer present in exon 4 and recruit SR proteins, as well as U2AF, to the upstream 3′ splice site (reviewed in Ref. 6). As a result, exon 4 is included in female-specific dsx mRNA, and polyadenylation occurs at the end of this exon. The resulting female dsx protein represses male differentiation, whereas the male protein represses female differentiation. Although in this particular case much has been learned about the molecular mechanisms responsible for splice-site selection, in most cases a clear understanding of the complex processes of alternative splicing awaits further investigation.

Figure 2. Cascade of alternative splicing events in the sex determination pathway of *Drosophila*. For simplicity, only those exons and introns involved in alternative splicing events are shown. In female flies, the sex lethal protein regulates its own synthesis and that of the tra protein by blocking the use of the 3′ splice site of the third and second exons of the sex-lethal and tra pre-mRNAs, respectively. Both of these exons contain a stop codon, as indicated. The tra protein, together with tra-2, interacts with a splicing enhancer in the fourth exon of the double-sex pre-mRNA and activates use of the upstream 3′ splice site. Exons are depicted as numbered boxes, and introns are depicted as solid lines. Dashed lines above the introns represent splicing events in females, and those below indicate splicing events in males. The sex-lethal (sxl), transformer (tra), and tra-2 proteins are indicated by circles. Polyadenylation is indicated by p(A). (Adapted from Ref. 21).

Alu Sequences

The genomes of almost all higher **eukaryotes** contain highly repetitive DNA sequences that are not clustered together. They are distributed throughout the genome, interspersed with longer stretches of DNA with unique (or moderately repetitive) sequences. In the human genome, the majority of such sequences belong to a single family of Sines called the **Alu family** . Each sequence is about 300 base pairs long. Although the many copies present are recognizably related, they are not precisely conserved in sequence. Their name derives from the fact that most contain a single site of cleavage for the **restriction enzyme AluI** near their middle. More than 500,000 Alu sequences are present in the human genome, accounting for 3 to 6% of the total DNA. Any particular segment of DNA of 5000 bp or longer has a high probability of containing at least one Alu sequence. Most Alu sequences are flanked by tandem direct repeats of DNA and move like transposable elements creating target-site duplications when they insert.

On average Alu DNA sequences contain about 80% identity between members of the family, but certain internal regions are more conserved: an internal 40-bp region and two sets of sequences, one near the 5′ end and another one farther down in the transcriptional direction, that are homologous to sequences found in the **promoter** for **RNA polymerase** III.

One end of the Alu DNA segment is defined precisely by comparing several Alu sequences. The other end occurs at, or is adjacent to, a run of A bases of variable length that may or may not be interrupted occasionally by other bases. The internal structure of an Alu sequence is dimeric and may consist of an ancestral duplication of a segment of approximately 150 bp. In some rodents, a major SINE is 130 bp long and has sequence similarities with half of the primate Alu sequences. As in Alu, it is bound on one side by a poly(dA) sequence.

1. Origin

The Alu sequence derives from an internally deleted host cell 7SL RNA gene that encodes the RNA component of the signal-recognition particle (SRP) that functions in **protein biosynthesis** (1, 2). Consequently, an Alu sequence can be considered to be a transposable element or an unusually mobile pseudogene. Alu sequences are transcribed from the 7SL RNA promoter, a polymerase III promoter internal to the transcript, so that it carries the information necessary for its own transcription wherever it moves. However, it needs to borrow a reverse transcriptase to transpose.

2. Evolution

The Alu sequences may be grouped into discrete subfamilies on the basis of their sequences. Distinct families have amplified within the human genome in recent evolutionary history (3). The Human Specific or Predicted Variant subfamily, one of the most recently formed group of Alu sequences, amplified to 500 copies within the human genome sometime after the human/great ape divergence, which is thought to have occurred 4 to 6 million years ago. Comparisons of the sequence and locations of the Alu sequences in different mammals suggest that they have multiplied only recently.

Polymorphism of the Alu family member differs from other types of **polymorphism**, such as Variable Number of Tandem Repeat (VNTR, or minisatellite DNA) or Restriction Fragment Length Polymorphism (RFLP), because individuals share Alu insertions based upon identity by descent from a common ancestor as a result of a single event that occurred one time within the human population (4). In contrast the VNTR and RFLP polymorphisms have arisen multiple times within a population. Alu sequences represent a unique source of human genetic variation and a molecular fossil record of genomic evolutionary history. These sequences are natural landmarks for physical gene mapping and for reconstructing the evolutionary history/expansion of tandemly arrayed gene families (4).

3. Possible Functions

The physiological role of Alu elements is unknown, although it has been proposed that they are involved in DNA replication, regulation of transcription, and transport of signal recognition particle RNA to the nucleus. For example, Alu RNA and proteins that bind to Alu elements have been identified in human cells. In particular, it has been demonstrated that some Alu sequences in human gene regions have been altered in sequence so that they are now important in controlling and enhancing transcription (5). The consensus sequence of one of the major Alu families contains a functional retinoic acid binding element (see Response Element). The random insertion throughout the primate genome of thousands of Alu repeats containing a retinoic acid response element might have altered the expression of numerous genes, thereby contributing to evolutionary potential (6).

Amber Mutation

An amber mutation is a nonsense mutation that changes a sense **codon** (one specifying an amino acid) into the translational stop codon UAG, causing premature termination of the polypeptide chain during translation. The mutation, the codon, and the mutant are all called amber. Amber mutations arise by single base changes in the codons for eight amino acids (and in the UAA stop codon, although this is not a nonsense mutation). Mutations in the anticodons of the transfer RNAs that read those eight codons, in principle, could give rise to amber suppressors, but suppressors are recovered only if another tRNA exists that reads the codon. In *Escherichia coli*, five amber suppressors that arise by a single base change have been identified. In addition, amber mutations are suppressed by ochre suppressors because of wobble pairing in the third position (5′) of the anticodon. Amber mutations in *E. coli* and its **bacteriophages** are easily identified by their pattern of suppression by known suppressors. In **bacteria**, amber suppressors have relatively mild effects. Many laboratory strains and even natural isolates of *E. coli* carry amber suppressors. This might be surprising, because amber suppressors are expected to prevent the proper termination of many proteins, but amber codons are used relatively infrequently in *E. coli* and related bacteria.

The name amber was originally given to mutants of bacteriophage T4 that grow on *E. coli* strain K12 (l) but not on *E. coli* strain B (1). It turned out that the K12 strain used has an amber suppressor, whereas the B strain does not. The word amber was inspired by Harris Bernstein who participated in the original experiment (Bernstein means amber in German), although published versions of the story disagree on whether the mutants were named after Harris Bernstein himself or his mother (2, 3). It also could be significant that at nearly the same time that amber mutants were being discovered, Seymour Benzer was also analyzing nonsense mutations in the *rII* genes of phage T4 and calling them “ambivalent” (4).

Amber Suppressor

Amber suppressors are mutant tRNAs that translate the UAG (amber) termination codon as a sense codon. Amber mutations cause protein synthesis to terminate prematurely, resulting in inactive, truncated polypeptides. Amber suppressors allow for protein synthesis beyond the translational block resulting in active protein. Hence the term “suppressor;” these mutant tRNAs “suppress” the phenotypes of amber mutations. These suppressors have been extensively used in prokaryotic genetic studies, and in studies of the translational apparatus and mechanisms. For complete discussions of these and other suppressors, see Nonsense Suppression, Suppressor tRNA, and Genetic Suppression.

Ames Test

The *Salmonella*/mammalian **microsome** test for mutagens was originally developed in the laboratory of Bruce Ames (1) and has become sufficiently used and well-recognized to be familiarly described by his name. The assay utilizes several specially constructed strains of *Salmonella typhimurium* that normally require histidine for growth and can be reverted to **prototrophy** by a wide range of different mutagens. The assay requires that test chemicals and bacteria be plated onto a minimal agar petri dish, incorporating trace amounts of histidine and biotin, which are required for growth, to allow all the bacteria to grow through a small number of generations. In the absence of mutagen, a small number of colonies will grow on these plates, whereas mutagenic chemicals may increase this number very considerably. Mutations are scored as the number of revertant colonies per dish, usually as a function of applied dose. The test protocol incorporates homogenates of (usually) rat liver directly into the petri dish, thereby permitting mammalian metabolism of many compounds that require activation before they will interact with cellular DNA.

The DNA sequence around the original mutation has been determined in those strains most commonly used for mutagenicity testing (Table 1). The bacteria have been made more sensitive to mutagens by the introduction of several additional characteristics. Many of the strains carry a deletion in the *uvrB* gene and are defective in the ability for DNA repair. The bacterial cell wall has increased permeability to bulky chemicals because of the *rfa* mutation, and certain introduced **plasmids** may increase the sensitivity of the bacteria to mutation by some types of chemicals. The Ames test was originally developed as a screen for chemical carcinogens (1), but this has only proved appropriate to certain chemical classes (eg, Ref. 2). Nevertheless, because of the enormous number of chemicals tested in this assay, it must still occupy a premier position in testing for mutagenic properties of chemicals.

Amidination

Amidination takes place when an amino group is treated with an imide ester.

The reaction proceeds with reasonable yield when conducted under alkaline conditions (pH around 10). Side reactions, such as cross-linking take place at lower pH. Both a- and ε-amino groups can be amidinated, and the basicity of the modified residue increases. The amidinyl groups incorporated are stable in acidic media. The role of amino groups in protein function can be investigated by amidination. Proteins can be readily **radiolabeled** by amidinating with ^{13}C- or ^{3}H-labeled imide ester. Amidination of the ε-amino group on lysine residues is particularly useful in peptide mapping and in determining the primary structure of a protein (see Protein Sequencing). The proteolytic enzyme **trypsin** does not cleave at the modified lysine residues, thereby limiting cleavage to arginine residues. Moreover, amidinyl groups are removed by aminolysis, and the resulting deprotected **peptides** are cleaved further with trypsin.

1. Acetamidination of Proteins

After reduction and alkylation of the protein (100–700 nmol), it is dissolved in a few mL of 0.2 M triethylamine-HCl buffer, pH 10.3, containing 5.0 M guanidinium chloride (GdmCl) (1). Ethyl (or methyl) acetamide hydrochloride is dissolved in an equivalent amount of NaOH solution to maintain a final acetamide concentration of 0.1 to 0.15 M (100-fold molar excess of acetamide over amino groups). The reaction mixture is incubated for 1 hr at 25°C, **dialyzed** against 0.05 M NH_4HCO_3 containing 2.5 M GdmCl, and then against 0.05 M NH_4HCO_3. The protein is finally lyophilized.

2. Deamidination by Methylaminolysis

Acetamidinated protein or peptide (2.7 mg) is dissolved in 1.6 mL of 6 to 9 M urea. Then 0.9 mL of methylamine-formic acid buffer (9.6 M methylamine adjusted with HCOOH to pH 11.5) is added, and the reaction mixture is held for 4 h at 25°C. The final concentration of methylamine is 3.5 M. The reaction mixture is exhaustively dialyzed against deionized water at 4°C or, for peptides, isolated by gel filtration on Sephadex G-10, equilibrated and eluted with 0.1 M NH_4HCO_3.

Amino Acid Analysis

The amino acid compositions of proteins are routinely determined by completely hydrolyzing the peptide bonds of the polypeptide chain, and then determining quantitatively the constituent amino acids that were released.

1. Peptide Bond Hydrolysis

The traditional method of hydrolyzing polypeptide chains has been to incubate them anaerobically in 6 *M* HCl at approximately 110°C for 24–72 h (1). More modern methods use other acids, higher temperatures, and shorter periods of time. Most peptide bonds hydrolyze at similar rates, but those between the large nonpolar amino acid residues, particularly **Val**, **Leu**, and **Ile**, are hydrolyzed more slowly and require longer hydrolysis times or the addition of organic acids such as trifluoroacetic acid. Hydrolysis is presumably hindered sterically by the bulky side chains.

Any chemical procedure that hydrolyzes the peptide bonds of the backbone will also hydrolyze the chemically similar amide side chains of **Asn** and **Gln** residues, to produce the amino acids aspartic acid and glutamic acid, respectively. It is feasible to measure the total number of Asn and Gln residues by measuring the amount of ammonia released during the hydrolysis, but otherwise it is not possible to distinguish between Asp and Asn and between Glu and Gln after hydrolysis of the polypeptide chain. In this case, it is common practice to designate such uncertain residues by the three-letter abbreviations Asx and Glx, and by the one-letter abbreviations B and Z, respectively.

Trp residues are usually destroyed completely by acid hydrolysis, probably as a result of reaction with chlorine produced by oxidation of the HCl. They can be protected by the addition of thiol or sulfonic acid compounds or of phenol to scavenge the chlorine (2). **Tyr** residues are also susceptible to chlorination, but they are usually lost only partially. The thiol groups of **Cys** residues are oxidized and the amino acid partially destroyed by acid hydrolysis; this residue is best analyzed after performic acid oxidation of the protein to convert all the Cys residues to cysteic acid.

Some of the problems with acid hydrolysis can be overcome by using other procedures, such as hydrolysis by alkali or by proteinases. Other amino acids, notably Ser and Thr, are destroyed by alkaline hydrolysis, however, and total proteinase digestion to amino acids is not straightforward. Consequently, acid hydrolysis remains in common use.

2. Quantifying the Amino Acids

The identities and quantities of the various amino acids present in a protein hydrolyzates are normally determined by automated amino acid analyzers. The amino acids are separated chromatographically and quantified as they emerge from the column. Traditional methods used ion-exchange chromatography of the free amino acids, followed by detection with ninhydrin or fluorescent reagents such as fluorescamine. Proline does not react in the usual manner with such reagents, due to absence of an amino group, so special procedures are required to measure it. More rapid and sensitive methods now predominate, in which the amino acids are reacted with suitable reagents prior to the chromatographic separation, rather than after. The favored method at present is to react the amino acids with phenylisothiocyate (see Edman Degradation) and then to separate the colored derivatives by reverse-phase chromatography. With this procedure, a complete quantitative amino acid analysis can be carried out in just a few minutes with only picomole quantities of amino acids (3).

The relative numbers of aromatic residues (**Phe**, **Tyr**, and **Trp**) in intact proteins and peptides can usually be determined from the UV absorbance spectrum under conditions in which the polypeptide chain is fully unfolded so that its spectrum is the sum of its constituent residues (4).

Amino acid analysis does not give directly the number of residues of each amino acid per polypeptide chain. The most accurate result is the molar ratios of the various amino acids. The true molecular weight of the polypeptide chain, in the absence of any non-amino acid moieties, must be known for the amino acid analysis results to be converted to the number of residues of each amino acid per chain. Only with very accurate results, or with very small proteins, are such values usually close to the actual integer values. An alternative procedure is to use progressive chemical modification of one type of amino acid side chain for counting residues.

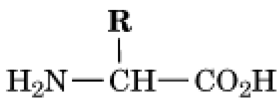
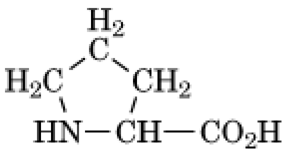
Amino Acids

Twenty amino acids are the building blocks of proteins. They are linked together in a linear polypeptide chain by forming peptide bonds between them, in an order ordained by the nucleotide sequence of the corresponding **gene** for the protein, **translated** from the corresponding messenger RNA.

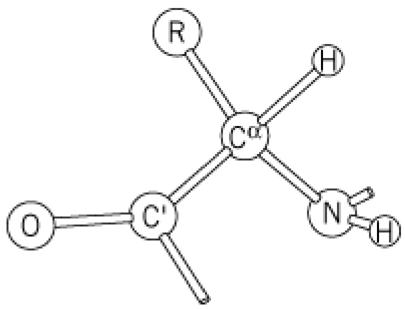
Nineteen of the amino acids have the general structure



and differ only in the chemical structures of the side chain R. The amino group and the carboxyl group give this class of compounds its name. At physiological pH values, both groups are ionized, and the zwitterion is the common form of the amino acid. The exceptional amino acid, proline, differs in that its side chain is bonded to the nitrogen atom of the amino group, which is then a secondary amine, and proline is an imino acid:



The central a-carbon atom is asymmetric in 19 of the amino acids and is always the L isomer:



The exception is glycine, in which the side chain is simply another hydrogen atom, so the C^a atom is no longer asymmetric.

The structures of the side chains of the 20 normal amino acids used in protein biosynthesis are described in Figure 1, and their properties are described in individual entries. The central, asymmetric carbon atom is designated as a, and the atoms of the side chains are commonly designated b, g, d, ε and z in order away from the C^a atom. Chemical groups are, however, usually designated by the carbon atom to which they are bonded; hence, the Nz atom of a lysine residue is part of the ε-amino group. A 21st amino acid that is used in protein biosynthesis in only a few instances is selenocysteine. Many variations of these 21 amino acids can be found in proteins as a result of post-translational modifications after synthesis of the polypeptide chain.

Figure 1. The side chains of the 20 amino acids that occur naturally in proteins. Small unlabeled spheres are hydrogen at labeled. Double bonds are black, and partial double bonds are shaded. In the case of proline, the bonds of the polypeptid included and are black. The three- and one-letter abbreviations commonly used appear below the name of the amino acic and threonine have asymmetric centers in their side chains, and only the isomer illustrated is used biologically.

Linking the amino acids into a polypeptide chain involves the condensation of the a-carboxyl group of one with the a-amino group of the next, with the elimination of one water molecule. The remaining amino acid within the polypeptide chain is then known as a *residue*. Each type of residue is frequently designated with either three- or one-letter abbreviations, which are given in Figure 1. The three-letter abbreviations are obvious, but the one-letter are preferred with long sequences, as they save space and are less likely to be confused; for example, Gln, Glu, and Gly can easily be confused, but not Q, E, and G. The sequences of amino acids in proteins are usually written with either abbreviation, starting at the left with the *N*-terminal residue, with the free a-amino group, which is considered the first residue of the polypeptide chain. Amino acid residues in polypeptide chains are properly referred to by changing the ending of their amino acid names, adding or replacing the frequent "-ine" ending with "-yl" (eg, glycyl or alanyl residues), but the amino acid names are commonly used for the residues also. This complication can be minimized by using the one- or three-letter abbreviations. Note that these abbreviations should be used for residues in proteins only, not for the free amino acids.

Depending on the organism and its circumstances, the amino acids are derived from breaking down proteins ingested in feeding and recycling them, and also in some cases by synthesis de novo. In the well-known case of humans, the following amino acids cannot be synthesized and must be obtained from the diet: histidine, isoleucine, leucine, lysine, threonine, tryptophan, and valine. Arginine is synthesized, but not at a rate sufficient during growth. Methionine is required in large amounts to produce cysteine if that amino acid is not supplied adequately; similarly, phenylalanine is required in the absence of tyrosine.

Amino Groups

Amino groups are widely distributed in biological substances such as proteins, **polynucleotides**, polysaccharides, and lipids. They play important roles in electrostatic interactions because of their nucleophilicity and positive charge. The amino groups in the **nucleotides** of nucleic acids are involved in pairing bases. Modification of these groups causes serious errors in nucleic acid replication, translation, and **gene expression**. Amino groups in proteins are important for maintaining their structure and solubility and, sometimes, for manifestating their biological function. In particular, an amino group plays a pivotal role in the enzymes that utilize pyridoxal phosphate derivatives as **coenzymes**.

There are two kinds of amino groups in proteins. One is the N-terminal a-amino group, that has a pK_a of 6 to 8, and the other is the ε-amino group of lysine residues that have pK_a values generally between 8 and 10.5. The N-terminal amino group is very important for elucidating the primary structure of a protein because a free N-terminal amino group is indispensable for Edman

Degradation. N-terminal amino groups in proteins are often protected by acylation as a posttranslational modification. Attaching ubiquitin molecules to the amino groups of proteins induces their degradation . Amino groups are reactive nucleophiles and are widely utilized to immobilize proteins on solid supports for affinity chromatography.

1. Chemical Modification of Amino Groups in Proteins

Many modification methods for amino groups have been invented based on their excellent nucleophilicities (1). An amino group is a strong nucleophile only in its nonprotonated form, so it is most reactive at high pH. Because of the differences in pK_a values between a- and ε-amino groups, the former may be selectively modified by controlling the pH of the reaction medium. Because many amino groups are exposed and not involved in the protein function, modification of amino groups is suitable for introducing reporter groups, such as chromophores, into proteins and for **radiolabeling** them. The number of amino groups present and subsequently the extent of their modification with some modifying reagents, is determined by trinitrophenylation with 2,4,6-**trinitrobenzene sulfonic acid**. The integral number of amino groups present in a protein can be counted. Representative modification methods for amino groups are shown in Table 1.

Table 1. Chemical Modification of Amino Groups of Proteins

Reaction	Reagent	pH

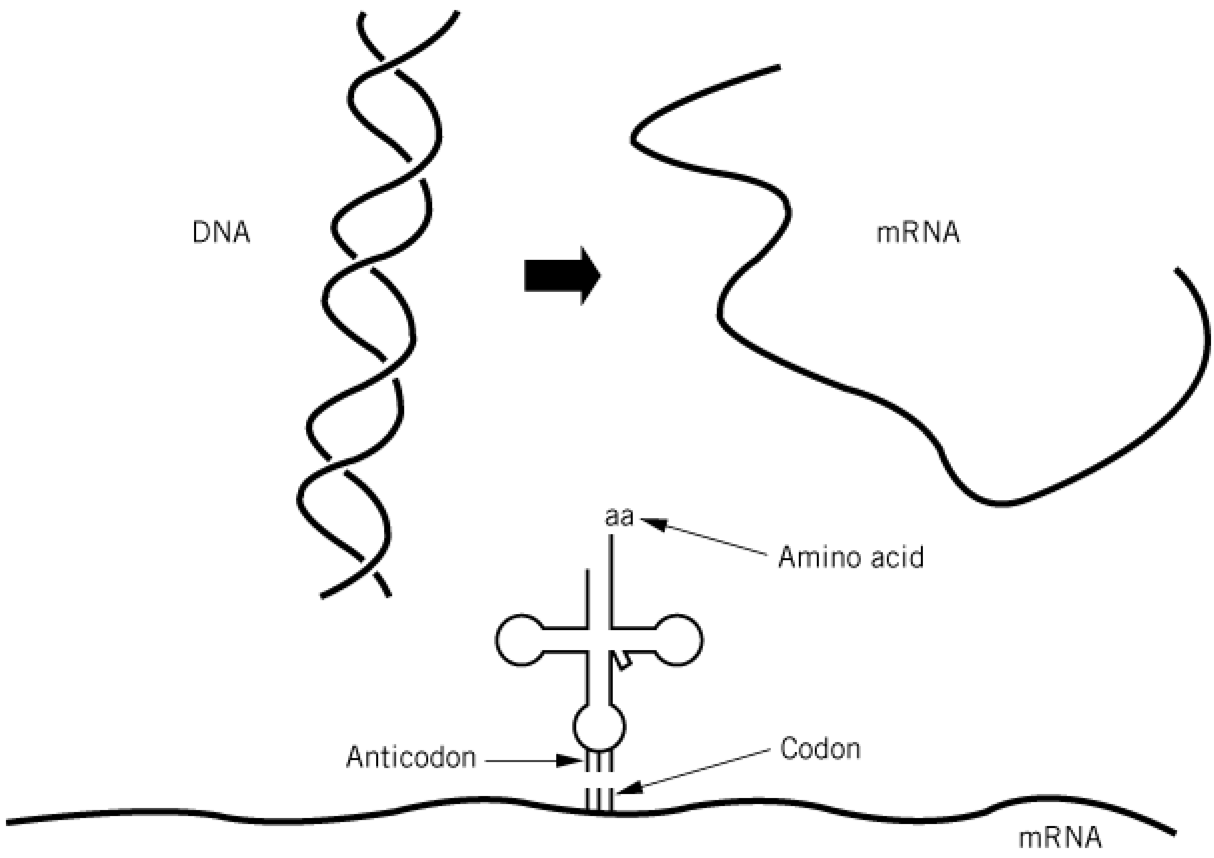
Aminoacyl tRNA Synthetases

The aminoacyl tRNA synthetases catalyze reactions that establish the rules of the genetic code. For this reason, there is great interest in these enzymes and their **evolutionary** development, which is thought to be closely connected to the establishment of the code. Research on the synthetases has led to the concept of an operational RNA code for amino acids that is imbedded in the acceptor stems of transfer RNA (**tRNA**) (1). The operational RNA code may have played an important role in the assembly of the genetic code and in the overall design of tRNA synthetases.

In the flow of genetic information, messenger RNA (mRNA) is **transcribed** from DNA, and the mRNA, in turn, is the template for protein synthesis (Fig. 1). The triplet **codons** of mRNA interact with the anticodons of tRNA through **complementary base pairing**. Amino acids joined to tRNA are incorporated into the growing polypeptide chain. The algorithm of the genetic code relates each amino acid to a specific trinucleotide codon. The triplet associated with a particular amino acid is determined in the aminoacylation reaction, where a given amino acid is linked to a tRNA bearing the anticodon trinucleotide that corresponds to that amino acid. These aminoacylation reactions are catalyzed by aminoacyl tRNA synthetases.

Figure 1. Flow of genetic information. Messenger RNA is synthesized from DNA. The mRNA has a string of trinucleotide codons that are translated into a polypeptide whose amino acid sequence is determined by the codons, according to the rules of the genetic code. The amino acid that is inserted into the polypeptide is determined by the codon–anticodon interaction with the tRNA that bears the amino acid corresponding to the particular anticodon. Therefore, the genetic code is determined by the linking of a particular amino acid with a particular anticodon triplet within a tRNA. The joining of amino acids to tRNA is catalyzed by aminoacyl tRNA synthetases. Thus, the genetic code is determined at the biochemical level in the aminoacylation reaction. (This figure was provided by Arturo Morales.)



1. Aminoacylation Reaction and the Genetic Code

For most tRNA synthetases, aminoacylation is carried out in a two-step reaction:

$$E + AA + ATP \leftrightarrow E(AA\text{-}AMP) + PP_i \tag{1}$$

$$E(AA\text{-}AMP) + tRNA \leftrightarrow AA\text{-}tRNA + AMP + E \tag{2}$$

In the first reaction, the enzyme, E, uses ATP to activate an amino acid, AA, to yield the firmly bound *aminoacyladenylate* (AA-AMP). In the second step, the activated amino acid is transferred to the 3′-end of the tRNA, where it is connected by an ester linkage to the 2′- or 3′-hydroxyl group (after initial attachment, the amino acid can migrate back and forth between the 2′ and the 3′ positions). While most synthetases can carry out amino acid activation in the absence of tRNA, there are a few exceptions (such as glutaminyl-, glutamyl-, and argininyl-tRNA synthetases) that require the presence of the cognate tRNA for amino acid activation.

Because each of the 20 natural amino acids used in protein synthesis has a corresponding, or **cognate**, aminoacyl tRNA synthetase, there are 20 of these enzymes in each cellular compartment where proteins are synthesized. Each of them must distinguish its amino acid from all others and, at the same time, recognize the cognate tRNA that bears the anticodon corresponding to that amino acid. In **prokaryotes** and in the cytoplasm of **eukaryotes**, there is typically one tRNA synthetase for each amino acid (eukaryotic mitochondria have an additional set of synthetases that are essential for mitochondrial protein synthesis). However, the degeneracy of the genetic code means that there are 61 trinucleotides coding for the 20 amino acids. Reading these 61 triplets requires more than just 20 tRNAs. As a consequence, there are multiple tRNA isoacceptors for many of the synthetases. The synthetases for a particular amino acid must, therefore, recognize and aminoacylate all tRNA isoacceptors for that amino acid. This consideration in itself has important implications.

For example, the codons for serine are sixfold degenerate. In order to read these six codons, the serine tRNA isoacceptors must collectively permute all three anticodon nucleotides. Thus, for a single seryl-tRNA synthetase to aminoacylate all these $tRNA^{Ser}$ isoacceptors, the anticodon is not suitable for discrimination. Direct experiments *in vitro* and the X-ray crystallography structure of the seryl-tRNA synthetase-$tRNA^{Ser}$ complex have demonstrated that, in fact, seryl-tRNA synthetase does not contact the anticodon trinucleotide (2). This observation, and others described below, showed that, for at least some amino acids, the relationship between an amino acid and the triplet of the genetic code is not direct.

2. Classes of Aminoacyl tRNA Synthetases

The synthetases are heterogeneous in quaternary structures and subunit sizes, and this heterogeneity obscured more fundamental relationships between these enzymes. For example, in *Escherichia coli*, the quaternary structures of synthetases include a, a_2, a_4, and a_2b_2 (3). Subunit sizes vary from 303 to 951 amino acid residues (4). The 20 aminoacyl tRNA synthetases are now known to be divided into two classes of 10 enzymes each (Table 1) (8, 9). These classes are based on conserved sequence motifs and the structural architecture of the catalytic domains (8, 9). The classification is also based on the fact that the site of initial amino acid attachment on the tRNA differs between the two classes (8). The classes appear to be fixed in evolution, because there is no example of an enzyme switching classes depending on the organism to which it belongs. Thus, the two classes may have developed early in evolution.

Table 1. Classes of Aminoacyl tRNA Synthetases

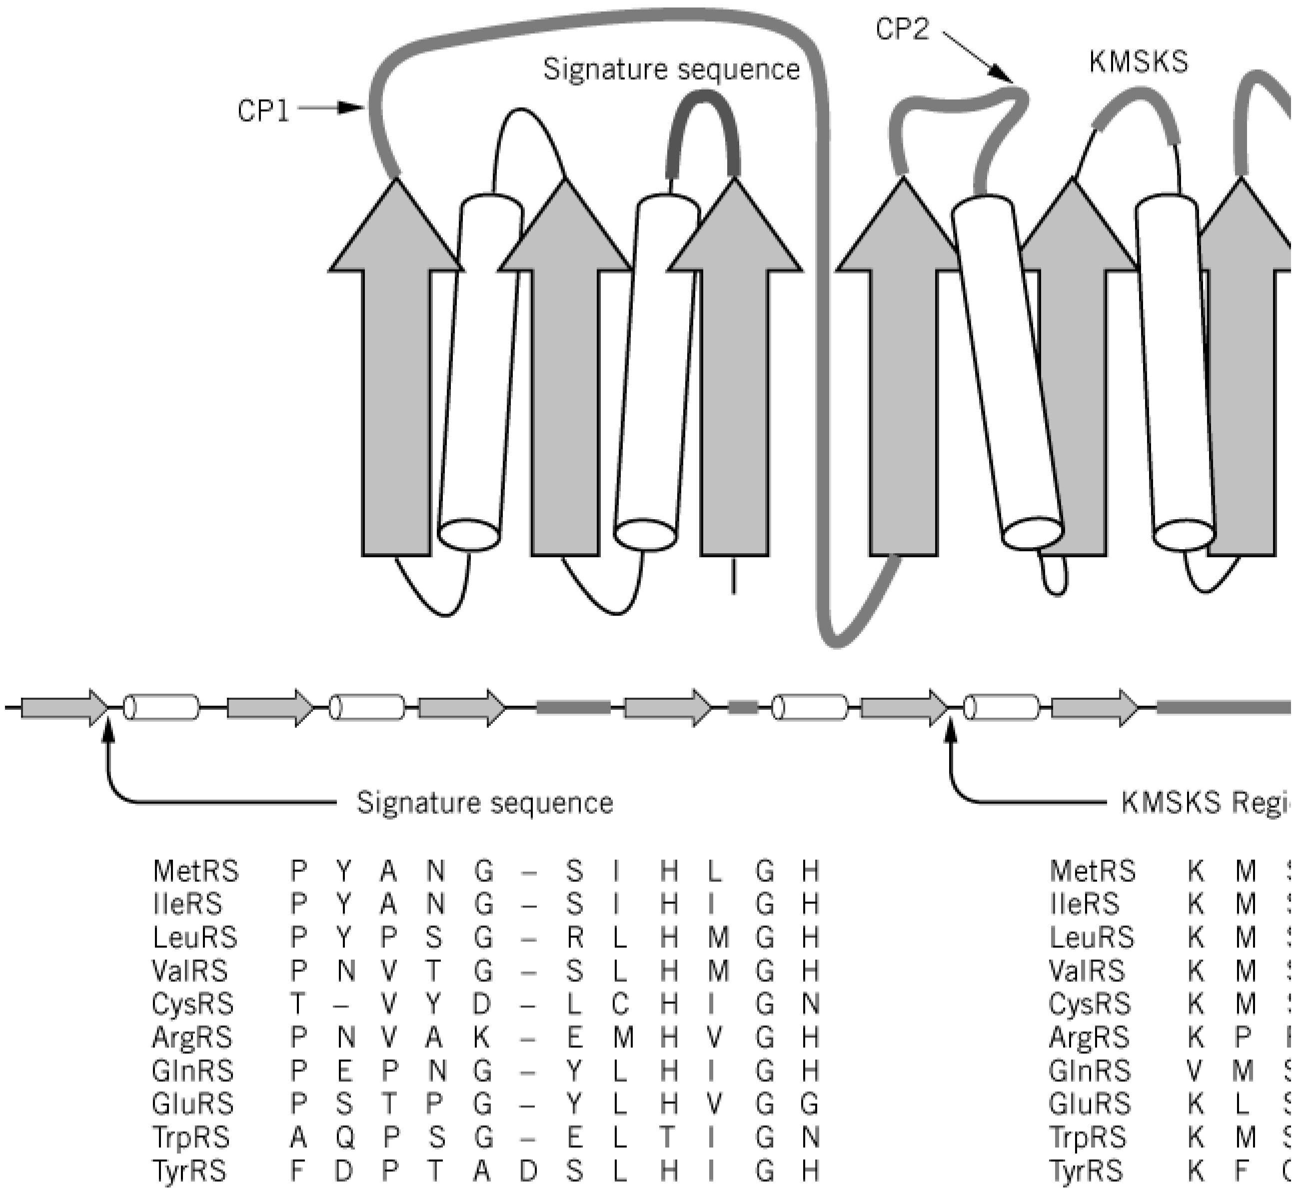
Class I	Class II
Arginine	Alanine
Cysteine	Asparagine[0]
Glutamic	Aspartate
Glutamine1	Glycine
Isoleucine	Histidine
Leucine	Lysine
Methionine	Phenylalanine
Tryptophan	Proline
Tyrosine	Serine
Valine	Threonine

Gram-positive bacteria, plant chloroplasts, and animal mitochondria have been shown to have less than 20 tRNA synthetases. Instead, glutamyl-tRNA synthetase catalyzes attachment of glutamic acid to both $tRNA^{Glu}$ and $tRNA^{Gln}$ and, similarly, aspartyl-tRNA synthetases catalyzes attachment of aspartate to both $tRNA^{Asp}$ and $tRNA^{Asn}$. An amidotransferase then catalyzes the amidation of Glu-$tRNA^{Gln}$ to give Gln-$tRNA^{Gln}$, and, likewise, amidation of Asp-$tRNA^{Asn}$ gives Asn-$tRNA^{Asn}$ (5-7).

2.1. Class I

These enzymes are usually monomers and are characterized by an architecture that is similar to that seen in dehydrogenases and other **nucleotide-binding** proteins. This structural motif is a **Rossmann** nucleotide-binding fold, which consists of alternating b-strands and a-helices (Fig. 2) (10-12). In the case of class I tRNA synthetases, the fold is divided into two b_3a_2 halves to give an overall b_6a_4 structure. In this structure, the b-strands are arranged in parallel. A polypeptide of variable length, designated as connective polypeptide 1 (CP1), links together the two halves of the active site (13). In some class I enzymes, this insertion plays a role in translational editing. It also contains some of the residues for binding the synthetase to the tRNA acceptor helix (14).

Figure 2. Design of a class I tRNA synthetase. The nucleotide-binding fold of class I tRNA synthetases consists of alter (cylinders) that form a b_6a_4 structure. A two-dimensional spatial arrangement of these elements is shown at the top, and below. A second domain of variable size occurs after the nucleotide-binding fold. The fold is split into two b_3a_2 halves b *polypeptide 1* (CPI). A second, smaller insertion (CP2) splits the second half of the fold. Two sequence elements were us enzymes. These are known as the *12-residue signature sequence*, which ends in the HIGH tetrapeptides (10, 11) and as t locations in the schematic structure are shown near the label signature sequence and KMSKS. By way of example, an ali sequences of the 10 class I *E. coli* enzymes is shown beneath the schematic figures. Similar alignments can be made for throughout evolution. (This figure was provided by Arturo Morales.)

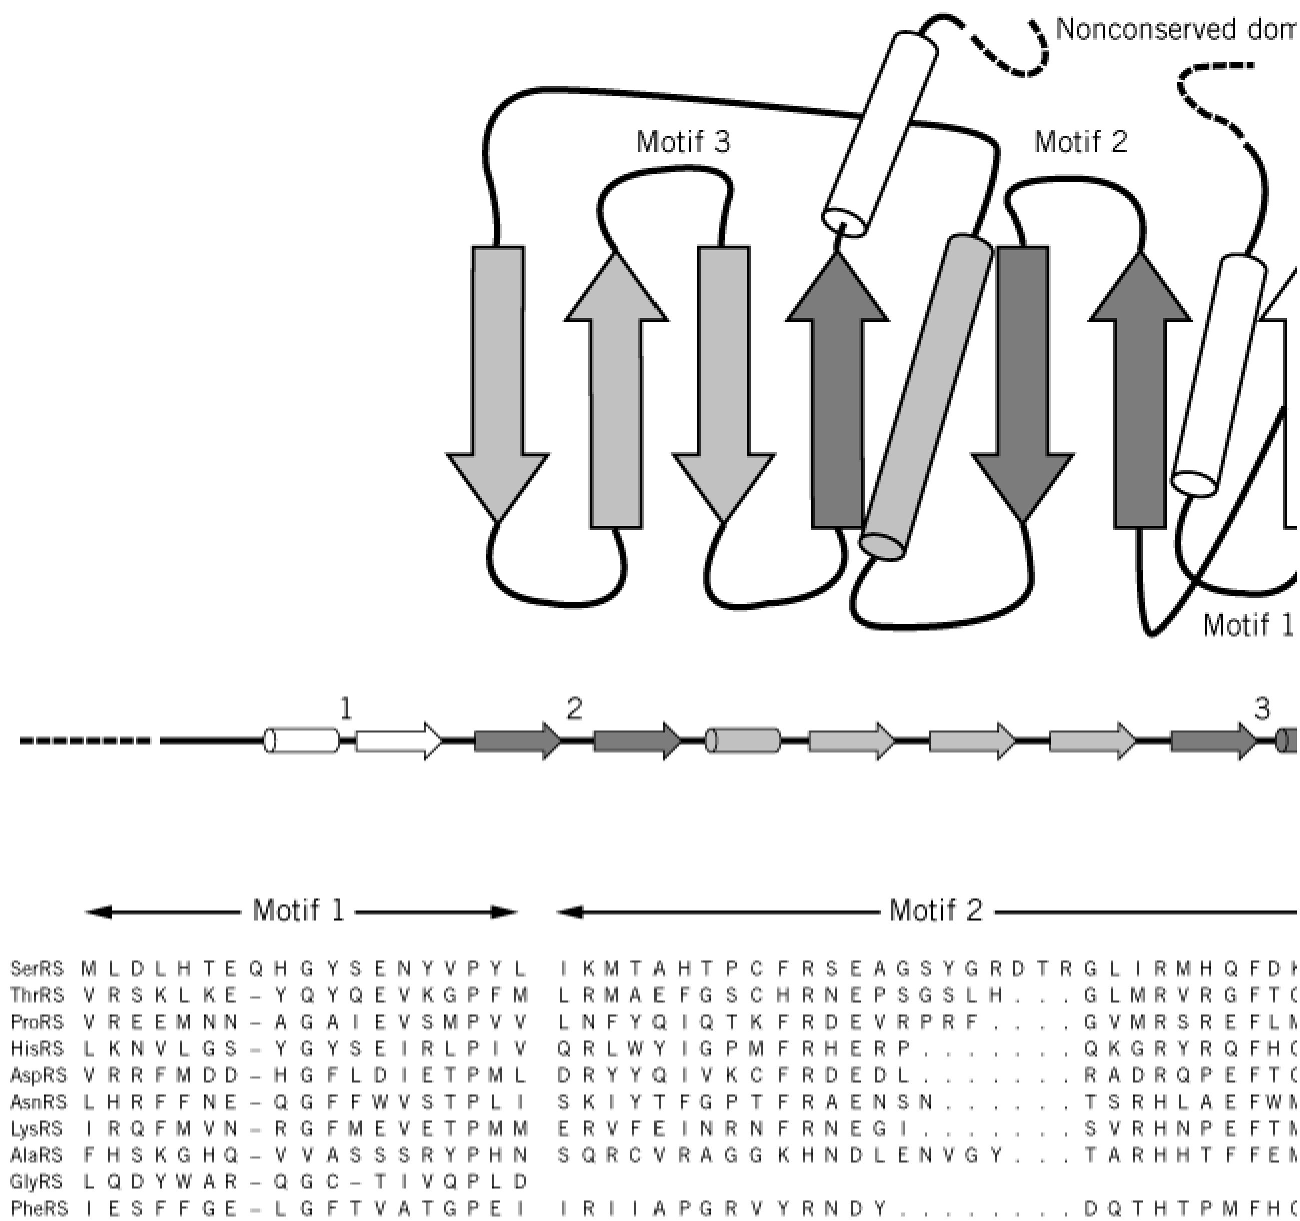


The nucleotide-binding fold contains the site for adenylate synthesis. This catalytic **domain** may be identified by two characteristic sequence motifs, without any knowledge of three-dimensional structure. One motif is the 11–amino acid element known as the signature sequence, which ends in the sequence–His–Ile–Gly–His, or HIGH in one-letter code (10, 11). This element is located in the first half of the nucleotide-binding fold at the end of the first b-strand and the beginning of the first a-helix. It was designated as a signature sequence because it served as a clear signature for a subgroup of related synthetases, before many crystal structures were determined. The second element is the KMSKS motif, located in the second half of the nucleotide-binding fold (15). These elements are critical parts of the active site.

2.2. Class II

The class II enzymes are mostly a_2 dimers. The active sites of class II enzymes have a completely different architecture that harbors three characteristic sequence motifs. The structure consists of a seven-stranded antiparallel b-sheet with three a-helices (9, 16-18) (Fig. 3) (8, 9, 19). The three characteristic sequence motifs are known as motifs 1, 2, and 3. The sequences of these motifs are highly degenerate (8, 9). They consist of a helix–loop–strand, strand–loop–strand, and strand–helix, respectively. All three of these motifs form part of the active site.

Figure 3. Design of a class II tRNA synthetase. The seven-stranded b-sheet with three a-helices is shown. The variable-s
line that may occur on either the *N*- or the *C*-terminal side of the class-defining domain. Three characteristic sequence m
and are distinguished in this illustration by their different shadings. These motifs are highly degenerate in sequence and c
strand–loop–strand (motif 2), and strand–helix. The locations of these motifs in the class-defining domain are shown. Ar
motifs for *E. coli* tRNA synthetases is also shown (8, 19). Note the high degeneracy of these sequence motifs, especially
sequence elements in class I enzymes (Fig. 2). (This figure was provided by Dr. Arturo Morales.)



2.3. Amino Acid Attachment

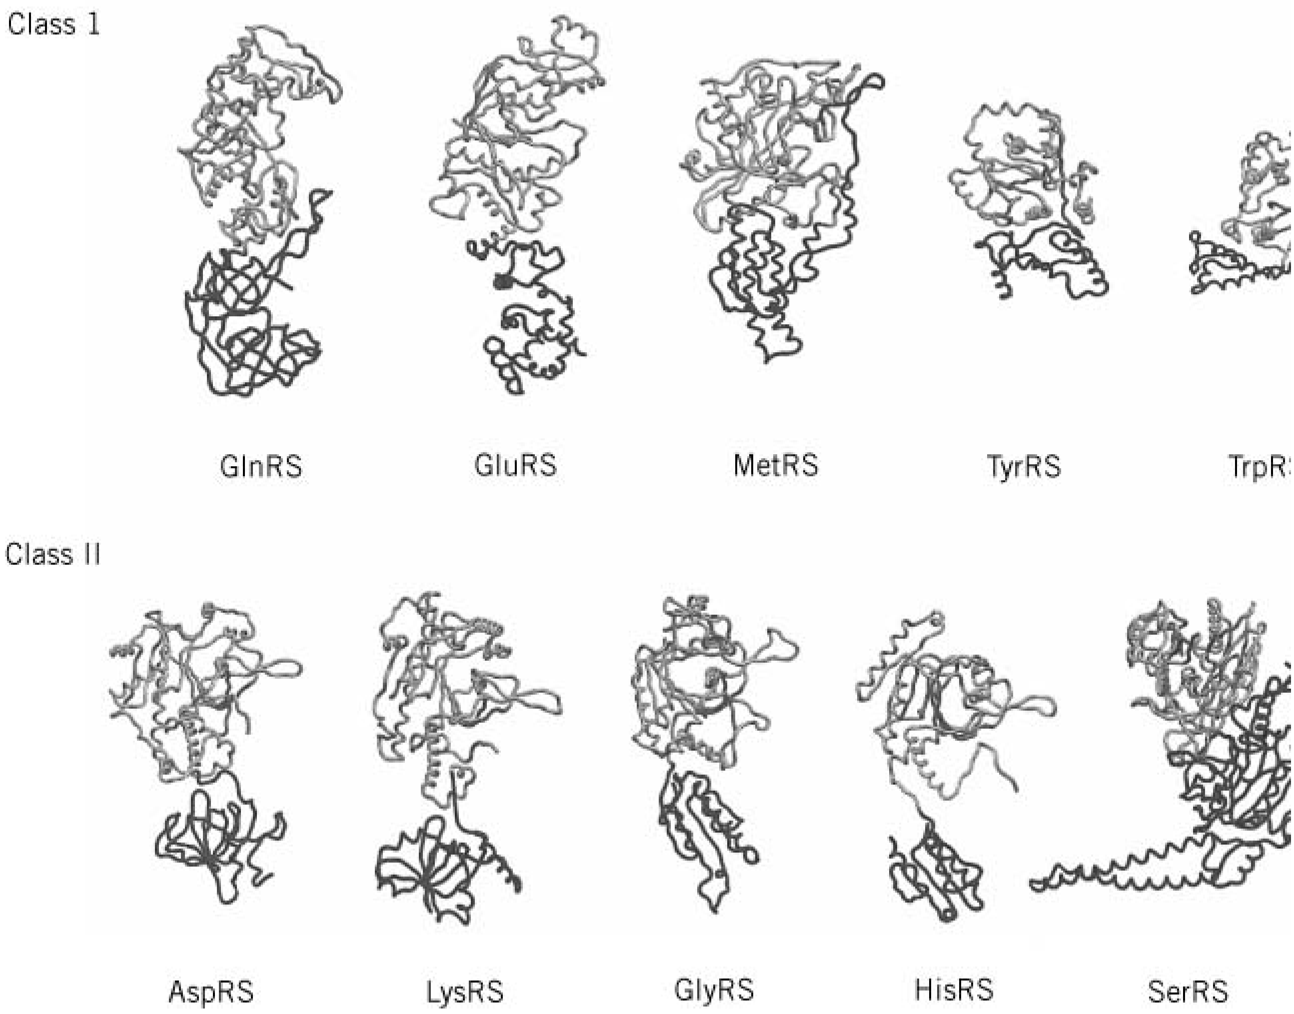
The site of initial amino acid attachment for class I enzymes is the 2′-hydroxyl, whereas the 3′-hydroxyl is used by class II enzymes (20). This distinction is now understood to result from a difference in the ways that the two enzymes approach the end of the tRNA. In particular, class I enzymes approach the end of the tRNA acceptor helix from the minor groove side, while class II enzymes approach from the major groove side (21).

3. Overall Structural Design and the Synthetase-tRNA Complex

The class-defining active-site domain is only a part of the tRNA synthetase structure. Inserted into the active-site domain are sequence motifs that enable the tRNA acceptor helix to bind with its 3′-end near the aminoacyl adenylate. These insertions are typically idiosyncratic to the synthetase. Two examples are the CP1 insertions of class I enzymes and the variable loops of motif 2 of class II enzymes, both of which have a role in docking the acceptor helices to the enzymes. However, in addition to insertions into the active-site domain, all synthetases have a second major domain. This domain, also typically idiosyncratic to the enzyme, provides for contacts with parts of the tRNA that are distal to the amino acid attachment site. For many (but not all) synthetases, this includes contacts with the anticodon. For the class I methionyl- and glutaminyl-tRNA synthetases, this second, anticodon-binding, domain is largely a-helical and largely b-structure, respectively (22, 23). This difference demonstrates that, even for enzymes in the same class, their second domains are completely unrelated. In the case of the class II seryl-tRNA synthetase, an unusual coiled-coil protrudes from the N-terminus of the enzyme. This structure, which is not found in many other class II enzymes, provides for contacts with the variable loop of $tRNA^{Ser}$ (2, 24).

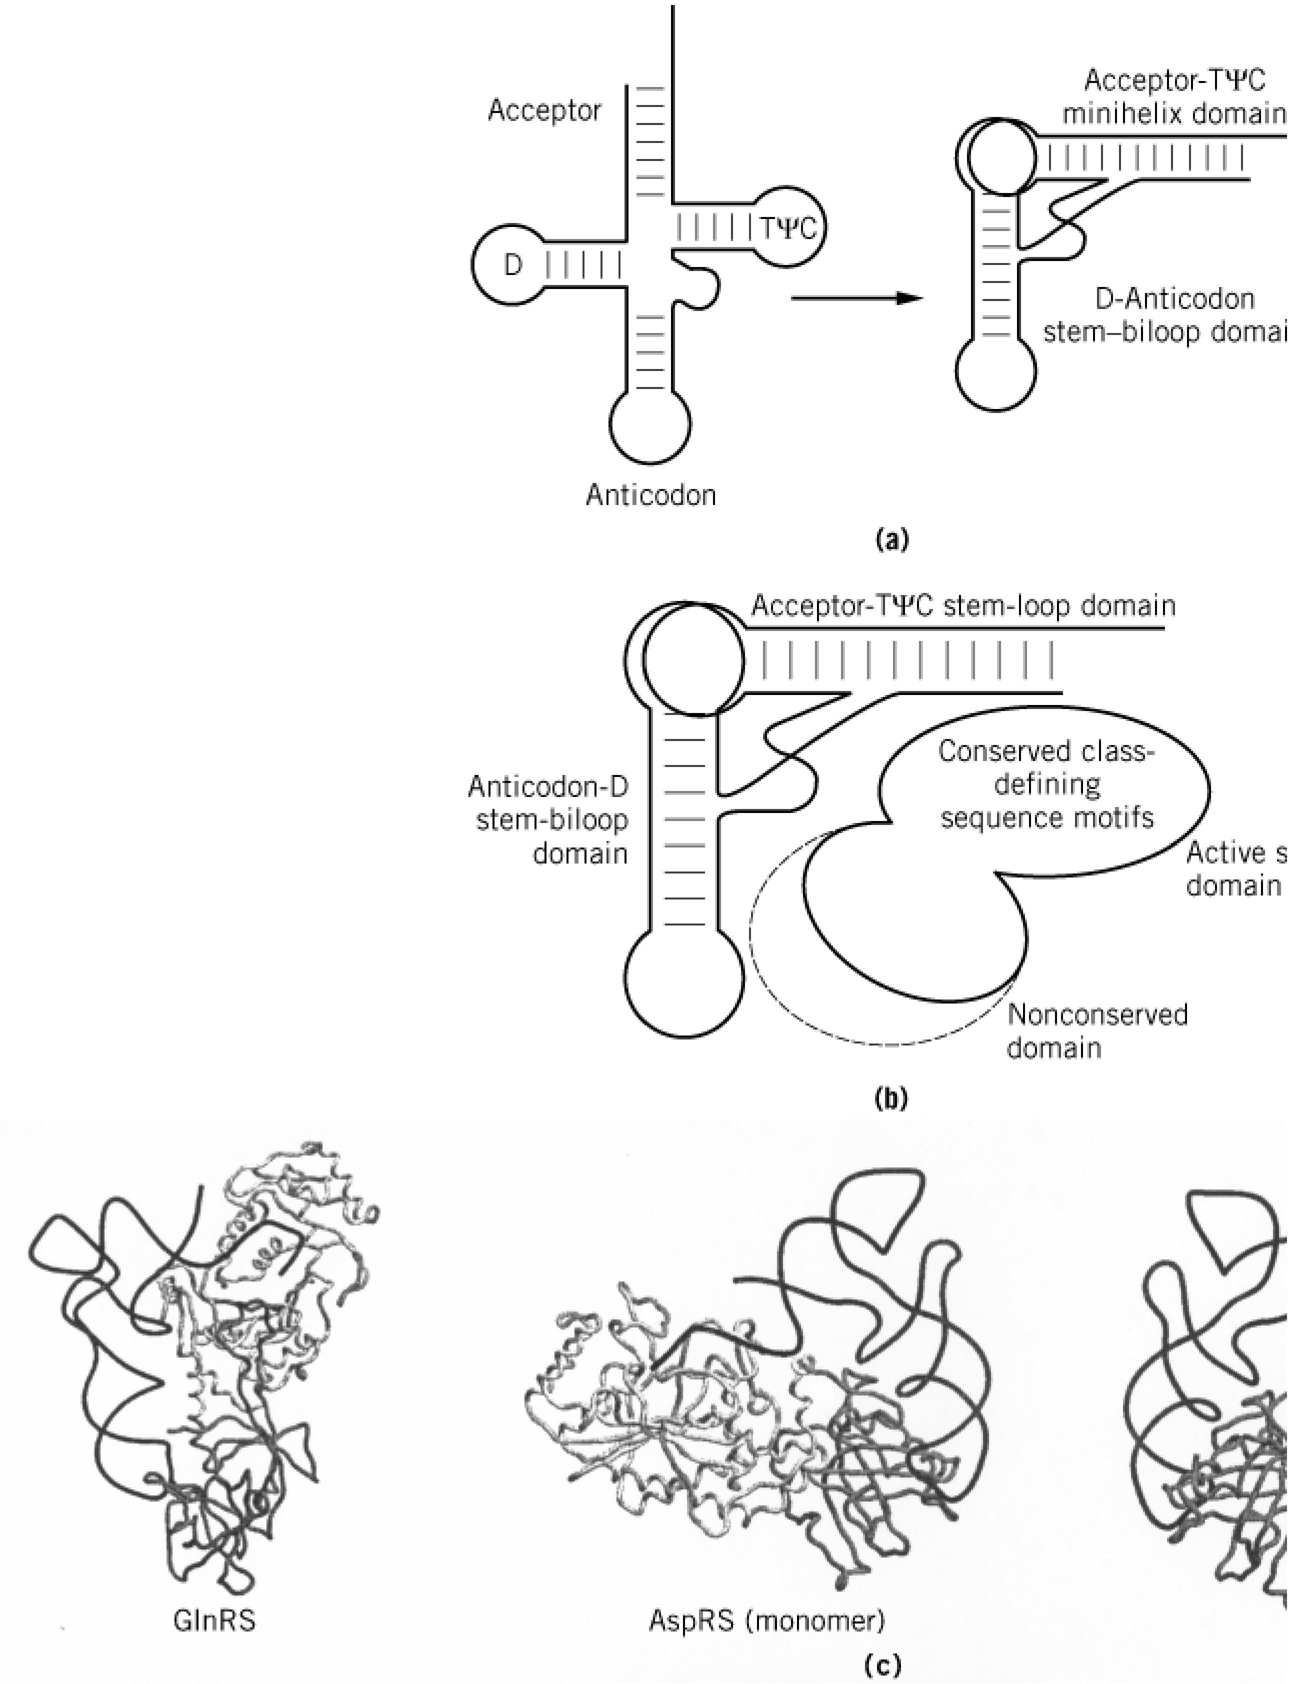
Thus, to a rough approximation, the synthetases comprise two major domains (9, 14, 16, 23, 25-31). The tRNA molecule also comprises two major domains, which consist of the four arms of the cloverleaf secondary structure (Fig. 4). One domain is the acceptor-TyC minihelix, where the amino acid acceptor end and the TyC stem stack together to make a helix of 12 base pairs. The second domain is formed by stacking of the dihydrouridine stem with the anticodon stem. The result is an L-shaped three-dimensional structure where the amino acid acceptor end and the anticodon-containing template-reading-head are segregated into separate structural units (see Transfer RNA).

Figure 4. Examples of crystal structures of class I and class II tRNA synthetases. Regardless of the class to which an enz assigned, its structure can be approximated as comprising two major domains. One is the class-defining active site doma which is shared by all members of the same class. This domain (gray) is thought to be the historical tRNA synthetase. Th second domain (dark gray) is typically idiosyncratic to the synthetase and is not shared by all members of the same class domain was probably added later to the synthetase structure. In these illustrations, the domains have been defined by the obvious visual divisions in the structures and, for that reason, the catalytic domain may extend somewhat beyond the reg contains the class-defining motifs. Some of these enzymes are homodimers; in all cases, only a single subunit is shown. I case of the tyrosyl tRNA synthetase, TyrRS, the structure of the second domain is not complete and therefore is truncate structural representation. Not shown is PheRS (25), which has an a_2b_2 quaternary structure. These structures were determ for GlnRS (14), GluRS (26), MetRS (23), TyrRS (27), TrpRS (28), AspRS (16), LysRS (29), GlyRS (30), HisRS (31), ar SerRS (9). (This figure was provided by Arturo Morales.)



The two major domains of the synthetase make contact with the two domains of the L-shaped tRNA molecule (Fig. 5). The catalytic domain, with insertions containing RNA-binding determinants, interacts with the acceptor-TyC minihelix. The second major domain interacts with the second domain of the tRNA, where interactions may extend as far as the anticodon trinucleotide or may involve contacts with special structures, such as the large variable loop of $tRNA^{Ser}$. The details of the interactions between tRNA and synthetase are described in RNA-binding proteins.

Figure 5. Two major domains of a synthetase interacting with two domains of a tRNA. (**a**) Schematic representation of t domains that segregate the amino acid attachment site into a 12-bp minihelix stem–loop and the anticodon triplet into a s TyC loops are indicated as common landmarks found in most all tRNA. (Adapted from Ref. 32.) (**b**) Domains of a synth of a tRNA. The second domain of the synthetase is shown with a dotted line to indicate that it varies in size and often ex 33.) (**c**) Examples of synthetase-tRNA complexes, with the active-site class-defining domain interacting with the accepto second, idiosyncratic domain of the synthetase interacting with the second domain of the tRNA (5, 16). Separate shades domains. In the case of aspartyl tRNA synthetase, the protein is a dimer. Binding of a single tRNA to the monomer is sh domain interactions. The dimeric complex with two bound tRNA is also shown at the right. (This figure was provided b

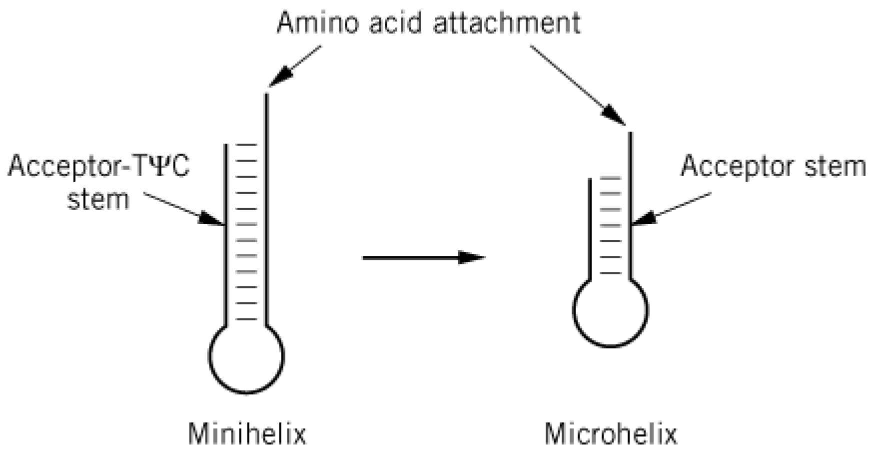


4. Operational RNA Code for Amino Acids

In addition to seryl-tRNA synthetase, alanyl-tRNA synthetase is an example of a synthetase that makes no contact with the anticodon (34). Instead, an acceptor helix G3:U70 **wobble** base pair is a major determinant of the identity of an alanine tRNA (35, 36). Alteration of this base pair to G:C, A:U, I:U, or U:G abolishes aminoacylation with alanine (37-39). Transfer of this base pair into other, nonalanine tRNA confers alanine acceptance on them. Thus, the G3:U70 pair marks a tRNA for charging with alanine.

Because the G3:U70 base pair is located in the acceptor helix, further experiments tested whether the 12-bp acceptor-TyC minihelix by itself would be a substrate for aminoacylation (Fig. 6) (40-42). Not only the minihelix, but also a 7-base-pair(bp) microhelix consisting of just the acceptor stem, is efficiently charged with alanine, provided that it contains the G3:U70 base pair (40, 43). Transfer of this base pair into other microhelices confers alanine acceptance on them. Thus, the charging behavior of the mini- and microhelices reproduces that seen with the full tRNA.

Figure 6. Minihelix and microhelix substrates for aminoacylation. The minihelix is derived from the 12-bp acceptor-TyC domain of the tRNA, while the microhelix is a hairpin helix whose base pairs consist of the 7-bp acceptor stem portion (40). These substrates for aminoacylation are devoid of the anticodon trinucleotides of the genetic code. About 11 examples of aminoacylation of minihelix or microhelix structures have been demonstrated. These substrates have been used to delineate the operational RNA code for amino acids (41). (Adapted from Ref. 42.)



The charging of specific RNA helices has now been demonstrated with at least 11 different tRNA synthetases, even for cases where the anticodon is known to play a significant role in the recognition of the related tRNA (41, 44-47). In the case of histidine, for example, an extra nucleotide at the 5′ end of the acceptor helix is characteristic of and unique to histidine tRNA throughout evolution. RNA microhelices that contain the extra base are charged with histidine (48). Thus, the 5′-appended nucleotide marks a molecule for charging with histidine. The smallest substrates seen to be charged with specific amino acids are stem–loop hairpins with as few as four base pairs stabilized by an RNA **tetraloop** motif (Fig. 7) (49).

Figure 7. RNA tetraloop substrates for aminoacylation. The amino acid that can be charged onto the designated structures is indicated (49). These short helices are stabilized by an RNA tetraloop motif that confers unusual stability to short RNA helices. (Adapted from Ref. 49.)

A	A	A	A
C	C	C	C
C	C	C	C
A	U	$^{-1}$G-C	A
^{1}G-C	^{1}G-C	^{1}G-C	^{1}C-A

G-U^{70}	G-C^{70}	G-C^{70}	C-G^{70}
C-G	C-G	C-G	G-C
U G	U G	U G	U G
U C	U C	U C	U C
Ala	Gly	His	Met

The charging of microhelix substrates is sometimes considerably less efficient than that for the corresponding tRNA. In each case, however, charging is sequence-specific and depends on two to four nucleotides near the amino acid attachment site. In a fine-structure mapping of the efficiently charged alanine microhelix, a constellation of atoms was identified as critical for the aminoacylation signal. Prominent among these atoms was the exocyclic 2-amino group of G of the G3:U70 base pair. Also important were specific 2′-hydroxyl groups that fell within a 5-Å (Å = 10^{-10} m) radius of the critical 2-amino group (39).

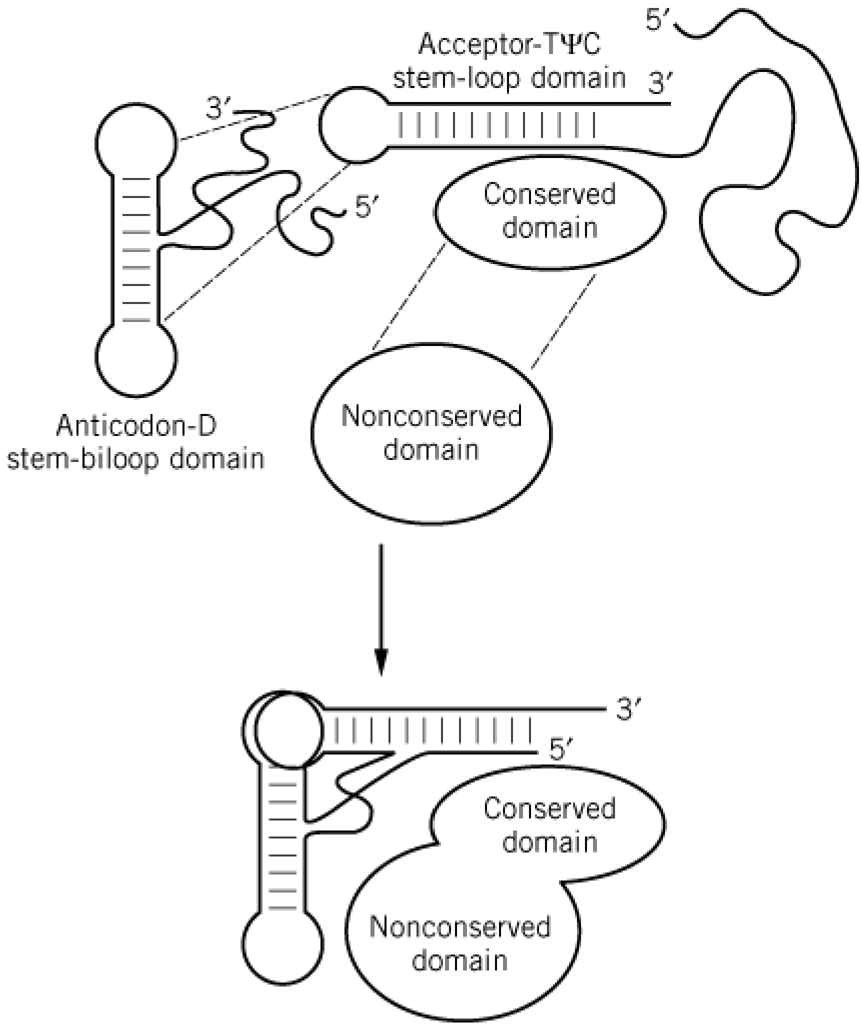
These anticodon-independent aminoacylations of oligonucleotide substrates demonstrate that specific RNA sequences and structures per se, rather than the trinucleotides of the genetic code, correspond to specific amino acids. The relationship between these RNA sequences and structures and particular amino acids constitutes an operational RNA code for amino acids that is distinct from, but related to, the genetic code. This operational RNA code may have predated the genetic code (1).

5. Assembly of the Synthetase-tRNA Complex and Relationship of the Operational RNA Code to the Genetic Code

Several considerations led to the proposal that the minihelix and anticodon-containing second domain of tRNA had distinct origins (1, 50-52). The minihelix, with its amino acid attachment site, is viewed as the historical, or earliest, part of the tRNA. Similarly, the class-defining catalytic domain of tRNA synthetases is thought to be the historical enzyme, with the idiosyncratic second domain added later. Experiments with alanyl-tRNA synthetase have demonstrated that a relatively small piece of the enzyme (containing the active site) can by itself charge an RNA microhelix. This result directly demonstrated a domain–domain interaction between discrete units of the tRNA and the synthetase that may somewhat resemble an evolutionarily earlier system (33, 54).

Thus, the early synthetase may have consisted solely of a domain for adenylate synthesis. Insertions into this domain allowed the docking of RNA substrates near the activated amino acid so that aminoacylation could occur (Fig. 8). Addition of the second domain of the tRNA, with its anticodon-containing template reading head, and of the second domain of the synthetases was a second, later event. This event led to the joining of the operational RNA code to the genetic code. This scheme also suggests that the relationship between a particular amino acid and the triplet of the code is random, and simply depends on which anticodon-containing domain happened to be fused to the minihelix domain of the tRNA.

Figure 8. Assembly of a tRNA synthetase in evolution. A primordial tRNA synthetase is envisioned as interacting with a minihelix-like structure. As the tRNA structure developed, a template reading head (anticodon domain) was added, along with the second domain for the synthetase. (Adapted from Ref. 1.)



6. Conclusions

The tRNA synthetases may be among the earliest proteins, arising in evolution contemporaneously with the development of the genetic code. The first synthetases may have been **ribozymes** that catalyzed aminoacylation reactions with a specificity that depended on the sequences and structures of the RNA substrates (54, 55). The proteins that replaced these ribozymes were probably small. As a result, they could not extend much beyond the amino acid attachment site and, for that reason, gave rise to a system of interactions that based specificity of aminoacylation on interactions near the end of the acceptor helix. How these charged RNA substrates were used to synthesize specific proteins is a question of great interest.

Aminopeptidases

Enzymes that catalyze the hydrolytic cleavage of the peptide bond that connects the N-terminal residue to the rest of a peptide, **polypeptide**, or protein are referred to as aminopeptidases (E.C. 3.4.11) (see Peptidases). The products of hydrolysis are, therefore, the released N-terminal amino acid and the remainder of the peptide chain. The latter can, in turn, also be an aminopeptidase substrate; hence these enzymes can release amino acids sequentially, ultimately resulting in complete hydrolysis of the polypeptide (though in practice this is not always observed). The principal determinant of specificity appears to be the free a-**amino group** of the N-terminal residue; hence these enzymes can release most, though not all, of the known amino acids, albeit at different rates. There are some aminopeptidases (eg, methionine aminopeptidase) that are quite limited in specificity. Usually, aminopeptidases can also act on amino acid amides and esters, which provide convenient substrates for routine assays. Some aminopeptidases sequentially remove dipeptides from the N-terminus of substrates, and these are referred to as dipeptidyl-peptidases. Others remove tripeptides and, hence, are tripeptidyl-peptidases.

Many aminopeptidases are zinc **metalloenzymes**, but some are serine proteinases or **thiol proteases**. Of those that require zinc, some have an active site containing a single ion (see Thermolysin), whereas others have a co-catalytic site that involves two closely spaced zinc ions.

Aminopeptidases are widely distributed in various tissues and cells. They can be monomeric (a single polypeptide chain) or have up to 12 subunits. Many are integral components of cell membranes, but they are also found in the **cytosol**. They have a broad range of biological functions, including regulation of hormone concentration, control of the cell cycle, and recovery of amino acids from dietary peptides and proteins (1). All proteins synthesized by **eukaryotic** cells begin at their N-terminus with methionine, and its removal by methionine aminopeptidase is often crucial, not only for biological function of the protein but even for cell survival. Aminopeptidases also play important roles in the food industry—for example, ripening of cheese (2) and production of soy sauce (3).

Aminopeptidases are inhibited by the antitumor antibiotic bestatin [(2*S*,3*R*)-3-amino-2-hydroxy-4-phenylbutanol]-L-leucine, isolated from culture filtrates of *Streptomyces olivoreticuli*. It is a potent inhibitor of bovine lens aminopeptidases, with a K_i of 1.3 nM, and has numerous biological activities when administered to laboratory animals.

Membrane-bound aminopeptidases have often been identified on the basis of some other property, and then, once their amino acid sequence has been established, they are recognized to be aminopeptidases. Thus, the B-lymphocyte differentiation factor BP-1/6C3, whose expression correlates with proliferation and transformation of immature B cells (antibody-producing lymphocytes), has been shown to be identical to glutamyl aminopeptidase, also known as aminopeptidase A (4). Also the myeloid leukemia antigen CD-13 has been identified as aminopeptidase N (5), and the amino acid sequence of leukotriene A4 hydrolase revealed an aminopeptidase-like structure that led to the recognition of its aminopeptidase activity (6). Aminopeptidase N has also been shown to have a function unrelated to its enzymatic activity; that is, it serves as a cell-surface **receptor** for certain coronaviruses that cause upper respiratory infections (7).

The amino acid sequence and three-dimensional structure of leucine aminopeptidase from bovine lens have been determined (8). This is a broad-specificity cytosolic enzyme found in tissues of all organisms. It has a high degree of sequence similarity to several other aminopeptidases, which suggests that they all share similar structures and catalytic mechanisms.

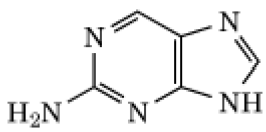
2-Aminopurine (AP)

AP is a base analogue that is a mutagen in a wide range of systems and species (1, 2) (Fig. 1). Freese (3, 4) originally described A.T → G.C and G.C → A.T transition mutations following AP treatment of **bacteria** and **bacteriophage**. The results were interpreted as resulting from **tautomeric** shifts and changes in base pairing behavior following the incorporation of AP into DNA. AP is readily metabolised to form deoxy-2-aminopurine triphosphate (dAPTP) (5), which may be incorporated opposite thymine during DNA replication, to form an AP.T base pair. During subsequent rounds of replication, incorporation of dCMP opposite the AP would lead directly to an A.T → G.C transition mutation. Law et al. (6) found that a DNA duplex containing AP.C is thermodynamically more stable than a DNA duplex containing A.C. This is in agreement with the suggestion that the rate of insertion of an improper base by a **DNA polymerase** is determined by differences in stability between the newly formed mismatch site and the corresponding normal **Watson–Crick base pair** (7). The probability that transition mutations will occur results from a combination of the likelihood of tautomeric shifting, the availability of the analogues to the DNA replicating machinery, and the discriminatory behavior and fidelity of the DNA polymerases.

Figure 1. Structure of the base analogue 2-aminopurine.



Although best known as a base-pair substitution mutagen, the earliest reports of AP activity focused on the production of unequal, multipolar **mitosis** in mouse tissue culture cells, producing **aneuploid** daughter cells also bearing chromosome mutations (1). AP also causes frameshift mutations—for example, in a set of lacZ mutant variants of *Escherichia coli* (2). *E. coli dam* mutants have reduced ability for methylation of adenine. Many of these mutants also have enhanced sensitivity to AP and increased mutability by this base analogue (8). It appears that AP is partially able to saturate or inactivate the methylation-directed mismatch repair system, allowing the escape from repair of replication errors that lead to frameshift mutation. This results in indirect mutations that can be detected at certain sites (2).

Aminopterin, Methotrexate, Trimethoprim, and Folic Acid

Aminopterin, methotrexate, and trimethoprim are all analogs of *folic acid* (Fig. 1) that antagonize folate-dependent metabolic pathways (1, 2). Folate is a water-soluble vitamin. Although some bacteria synthesize folate, mammalian cells cannot, and consequently it is an absolute dietary requirement. Reduced folates function as **cofactors** in many metabolic processes common to nearly all cells, such as **thymidylate** and **purine** synthesis and donation of methyl groups (Fig. 2) (1). Folates gain entry into mammalian cells by either the reduced folate carrier (RFC) and/or a hydrophobic membrane-associated folate receptor (FR) found in placental, choroid plexus and kidney cells (3). The FR is unidirectional and, once inside, cellular retention of folate is enhanced by its polyglutamation, catalyzed by the enzyme folylpolyglutamyl synthetase (FPGS) (4). FPGS adds up to six or seven glutamic acid residues via an unusual peptide bond through their g-carboxyl group, rather than the normal a. The number of glutamic acid residues added may play a role in regulating and distributing reduced folates, and in guaranteeing their availability as cofactors. Polyglutamation also increases the affinity of folate for folate-dependent enzymes, such as thymidylate synthase (TS), aminoimidazole carboxamide ribonucleotide and glycinamide ribonucleotide transformylases. The latter two are involved in purine synthesis. In cells synthesizing DNA, 5,10-methylenetetrahydrofolate serves in thymidylate synthesis as a methyl group donor for converting dUMP to dTMP. This is the only reaction in which tetrahydrofolate is partially oxidized to dihydrofolate (1, 4). Dihydrofolate reductase (DHFR) is the critical enzyme involved in converting dihydrofolate back to tetrahydrofolate, thus maintaining reduced folate pools to serve as one-carbon group carriers (see Fig. 2).

Folate homeostasis is recognized as important. The structure of DHFR has been determined by X-ray crystallography. One proposed mechanism of resistance to methotrexate involves DHFR gene amplification (5-7). The FR is overexpressed in some carcinomas, and its gene has been localized to the 11q13 region (3). Human FPGS has been cloned and mapped to chromosome 9q (4). The complementary DNA for RFC has been **cloned** and the RFC gene localized to the long arm of chromosome 21 (8-11).

1. Methotrexate (MTX)

Folate analogs entered cancer therapy in the 1940s, when aminopterin was successfully used to induce temporary remissions in children with acute lymphoblastic leukemia (ALL) (12). Because of a better therapeutic index, MTX eventually emerged as the antifolate used clinically in treating cancers, such as leukemias, lymphomas, osteosarcoma, breast cancer, choriocarcinoma, head and neck cancers, and nonmalignant disorders, such as arthritis and asthma (4, 13).

Like folates, MTX enters mammalian cells via the RFC. MTX has an apparent **dissociation constant** in the micromolar range, and via the FR has higher affinity in the nanomolar range (3). Cellular retention of MTX is enhanced by polyglutamation, which also enhances the affinity of the drug for enzymes. Once inside the cell, MTX acts as a tight-binding **competitive inhibitor** of DHFR. This leads to an accumulation of dihydrofolate and depletion of the reduced folate pools in cells actively making dTMP via the *de novo* pathway. Accumulated dihydrofolate polyglutamates are also inhibitors of TS and the enzymes involved in the *de novo* synthesis of purines (1). The resulting imbalance of nucleotides causes base substitutions, which lead to errors in DNA synthesis and ultimately to cell death.

2. Aminopterin (AMT)

Aminopterin (AMT) was the first antifolate drug used clinically in childhood ALL (12) (see previous). Although more potent than MTX, in preclinical studies the toxicity of AMT was more severe and more unpredictable (13-15). Transport and metabolic studies *in vitro* have shown that AMT is the preferred substrate (16, 17). This results in greater AMT accumulation at lower concentrations and more complete polyglutamation, leading to improved cellular retention for the cytotoxic effect.

The greater potency of AMT compared to MTX has led to renewed clinical interest. AMT may find a role in treating patients with resistant or refractory malignancies or those patients in whom *in vitro* studies indicate AMT is the better choice on the basis of metabolism and accumulation (16).

3. Trimethoprim

Trimethoprim is an antibacterial agent developed in the 1950s. Studies by Hitchings (2) showed that its mechanism of action is the competitive inhibition of DHFR. Unique to trimethoprim is its much greater affinity (50,000- to 100,000-fold) for bacterial DHFR than for mammalian DHFR (18, 19). Trimethoprim is lipid-soluble and enters cells rapidly without requiring specific transport mechanisms. Its selective toxicity is further enhanced by the ability of folinic acid to reverse even the slight effects of trimethoprim on mammalian cells, whereas bacterial cells, unable to transport folinic acid, are not rescued by folinic acid administration (19, 20). In addition to its antibacterial activity, the drug has activity against *Pneumocystis carinii*, an opportunistic infection of the lungs encountered in severely immunocompromised patients (especially HIV patients).

Amphipathic

Compounds that contain both highly polar and nonpolar, **hydrophobic** moieties are *amphipathic*. In the presence of water, these compounds tend to aggregate, forming structures that are strongly influenced by the relative extents of the polar and hydrophobic characters of the molecule, with the polar groups acting to shield the hydrophobic moieties from the solvent. In lipids, the hydrophobic group is the hydrocarbon domain of the aliphatic chain (see Lipids and Fatty Acids). Typical examples are (a) the sodium salts of fatty acids, which form micelles in water, and (b) phospholipids, which form bilayers in membranes. The presence of significant amounts of nonpolar amino acids, such as alanine, valine, leucine, isoleucine, proline, methionine, phenylalanine, and tryptophan, make certain proteins amphipathic; these amino acids are believed to increase the accessibility of the proteins to the hydrophobic domain of the membrane bilayer (see Fluid Mosaic Model).

Amphoteric

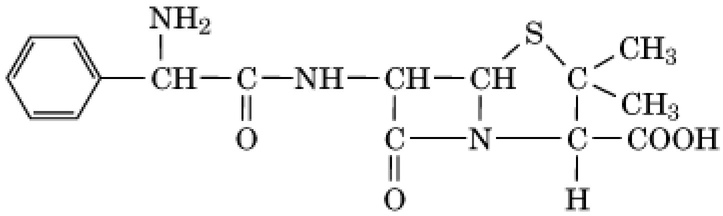
An amphoteric molecule is one that has both acidic and basic chemical features. For example, proteins are amphoteric electrolytes because they generally have both acidic and basic groups on the side chains of their amino acid residues. Extreme examples of amphoteric molecules are the ampholytes used to establish pH gradients in isoelectric focusing.

Ampicillin

Ampicillin (D[–]-a-aminobenzylpenicillin; Fig. 1) is a member of a growing family of antimicrobial agents known as the semisynthetic penicillins. The semisynthetic penicillins are derivatives of the natural product, 6-aminopencillanic acid, that have been deliberately modified chemically (1). The chemical modifications are introduced to create new compounds with specific desirable properties.

In the case of ampicillin, the addition of the aminobenzyl side chain results in a product with an increased resistance to acidic pH. Thus, ampicillin is medically significant because it was the first penicillin to be administered orally in chemotherapeutic practice. Furthermore, ampicillin exhibits a broader antibacterial spectrum than do the naturally occurring penicillins and is effective against many Gram-negative bacterial species. The outer membrane component of the Gram-negative bacterial cell wall represents a permeability barrier to many antibiotics, including the natural penicillins (2). The broad activity spectrum and the relative low cost of ampicillin have made it an invaluable tool in molecular biology and genetics for studying Gram-negative model organisms, such as *Escherichia coli* and *Haemophilus influenzae*. Applications that employ ampicillin are summarized below.

Figure 1. Structure of ampicillin.



The first application of penicillin in genetics was for the selection of auxotrophic mutants of *E. coli* (3, 4). This technique, penicillin selection, was based on the fact that penicillin kills only actively growing bacteria, whereas nongrowing bacteria are penicillin-tolerant (see Penicillin). Although benzylpenicillin (penicillin G) was employed in the original studies describing this technique, ampicillin would be far more effective for this purpose because of its broad spectrum.

Molecular biologists have extensively exploited genetic elements encoding b-lactamase (see Penicillin-Binding Proteins), especially the enzyme designated TEM-1. TEM-1 is a broad spectrum b-lactamase that confers effective high level resistance to penicillins (5). The gene encoding TEM-1 was incorporated into the first plasmid cloning vectors (6) and has been widely used in cloning vectors since. Ampicillin has been used routinely for the selection and maintenance of bacteria carrying recombinant plasmids encoding b-lactamase, and this is undoubtedly its most common application in molecular biology. For this purpose, ampicillin is incorporated into bacteriological media at final concentrations ranging from about 50–100 µg/mL. For *E. coli*, these levels are about 10–20 times higher than the minimum inhibitory concentration (MIC) of ampicillin. The MIC is defined as the minimum concentration of the antibiotic that is necessary to inhibit bacterial growth.

When a mixture of ampicillin-sensitive and ampicillin-resistant bacteria are plated on solid media containing ampicillin, such as for selection of transformants carrying a b-lactamase-encoded plasmid, it is not uncommon to find large colonies formed by ampicillin-resistant bacteria surrounded by a zone of smaller colonies. The ampicillin-resistant bacteria in the large central colonies produce and secrete b-lactamase. The activity of the secreted b-lactamase creates a zone of reduced ampicillin concentration around the resistant colonies, and this permits the ampicillin-sensitive bacteria in the vicinity to grow. The subsequent growth of the ampicillin-sensitive bacteria results in the formation of the smaller so-called satellite colonies. The satellite colonies normally do not represent a major hindrance in these procedures, because the desired ampicillin-resistant bacteria can be readily purified by streaking on an ampicillin-containing medium. However, the problem of satellite colony formation can be minimized by substituting carbenicillin, another semisynthetic penicillin (see Fig. 1 in Penicillin) for ampicillin in the selection medium at a concentration of 50–100 µg/mL (7). Carbenicillin is less susceptible to hydrolysis by the b-lactamase and is therefore less likely to promote satellite colony formation. It is therefore often used in place of ampicillin.

The b-lactamase gene has also been introduced into plaque-forming and defective derivatives of the *E. coli* bacteriophage Mu (8). These ampicillin-selectable phages have been used for mutagenesis and for the construction of *lac* fusions in applications that take advantage of the ability of Mu to **transpose** randomly.

The concept of transposon mutagenesis has been applied to transposable genetic elements encoding b-lactamases for the generation of random gene fusions that are directly selectable with ampicillin (or carbenicillin). For example, a derivative of Tn*3* designated Tn*3*-HoHo1 (9) is a *lacZ*-containing transposon capable of producing both transcriptional and translational **beta-galactosidase** fusions. Although it was originally developed for studies on Agrobacterium *tumefaciens*, it has been adapted for use in other bacterial genera.

b-Lactamase is a periplasmic enzyme. It has served as an important model for studying protein export to the bacterial periplasm. Urbain et al. (10) have recently developed a technique for quantifying b-lactamase activity in cultures of *E. coli* carrying recombinant plasmids that confer ampicillin resistance. Their assay involved determining the conversion of ampicillin to aminobenzylpenicilloic acid in periplasmic extracts of cells by quantitative high performance liquid chromatography (**HPLC**). The procedure may be useful for investigating the mechanism of b-lactamase translocation. It may also prove useful in studies on protein expression. For example, since b-lactamase is expressed constitutively from ampicillin-selectable recombinant plasmids, its activity could serve as a useful internal standard in protein coexpression studies.

b-lactamase has also been used as a genetic tool for studying membrane proteins, and these applications are based on the fact that b-lactamase is an exported protein (11, 12). A plasmid vector that permits the *in vitro* construction of translational fusions between a gene of interest, encoding either a membrane protein or an exported protein, and the mature form (ie, the exported form) of the TEM b-lactamase has been described (13). Transformants carrying recombinant plasmids with in-frame fusions are ampicillin-selectable. This technique may be used for the analysis of protein export signals or for determining the topological organization of membrane proteins. A strategy for maximizing yields of membrane and exported proteins based on this vector has also been described (14). It is notable that alkaline phosphatase has been used widely for studying protein export signals and for topological mapping of membrane proteins (15). The b-lactamase system is an attractive alternative to alkaline phosphatase for these purposes (13, 14) (see Reporter Genes). For example, b-lactamase fusions are directly selectable (with ampicillin), whereas the identification of alkaline phosphatase fusions is based on phenotypic screening. Moreover, only the periplasmic form of alkaline phosphatase is enzymatically active, whereas both the cytoplasmic and periplasmic forms of b-lactamase are active. Consequently, the cellular location of the b-lactamase fusions can be determined on the basis of the levels of ampicillin resistance; cytoplasmic b-lactamase confers ampicillin resistance only at high cell density, whereas periplasmic b-lactamase confers ampicillin resistance at low cell density. As an extension of these studies, Broome-Smith et al. (16) have constructed a transposable b-lactamase element, designated *TnblaM*, that is equivalent to the transposable alkaline phosphatase element, *TnphoA*. The b-lactamase fusions constructed with *TnblaM* are directly selectable with ampicillin, and this is a major advantage over alkaline phosphatase system, which as already noted is based on phenotypic screening.

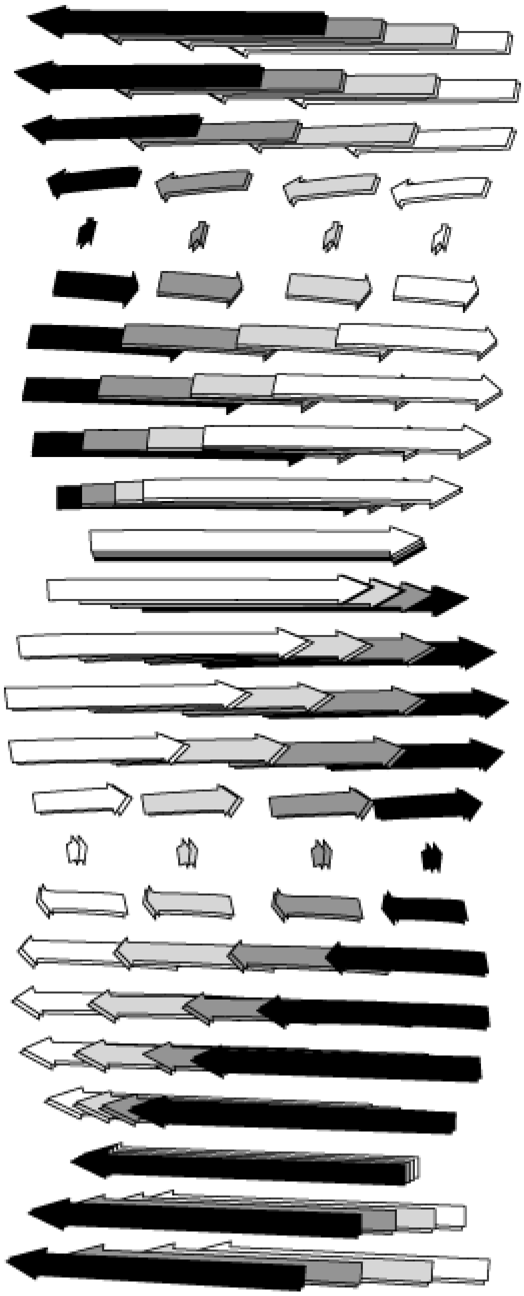
Amyloid

Amyloid is an insoluble, proteinaceous, fibrous material associated with a number of prominent disease states (1), which can also form spontaneously *in vitro* from oligopeptides and **denatured** proteins. The disease states in which amyloid has been implicated as an important, or even causal, factor include Alzheimer's disease (see Amyloid Precursor Protein), the transmissible spongiform encephalopathies (see Scrapie), non-insulin-dependent (type II) diabetes, and a number of polyneuropathies. It is thought that the extreme stability of amyloid fibrils permits their progressive accumulation in the extracellular spaces of vital organs whose functioning is thereby inhibited, leading to organ failure and death. The *in vivo* development of amyloid deposits from globular precursor proteins is linked to either genetic mutation, incorrect processing, or the abnormal accumulation of wild-type proteins. Probably the most remarkable feature of amyloid is that its molecular structure appears to be constant and independent of the protein precursors. For example, all amyloids, regardless of the disease involved or the source of the fibrils, share similar morphological (2), tinctorial (3), and structural (4, 5) properties. This implies that amyloid formation is not a simple aggregation process but a structural conversion of globular proteins to a state that can be incorporated into a particular type of fibrous protein structure. The amyloid diseases may therefore be defined as diseases of protein misfolding.

At least 15 different proteins can form amyloid fibrils *in vivo* (1), and recently the involvement of amyloid fibrils in Huntingdon's disease has also been demonstrated (6). In the **electron microscope**, amyloid fibers are about 100 Å (10 nm) in diameter and usually straight or only slightly curved. Closer examination shows the fibrils to be composed of a number of smaller diameter protofilaments, arranged in a more or less parallel array. In those fibrils so far examined, the protofilaments give the fibrils the appearance of hollow cylinders or ribbons when observed in cross section. Although the number, size, and arrangement of these constituent protofilaments appear to differ somewhat, the ribbons may be merely unrolled or unformed cylinders, and hence the variation may not be so great as appears. The molecular structure of the amyloid fibrils has been established by X-ray fiber diffraction. The first diffraction patterns (7, 8) showed the intense 4.7 Å (0.47 nm) meridional and 10 Å (1 nm) equatorial reflections that have been subsequently shown to characterize all amyloid X-ray patterns. These reflections indicate that the molecular structure of amyloid is composed of beta-sheets arranged parallel to the fiber axis, with their constituent beta-strands at right angles to the axis of the fibril (4, 9). This so-called “cross-b” structure is quite different from the more common insect silk **chorions**, whose fibers are formed from b-sheets having their b-strands parallel to the fiber axis. The first use of intense synchrotron X-ray sources on amyloid (10) extended the observable X-ray pattern to 2 Å (0.2 nm) and revealed how this “classic” amyloid model could be reconciled with low-energy twisted b-sheets (11). These new data revealed a previously unobserved repeat distance of 115 Å (11.5 nm) along the fiber axis of the transthyretin amyloid of familial amyloidotic polyneuropathy (FAP), which was proposed (10) to correspond to the repeat distance of a complete helical turn of a twisted b-sheet, whose helix axis was parallel to the fiber axis. The basic helical unit therefore consists of a segment of b-sheet whose 24 b-strands complete one helical turn. This beta-helix model of the molecular structure of the amyloid protofilament is shown in Figure 1. Given that all amyloid fibrils share common morphological, tinctorial, and structural properties, it is reasonable to see the b-helix model as characteristic of all amyloid protofilaments. The b-helix model is distinct from other fibrous proteins, showing that the amyloid structure is unique. Its features enable low energy twisted b-sheets to be incorporated in a linear fibril in such a way that continuous b-type **hydrogen bonding** can be extended over the total length of the fibril. This, together with the opportunity for a continuous **hydrophobic** core to stabilize the b-sheet interactions along the length of the fibril, can be reasonably held to account for the known extreme stability of amyloid fibrils, which is central to their role in disease.

Figure 1. Drawing of one complete turn of the proposed b-helix structure of the amyloid fibril. The arrows represent b-strands and are shaded to represent the different b-sheets. The direction of the arrows has no significance, and no b-strand connections are shown.

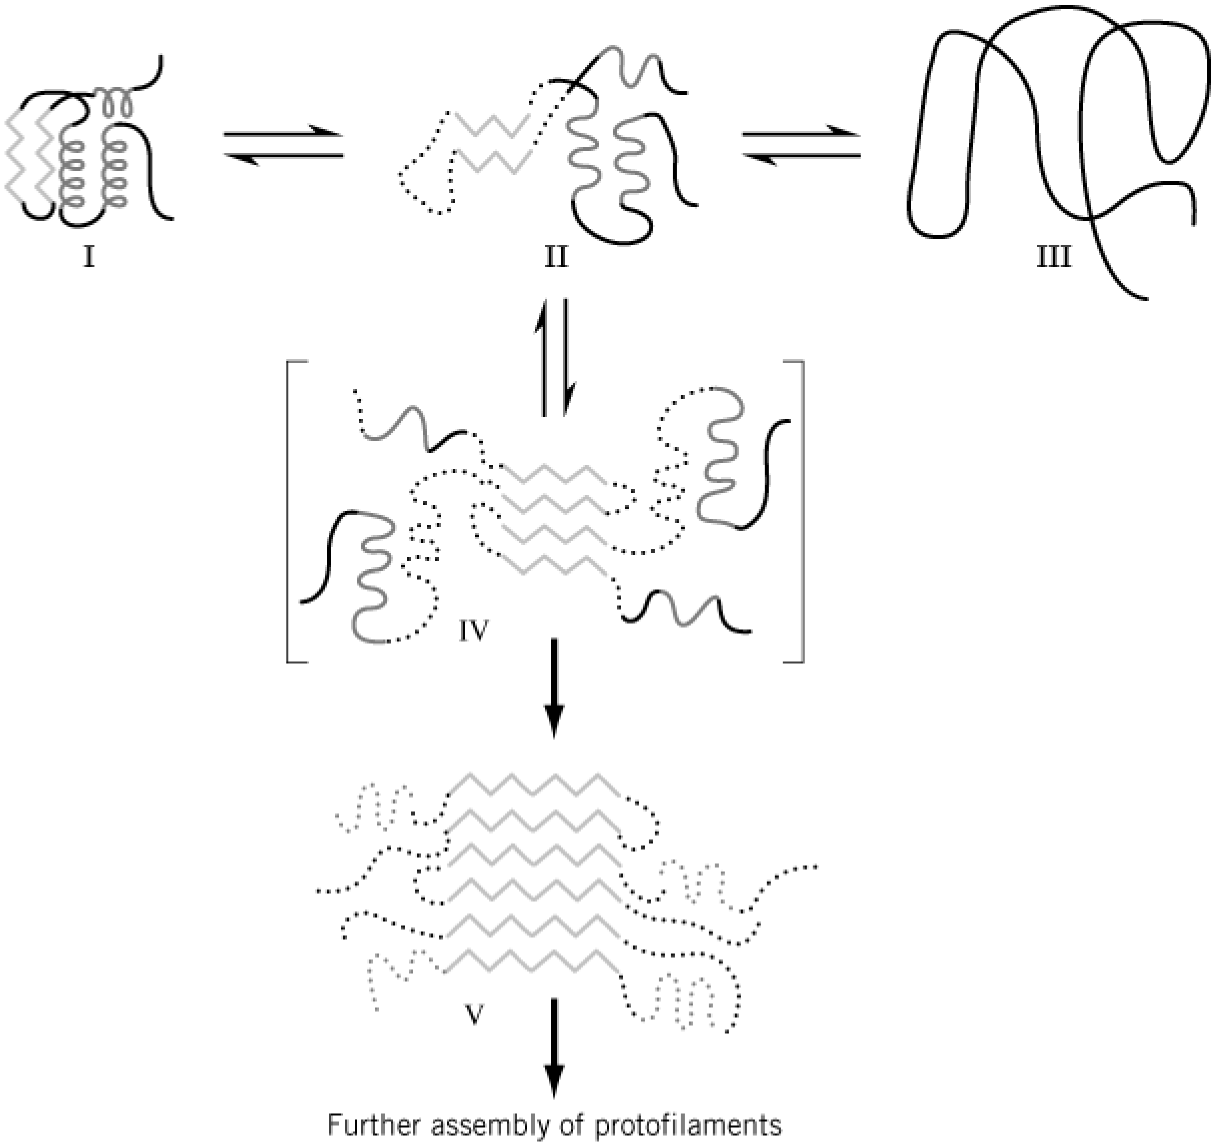


A remarkable property of amyloid fibrils is that they appear to be very similar whatever their source. This has recently been critically tested (5) by showing that the high resolution synchrotron X-ray patterns from eight different amyloids, of both disease and synthetic origins, have the same structural characteristics. This observation suggests that amyloid is a highly stable generic structure capable of accommodating proteins and peptides with a wide range of chain lengths and structures within a common fibrillar form. The repetition of b-strands in the fibril model allows polypeptide chains of different lengths to occupy the same structural framework. For example, a 10-residue peptide could form a single b-strand of the amyloid structure, consistent with the known lower limit on the length of peptides capable of forming amyloid, while longer polypeptide chains could fold back and forward on themselves, thereby forming a number of consecutive b-strands of the amyloid b-sheets. The need for loops of chain of different lengths or conformation between successive b-strands to maximize the b-strand propensity, and to generate a stable hydrophobic core between the b-sheets, is likely to give each fibril a characteristic structure within the core amyloid framework. Thus it is probably realistic to consider amyloids as a closely related family of fibrils, each with its own detailed structural differences, while maintaining a similar overall core structure.

The nature of the processes that convert the globular, soluble protein precursors into amyloid fibrils, known as either *amyloidogenesis* or *fibrillogenesis*, are important, as they underpin the development of amyloid diseases and represent a novel field of scientific investigation. It is evident that some of the proteins forming the predominantly b-structured amyloid fibrils are themselves largely a-helical in their normal soluble states, for example, lysozyme, the prion protein, and the Ab peptide in Alzheimer's disease (see Amyloid Precursor Protein). The nature of this structural rearrangement has been particularly studied in two amyloidogenic proteins: transthyretin (TTR) and lysozyme. Transthyretin amyloidosis is associated with familial amyloidotic polyneuropathy (FAP) and senile systemic amyloidosis (SAA). Both the wild-type protein (SAA) and more than 50 different genetic variants (FAP) (13) give rise to amyloid. That so many variants of transthyretin are amyloidogenic (nearly 40% of all its residues), suggests that the structure of this protein allows a particularly facile transformation into the fibrillar form. As transthyretin is a 55-kDa homotetramer, with the four monomers associating in such a way as to generate a stack of four 8-stranded b-sheets (14), there is a superficial structural similarity with amyloid fibril (10). Nevertheless there is evidence that the tetrameric form of TTR is not a building block for the fibril (15), and the discovery of a molecular hotspot in the pattern of amyloidogenic variants (16) suggests that structural change to the monomer is also required prior to its incorporation into the fibril. It is therefore evident that even all-b proteins, such as TTR, must undergo a significant degree of structural rearrangement to form amyloid.

The human lysozyme molecule (see Lysozymes) has about 35% a-helix and only 10% b-sheet structure, segregated into an a- and a b-domain. Hence the structural changes that must accompany its incorporation into the predominantly b-structured amyloid fibril will need to be extensive. Two genetic variants of human lysozyme are known to form amyloid *in vivo*, Ile56Thr and Asp67His (17). A thorough biophysical study of these variants has highlighted major differences in their stability and folding behavior as compared with the wild type (18). It has generated a possible mechanism of the a- to b-structural transformation of fibril formation of lysozyme, shown in Figure 2, which may be applicable *mutatis mutandis* to other amyloidogenic proteins. Thermal denaturation studies show that the variants unfold at temperatures at least 10°C lower than wild-type lysozyme and, unlike the wild type, do not regain activity when returned to physiological conditions. Fourier transform infrared spectroscopy (see Vibrational Spectroscopy) of Asp67His lysozyme shows a significant gain in b-structure and loss of a-structure in the soluble material, demonstrating that an a-to-b structural interconversion is associated with fibril formation. Detection of an unfolding intermediate displaying the characteristic binding to the hydrophobic dye 1-anilinonaphthalene sulfonic acid (**ANS**) is consistent with a **molten globule**-like intermediate, as shown in Figure 2. Hydrogen exchange shows that the flexibilities of the native folds of the variants have been dramatically increased by the mutations. Inspection of the X-ray crystallography structures of the two variants (18) suggests that the key to both amyloidogenic mutations in human lysozyme lies in the effect they produce at the interface between the a- and b-domains, with the result that domain adhesion may be weakened. Both variant lysozymes unfold dramatically faster than the wild-type protein, because the docking of the two domains, required for achieving the final rigid protein fold (19), is compromised by the presence of a threonine side-chain in the place of the wild-type **hydrophobic** anchoring residue, isoleucine.

Figure 2. Schematic drawing of the possible mechanism of fibril formation in human lysozyme. (—) b-sheet structure; (**—**) a-helical structure. A partly-folded, molten-globule form (II), distinct from the native (I), and denatured (III) forms, self-associates through the b-domain (IV) to initiate fibril formation. This provides a template for further deposition and the development of a b-sheet core structure of the amyloid fibril (V). Undefined structures are shown as broken lines.



Detailed study of the structure and behavior of variants of lysozyme has led to the proposal that transient populations of amyloidogenic proteins in a molten-globule state that lacks global cooperativity are an important feature of the conversion from a soluble to the fibrillar state (18). These observations lead to a model of the mechanism for amyloid formation for amyloidogenic lysozyme shown in Figure 2. Such a mechanism may also operate for other amyloidogenic proteins. For example, the structure of the 121–231 domain of the prion protein (20) also demonstrates that mutations associated with prion disease are involved in the maintenance of the hydrophobic core, which may be related to the earlier suggestion of a molten globule intermediate in the formation of aggregates in scrapie (21) (see Prion). Recent evidence supports the hypothesis that conformational plasticity is a key feature in prion fibril formation. A similar observation has been made for the Ab protein forming the amyloid in Alzheimer's disease (22) (see Amyloid Precursor Protein). The mechanism for helix-to-sheet conversion in lysozyme, proceeding from soluble forms of the amyloidogenic precursor proteins through transient populations of intermediates with the characteristics of molten globules, and on to intermolecular b-sheet association, seems to parallel the processes in the aggregation of prions and the Ab amyloid peptides, and it may occur generally in the amyloidoses. Studies of these processes is certain to extend our knowledge of **protein folding** behavior into new areas and coincidentally address some of the more intractable diseases of our times.

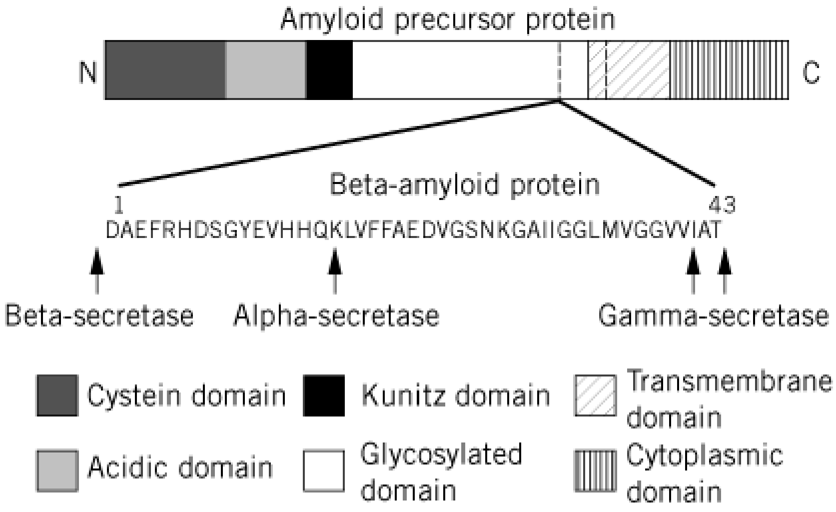
Amyloid Precursor Protein

At the molecular level, the necessary, and probably sufficient, cause for the brain dysfunction in Alzheimer's disease is the deposition of aggregated forms of the amyloid b-protein (Ab or bA4), a **proteolytic** fragment of the amyloid precursor protein (APP), in the brain parenchyma and vascular system (1). In the Western world, dementia is the most common neurological diagnosis and is the third leading cause of natural death, and Alzheimer's disease is by far the dominant cause of dementia (2). It has been estimated that there are 3 million patients in the United States alone with Alzheimer's disease (3). In addition, older patients with Down's syndrome (trisomy 21) tend to develop a neuropathology that is very similar to that seen in Alzheimer's patients (4) The disease is chronic, progressive, and at present untreatable. The progression of the disease begins with loss of short-term memory and disorientation, followed by complete impairment of memory, judgment, and reasoning. Firm diagnosis of the disease can be given only after postmortem examination of the brain, which is characterized by extensive loss of neurons and particular microscopic lesions, which include what are now called "neurofibrillar tangles" and "senile plaques." The neurofibrillar tangles are composed of paired helical filaments consisting of phosphorylated **tau protein**, which is normally associated with microtubules. The senile plaques are composed mainly of Ab deposited in the brain parenchyma. Also present in the brain is congophilic amyloid angiopathy from the accumulation of the Ab peptide in the walls of blood vessels. The Ab protein in the senile plaques and in the vascular deposits is present in the form of amyloid (5, 6), long, stable fibrils resulting from the accumulation of precursor peptides that adopt a continuous beta-sheet structure. In this regard, Alzheimer's disease is related to Creutzfeldt–Jakob disease (CJD) and other spongiform encephalopathies, which are also characterized by the presence of amyloid deposits, in that case composed of the prion protein. All known risk factors for Alzheimer's disease appear to influence one or more of the following: (1) the concentration of Ab (7); (2) the amount of the longer, more amyloidogenic Ab chains (8, 9); or (3) the initiation of amyloid formation (10). Increases in any of these factors appear to increase the risk of Alzheimer's disease. Study of the origins of the b-amyloid protein from APP, its aggregation into amyloid fibrils, and the identification of genes involved in its inherited susceptibility are therefore central to understanding of, and devising therapies against, the scourge of Alzheimer's disease.

The amyloid precursor protein (APP), is a 110–130-kDa protein with the features of a transmembrane cell-surface **glycoprotein**. It is encoded by a gene localized on chromosome 21 encoded by 18 exons (see Introns, Exons). A family of eight transmembrane glycoproteins is generated by alternative splicing of some of these exons (11). The amino acid sequence predicts that the single transmembrane domain of APP is near the *C*-terminus (Fig. 1) (12). The Ab sequence consists of a maximum 43-residue segment straddling the transmembrane and extracellular portions of the APP chain, and encoded by parts of exons 16 and 17. APP is processed in two distinct pathways : a major nonamyloidogenic route involving **proteolytic** cleavage within the region carrying the Ab segment to separate the extracellular and membrane-bound domains (13): and an amyloidogenic route, shown in Figure 1, leading to the release of the Ab segment (7). The cleaving of the Ab sequence from an internal site in the APP chain implies that two distinct proteolytic events are required to generate the *N*-terminus and the *C*-terminus of the Ab peptide. The proteolytic enzymes involved in processing APP are termed *secretases*: a-secretase for cleavage of APP within the Ab segment, and b- and g-secretases for cleavage of APP at the *N*- and *C*-terminal sides of the Ab segment, respectively. Soluble, *C*-truncated forms of APP are generated by two pathways: (1) by a-secretases cutting within the Ab sequence, thereby precluding the release of Ab (13); and (2) by b-secretases cleaving near the *N*-terminus of Ab producing *C*-terminal fragments containing the complete Ab (14). The generation of intact Ab chains suggests that g-secretases generate the *C*-terminus of b-amyloid from these *C*-terminal fragments of APP after release of the transmembrane domain from the lipid bilayer (7). The identity and location of the secretases have proved elusive, but clearly they are of prime importance in Alzheimer's disease, and targets for therapies.

Figure 1. Schematic diagram of the derivation of the 4-kDa b-amyloid protein (Ab) from the 110–130-kDa amyloid precursor protein (APP) by the action of the a-, b-, and g-secretase enzymes. The probable domain structure of APP has been simplified.



Electron microscope and X-ray fiber diffraction analyses, often using synthetic analogs or fragments of the Ab peptide, have revealed the molecular characteristics of the Ab amyloid fibrils. In the electron microscope, different forms of Ab amyloids are seen at different pH values, but the physiological form appears to be represented by a fibril about 90 Å (9 nm) diameter, composed of five or six parallel protofilaments 25–30 Å (2.5–3 nm) in diameter arranged around a hollow core (15). The X-ray fiber diffraction patterns of Ab amyloid (16, 17) show the usual 4.7 Å (0.47 nm) meridional reflection and 10 Å (1 nm) equatorial reflection that demonstrate that the molecular structure of amyloid consists of paired b-sheets running parallel to the fiber axis, with their constituent b-strands perpendicular to the fiber axis. This structure is very similar to that observed in other amyloids produced from a variety of proteins and peptides (see Amyloid). Some shorter Ab chains, such as residues 11–28, particularly when aligned in a strong magnetic field, form pseudocrystals (18), which give more detailed X-ray diffraction patterns that may be capable of yielding greater structural detail and hence begin to define the features that dispose them to form amyloid.

The discovery that Ab is produced and secreted by cells continuously under normal metabolic conditions, and is present in a soluble form in biological fluids (14, 19), suggests that other factors are involved in Ab amyloidosis. It has been proposed that the isolated Ab protein exists in two forms: a soluble form that may represent a normal host protein and a modified amyloidogenic form (20). These two forms have identical sequences and hence are likely to represent conformation isomers. The soluble form is easily degraded and appears to have an **alpha-helical/random coil** structure: NMR analysis of synthetic Ab 1–40 (21) has shown that residues 15–23 and 31–35 form a-helices, while the rest of the peptide is in a random-coil conformation, and no stable tertiary structure is present. The amyloidogenic form is more resistant to degradation, has a high b-sheet content, and forms the fibrillar aggregates found in brains with Alzheimer's disease. This behavior is very reminiscent of the normal and scrapie forms of the prion protein, which is also an agent for amyloid brain diseases (see Prion, Scrapie, and Amyloid). The existence of two structural forms for the Ab protein implies the possibility that other proteins may be involved in regulating their interconversion. It is known, for example, that in the rare early-onset (30–60 years of age) form of Alzheimer's disease, the disease has been linked to mutations on chromosomes 1 and 14, in addition to chromosome 21, which carries the APP gene. The genes on chromosomes 14 and 1 have been identified with presenilin 1 (22) and presenilin 2 (23, 24), respectively. The two presenilins have 65% amino acid sequence identity, and hydrophobicity plots predict seven transmembrane regions resembling a structural membrane protein. The genetic variants of presenilin 1 allow the secretion of Ab peptides of longer length, and hence more amyloidogenic (25), possibly through a mechanism involving protein sorting and trafficking of APP.

The more common sporadic and familial late onset (>65 years) form of the disease has been linked with mutations on chromosome 19, subsequently narrowed to the ϵ4 allele of the **apolipoprotein** E (apoE) gene (26, 27). These studies have shown that carriers of the ϵ4 allele have an increased risk of developing Alzheimer's disease and that the inheritance of the e4 allele correlates with an increased deposition of Ab amyloid in blood vessels and plaques. The apoE4 **isoform** differs from apoE3, the most common isoform, by an Arg/Cys substitution at position 112. The apoE protein is known to be one of the proteins associated with amyloid deposits (28). It has been found that apoE can form complexes with synthetic Ab analogues and to enhance amyloid fibril formation by Ab *in vitro* (29), possibly by a direct physical interaction. Frangione and his colleagues (30) have made the intriguing proposal that apoE can itself possibly form an amyloid-like structure (there is experimental evidence for this in its *C*-terminal domain), which may be able to induce other proteins such as Ab to misfold into a b-sheet structure that could allow them to be incorporated into a growing amyloid fibril. They term this process "conformational mimicry," and certainly the most recent analyses of *in vivo* amyloid formation characterize it as a disease of protein misfolding, which is possibly **cooperative** (see Amyloid).

Analogy

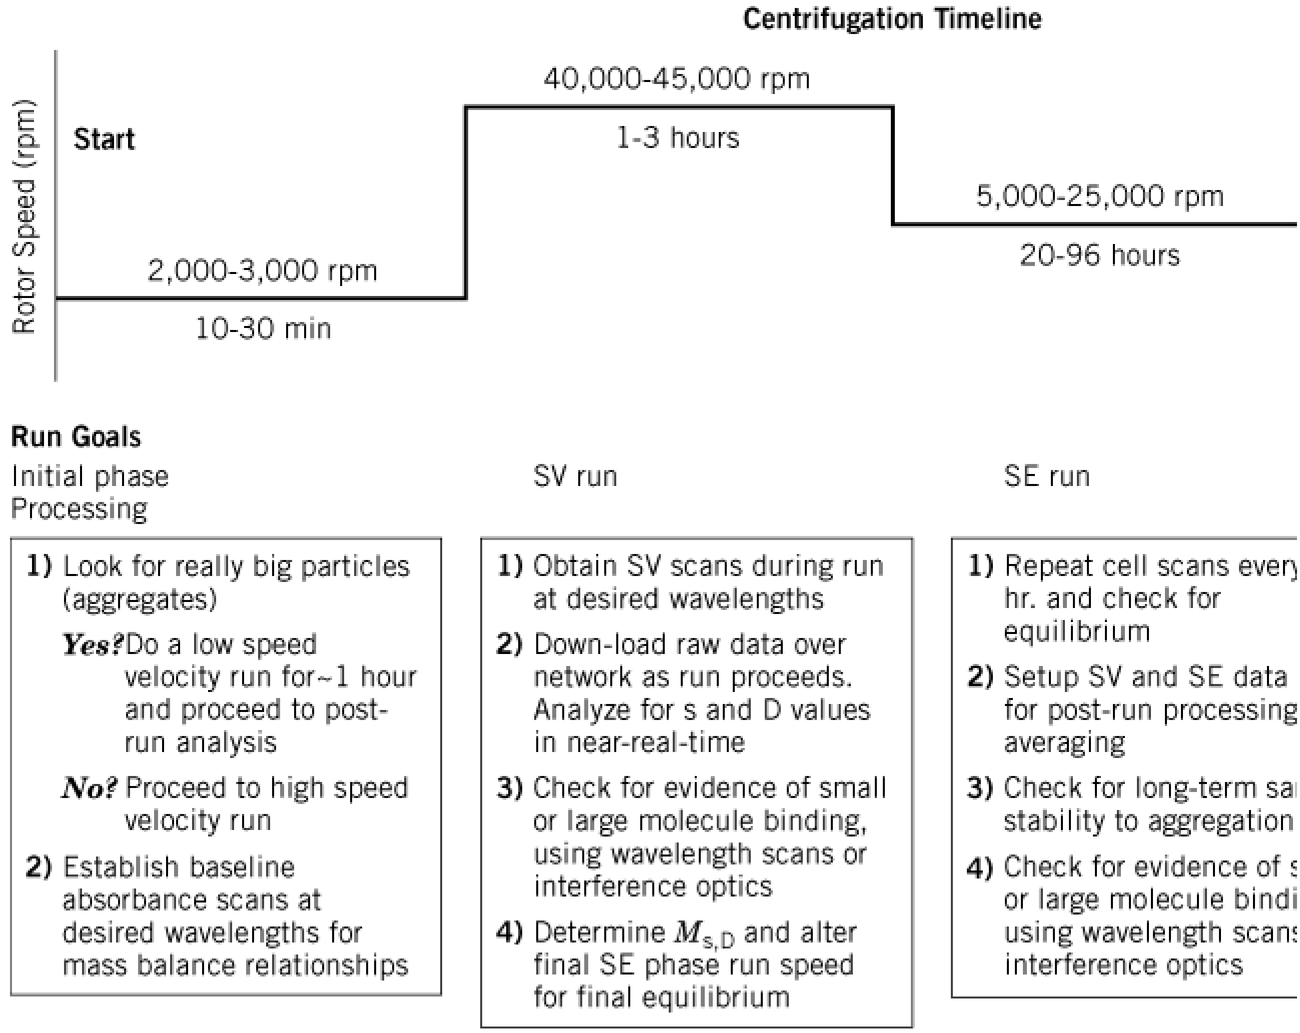
Analogy is a similarity caused by factors other than a common genetic ancestry. In general, analogy is a similarity arising by convergent evolution. Therefore, in contrast to homology, analogy between two traits of interest is not based on the sharing of a common ancestor. Originally, the term “analogy” was used mostly for morphological characters. For example, the wings of bats and insects are said to be analogous organs, as they perform the same function in different species, even though they do not show a common underlying plan of structure. It is obvious that the wings of bats and insects were not derived evolutionarily from the same organ in a common ancestor.

When the similarity between two different molecules is found at the level of **nucleotide sequences**, amino acid sequences, and the tertiary structure of proteins, it is important to know whether the similarity is homologous or analogous. In particular, characteristic patterns of amino acids (“amino acid sequence motifs”) and the tertiary structures of protein molecules may exhibit analogy rather than homology. In contrast, any sequence similarities of nucleotides and amino acids are explained mostly by homology, because the probability that the two sequences of interest are similar by chance can be computed easily and is usually extremely small.

Analytical Ultracentrifugation

Analytical ultracentrifugation experiments fall into two different categories, termed **sedimentation velocity** and **sedimentation equilibrium**. However, they are often employed sequentially on a given macromolecule under analysis (Fig. 1), and they yield related, complementary information about the solution behavior of a macromolecule that is of great interest for a variety reasons. The need may be simple, for example, to determine whether a macromolecule aggregates when prepared or stored in various ways, e.g., refrigerated, frozen, or lyophilized. On a much more complex level and much more important in the context of modern protein biochemistry and molecular biology is to detect and measure the interactions of macromolecules with themselves or with other molecules and to relate this to their functional roles. For these studies, the precise analysis of their behavior in solution is necessary. Finally, analytical ultracentrifugation plays an important role in medicine and industry. It is the reference method for analyzing the concentration-dependent solution behavior of recombinant proteins and other macromolecules employed in pharmaceutical/pharmacological research and in structure-based drug design (1).

Figure 1. Typical execution scheme for sedimentation velocity (SV) and sedimentation equilibrium (SE) runs.



Analytical ultracentrifugation differs from preparative centrifugation in several important respects. First and foremost as the name implies, it is an *analytical* technique. If carefully applied, it can give hydrodynamic information that is precise, accurate, and unobtainable by any other single method. The hydrodynamic parameters (**molecular weights** and sedimentation coefficients) obtained from analytical ultracentrifugation are absolute measurements because the technique is an absolute physical method in the strictest sense. It measures either the intensive or extensive physical properties of solutes directly and requires only knowledge of the rotational rate of the centrifuge rotor, the sample temperature, and the solution density and viscosity (which are extensive properties of the solute–solvent system).

Similarly, calculations of molecular properties from ultracentrifugation data are based on direct, first-principle analyses of solute behavior in solution. Unlike indirect methods, such as static light-scattering, the calculations in analyzing data from the analytical ultracentrifuge do not rely on comparison to a known standard. For example, in static light scattering the scattering behavior of a low molecular weight organic molecule (toluene, for example) is required to calibrate the instrument. Dynamic light scattering provides absolute diffusion coefficients, but the molecular weights estimated from the diffusion coefficients are indirect and depend upon the solution density, viscosity, etc. and on assumptions about molecular dimensions.

Another major difference between preparative centrifugation and analytical ultracentrifugation is that the latter is usually applied to highly purified solute samples. Although samples must be pure, analytical analyses usually require only small amounts of sample material, in the range of 10 to 1000 µg per sample. Finally, although analytical ultracentrifugation is inherently a nondestructive technique, it is not routine to recover or reuse samples that have been analyzed because analytical ultracentrifuge cells and rotors (Figs. 2 and 3), especially those that are most useful for analyzing numerous samples, are not designed for facile sample recovery. Although analytical ultracentrifugation was at one time a useful tool for evaluating the purity of certain biological macromolecules, its use as a simple tool for purity analysis has been superseded by a variety of other bioanalytical techniques. For example, inexpensive SDS-PAGE is routinely the technique of choice for analyzing protein purity during a protein separation protocol and for estimating the molecular weights of polypeptide chains present.

Figure 2. A four-hole analytical ultracentrifuge rotor and a vertically exploded view of the cell assembly with a double-sector, long-channel centerpiece. Sample and reference solutions for analysis (~400 to 500 µl) are introduced into the sealed centerpiece with an appropriate syringe system. Then the cell is placed in the rotor and subjected to centrifugation. Depending upon the analyses performed, it is possible after centrifugation to recover a portion of the sample using the same syringe system (figure courtesy of Beckman Instruments, by permission).

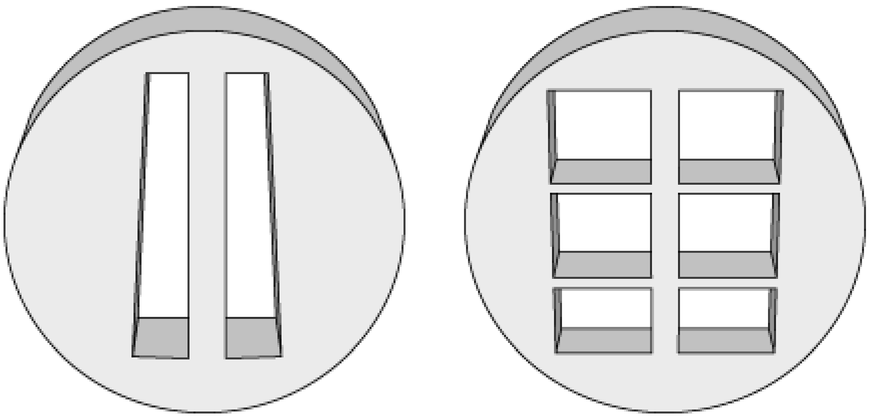
Figure 3. Illustrations of centerpieces used in analytical ultracentrifugation. Left, a long-column, double-sector centerpiece used for sedimentation velocity and equilibrium studies that require large data sets. Right, the multichannel centerpiece (or "Yphantis" centerpiece after its inventor, Dr. David Yphantis) used primarily for sedimentation equilibrium studies where analysis of a larger number of samples is desired.



The present (and likely future) value of analytical ultracentrifugation lies in its unmatched ability to provide direct information in two primary areas: (1) the extent to which an otherwise chemically pure sample of a macromolecular solute exhibits monodispersity or polydispersity and (2) the extent to which different chemically pure molecules interact. Because these two questions are fundamental to all areas of modern cellular and molecular biology and biochemistry, analytical ultracentrifugation remains a unique and extremely powerful biophysical tool.

1. The Modern Analytical Ultracentrifuge

The technique requires only small sample volumes, ~20 µl to ~500 µl depending upon the type of centerpiece employed (Figs. 2 and 3). A computer-controlled optical system detects the exact extent and position of the radial displacement of solute molecules at various times during the centrifugation run. Optical detection is accomplished by directly measuring the concentration of the solute as a function of radial position in the sample cell, either by its absorbance or by the change in refractive index, using Rayleigh interference optics. Like dual-beam optical spectroscopy, the technique is also differential in that it employs a sample solution to be measured and a reference solution used to "blank out" or "subtract" a signal background. The only modern, commercially available analytical ultracentrifuges are the XLA/XLI models manufactured by Beckman Instruments, which operate at speeds ranging from ~2,000 to ~50,000 rpm . The precise speed or speed range of operation for an experiment is determined by the type of measurement(s) to be made and depends on the size of the molecules being studied and on the type of sample cell centerpieces, centrifuge rotor, and the data collection system used.

The XLA/XLI analytical ultracentrifuges offer either absorbance-based optical detection (XLA, Fig. 4) or both absorbance and interference-based optical detection (XLI, Fig. 5). In addition to measuring the molecular weights and sedimentation coefficients of individual molecules, their distributions in samples can also be measured. The analytical ultracentrifuge can also be also used for direct determination of **ligand-binding** constants and stoichiometries. Further, when combined with other physical measurements, these instruments are useful for determining the diffusion coefficients and molecular shapes of macromolecules. Thus, changes in shape related to ligand binding or solvent perturbations can also be evaluated.

Figure 4. Absorbance-based optical system of the XLA analytical ultracentrifuge from Beckman Instruments. Light from a high intensity flash lamp passes along an optical tube to a computer-controlled toroidal diffraction grating, which selects the wavelength(s) of observation. Light at the selected wavelength, within the range ~200–800 nm , is focused on the sample cell in the rotor. Light passing through the sample is recorded by the radially tracking photomultiplier. Then the data are analyzed using specialized software on an associated computer (figure courtesy of Beckman Instruments, by permission).

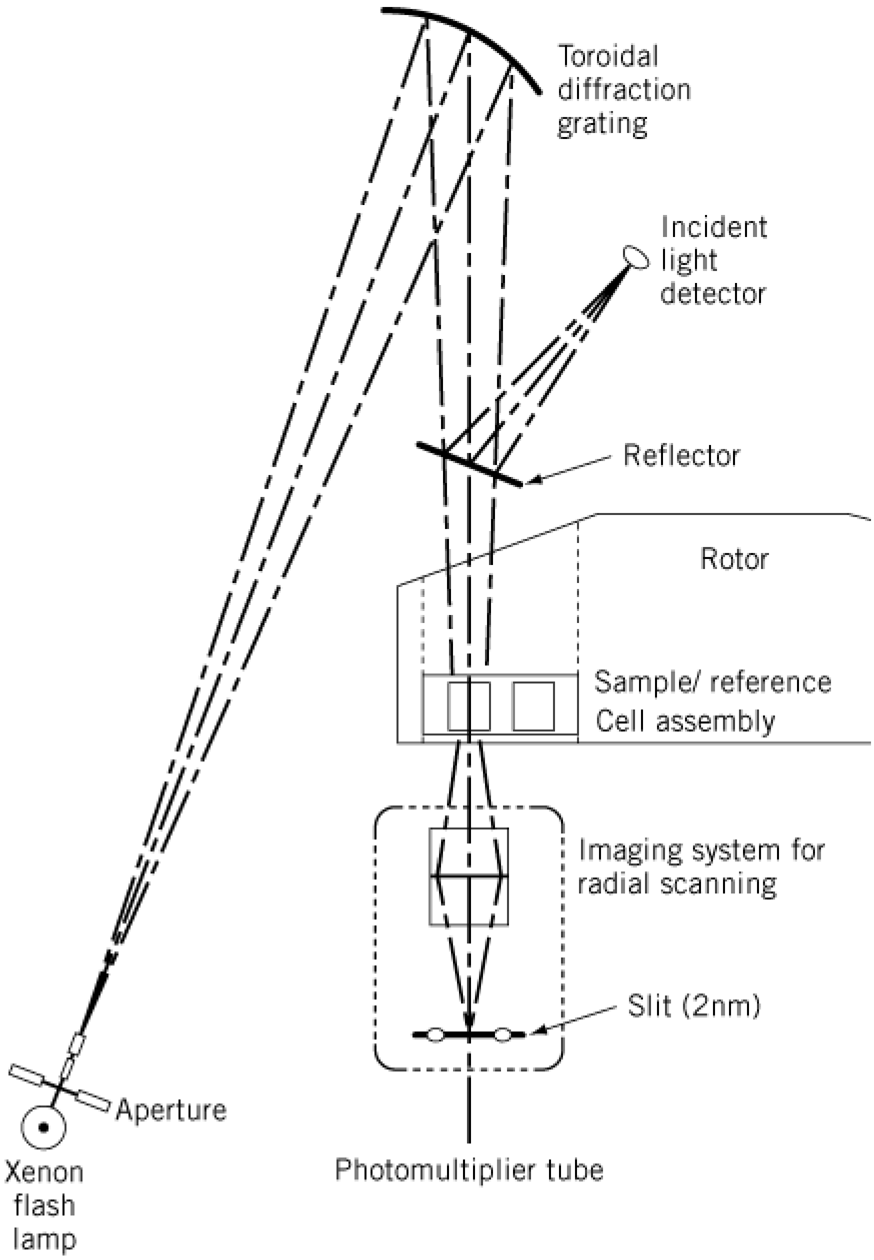


Figure 5. Interference and/or absorbance-based optical system of the XLI ultracentrifuge from Beckman Instruments. The absorbance-based optical system is outlined in Fig. 4. For interference measurements, a laser light source is attached to the absorbance optical tower, and an additional optical path and detector system is employed (lower right quadrant of figure). The interference system uses Rayleigh interference optics and a computer-controlled CCD camera detection system. Data are analyzed using specialized software on an associated computer. Using an eight-hole centrifuge rotor and centerpieces that hold three sample and reference solutions each, it is possible to analyze 21 samples in a single ultracentrifuge run (figure courtesy of Beckman Instruments, by permission).

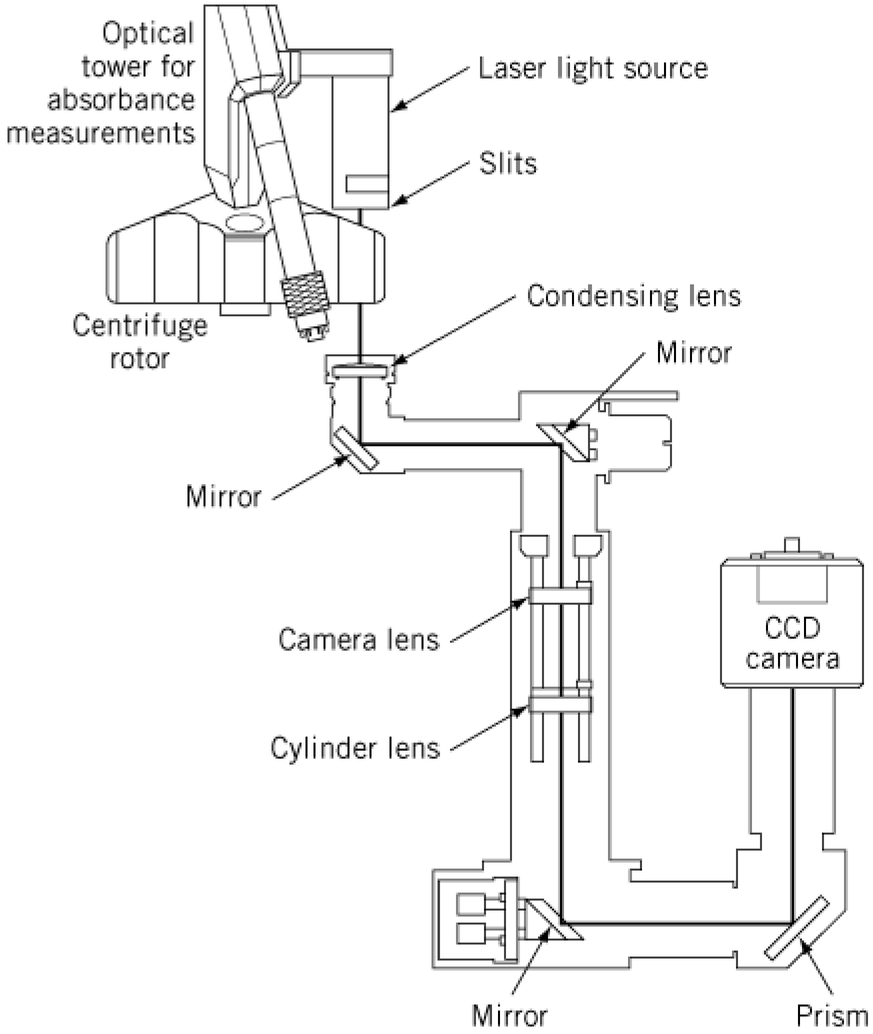

1.1. Choosing an Optical System for Measurements

Although it is often useful to employ both absorbance and optical interference measurements when examining a sample, some considerations make one type of measurement preferable to the other. The possible choices for various types of samples are outlined in Table 1. In addition to the general preferences for detecting various analytes, other important factors influence the choice of detection methods. The relative sensitivities and dynamic ranges of absorbance versus interference detection can be a consideration. The typical useful range for absorbance measurements in a sedimentation equilibrium centrifugation experiment for an "average" protein with an absorbance at 280 nm of 1.0 $(mg/ml)^{-1}(cm)^{-1}$ is in the range of ~10 µg/ml to ~4 mg/ml , when the measurements employ centerpieces with both standard (12 mm) and reduced (3 mm) path lengths. In **sedimentation velocity experiments** using absorbance detection at 280 nm, the practical low end of the concentration range is about 50 to 100 µg/ml. Sensitivity for proteins can be increased by using light with wavelengths in the range of 215 to 240 nm, where the protein peptide backbone absorbs and the absorbance of a protein is typically 3- to 10-fold greater, although this is technically more demanding. Alternatively, the protein may have a natural cofactor chromophore with a large extinction coefficient, or chemical modification can be used to introduce such a chromophore. Optical interference measurements have roughly the same absolute dynamic range as absorbance measurements, but they are routinely more useful in the mid-to-high concentration range, i.e., ~0.1 to ~10 mg/ml .

Table 1. General Preferences in Analytical Ultracentrifugation for Detecting Different Analytes

Analyte	Absorbance Detection	Interference Detection
Carbohydrates	Usually not useful unless solute has appreciable UV or visible absorbance properties	Usually the method of choice
Nucleic acids	Follow absorbance at ~260 nm	Possible, can be used at high analyte concentrations
Organic polymers	Usually not useful unless solute has appreciableUV or visible absorbance properties	Usually the method of choice
Polysaccharides	Usually not useful unless solute has appreciableUV or visible absorbance properties	Usually the method of choice
Proteins	Useful if protein contains Trp and/or Tyr residues, so that it absorbs at 280 nm	Useful if protein lacks Trp and Tyr residues

The selectivity of the detection technique can also be a factor in performing an experiment. The use of this approach is illustrated in Fig. 6 for examining the potential for interactions between the Alzheimer's disease beta-amyloid peptide and the serum C1Q component of the complement system, which other studies had suggested is a trigger for activating the complement cascade and for potential neuronal cell loss. In this work, a 5-kDa peptide was labeled with the chromophore *fluorescein*. Binding of the labeled peptide to a ~150 kDa antifluorescein antibody was used as a positive control to examine the potential for b-amyloid peptide to bind to C1q. The labeled peptide binds to the antibody as expected, but it does not bind to C1q.

Figure 6. Binding of a xanthene-labeled Alzheimer's b-amyloid peptide to an antifluorescein antibody but not to serum complement C1q, as analyzed at sedimentation equilibrium at low speed (5000 rpm). The fluorescein analog, xanthene, absorbs light at 510 nm (solid line), and the proteins absorb light at 280 nm (dotted line). Panel (**a**) shows the radial distributions of labeled peptide alone at 280 and 510 nm (no sedimentation). Panel (**b**) shows the labeled peptide sedimented in the presence of C1q, C1q tended to sediment, but the peptide did not. Panel (**c**) shows the control experiment where the labeled peptide was sedimented in the presence of an anti fluorescein antibody. The peptide binds to the antibody and sediments with a molecular weight equivalent to that of the antibody. These results demonstrate that the monomeric form of the amyloid peptide implicated in Alzheimer's disease is unlikely to bind to complement C1q and thus induce complement-mediated neural cell death (from Ref. 8, with permission).

In analytical ultracentrifugation, another important consideration is sample and reference solution buffer matching. If the solutions are poorly matched, the resulting data are usually poor, even with the extensive signal averaging employed with advanced detectors and software.

Interference detection measurements are based on the change in the refractive index of the solution caused by a solute, which is a function of its concentration. For these measurements, the system records the differential change in the refractive index of the sample versus the reference cell, as a function of radial position. The refractive index of a solution is a function of the mass of all solutes, not of their absorbance or molarity, and it is not possible to distinguish between different solutes. In fact, buffers and salts routinely contribute most of the change in refractive index because they are present in much higher concentrations than the protein. Therefore, interference measurements are extremely sensitive to small mismatches in refractive index between the buffers of the sample and reference solutions. As a result, samples analyzed by interference measurements routinely require exhaustive dialysis. With appropriate sample/reference solution preparation, it is possible to achieve protein concentrations of >100 mg/ml routinely. The only effective upper limit is the intrinsic solubility of the protein itself under the conditions of analysis (rotor velocity, temperature, pH, etc., which can be easily changed). For both absorbance and interference measurements, the lower limit on size is a molecular weight of ~200 Da, and the upper limit is effectively about 30×10^6 Da.

Absorbance optics permit the differential absorbance of two molecules to be employed to distinguish their sedimentation properties (as in Fig. 6). This is not possible with interference optics, however, so it is not possible to distinguish between two different solute molecules with similar masses.

Another feature of interference measurements is their use in a differential mode. Because the interference optical system is double-beam, differential centrifugation experiments can be performed where the protein is present in both cells and a small ligand only in one. Consequently, the signal from the protein is blanked out, leaving only the signal from the ligand. A ligand that binds to the protein (even weakly) is displaced along the radial axis of centrifugal force in the centrifuge cell. Because the protein signal is blanked out, the only change in refractive index observed along the radial (force) axis is caused by the change in radial distribution of the ligand (2, 3).

Absorbance measurements generally have less stringent referencing requirements. In practice it is necessary only that the reference buffer has an absorbance at the wavelength of analysis at which it is electronically possible for the instrument to perform the desired subtraction. Therefore, absorbance measurements are relatively more forgiving for buffer matching in sample/reference preparation. They are not without other intrinsic problems, however, in particular those related to the absorbance of buffers and solute extinction coefficients. Most biologically useful buffers and common solution additives have some characteristic absorbance in the wavelengths used to analyze proteins in solution. Because of the high total sample/reference solution absorbance, it may be difficult or impossible to make the requisite difference absorbance measurements. However, under these conditions protein samples that have been carefully prepared by dialysis but are optically opaque at UV wavelengths, may be routinely analyzed by interference rather than absorbance detection (as above). Finally, one interesting drawback to absorbance measurements, which is routinely neglected in sedimentation equilibrium analyses (in particular), is that the analyte solution extinction coefficient(s) may vary with the composition of the solution, so that its absorbance can change during a centrifugation run. Homo- or heteroassociation processes may alter the protein extinction coefficients, which contributes nonlinear perturbations to the total absorbance. Thus careful analyses require that the radial distributions of molecules undergoing such associations be measured at several wavelengths. Interference measurements, in comparison, are insensitive to these alterations in solute extinction coefficient.

1.2. Monodispersity, Polydispersity, Paucidispersity, and Nonideality

A solute is said to be monodisperse if it exhibits behavior characteristic of a single species in solution. If the solute undergoes indefinite self-association under the solution conditions examined, it is said to exhibit *polydispersity*. If a sample of solute molecules is composed of a mixture of a limited number of species with different chemical compositions, its solution behavior is *poly*disperse, for example, with respect to its molecular weight distribution, but the sample is termed *pauci*disperse. The differences between various types of solute behavior in solution are outlined in Table 2. It is often useful to define molecular weight distributions in terms of the molecular weight averages M_n, M_w, and M_z, which are the number-, weight-, and z-averages, respectively (Table 3). They are valuable for estimating sample homogeneity. A pure solute gives identical values of M_n, M_w, and M_z. Different methods of measurement give different averages.

Table 2. Summary of Types of Solute Hydrodynamic Behavior

Hydrodynamic Characteristic	Example	Sedimentation Velocity Behavior	Sedimentation Equilibrium Behavior	Consequences
Monodisperse	Solute is pure, a single spherelike chemical entity that does not undergo self-interaction	Velocity profiles fit a single-term Lamm equation (see Sedimentation Velocity Centrifugation), and the single sedimenting boundary gives unique values of *s* and *D* during run	Data fit a single exponential term at all rotor speeds and solute concentrations	Molecular weight, *s*, and *D* have minimal or no dependencies on concentration; solute solution behavior is “ideal” or nearly so
Paucidisperse	Sample comprises a small number of chemically distinct solutes, which may or may not interact	Velocity profiles fit a multiple-term Lamm equation, and sedimenting boundaries give multiple values of *s* and *D* during run	Data do not fit a single exponential term at all rotor speeds and solute concentrations	Molecular weight, *s*, and *D* depend on concentration
		It may be possible to resolve separate sedimenting g*	Chances for extracting binding constants for a	

		(s) distributions	macromolecular assembly are usually severely diminished	
Polydisperse	Sample comprises multiple solutes, which may or may not interact	Velocity profiles fit a multiple-term Lamm equation, and sedimenting boundaries give multiple values of s and D during run	Data do not fit a single exponential term at all rotor speeds and solute concentrations	Molecular weight, s, and D depend on concentration, solute solution behavior is usually termed "nonideal"
	Sample is pure, a single spherelike chemical entity that aggregates	It may be possible to resolve separate sedimenting $g^*(s)$ distributions	Depending upon nature of self-association, it may be possible to extract binding constants for a macromolecular assembly process	
Nonideal	Sample comprises a single, highly asymmetric chemical entity that undergoes self-interaction	Velocity profiles fit a multiple-term Lamm equation, and sedimenting boundaries give multiple values of s and D during run	Data exhibit skewed behavior and cannot be fit by conventional analyses	s and D depend on concentration, solute solution behavior is "nonideal"
		It may be possible to resolve separate sedimenting $g^*(s)$ distributions	Usually not possible to extract binding constants for a macromolecular assembly process	

Table 3. Molecular Weight Averages

Type	Equation[a]	Methods to Determine
M_n, number-average	$\frac{\sum_i c_i}{\sum_i (c_i/M_i)}$	Osmotic pressure, sedimentation equilibrium

M_w, weight-average	$\frac{\sum_i C_i M_i}{\sum_i C_i}$	Sedimentation equilibrium; light scattering
M_z, z-average	$\frac{\sum_i C_i M_i^2}{\sum_i C_i M_i}$	Sedimentation equilibrium

[a] C_i is the concentration, and M_i is the molecular weight of the *i*th species in weight per unit volume.

Nonideality is typically observed at high concentrations of a solute and is caused by the effects of excluded volume (versus actual molecular volume) on solute hydrodynamic behavior. The effects of nonideality are small for spherical molecules, because their excluded and actual volumes are essentially equivalent. With such molecules, their hydrodynamic behavior varies in direct proportion to the size of the molecular sphere. When molecules are rodlike, nonideality becomes more pronounced. As the concentration increases, the effect is nonlinear and it is significantly worse at greater ratios of molecular length to width. Intermolecular interactions are another cause of nonideality. For example, electrostatic charge–charge repulsion can be significant at high solute concentrations and low solution ionic strengths. Experimentally, such charge–charge effects are usually reduced by increasing the solution ionic strength. The role of nonideality in sample behavior is identified by performing a series of studies at different solute concentrations and extrapolating the measured hydrodynamic parameters to infinite dilution.

1.3. Other Physical Measurements Necessary to Analyze Ultracentrifuge Data

Calculating results from sedimentation equilibrium and velocity experiments requires several additional physical measurements of the solute and of the solutions employed. To calculate the anhydrous weight-average molecular weight, the density of the solvent and the partial specific volume of the solute must be known.

There are typically two ways to obtain these values. They can be measured with an ultrasonic density meter or pyncnometer or estimated from various tables if the specific buffer and solute chemical compositions are known. For a protein, the approximate partial specific volume is calculated from its amino acid composition (4, 5). The density of a buffer of exact composition can be estimated from an appropriate reference table (for example, from the *CRC Handbook of Chemistry and Physics*). Of the two direct methods for determining solvent densities and solute partial specific volumes, ultrasonic densitometry is preferred because it requires less solute for measurements. It is good experimental practice to measure both the solvent density and the partial specific volume of a solute sample of interest. In the case of proteins, this is particularly true if the studies analyze the tendencies of the proteins to undergo association or conformational changes when bound to a ligand. Such interactions are often accompanied by significant changes in the volume of the protein that are unaccounted for if the specific volumes of the individual amino acids comprising the protein are used in the calculation (6, 7). Additionally, if the protein contains carbohydrate (a **glycoprotein**, for example) or bound lipid (a **lipoprotein**), estimates from reference tables can, at best, be charitably characterized as a guess.

The final physical measurement necessary is the measurement of the solution viscosity . This value can be estimated from tables (5) (as for buffer density), but again it is good experimental practice to measure the solution viscosity directly with a simple, commercially available viscometer.

Androgenesis

Androgenesis is the mode of **reproduction** of **eukaryotes** where both sets of chromosomes of the offspring are of paternal origin. In higher **plants**, androgenesis can be obtained either *in vitro* with anther cultures or with isolated pollen grains. In animals, androgenesis can be obtained only experimentally. A technique similar to that described in the entry **Digynism** can be used, that of pronuclear transplantation: the male **pronucleus** is removed from a fertilized egg and injected into another egg, from which the female pronucleus is then removed, so that now the zygote contains two paternally derived sets of chromosomes.

Rarely, diandric embryos arise spontaneously when a fertilized egg loses its female pronucleus. These embryos are not viable. In humans, their implantation results in a uterine tumor called a hydatiform mole. In spontaneous abortions, diandric embryos are a minority among triploid conceptuses (1).

Diandric embryos are useful for studies of genetic imprinting.

Aneuploidy

An aneuploid cell has one or more complete chromosomes either in excess or less than the normal haploid, **diploid**, or polyploid number characteristic of the species from which the cell derives. In other words, the chromosome number is not a multiple of the haploid cell number of chromosome.

Fluorescence in situ hybridization (FISH) with chromosome-specific probes has been successfully applied to rapidly detect numerical aberrations in metaphase and interphase amniotic cells (1). Aneuploidy arises primarily by the process of **nondisjunction**, probably caused by nonrandom premature centromere division in the first meiotic division of maternal **meiosis**. This varies among chromosomes, however, and a significant proportion of paternal and/or meiosis II errors have been described.

The presence of kinetochores or kinetochore proteins (detected immunochemically) in the **micronuclei** of binucleated cells indicates a cell with a high probability for aneuploidy following **cytokinesis** (2, 3). The relationship between Y-Chromosome aneuploidy in male humans, the number of micronuclei, the status of kinetochore proteins, and aging has been reviewed (4).

Angiogenin

Angiogenin (Ang) is one of a group of proteins that are potent inducers of angiogenesis, the process by which new blood vessels are formed (see Epidermal Growth Factor, Fibroblast Growth Factors, Transforming Growth Factors, Tumor Necrosis Factor). It was first isolated from medium conditioned by human adenocarcinoma (HT-29) cells based on the premise that tumor cells must secrete angiogenic factors in order to attract blood vessels so that they can grow. Ang was identified by its ability to stimulate angiogenesis on the chorioallantois, the outer membrane that surrounds the embryo in fertilized chicken eggs. Subsequently, it was shown to be present in normal human plasma, bovine milk, and bovine and mouse serum. It is a 14-kDa basic protein that has 33%

sequence identity to bovine pancreatic ribonuclease A and is one of several members of the RNase A superfamily of proteins that have unusual biological activities. It is the only angiogenic protein that is a ribonuclease, and the only ribonuclease that is angiogenic. It is an important protein that may be involved in wound healing, is critical for the growth of solid tumors, and has become a target for the treatment of metastatic cancer and other angiogenesis-related diseases. For recent reviews on Ang see Refs. 1 and 2.

1. Protein Chemistry

Human Ang is a single polypeptide chain of 123 amino-acid residues and three disulfide bonds (Fig. 1). All of the main components of the catalytic site (see Active Site) of RNase A are present in Ang, and thus it is not surprising that it has enzymatic activity toward RNA and dinucleotides and which, like that of RNase A, is limited to cleavage after pyrimidines. What is surprising is that this activity is four to six orders of magnitude less than that of RNase A. Nevertheless, it is essential for angiogenic activity. Part of the reason for such low activity was revealed by X-ray crystallography (Fig. 2). The structure of Ang is closely similar to that of RNase A, but with two major differences. On the one hand, the pyrimidine-binding (B_1) component of the catalytic active site was found to be occluded by the side chain of Gln117. On the other, the second (B_2) component of this site is structurally quite different from that in RNase A. In the latter, it is part of an eight-residue disulfide loop that is found in all of the 55 known mammalian members of the ribonuclease superfamily but missing in all of the nine known Ang. Instead, it is replaced by a sequence of residues that interacts with a cell-surface binding protein (see text below). Despite these likely impediments to substrate binding, Ang does catalyze RNA hydrolysis, albeit very weakly.

Figure 1. Amino acid sequence of human angiogenin. The active site histidine (H) and lysine (K) residues are in bold, and the disulfide bridges between cysteine (C) residues are indicated by dotted lines.

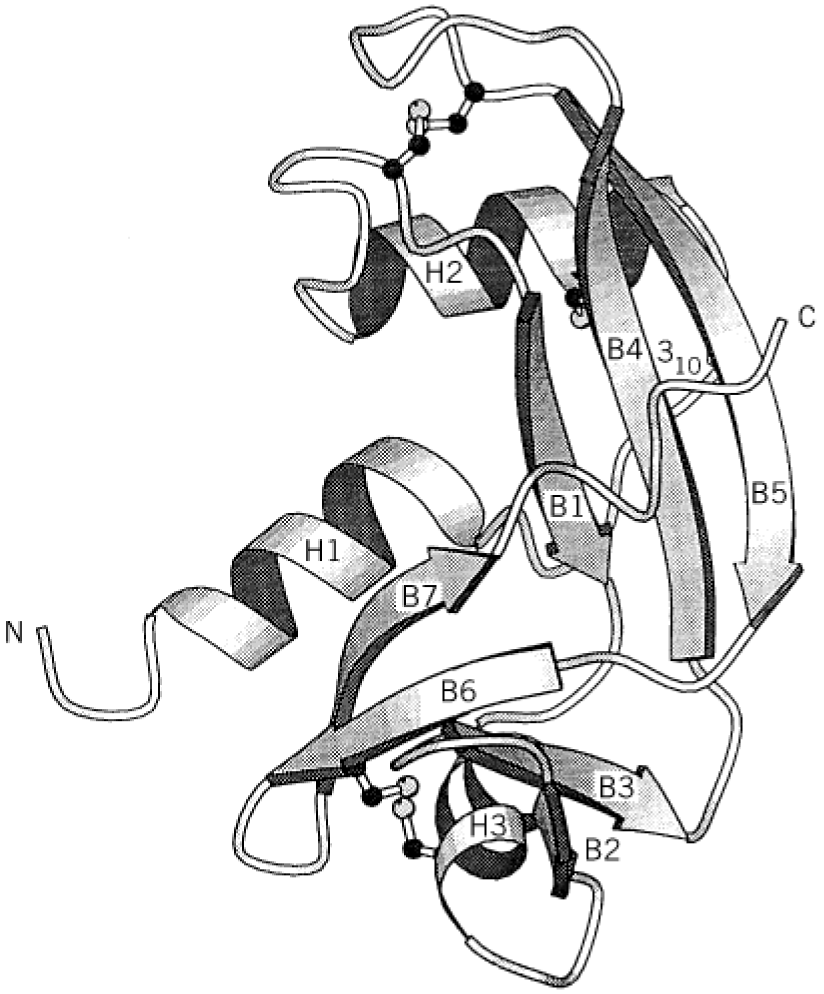
CKLHGGSPWP PCQYRATAGF RNVVVACENG LPV**H**LDQSIF

RRP

Figure 2. The polypeptide fold for human angiogenin drawn with the program MOLSCRIPT. (From Ref. 9, with permission.)



It has been suggested that through evolution Ang was endowed with a unique structure that attenuates its catalytic potency toward RNA in general, but that undergoes a conformational change when Ang is brought together with its specific, yet unidentified, substrate (3). Whether this structural rearrangement activates Ang or merely ensures its specificity is unknown. It may be that the very low activity of Ang is perfectly adequate for carrying out its unique biological function. It should be noted, however, that Ang is an effective inhibitor of cell-free protein synthesis by virtue of its ability to cleave 18S rRNA when this substrate is present in the intact ribosome, and in fact is an even more effective inhibitor than RNase A. When isolated 18S RNA is used as substrate, the activity of Ang is markedly decreased relative to RNase A. This suggests that the activity of Ang depends on the environment of its substrate.

2. Molecular Biology

The human *Ang* gene, localized to chromosome band 14q11, is present as a single copy per haploid genome, with no **introns** in the protein-coding region (1, 2). The gene has been cloned and expressed in both *Escherichia coli* and BHK cells, and well over 40 Ang variants have been prepared in order to explore various aspects of its structure–function relationships. Thus, site-directed mutagenesis of His13, His114, or Lys40 (the equivalents of the catalytic residues His12, His119, and Lys41 in RNase A) abolishes *both* the ribonucleolytic and the angiogenic activity of Ang. Although angiogenically inactive, these variants block the angiogenic activity of native angiogenin. By contrast, an Ang variant in which residues 58 to 70 were replaced by residues 59 to 73 of RNase A had 300- to 600-fold more activity toward RNA substrates but was angiogenically inactive. Thus, ribonuclease activity is essential but not sufficient for angiogenic activity. Moreover, this variant, unlike the active site variants, was unable to block the angiogenic activity of native Ang, suggesting that the mutated region of the protein is involved in cell binding, probably interacting with a cell-surface binding protein. Recall that in RNase A this region of the molecule constitutes the B_2 component of the substrate binding site. In Ang it apparently has evolved into a cell binding site, with loss of catalytic activity but concomitant acquisition of a new biological potential.

3. Cell Biology

Blood vessels are composed of specialized cells known as endothelial cells. It is not surprising, given its function, that ^{125}I-labeled Ang binds to endothelial cells, and it does so in a manner that is characteristic of receptor binding—that is, time- and concentration-dependent, reversible, saturable, and competitive with unlabeled Ang. Yet Ang is a plasma protein (200 to 400 mg/L), and obviously it does not continuously stimulate new blood vessel formation as it circulates through the vasculature. This is explained by the fact that the angiogenin **receptor** is only expressed in sparsely cultured endothelial cells, not in confluent cells (as exist in blood vessels) (4). The receptor, not yet fully characterized, is a 170-kDa transmembrane protein whose presence on the cell surface correlates with the mitogenic activity of Ang. When the receptor is present, the cells respond to Ang by both increased thymidine uptake and cell proliferation. Confluent cells lack the receptor and, hence, do not respond this way to Ang.

Experiments with protein cross-linking reagents have demonstrated that Ang also interacts with a 42-kDa endothelial cell-surface protein that is a member of the actin family (1, 2). On binding Ang, it dissociates from the cell surface as an Ang–actin complex. Remarkably, this complex activates tissue plasminogen activator (tPA) and thus generates plasmin (see Plasminogen). This, in turn, stimulates cell-associated proteolytic activity to degrade the extracellular matrix and thereby facilitates cell migration, an essential feature of the angiogenesis process. Ang also acts as a cell adhesion molecule and, when coated on a plastic surface, mediates the binding of endothelial and tumor cells. *In vivo* it may help direct migrating blood vessels toward Ang-secreting tumor cells.

Addition of Ang to cultured endothelial cells stimulates a transient increase in cellular **diacylglycerol**, seemingly the result of an Ang-induced activation of phospholipase C, as well as an increase in prostacyclin secretion owing to activation of phospholipase A_2. Interpretation of these second messenger responses has not been possible, thus far, largely because the systems are complex and may only be stimulated indirectly by Ang.

4. Nuclear Translocation

Angiogenin undergoes endocytosis by sparsely cultured endothelial cells and is rapidly translocated from the cell surface to the nucleus, where it accumulates in the nucleolus (1, 2). This process is receptor-mediated and regulated by a nuclear localization signal (see Nuclear Import, Export) that involves three basic residues, Arg31-Arg32-Arg33, of Ang. This signal is essential for angiogenesis and suggests that the substrate for the ribonucleolytic activity of Ang is located in the nucleolus, a highly specialized region where biogenesis of ribosomes takes place (see Nucleolus and Ribosomes). One possibility is that the ribonucleolytic activity of Ang enhances the transcription and processing of rRNA. Two enzymatically inactive variants of angiogenin whose cell-binding site is intact also accumulate in the nucleolus when added to endothelial cells, but they are angiogenically inactive. This suggests that not only is nuclear localization essential for the biological activity of Ang but, in addition, the translocated protein must be enzymatically active. This has been confirmed by recent studies in which a DNA aptamer (an oligonucleotide that binds fairly tightly to Ang) that inhibits both the enzymatic and angiogenic activities of Ang is also translocated to nucleus, but only when added to endothelial cells together with Ang. The inhibitor and the protein accumulate in the nucleus in a 1:1 stoichiometric ratio (5).

5. Mechanism of Action

Although Ang may well be involved in a variety of angiogenesis-related situations, its mechanism of action is likely to be quite similar for each of them; hence it is only summarized here in the context of tumor-induced angiogenesis. All tumor cells that have been examined have been found to secrete Ang, and in at least one case, pancreatic cancer, the aggressiveness of the tumor is related to the amount of angiogenin produced (6). Ang secreted by tumor cells migrates through the extracellular matrix until it reaches an endothelial cell. There it combines with cell-surface actin and dissociates as a complex that stimulates the activity of tPA and the formation of plasmin. Degradation of the extracellular matrix—for example, by plasmin-activated matrix metalloproteinases—may stimulate a few endothelial cells to migrate, and this could trigger expression of the Ang receptor. Binding of Ang to the receptor would then, on the one hand, initiate a second-messenger response, perhaps through activation of the above-mentioned phospholipases, and, on the other, promote endocytosis and nuclear localization of Ang. The ribonucleolytic action of Ang within the nucleolus would, together with signals generated via the second messengers, activate processes leading to cell proliferation. The proliferating endothelial cells would migrate through the now degraded extracellular matrix toward the tumor cell from which the Ang was released. The cell-adhesion properties of Ang may be important for ensuring cell migration in the proper direction. At present, this view of the mode of action of Ang is largely speculative, particularly because nothing is known about the events that occur within the nucleus and lead to cell division. Nevertheless, it summarizes current thinking and is a useful basis for further investigation.

6. Tumor Biology

The levels of Ang and its messenger RNA are increased in the tissues and cells of patients with various types of cancers, indicative of an *in vivo* role for Ang in the process of tumor angiogenesis. This being the case, anti-angiogenin agents could have potential importance in the treatment of cancer and other angiogenesis-related diseases. The most potent inhibitor of Ang is a 50-kDa protein originally isolated from placenta as an inhibitor of RNase A, hence known as placental ribonuclease inhibitor (RI) (1, 2). It inhibits Ang with a K_i of 0.7 fM, one of the strongest protein–protein interactions known, and is 60-fold stronger than its inhibition of RNase A. Unfortunately, RI is evidently unstable in extracellular fluids and has not been found to be effective in treating tumors in laboratory animals.

Monoclonal antibodies raised against Ang have been used to treat athymic mice injected with HT-29 colon carcinoma cells, and they reduced the incidence of tumors by up to 65%. Similar results have been observed with other types of tumors, and when used in conjunction with conventional therapeutic agents, a synergistic effect was seen (2). Actin was also tested for its anti-tumor activity, and it too was capable of preventing tumor growth in more than 60% of treated animals. It should be noted that anti-angiogenin agents do not affect the growth of already-established tumors. They are only effective when administered to animals at the same time as the tumor cells. They are thought to act by specific extracellular inactivation of tumor-secreted Ang and the consequent inhibition of tumor angiogenesis. These experiments are important in that they provide clear evidence of a crucial role for angiogenin in the early stages of development of these tumors.

7. Other Biological Properties

One of the major complications associated with regular hemodialysis is the increased morbidity and mortality arising from infections. This has been attributed to dysfunction of polymorphonuclear leukocytes. Indeed, a number of compounds have been isolated from uremic serum and shown to inhibit the biological activity of these white cells. One of these is an inhibitor of leukocyte degranulation that turns out to be Ang (7). Nanomolar concentrations of Ang inhibit both spontaneous and peptide-stimulated degranulation by 60% and 30%, respectively. However, Ang has no other effect on the cellular responses of polymorphonuclear leukocytes, such as chemotaxis, phagocytosis or their peptide-stimulated oxidative respiratory burst.

Ang has also been reported to suppress significantly the proliferation of human lymphocytes stimulated by a mixed-lymphocyte culture or by phytohemagglutinin or concanavalin A (8). A maximal immunosuppressive effect was seen at an Ang dose of 50 to 100 mg/mL. It was thought that this effect might synergize with the effect of Ang on neovascularization of tumors and thereby contribute to tumor development.

8. Conclusions

Ang is now recognized as a pleiotropic molecule capable of inducing several intra- and extracellular activities. It induces most of the individual events in the process of angiogenesis including binding to endothelial cells, stimulating second messengers, mediating cell adhesion, activating cell-associated proteinases, inducing cell invasion, stimulating DNA synthesis and cell proliferation, and organizing the formation of tubular structures from cultured endothelial cells. Characterization of its cellular receptors, elucidation of its mechanism of nuclear translocation, identification of its intranucleolar target substrate, and understanding how these events result in cellular proliferation and blood vessel formation will provide important and novel information that can be utilized for either promoting or inhibiting angiogenesis for therapeutic purposes.

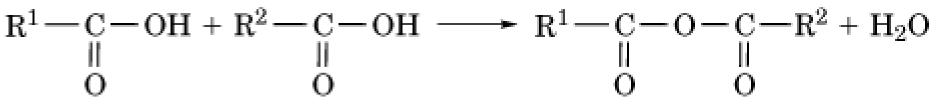
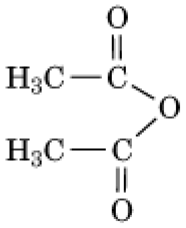
Anhydrides

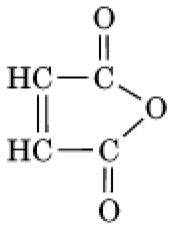
"Anhydride" means "without water," and many anhydrides are present in nature. Anhydrides are easily hydrated in the presence of water to acids or bases. Inorganic anhydrides include SO_3, P_2O_5, CaO, Na_2O, etc. Acid anhydrides are the most important anhydrides in biochemistry. An acid anhydride [I] is formed by eliminating a molecule of water from two acids (Scheme 1):



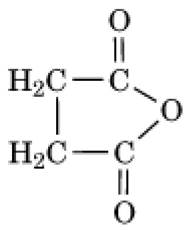
[I] Carboxylic acid anhydride



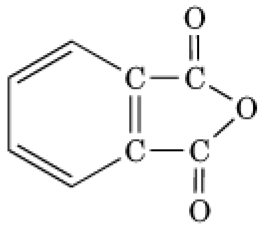
[II] Acetic anhydride



[III] Maleic anhydride



[IV] Succinic anhydride



[V] Phthalic anhydride

Adding a molecule of water reverses the reaction. Practically, a carboxylic acid anhydride is prepared by the nucleophilic displacement of chloride ion from acyl chlorides by carboxylate ion.

Acid anhydrides are reactive and are good acylating agents. They react with water to yield acids, with amino groups to yield amides, and with alcohols to yield esters. Acid anhydrides are utilized as reactive intermediates in organic syntheses, such as peptide synthesis, and sometimes as **enzyme-substrate** intermediates. Acid anhydrides are unstable and therefore have large standard **free energies** of hydrolysis. The two terminal phosphate linkages in ATP are anhydride linkages, and acid anhydrides play important roles in bioenergetics (see Adenylate Charge). Acid anhydrides are widely employed for chemical modification of proteins, particularly of amino groups. The acetylation reaction by an acid anhydride with amino groups in a protein proceeds so easily that this reaction is suitable for the **radiolabeling** of a protein with a radioisotope-labeled acid anhydride (1). Acetic anhydride [II], maleic anhydride [III], and succinic anhydride [IV] are frequently employed in chemical reactions and chemical modifications of proteins. Phthalic anhydride [V] is an aromatic anhydride and is a good leaving group.

1. Acetic Anhydride

Acetic anhydride is the most important acid anhydride. Its boiling point is 139.6°C, and it has a characteristic penetrating odor. It is widely employed in organic syntheses. It is used to introduce the acetate group into organic compounds and is called an acetylating agent. To acetyle amino groups in a protein (2), prepare a protein solution (2 to 10%, w/v) in half-saturated sodium acetate. Over a period of 1 h at 0°C, add, in five equal portions, a weight of acetic anhydride equal to that of the protein, and continue stirring for an additional hour.

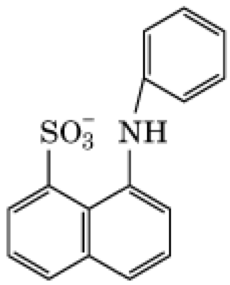
8-Anilinonaphthalene-1-Sulfonic Acid

8-Anilinonaphthalene-1-sulfonic acid (ANS) (Fig. 1) and its dimer, 1,1′-bis(4-anilino-5-naphthalenesulfonic acid) (bis ANS) are two widely used "**hydrophobic**" probes in **fluorescence** studies of proteins and membranes (1). These dyes are minimally fluorescent in polar environments, such as aqueous solutions, but their fluorescent emission is dramatically increased in nonpolar environments. An increase in quantum yield (intensity) and a blue shift in the wavelength of maximum emission (l_{max}) is observed when binding to macromolecules.

Figure 1. The structure of 8-anilinonaphthalene-1-sulfonic acid (ANS).



The most common uses of ANS (and bis-ANS) are (1) to monitor conformational changes in proteins (2, 3); (2) to follow the kinetics of **protein folding** and unfolding (4-6); (3) to detect and characterize partially folded intermediates of proteins (both transient and equilibrium) (7, 8); (4) to measure changes in membrane properties (9, 10); (5) to detect the presence of exposed hydrophobic accessible surfaces (11); and (6) to study **ligand binding** through displacement assays (12, 13). Photoincorporation of bis-ANS has been used to locate solvent-exposed hydrophobic regions in proteins (14) and more specifically (1) to investigate **virus** capsid structure and assembly (15, 16); (2) to monitor tubulin assembly and interaction with drugs (17) because bis-ANS specifically inhibits assembly of tubulin (18); (3) to measure distances via fluorescent energy transfer from tryptophan residues to bound ANS (17, 19); (4) to study **enzyme**–substrate interactions (20), including **nucleotide** binding (21); and (5) as a sensitive staining method for proteins in SDS-PAGE (22). ANS has been used to detect conformational changes in a wide variety of functional proteins during ligand binding (ranging from small molecules to DNA) (13, 23).

The advantages of ANS as a probe reflect the simplicity of fluorescence experiments and the sensitivity of ANS to its immediate environment. Although most commonly used in the fluorescent steady-state mode, it has also been used in more complex experiments (6, 25). The **absorbance** spectrum of ANS has maxima at ~270 nm and in the 345 to 380 nm range. The fluorescent emission spectrum is very sensitive to the environment and has a maximum of ~520 nm in water, which becomes progressively blue-shifted with decreasing polarity and reaches 464 nm in very nonpolar environments. A corresponding change occurs in the fluorescent lifetime from ~0.25 ns in water to ~15 ns in hydrophobic environments. The overlap between ANS excitation and tryptophan emission in the vicinity of 350 nm provides a useful donor/acceptor energy transfer system. Although the properties of ANS and bis-ANS are similar, the dimer has substantially higher affinity for many protein sites (26).

It is commonly assumed that ANS and bis-ANS bind to proteins and membranes by hydrophobic interactions mediated by the two aromatic rings, although there is little direct data (such as X-ray crystallography or NMR structures) to support this hypothesis. These dyes are anions over most of the commonly used pH range and electrostatic interactions are also important (possibly even critical) in ANS binding to proteins and membranes (27).

The applications of ANS to biomembrane studies have been summarized (24) and are not presented in any depth here. ANS binds to membranes in the vicinity of the phospholipid polar headgroups. The nonpolar part of the ANS molecule is directed toward the region of the fatty acid side chains, but the ANS does not penetrate very far into the nonpolar region of the bilayer. The binding is very sensitive to the nature of the phospholipids and to the presence of other membrane components, such as cholesterol.

For proteins, it is likely that only those ANS molecules that bind in hydrophobic regions exhibit the characteristic strong fluorescence. The remaining ANS molecules are bound to cationic sites exposed to aqueous solvent and hence are quenched (28). The thermodynamics of ANS binding to a protein have been determined: the binding is enthalpically driven at all temperatures and entropically opposed at temperatures greater than 14°C (27). The self-association of ANS and bis-ANS in water correlates with their tendency to form complexes with proteins (29). Thus care must be taken, especially when working at low pH and high ANS concentrations, to avoid ANS aggregation.

It has been recognized for some time that ANS and bis-ANS are excellent probes for partially folded intermediate states of proteins, such as the molten globule (7-30). Because the dyes do not normally bind significantly to the native states of most proteins nor to the fully **unfolded** states, they are widely used as a diagnostic for the presence of partially folded intermediates. However, ANS and bis-ANS do bind to some native proteins, usually to a specific site, e.g., the heme-binding site in apo-**myoglobin** (31). The predilection of ANS for nonnative conformations has been useful in investigating designed proteins to determine whether they have a rigid, tightly packed core, or are more like a molten globule (32), and in studies to determine the conformational state of substrate proteins interacting with molecular chaperones (33).

Fluorescent changes that correspond to binding and release of ANS during protein folding are frequently used to characterize the kinetics of folding, especially the buildup and decay of transient intermediates (34-36). Differences in partially folded intermediate conformations of proteins are distinguished by differences in the properties of bound ANS (5, 37).

The interpretation of results from ANS probe experiments is not without hazards, in part because the dyes perturb the system under investigation. For example, in experiments to monitor the kinetics of protein folding, the presence of ANS or bis-ANS and their strong affinity for transient intermediates significantly perturb the kinetics of folding (35). Similarly, it is customarily assumed that if ANS or bis-ANS is added to the native protein and binding is observed, it is to the native state. However, when the native state is only nominally predominant, preferential binding of the dye to a partially folded intermediate effectively shifts the equilibrium to favor the intermediate conformation (19). The presence of tight-binding ligands (eg, substrates) to the native state shifts the equilibrium back to the native conformation (19). Another source of potential complications in interpreting results arises from the fact that the dye concentration used in many studies drastically exceeds the protein concentration. It is important to use purified ANS. Most commercial preparations contain some bis-ANS, which produces misleading results because bis-ANS often binds much more tightly than ANS. The bis-ANS is removed by Sephadex LH-20 chromatography (38).

Animal Pole, Vegetal Pole

The cell mass of an egg is not uniformly distributed, but it exhibits significant differences in terms of morphology and at the molecular level. In order to describe this polarity, the terms animal pole and *vegetal pole* were invented to describe the two opposite poles of the egg.

Unlike the eggs of insects, which are elliptically shaped, most **oocytes** of amphibians and mammalians exhibit a less pronounced asymmetry. One element of asymmetry is the location of the cell nucleus, which is normally not right in the center of the oocyte, but is more peripheral, sometimes even adjacent to the egg membrane. Due to gravitational forces, the yolk within settles to the bottom of the egg and forms the vegetal pole; consequently, the polarity becomes more apparent when more yolk is present in the egg. Another component causing asymmetry is that **polar bodies** extruded during **meiosis** are frequently located in the region of the animal pole. In ascidians, sperm enters the egg somewhere in the animal hemisphere (1), causing cytoplasmic movements and rotation of the egg cortex. As a consequence, a further distinct region, the *gray crescent*, becomes visible in the fertilized egg. The gray crescent is also visible in amphibians, but is not very apparent in sea urchins. In the egg of *Unio elongatulus*, sperm entry occurs only at the vegetal pole. This is attributed to the presence of a 220-kDa binding protein that is concentrated in a restricted region of the crater region within the vegetal pole (2).

The naming of the two poles, animal and vegetal, is not based on a precise function; rather, the names have arisen from the idea that the “higher” organs evolve in the animal polar region, whereas the vegetal pole was assumed to be destined to form the “lower” organs necessary for reproduction and providing nutrition. The two poles form one of three possible coordinates, and further developmental changes in a number of amphibians correlate with the subsequent dorsal-ventral body axis of the animal. In mammals, the mechanism by which the inner cell mass settles in certain places is not fully understood. However, it was shown in the mouse that the bilateral symmetry of the early blastocyst is normally aligned with the animal-vegetal axis of the zygote. The embryonic-abembryonic axis is oriented orthogonally to the animal-vegetal axis (3).

After a sperm activates the egg, karyogamy of the male and female **pronuclei** occurs, and the egg starts to divide by **mitosis**. Most important, the cell mass does not increase during the first cell divisions; starting from the one cell, two cells are formed, after another round of divisions four cells, then eight cells, 16 cells, and so forth, until a great number of smaller cells are formed at the morula stage. These cells do not all have the same size; the smaller ones are called micromeres, whereas the larger ones are named *macromeres*. During these cleavage steps, there is relatively little **gene expression** from the nucleus of the new individual cells. In other words, the genome of the new cell does not determine its own development after fertilization and karyogamy at these very early stages of development. With regard to the new cells, the regulating elements are external, maternally derived gene products. These substances, mostly **RNA** molecules, are already present in the unfertilized egg, and they are the important factors that determine the fate of the divided cells. This has been shown by a number of experiments. Chemical inactivation or enucleation in embryos has shown that the nucleus is not necessary for the initial rounds of cleavage. Even enucleated egg fragments are able to perform developmental changes, and cross-fertilization experiments revealed that cells follow the maternal pattern of development. These maternally derived gene products are not evenly distributed in the egg, indicating that the animal and vegetal pole are not only a matter of morphological appearance, but are also related to the presence of a concentration gradient of different gene products. This was demonstrated in experiments in which sections of the animal or vegetal pole were excised and recultivated. When micromeres of the vegetal pole at the 16-cell stage were implanted into the animal pole of a donor embryo, a complete second gut developed; the micromeres are capable of changing the fate of neighboring cells (4). Cutting sea urchin eggs at the eight-cell stage into two halves, to produce two embryos each with an animal and a vegetal cell, generates two pluteus capable of normal development. In contrast, cutting the cell into an animal and an vegetal hemisphere causes considerable aberrations from the normal development.

One of the most quoted experiments to show that animal and vegetal pole cells differ significantly involved excision in which the fate of sections at the 64-cell stage were investigated. The individual cells alone were capable of forming only a **blastula**. However, adding at least four micromeres from the vegetal pole could compensate for this defect and lead to a pluteus. Fewer numbers of micromeres resulted in forms intermediate between blastula and normal pluteus. Interestingly, the vegetalization occurs not only after the addition of micromeres, but also when Li^+ ions were provided. At the animal pole, messenger RNA were found that code for cell-surface proteins. These mRNA were found only in the macromeres and mesomeres, not in the micromeres (5). In the vegetal pole region are localized dorsal determinants that are necessary for dorsal axis development in Xenopus. The dorsal determinants move from the vegetal pole to a subequatorial region, where they are incorporated into gastrulating cells (6). However, dorsal development may be also activated by the contact between the cortical dorsal determinant and the equatorial core cytoplasm that are brought together by cortical rotation upon fertilization (7).

Gastrulation is the next morphogenic event, and it starts in the region of the vegetal pole or near to the gray crescent, depending on the species. At least five different epigenic movements are observable in the further process of differentiation: invagination of cells, immigration, delamination, proliferation, and epiboly. This means that, although the polarity of the egg determines the fate of the cells at different positions, further movements and reorganization take place that are necessary for organogenesis in higher mammals. One predominantly epigenic movement is invagination during gastrulation. It was shown that vegetal egg cytoplasm is responsible for the specification of vegetal blastomeres and promotes gastrulation. Vegetal-deficient embryos of *Halocynthia roretzi* fail to enter gastrulation. They are animalized and arrested at the blastula stage. Reimplantation of the vegetal pole cytoplasm into vegetal-deficient embryos caused gastrulation at the site where implantation occurred (8).

Ankyrins

Ankyrins are a family of conserved proteins whose prime function is to act as a link between integral membrane proteins and the **spectrin**- or fodrin-based framework lying on the cytoplasmic side of the plasmalemma. The ankyrins were first characterized as those proteins that displayed a strong affinity for spectrin in **erythrocyte** membranes. They are expressed in particularly high levels in vertebrate brain but are also found in tissues such as skeletal muscle, lymphocytes, neutrophils and many epithelial tissues (1); they are also found in such primitive organisms as worms (nematodes) and fruit flies (***Drosophila***). Associations between ankyrins and a diverse selection of membrane proteins such as cell adhesion molecules and **ion channels** (the **anion exchanger**, or band 3 protein, Na^+/K^+ ATPase and the voltage-sensitive **sodium channel**) have been characterized and confirm that a key role of the ankyrins is to mediate interactions between spectrin in erythrocytes (known as fodrin in other cells) and proteins constituting the cell membrane. Deficiencies in ankyrin (as well as spectrin and some other membrane-associated proteins) have been correlated with structurally weak erythrocytes.

Ankyrins from erythrocytes (Ank1) and brain (Ank2) are monomeric proteins with a simple **domain** substructure. Each protein has an *N*-terminal domain (about 89 to 95 kDa) with membrane-binding abilities that can interact with the anion exchanger and tubulin (amongst others). Most of this globular region comprises 24 tandem quasi-repeats of a 33-residue motif. Because six such repeats appear to represent the smallest structural entity, it is possible that there are four subdomains within the *N*-terminal domain. It has also been suggested that the 33-residue structures, while folding up in a common manner, could position nonconserved residues on surface sites that would enable them to interact with a wide range of different protein ligands, rather than with a single ligand multiple times. The sequence of the 33-residue motif is very similar to those found in transcription factors, in cell-cycle control proteins, and in proteins regulating tissue differentiation. The second domain of ankyrin (about 62 kDa) can be subdivided into two parts; the first is acidic, proline-rich, and about 80 residues in length. In erythrocytes it links the cytoplasmic domain of the transmembrane anion exchanger to b-spectrin at about the midpoint of the tetrameric structure that b-spectrin forms with a-spectrin (see Spectrin). The second portion is basic and much larger (almost 500 residues). It contains the consensus sequence (Arg–Arg–Arg–Lys–Phe–His–Lys/Arg) that is also required for spectrin- or fodrin-binding. It is also much more highly conserved in sequence than the acidic 80-residue subdomain. The *C*-terminal domain is about 70 kDa in both Ank1 and one variant of Ank2, but about 290 kDa in an **isoform** of Ank2 that is generated by alternative splicing. The smaller isoform of Ank2 (molecular weight about 220 kDa) is common in adult rats, while the larger one (about 440 kDa) is expressed highly in neonatal animals. Furthermore, the 220-kDa protein is found widely in the brain (neuron cell bodies, dendrites and glia), whereas the 440-kDa protein seems to be found specifically in unmyelinated axons and dendrites (2). In both Ank1 and Ank2, the *C*-terminal domain has a regulatory role arising from its ability to modulate the binding affinities of both the membrane-binding and spectrin-binding domains. The sequences of the *C*-terminal domains differ in size, and the overall homology is not high, although there are some regions of similarity.

Ank3, which is the major ankyrin in kidney, is found in most epithelial cells, axons and muscle cells and has many structural similarities to Ank1 and Ank2. It too has an *N*-terminal domain (89 kDa) containing a 33-residue repeat with the **consensus sequence** (Asp/Asn–Gly–apolar–Thr–Pro/Ala–Leu–His–apolar–Ala–Ala–X–X–Gly–His/Asn–apolar–X–Val/Ile–Val/Ala–X–apolar–Leu–Leu–X–X–Gly–Ala–X–Apolar/Pro–Asn/Asp–Ala–X–Thr–Basic), a 65-kDa domain with spectrin-binding ability, and a *C*-terminal domain (56 kDa) with regulatory attributes (2). Interestingly, however, multiple transcripts are expressed, some of which lack the repeat domain at the *N*-terminal end of the molecule. It is possible that these ankyrins are involved in intracellular vesicle stabilization, sorting, or targeting (2).

Annealing, Nucleic Acids

When two complementary nucleic acid strands are mixed under conditions favoring complex formation, the fully associated duplex is the lowest free-energy state of the system. The annealing process involves formation and disruption of partially **base-paired** regions and expansion of those regions as the system samples progressively more extensively base-paired intermediate states on the path to the lowest energy fully base-paired state. This lowest energy state may not be achieved due to kinetically trapped structures.

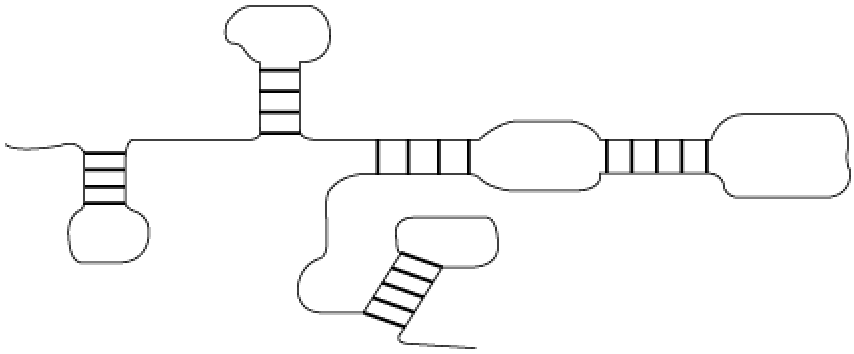
Denaturation of short oligonucleotide duplexes is a thermodynamically and kinetically reversible process. When the solution is cooled after melting of the duplex, the optical and hydrodynamic properties of oligonucleotide duplexes return to the initial values. The denaturation of synthetic polymers of repeating sequence are optically reversible, which indicates that most bases are in intact base pairs. However, the hydrodynamic properties display hysteresis. The change in hydrodynamic properties is due to the formation of branched structures comprised of hairpin loops and concatenated aggregates. Natural DNAs display hysteresis in both optical and hydrodynamic properties, indicating failure of a significant fraction of the bases to find a partner base and the presence of a nonlinear structure.

When two nucleic acid polymers encounter each other during hybridization or renaturation, the probability of an exact match of base pairs in the initial complex is very small. Instead, small stretches of duplex are nucleated. These complexes may grow if the sequences of the two strands permit. If there is sufficient thermal energy, ie, sufficiently high temperature, the nucleated regions will form and disassociate as the system seeks the lowest free-energy state. If there is not sufficient thermal energy, unproductive complexes will dominate, and the equilibrium configuration will not be achieved. Conversely, if there is too much thermal energy, formation of the duplex regions will be disfavored, and the strands will separate.

This leads to a common strategy of duplex formation. The annealing process is optimized by incubation at the "melting" temperature, T_m, followed by slow cooling to permit the facile reorganization of the duplex regions, to optimize sequence alignment.

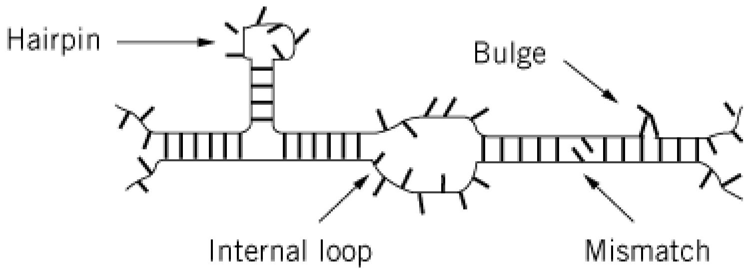
Intramolecular hairpins and internal loops in single-stranded nucleic acid polymers present a significant impediment to annealing (Fig. 1). These structures form rapidly compared to duplex structures. The rate constant for hairpin formation is 10^5–10^7 s^{-1} , meaning the structures form on the microsecond timescale. The second-order rate constant for oligonucleotide duplex formation is 10^5–10^7 M^{-1} s^{-1}. Therefore, at the low concentration of annealing experiments, duplexes form on a time scale of seconds or longer. Intramolecular structures are at a lower energy than is the fully unfolded single-stranded structure. These competing structures must be unfolded for the annealing process to proceed toward the formation of the complementary duplex. The activation energy associated with this unfolding process is large, so that at temperatures well below the T_m of these single-stranded structures, the rate of duplex formation is very slow.

Figure 1. Intramolecular structures formed by nucleic acid single strands.



Defects in the alignment of base sequences (Fig. 2), including hairpins and internal loops, as well as mismatches and bulges, can occur in duplexes. Here the activation energy, and thus the time required for conversion, is even greater than for single-stranded structures. Because the alphabet of nucleic acids contains only four letters, there are regions of nucleotide sequence complementarity even in random sequences. These regions may form nucleation complexes that cannot be extended, resulting in large numbers of nonproductive intermediate states. In highly repetative sequences, large numbers of such structures may be formed. Under permissive conditions, they are readily interconvertable, and the proper sequence alignment can be achieved.

Figure 2. Misalignment structures in nucleic acid duplexes.



In contrast to polymers where sequence alignment dominates the kinetics of annealing, formation of short oligonucleotide duplexes is dominated by the frequency of encounter of the complementary strands. Once nucleation occurs, the pairing of the remaining bases is rapid.

Short oligonucleotide duplexes can form without appreciable competing structures. However, competition between the duplex and single-stranded hairpin structures can occur with oligonucleotides of appropriate sequence. The *unfolded single-strand-to-hairpin* and *unfolded single-strand-to-duplex* equilibria are in competition. The two equilibria differ in molecularity, so they can be distinguished experimentally by the concentration dependence. The hairpin structure will be favored at low concentration; and the duplex, at high strand concentration. The salt concentration also affects these equilibria. Because of its lower charge density, the hairpin is favored at low salt concentrations. Therefore, a combination of salt and oligonucleotide concentration can be used to isolate one of the structures.

Because the formation of a complex involves more than one nucleic acid strand, the concentration and the length of the constituent strands also influence the stability of the nucleic acid complex. There is a complex interplay between the length and concentration in determining complex stability. Two events contribute to the formation and stabilization of the complex. The nucleation event (Fig. 3), in which the strands make initial productive contacts, is a multimolecular (bimolecular for duplex formation) process that depends on strand concentration. The propagation process (Fig. 4), also called zipping, in which the prenucleated base-paired chain is extended, is a pseudomonomolecular process. Formally more than one strand is involved, but the formation of a closed base pair adjacent to a preformed base pair is effectively a monomolecular process analogous to extension of a hairpin.

Figure 3. The nucleation event. The number of strands that are interacting changes. The process is bimolecular and depends on strand concentration.

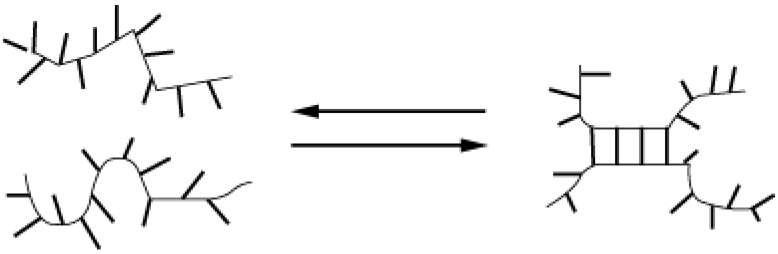


Figure 4. The propagation (zipping) event. The number of strands in the complex does not change; therefore, the process is pseudomonomolecular.

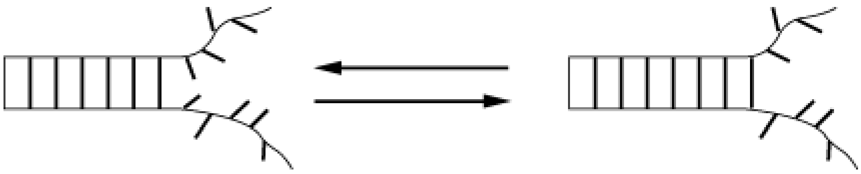

For short oligonucleotides, the nucleation event dominates complex formation. The concentration dependence of the stability is simple and described adequately by the conventional mass-action model. For polymeric complexes, nucleation accounts for a relatively small part of the total stabilizing free energy. The concentration dependence of complex formation disappears for polymeric nucleic acids. For complexes of intermediate length, both nucleation and propagation make nontrivial contributions to complex formation and stability. The concentration dependence of intermediate length complex stability is reduced relative to that for short complexes of short oligonucleotides, but not vanishing as for polymers.

Annexins

Annexins are a family of structurally homologous, calcium- and membrane-binding proteins from eukaryotic sources including animals, plants, protists, and fungi. More than twenty distinct annexins have been characterized. Annexin homologues, notably 14-3-3 proteins, have also been identified through sequence similarities. Intracellularly, annexins vary in their organ, tissue, cell, and subcellular distribution and localization, and some annexins also occur extracellularly. The mechanism of release of annexins into the extracellular milieu is unclear because annexins lack **signal sequences**. Depending on the source, some annexins constitute a significant proportion (>1%) of total cell protein. Though their *in vivo* functions are not yet established, annexins have been implicated in many processes, including cell proliferation and differentiation, signal transduction, membrane trafficking and secretion, **vesicle** aggregation, cell adhesion, interactions with cytoskeletal elements, apoptosis, anticoagulation, phospholipase A_2 inhibition, and **ion channel** activity or regulation. **Phosphorylation** may regulate some annexin-mediated processes. At least two annexins are major substrates for the tyrosine kinases, epidermal growth factor receptor, and retrovirus-encoded protein tyrosine kinase pp60v-src. Phosphorylations through other **tyrosine kinases** or **serine/threonine kinases**, for example, protein kinase C and cAMP-dependent protein kinase A, also have been observed.

Before annexins were recognized as a family, the proteins were identified in many laboratories by their calcium-dependent binding to particulate fractions or hydrophobic chromatographic column matrices. Initially these proteins were given diverse names, which reflected either their source or putative function, including lipocortins, calpactins, endonexins, placental anticoagulant proteins (PAPs), chromobindins, calcimedins, and calelectrins. Subsequent sequence analysis revealed that many of these proteins have a common identity. The general term *annexin* subsequently was adopted in reference to their common ability to *annex to* membranes. In common nomenclature, individual annexins are designated by Roman numerals for example, annexin VII.

1. Macromolecular Interactions

The binding of calcium ions to annexins is relatively weak, with **dissociation constants** K_d in the millimolar-to-micromolar range. Complexation with membranes or other proteins increases their calcium-binding affinities. *In vitro*, annexins bind lanthanides and divalent cations, such as strontium, barium, and zinc. Calcium-dependent binding to membranes is high-affinity, and K_d is in the nanomolar range, whereas phospholipid monomers are bound poorly. In many systems, the annexin-membrane association is reversible upon addition of calcium chelators. In other systems, annexins behave more like integral membrane proteins. Typically, acidic phospholipids, such as phosphatidylserine, are strongly preferred by annexins, whereas binding to pure phosphatidylcholine membranes has not been observed. Such phospholipid binding preferences may target annexins to specific locations. The strong response of annexin V to extracellular exposure of phosphatidylserine is widely used as the basis of flow cytometric assays to detect membrane phospholipid asymmetry in apoptosis and other cellular processes.

In addition to their membrane lipid-binding properties, some annexins interact with other proteins. Some annexins interact with members of the **EF-hand** family, which suggests structural complementarity between the two protein families.

Annexins II and XI each form heterocomplexes in which the heavy chain is an annexin and the light chain resembles S-100 protein. Extracellular annexins have been described as cell surface **receptors** for some **viruses** (1, 2) and matrix proteins, such as collagen (reviewed in Ref. 3) and tenascin C (4). Annexin II is identified as a co-receptor for **plasminogen**/tissue plasminogen activator (reviewed in Ref. 5). Calcium-dependent lectin activity has been identified in some annexins that bind to specific sialoglycoproteins and glycosoaminoglycans, such as heparin (6, 7). The biological importance of this interaction is not yet understood, but it may be related to cell surface function.

2. Primary Structures and Molecular Evolution

Annexin sequences are comprised of two regions, a variable N-terminal region and a conserved C-terminal core region. The core region consists of four or eight canonical repeats of approximately 70 amino acid residues. Sequence homology exists between repeats within an individual annexin and between annexins. The sequence data suggest that gene duplication and subsequent gene fusion produced a four-**domain** ancestral precursor. Further gene fusion of two four-domain annexins produced annexin VI, which is unique in its possession of eight repeats. The core region is associated with the calcium-dependent phospholipid-binding properties of annexins. Each repeat contains a highly conserved stretch of amino acid residues with a **consensus** calcium-binding sequence (Lys/Arg)-Gly-X-Gly-Thr-X_{38}-(Asp/Glu).

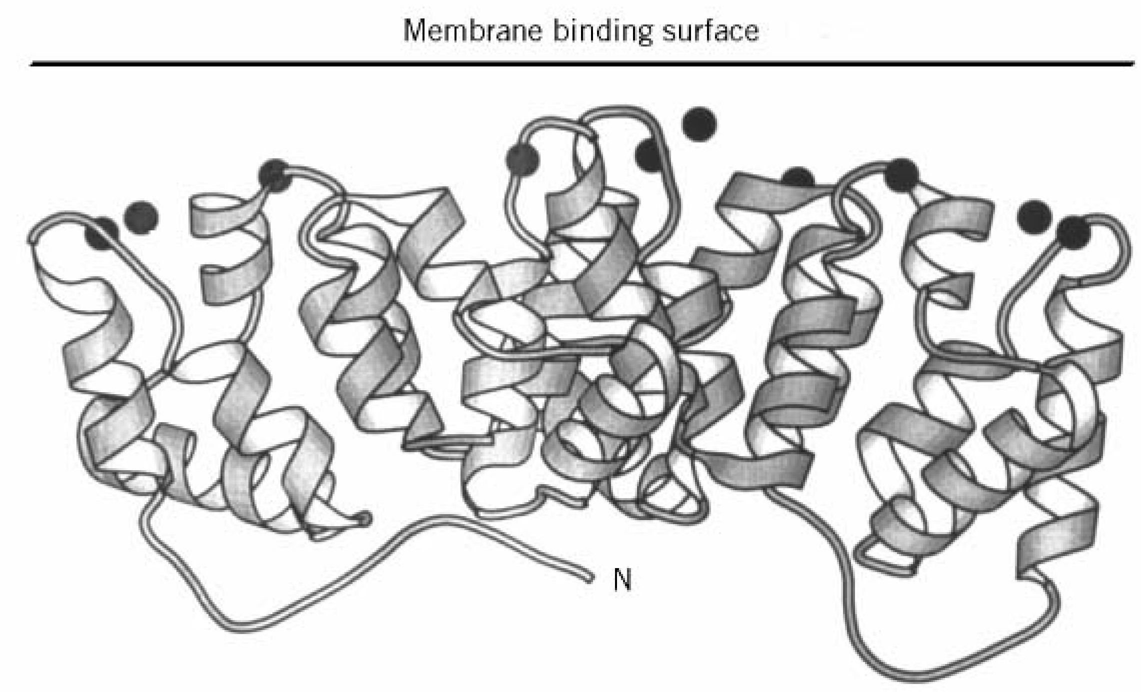
The variable N-terminal regions of annexins exhibit little homology and confer the distinct functional properties of individual annexins. Here the **intron**-exon structures are not highly conserved, whereas they are in the core region. The N-terminal region in annexins may consist of only a few amino acid residues or hundreds. Annexins VII (synexin) and XI have the largest and most hydrophobic N-terminal regions. These may considerably modify the properties of these proteins that arise from the common annexin core. In many annexins, phosphorylation sites occur within the N-terminal regions, as do some protein–protein interaction sites.

3. Crystal Structures of Annexins

Annexin crystal structures reveal a highly conserved **alpha-helical** fold in the C-terminal core region characteristic of this family. Each basic repeating unit is made up of five a-helices, four of which run antiparallel, in a four-helix bundle and the fifth helix is perpendicular. The four-domain annexin structure is nearly planar, and the domains are arranged as a symmetrical array. The eight-domain annexin VI resembles two four-domain annexin structures that are approximately perpendicular to each other and are linked by a long, a-helical segment (8, 9). Most annexin crystal structures lack the variable N-terminal domains, which are intentionally truncated or lost through proteolysis. The only exception to date, that of full-length annexin I, reveals an unexpected juxtaposition between helices in the N-terminus and core domains, a finding that may suggest a mechanism for membrane aggregation (10).

In annexin crystal structures, numerous bound calcium ions are observed in loops along one surface of the protein molecule. These loops have structural motifs that are distinct from those in EF-hand proteins or C2-domain proteins. There are several structural motifs for these calcium-binding sites. The site corresponding to the consensus calcium-binding sequence has the highest affinity for calcium and structurally resembles a type of site observed in phospholipase A_2. Other sites bind lanthanides more strongly than calcium. Annexin V (Fig. 1) adopts two distinct molecular conformations, depending on whether a tryptophan side chain in the third domain extends outward from the protein surface or lies buried within the protein core. Spectroscopic and biochemical evidence indicates that the two states are interrelated and may describe a calcium-dependent conformational change that influences membrane binding. The crystal structures of annexin V complexes with calcium and phospholipid head group analogs indicate that calcium ions are involved directly in the attachment to membranes (11).

Figure 1. Ribbon diagram of annexin V (10). N-terminus as labeled, calcium ions as filled spheres.



4. Membrane-Bound Annexins

The membrane-bound structures of two annexins have been investigated by electron microscopy, and there is little evidence that the protein penetrates into the lipid bilayer. The molecular structures of membrane-bound annexins are essentially the same as in their crystals, except that the molecules reorient themselves so that their calcium-binding sites are in contact with the membrane (8, 12, 13). Several annexins exhibit calcium-dependent self-association and/or form two-dimensional arrays on membrane surfaces, a property that may underlie their biological functions (14, 15).

Structure-based mechanisms for annexin function have been proposed, but are not fully established. Two hypotheses have been presented to explain the annexin-induced calcium channel activity observed *in vitro*. In the "microscopic electroporation" model described for annexin V, the peripheral binding of the protein changes the electrostatic properties of the membrane (16). The calcium ion is translocated to the **cytosol** through a putative central pore in the annexin molecule. In an alternative model of calcium channel activity, based on hydra annexin XII, the protein hexamer inserts into the bilayer and creates a transmembrane structure resembling an inverted micelle (17, 18). Experimental data have been offered to support both hypotheses, but the mechanism and physiological relevance of the channel activity remains controversial. Mechanistic models in which annexins restrict access to membrane phospholipids and/or surfaces have been proposed to explain their inhibition of phospholipase A_2 (19) and thrombin (14), and various models have been suggested for processes, such as vesicle aggregation and membrane fusion. The *in vivo* functions of annexins remain under intensive investigation.

Anomalous Dispersion

If an atom is hit by an X-ray beam, as in X-ray crystallography, it scatters the beam in all directions. The scattered radiation can have the same wavelength as the primary beam (Rayleigh or coherent or elastic scattering) or a longer wavelength (Compton or incoherent or inelastic scattering). For diffraction, only the coherent part of the scattering is of interest. Incoherent scattering simply increases the background.

Electrons in an atom are bound by the nucleus and are, in principle, not free electrons. However, they can be regarded as such if the frequency of the incident radiation w is large compared with the natural absorption frequencies w_n of the scattering atom, or if the wavelength of the incident radiation is short compared with the absorption edge wavelength. This is normally true for the light atoms but not for the heavy atoms (Table 1).

Table 1. The Position of the Ka-Edge for Some Elements

Atomic number	**6**	**16**	**26**	**34**	**78**
Element	C	S	Fe	Se	Pt
Ka edge (Å)	43.68	5.018	1.743	0.980	0.158

If the electrons in an atom are regarded as free electrons, the atomic scattering amplitude (atomic scattering factor in units of electron scattering) is a real quantity *f* because the electron cloud is centrosymmetric. If they are not free electrons, the atomic scattering factor becomes an imaginary quantity, the scattering amplitude per electron:

$$f(\text{per electron}) = \frac{E_0 e^2}{mc^2} \times \frac{\omega^2}{\omega^2 - \omega_n^2 - i\kappa_n\omega} \qquad (1)$$

where E_0 is the amplitude of the electric vector of the incident beam, and k_n is a damping factor for the *n*th orbit (K or L or ¼). For w > w_n, Eq. (1) approaches $f = E_0e^2/mc^2$, the scattering amplitude of a free electron (1-3).

In practice, the complex atomic scattering factor, called $f_{\text{anomalous}}$, is separated into three parts: $f_{\text{anomalous}} = f + f' + if''$. f is the contribution to the scattering if the electrons were free electrons, f' is the real part of the correction to be applied for non-free electrons, and f'' is the imaginary correction. $f + f'$ is the total real part of the atomic scattering factor. Values for f, f' , and f'' are always given in units equal to the scattering by one free electron and are listed in Ref. 3. Because the anomalous contribution to the atomic scattering factor is mainly due to the electrons close to the nucleus, the value of the correction factors diminishes slowly as a function of the scattering angle, slower than for *f*.

Anomalous scattering causes a violation of Friedel's law: I(h k ℓ) is no longer equal to *I*(h k ℓ). This fact can be used profitably for determining the absolute configuration (4). Moreover, it can assist in the structural determination of proteins.

Antennapedia Complex

The antennapedia complex (ANT-C) is a group of tightly linked **genes** that is found in the proximal portion of the right arm of the third chromosome of *Drosophila melanogaster*. The most prominent members of the complex produce striking **homeotic** transformations in adult flies carrying mutations in these genes. Thus mutations in the *Antennapedia* (*Antp*) locus cause a transformation of the antenna of the adult fly into a leg, while lesions in the *proboscipedia* (*pb*) gene cause the adult mouth parts to develop into legs rather than the normal palps used in feeding. The existence of the homeotic ANT-C was originally proposed based on the tight linkage of the *proboscipedia* (*pb*), *Sex combs reduced* (*Scr*), and *Antennapedia* (*Antp*) loci. Subsequent genetic analyses have shown that two other homeotic loci, *labial* (*lab*) and *Deformed* (*Dfd*), are also members of the complex. The homeotic loci of the ANT-C are involved in the specification of segmental identity in the posterior head (gnathocephalic) and anterior thoracic regions of the embryo and adult. Moreover, the linear order of the homeotic loci in the complex, *lab*, *pb*, *Dfd*, *Scr*, and *Antp*, corresponds to the anterior–posterior order of altered segments (intercalary, mandibular, maxillary, labial, and thoracic) found in animals bearing mutations in each of the resident loci. Taken together, the results of mutational analyses indicate that members of the complex are necessary to repress head development in the thorax (*Antp*) and elicit normal segmental identity in the anterior thorax (*Scr*) and posterior head (*Scr*, *Dfd*, *pb*, and *lab*).

A similar group of homeotic genes called the Bithorax Complex (BX-C) is found more distally on the third chromosome. This set of three homeotic genes (*Ultrabithorax*, *abdominal-A*, and *Abdominal-B*) acts in a similar fashion to the ANT-C, but in the posterior of the thorax and in the abdomen. The ANT-C is distinguished from the BX-C not only by virtue of the domain of action of its homeotic loci (anterior versus posterior) but also by the presence of loci that are not overtly homeotic in character. Two of these, *fushi tarazu* (*ftz*) and *zerknullt* (*zen*), have been shown to affect segment enumeration (*ftz*) and the formation of dorsal structures (*zen*) in the early embryo. A third nonhomeotic gene is bicoid (*bcd*). Mutations in this locus result in female sterility and maternal effect lethality. Eggs laid by *bcd* females fail to develop normal anterior ends and instead produce mirror-image duplications of structures normally produced at the posterior terminus of the embryo.

In addition to these genetically defined loci, several other genes have been found in the ANT-C by molecular mapping. The first of these is a cluster of cuticle-protein-related genes that map between the *lab* and *pb* loci. Eight small (about 1 kbp) transcription units make up the cluster, and all have sequence similarities to known cuticle protein genes. These genes (*cc1* through *cc8*) are also apparently regulated by ecdysone in imaginal discs. Deletion of the entire cluster has no apparent effect on the development or cuticle morphology of embryos, larvae, or adults. The second molecularly identified gene is the *Amalgam* (*Ama*) transcription unit. The encoded protein places the gene in the immunoglobulin superfamily and, like the cuticle cluster, the locus can be deleted from the genome with no discernible effect on the organism. Finally, there is the *zen2* or *z2* transcription unit that resides immediately adjacent to the *zen* gene. This locus is similar in structure and sequence to *zen*, but like *Ama* and the *cc* genes has no discernible function.

The entire complex has been **cloned** and sequenced and shown to cover 335 kbp of genomic DNA. The most distal transcription unit is *Antp*, which covers the distalmost 100 kbp of the complex and is made up of eight exons. Proximally, the next 75 kbp contain the *Scr* and *ftz* loci. The distal 50 kbp of this interval contain sequences necessary for *Scr* expression, as well as the two exons of the *ftz* locus and its associated regulatory elements. The proximal 25 kbp contain the three identified exons of the *Scr* transcription unit. The five exons of the *Dfd* gene are found in the central portion of the next-most-proximal 55-kbp interval. The *Dfd* transcription unit covers only 11 kbp of this region, and the 20-kbp interval flanking the gene proximally is the location of cis-acting regulatory elements for the locus. The next 25-kbp interval contains four of the nonhomeotic transcription units that help distinguish the ANT-C and BX-C. The distalmost is *Ama*, next *bcd*, and finally *zen* and *z2*. The *z2*, *zen*, and *Ama* transcription units are all relatively small (1 to 2 kbp) and comprise two exons each. The *bcd* gene is somewhat larger (3.6 kbp) and is made up of four exons. Immediately proximal to the *z2* transcription unit (about 1 kbp from its 3′ end) is the 5′ end of *pb*, which extends over the next 35 kbp of genomic DNA and contains nine exons. The next 25 kbp of the complex contain the cuticle cluster and its eight identified transcription units. The final 25 kbp are the sites of the *lab* gene, which is made up of three exons. Despite the nonhomeotic nature of three of the smaller transcription units (*zen*, *bcd*, and *ftz*) resident in the complex, these loci are tied to the larger homeotic genes of the region by the nature of their protein products. All five of the large homeotics (*Antp*, *Scr*, *Dfd*, *pb*, and *lab*), and the three small genes, have a **homeobox** motif, and their protein products are found in the **nuclei** of the cells in which they are expressed. Thus eight of the genes in the ANT-C encode regulatory proteins that act as transcription factors. The *z2* gene also contains a homeobox; however, the biological significance of the gene is not known, as deletions of this transcription unit have no discernible effect. The cuticle-like genes and *Ama* do not contain a homeobox.

The reasons for the clustering of these developmentally significant loci of similar function are not known. The existence of common or overlapping regulatory elements, the need to insulate regulatory sequences from chromosomal position effect, and the possibility of higher-order chromatin structures for proper expression have all been proposed. Whatever the reason, the homeotic complex structure has a long evolutionary standing. Similar clusters are found in vertebrates, an observation consistent with a very early origin of these genes, probably predating the separation of protostomes and deuterostomes.

Antibiotic Resistance

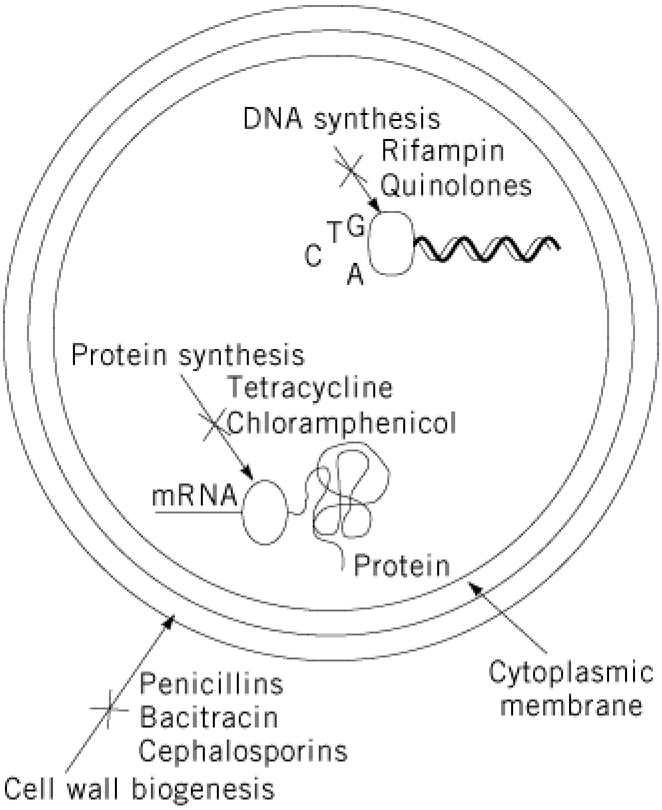
In the 1940s, the clinical use of antibiotics first curbed the widespread threat of deadly bacterial infection. These drugs effectively inhibited bacterial growth that had gone unchecked for decades. Antibiotics did not, however, eradicate the threat of bacterial infection. In fact, the widespread use of antibiotics gave a selective advantage to bacteria that had antibiotic resistance. Many strains of bacteria have developed antibiotic resistance, or insensitivity to antibiotic drugs, in response to antibiotic selection pressures. Now, bacteria employ a myriad of resistance mechanisms to circumvent the best efforts of antibiotic researchers and clinicians. Only with the development of new and potent antibiotics and the appropriate use of existing antibiotics will researchers regain control over this resilient lifeform, bacteria.

1. A Historical Perspective

The development of antibiotics as therapeutic agents began in the late 1930s to combat the most common cause of death, infectious disease. In the preantibiotic era, any infection could prove mortal. Subsequently, over 150 different antibiotics have been synthesized or discovered, and these drugs are used to treat bacterial infections, such as pneumonia, malaria, and tuberculosis (1, 2).

Antibiotics are a collection of natural products and synthetic compounds that kill bacteria. Naturally occurring antibiotics are isolated from molds, yeasts, and bacteria. These organisms use antibiotics as defense mechanisms to kill other bacteria. Alternatively, synthetic antibiotics are developed by understanding the architecture and function of bacteria (see Fig. 1). Some bacteria have cell walls, and many effective antibiotics, such as penicillin, bacitracin, and cephalosporin, inhibit the synthesis of this cell wall. The bacterial machinery for **protein biosynthesis** differs from that of many host organisms and, therefore, is a good target for antibiotics, such as tetracycline and chloramphenicol. Additionally, antibiotics, such as **rifampin** and quinolones, specifically inhibit DNA replication in bacteria (1).

Figure 1. Mechanisms of action of some common antibiotics. A schematic of some basic functions of bacterial cells to which antibiotics are targeted. The X indicates an inhibition of that function by the antibiotics noted (see text for details).



Antibiotics were considered the “wonder drugs” of their time, and in retrospect, this highly favored opinion resulted in their overuse. Antibiotics were commonly prescribed by physicians to cure and to appease their patients. Some patients would have genuine bacterial infections, for which antibiotic treatment is appropriate, whereas others would request antibiotics for viral infections that are not susceptible to these drugs. In addition, individuals who have suppressed immune systems, such as AIDS patients or organ transplants patients, would harbor bacteria that acquire resistance more easily. Antibiotics were also used prophylactically in agriculture and aquaculture industries to keep livestock healthy (3).

By the late 1960s, infectious disease appeared to be under control by the use of a variety of antibiotics. However, antibiotics simply depressed the propagation of bacteria. They did not eradicate it. Nonetheless, research in human health changed its focus from infectious diseases to chronic diseases, and new antibiotics were no longer being developed (2, 4). Many microbiologists warned the human health community that bacteria were potent, infectious pathogens that should not be underestimated. Bacteria have survived for more than three billion years despite numerous environmental changes on earth, and industrial wastes, insecticides, and herbicides. Obviously, the mechanisms bacteria use to survive and adapt to these adversities were very effective.

2. The Origins of Antibiotic Resistance

Even before the first clinical application of antibiotics, antibiotic resistance, the ability of bacteria to evade the deleterious effects of antibiotics, was postulated. In 1940, Abraham and Chain identified a bacterial enzyme that inactivates one of the first antibiotics, penicillin. Then, any bacterium that produces this enzyme would be resistant to penicillin (5). Moreover, microorganisms that use an antibiotic as defense mechanisms would require immunity to that antibiotic. This inherent resistance to a particular antibiotic was defined as a naturally-occurring trait called intrinsic resistance. A few strains of bacteria with intrinsic resistance to a particular antibiotic would not constitute a clinical threat because many diverse antibiotics are available. However, the ability of bacteria to propagate this antibiotic resistance to other strains of bacteria had been underestimated.

The exchange of genetic information between bacteria of the same strain is a common, yet typically slow process. Mechanisms of exchange include (1) **conjugation**—a single DNA strand from one bacterium enters another bacterium and is replicated as a part of that genome, (2) **transduction**—foreign DNA is introduced into bacteria by transducing bacteriophages, and (3) transformation—autonomously replicating circular DNA plasmids are obtained by bacteria (1). Originally, it was believed that these genetic exchange mechanisms were restricted to bacteria of the same strain. However, a new method of gene exchange, using integrons, was recently identified (6, 7).

Integrons are independent, mobile elements that encode **genes** for protein functions, and encode additional DNA to guarantee the integron's expression and integration into the bacterial genome. Integrons effectively generate widespread antibiotic resistance by donating antibiotic resistance genes to any strain of bacteria. Ironically, it is widely believed that integrons evolved only recently in response to antibiotic selection pressure. In other words, the use of antibiotics advanced the widespread occurrence of antibiotic resistance.

In addition to the acquisition of genes by the exchange of genetic information, bacteria also have a high mutation rate that allows them to respond to the selective pressure of antibiotics by using their own genome. For example, if bacteria were subjected to tetracycline, a random mutation in the 30S ribosome to weaken tetracycline binding would be advantageous and, therefore, would be perpetuated by the survival of the tetracycline-resistant bacteria (1). It has also been postulated that **housekeeping genes**, like acyltransferases, may have mutated to gain the ability to modify and inactivate aminoglycoside antibiotics (8-10).

The widespread phenomenon of antibiotic resistance has developed from the promiscuity of bacteria and their genomes. Initially, intrinsic antibiotic resistances were isolated incidents, but the threat of antibiotics has been readily circumvented using the acquisition of antibiotic resistance genes and the high mutational frequency of individual bacteria.

3. Mechanisms of Antibiotic Resistance

Using both newly acquired genes and their own mutated genes, bacteria utilize three basic mechanisms to support antibiotic resistance. Enzymes that degrade antibiotics inside the cell are key players in antibiotic resistance. Bacteria can also alter their permeability barriers to keep antibiotic concentrations below toxic levels inside the cell. Furthermore, the cellular targets of antibiotics can be modified to evade the effects of the antibiotics. These mechanisms of antibiotic resistance are distinct, but all are obtained through the acquisition or mutation of genes.

3.1. Enzymatic Inactivation of Antibiotics

Degradative enzymes are a common mechanism by which bacteria become resistant to antibiotics. Such enzymes chemically modify antibiotics so that they no longer function. The genes for these degradative enzymes are obtained by acquisition of exogenous genes or mutation of endogenous genes. The expression of these genes also governs the level of antibiotic resistance in bacteria.

b-Lactamases are common examples of degradative enzymes that generate antibiotic resistance. b-Lactamases inactivate b-lactam antibiotics, a structurally similar group of penicillin-like antibiotics, all of which have a b-lactam ring structure. b-Lactamases are typically grouped into two major classes, penicillinases and cephalosporinases, based on their substrate affinity (11, 12). In addition to b-lactamases, other enzymes also degrade different antibiotics, such as the aminoglycosides, gentamycin, tobramycin, and amikacin.

All b-lactam antibiotics function similarly. Their b-lactam ring structure inhibits the final step of bacterial cell wall synthesis. Bacterial cell walls are constructed of alternating *N*-acetylglucosamine and *N*-acetyl-muramic acid residues that form long peptidoglycan chains, and the final step in cell wall synthesis involves the enzymatic crosslinking of these peptidoglycan chains by a transpeptidase. Because the b-lactam bond resembles a portion of the peptidoglycan chains, this transpeptidase can mistake a b-lactam antibiotic for its natural substrate and hydrolyze the b-lactam bond. This hydrolysis covalently links the b-lactam drug to the transpeptidase and renders it nonfunctional (13) (see also Penicillin-Binding Proteins).

Although b-lactamases are effective at degrading some antibiotics, their mere presence is not sufficient to cause clinically relevant antibiotic resistance. In fact, these enzymes are found ubiquitously in almost all bacteria, and in some blue-green algae and mammalian tissues. b-lactamases must be present in sufficient quantities to degrade the b-lactam antibiotics effectively before they inhibit cell wall synthesis. The cellular concentration of a b-lactamase depends on its gene expression, and b-lactam antibiotics are inducers of b-lactamase expression. Furthermore, particular b-lactamases have variable affinities for b-lactam antibiotics. Therefore, the degree of antibiotic resistance due to b-lactamases is based on a combination of the ability of the b-lactam antibiotic to induce the expression of b-lactamase, and its ability to be a substrate for b-lactamase (14).

As researchers began to understand this mechanism of antibiotic resistance, more effective b-lactam antibiotics were developed. The early cephalosporins, like penicillin and amoxicillin, are extremely sensitive to b-lactamases, because these b-lactam antibiotics are potent inducers of b-lactamase expression and good substrates for the b-lactamase. In contrast, the more recently developed antibiotic, imipenem, is a strong inducer of b-lactamase expression but maintains its antibiotic activity because it is a poor substrate for most b-lactamases (15). In addition to these new antibiotics, combination therapies are also being implemented to combat antibiotic resistance. Such therapies are comprised of a b-lactam antibiotic together with b-lactamase inhibitors, like clavulanic acid, sulbactam, and tazobactum (16).

3.2. Altered Permeability Barriers: Pore Proteins and Efflux Systems.
The bacterial cell membrane is the major permeable barrier separating the outside of the cell from the inside. The fluidity of the membrane is generally balanced to include most nutrients, while excluding many toxins. Adjusting this fluidity impedes the function of the membrane. Therefore, bacteria cannot protect themselves by changing the fluidity of their membrane. Instead, bacteria have additional structures that surround the cytoplasmic membrane or form pores through it. The alteration of these structures to exclude antibiotics is another mechanism of antibiotic resistance.

Gram-positive and Gram-Negative Bacteria have distinct structures that surround their cytoplasmic membranes. Most Gram-positive bacteria have thick cell walls that are mechanically quite strong, although very porous. Although the cell wall helps Gram-positive bacteria retain their shape, it does not exclude most antibiotics and, therefore, is not a good barrier. Thus, Gram-positive bacteria are relatively susceptible to the influx of antibiotics. Alternatively, a more effective barrier, a second lipid bilayer or membrane, surrounds Gram-negative bacteria. This outer membrane is partially composed of a lipid, lipopolysaccharide (LPS), that is not commonly found in cytoplasmic membranes. The distinguishing feature of LPS is its decreased fluidity, which makes the LPS bilayer an efficient barrier that prevents the permeation of most **hydrophobic** antibiotics into Gram-negative bacteria (17).

Enveloped by effective barriers, bacteria use pore-forming proteins, called porins, to obtain nutrients from outside the cell. Porins are transmembrane proteins that function as nonspecific, aqueous channels, and allows nutrients to diffuse across the membrane. Porins generally exclude antibiotics because they are narrow and restrictive. Most antibiotics are large, uncharged molecules that cannot easily traverse the narrow porin channels that are lined with charged amino acid residues. However, some antibiotics enter the bacteria through porins, and the deletion or alteration of these porins to exclude particular antibiotics is linked to antibiotic resistance.

Because bacteria cannot develop barriers that are impermeable to all molecules, some toxins do diffuse into bacteria along with nutrients. Therefore, bacterial cell membranes also contain transport proteins that cross the membranes and use energy to remove toxins. They are called active efflux systems, and some are directly identified as another significant cause of antibiotic resistance.

Many active efflux systems resemble other transport proteins that catalyze the efflux of common, small molecules, like glucose or cations, and it is likely that mutation has modified them to transport antibiotics. Based on their overall structure, mechanism, and sequence homologies, these transport proteins are classified into four families: (1) the major facilitator family; (2) the resistance nodulation division family; (3) the staphylococcal multidrug resistance family; and (4) the ATP-binding cassette (ABC) transporters. Of these four families, only the ABC transporters use the chemical energy generated from the hydrolysis of ATP to drive molecules across the membrane. Members of the three other families use an electrochemical proton gradient, or proton-motive force, as the source of energy (18, 19).

Some active efflux systems exclude a variety of unrelated toxins from the cell. These multidrug resistance (MDR) efflux systems in bacteria are comparable to those found in mammalian cells (see Drug Resistance). An example of a bacterial MDR efflux system is the Bmr transporter that transports drugs which have diverse chemical structures and physical properties and include cationic dyes, rhodamine-6G, ethidium bromide, and the antibiotics netropsin, puromycin, and fluoroquinone (20). Other MDR efflux systems characterized in bacteria include NorA in *Staphylococcus aureus*, MexB in *Pseudomonas aeruginosa*, and EmrB in *Escherichia coli*. If MDR efflux systems occur extensively in bacteria as the source of many antibiotic resistances, they pose a far more formidable challenge than more specific mechanisms of resistance.

3.3. Modification of the Antibiotic's Target

Antibiotics inhibit bacterial growth by inactivating different key proteins that are essential for bacterial survival (see Fig. 1). However, the antibiotic sensitivity of these target proteins can be altered. Typically, antibiotic targets are altered by reducing their affinity for the antibiotic. Bacteria accomplish this change in affinity several ways. Bacteria acquire exogenous DNA for a mutated target protein that no longer interacts with the antibiotic, yet retains the original target protein's function. Alternatively, bacteria's endogenous genes can be mutated to achieve the same end. In contrast, DNA for novel modifying enzymes can be acquired to alter the antibiotic target posttranslationally, reducing its affinity for the antibiotic.

Altering an antibiotic's target protein directly at the DNA level is a common mechanism of target modification. An example of this modification is the mutation of genes for penicillin-binding proteins (PBPs). PBPs are transpeptidases, previously discussed, that catalyze the final step in bacterial cell wall synthesis. These PBPs have high affinity for penicillin and its derivatives, and the binding of penicillin permanently inactivates PBPs. Originating from both endogenous and exogenous DNA sources, mutated PBPs can have a lower affinity for penicillin. Therefore, PBPs are resistant to the antibiotic, yet still provide a crucial function in bacterial cell wall synthesis (21, 22). Another example of target modification via mutated DNA is a single amino acid mutation in the quinolone resistance-determining region of the **DNA gyrase** gene, gyrA, that can provide up to a 20-fold increase in quinolone resistance (23).

In addition to using mutated antibiotic targets, bacteria can acquire new genes that produce proteins that, in turn, alter antibiotic targets. A well-studied example is the resistance of Staphylococci to **erythromycin**. It is known that Staphylococci have acquired genes to produce a protein that methylates a residue on the 23S ribosome. The 23S ribosome is the target of erythromycin, but methylated 23S ribosome has a low affinity for erythromycin. This exogenous gene is expressed and prevents the binding of erythromycin to the ribosomes, making the bacteria erythromycin-resistant (24).

Antibody

Antibodies are specific proteins, termed immunoglobulins, that are produced by B cells upon stimulation with antigens, which may be proteins, polysaccharides, nucleic acids, and so on, either in soluble form or as part of complex cellular organisms, such as bacteria, parasites, **viruses**, eukaryotic cells of animal or plant tissues, and pollens. In fact, the immune system is so built as to have the potential to make antibodies against any macromolecule of the living world. It was reported at the end of the nineteenth century by von Behring and Kitasato that a group of guinea pigs immunized against a sublethal dose of diphtheria toxin became resistant to diphtheria, whereas another group that received tetanus toxin resisted further challenge with a normally lethal dose of tetanus toxin. This key experiment showed that the protection was specific toward the immunizing agent. Thus, one master word in immunology is specificity, and this immediately raises the problem of what immunologists call the repertoire. How is it possible to make the billions of different molecules that are potentially necessary to assume specific recognition of an obviously astronomical number of potential antigens? What structures are recognized on an antigen? What are the structural bases for antibody specificity? All these are basic questions that have been solved progressively during the past 40 years.

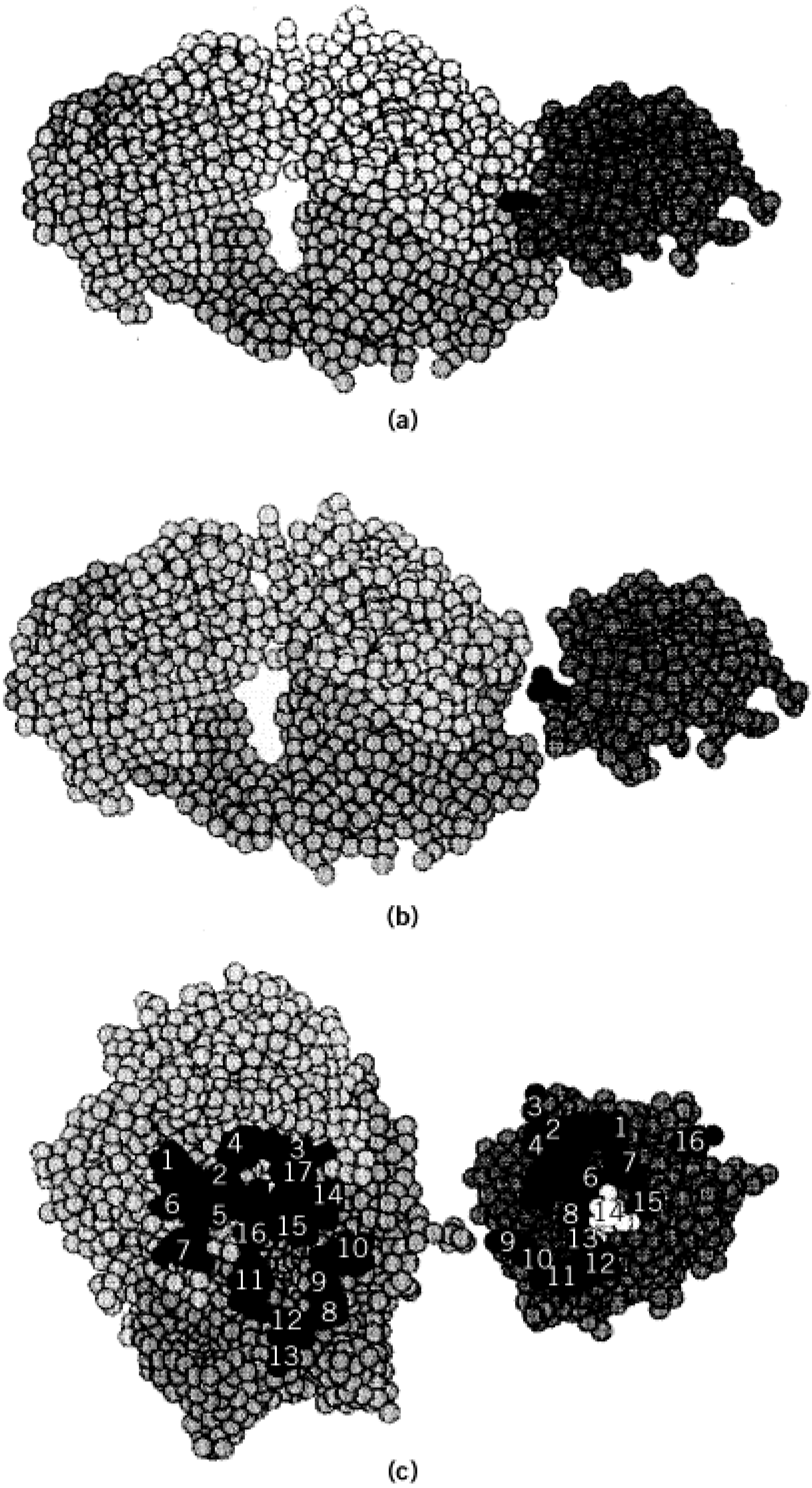
The protein nature of antibodies was established by M. Heidelberger in 1928, by showing that protein nitrogen was present in a specific antigen–antibody precipitate in which the antigen was a polysaccharide, which must have originated from the antibody part of the precipitate. Progress in the knowledge of the structure of antibodies paralleled the emergence of new technological tools in biochemistry and in molecular biology. Analytical ultracentrifugation performed by Kabat and Tiselius at the end of the 1930 indicated that antibodies were found in several classes of sizes, mostly with sedimentation coefficients of between 19S and 7S. **Electrophoretic** characterization of serum, also studied by Kabat in the same period, revealed that antibodies were located in the globulin part of the spectrum, mostly in the slowest moving g-globulin fraction. This name remained in use for years until it was replaced by a more generic one, that of immunoglobulins. Immunoglobulins are thus defined as the immune proteins synthesized specifically by B cells. They are expressed in two forms: (*1*) as integral membrane proteins at the surface of B lymphocytes, where they represent the B-cell receptor (BCR), by analogy with the T-cell receptor (TCR) expressed at the surface of T cells; and (*2*) as a soluble form, secreted in the bloodstream by the plasma cells, which represent the terminal stage of differentiation of the B lineage. This soluble form is what immunologists call circulating antibodies, or simply antibodies.

A main difficulty encountered in studying antibody structure was due to their extraordinary heterogeneity, which deserves some comments. As a rule, when an antigen such as hemoglobin or serum albumin, or in fact any protein, is used as an immunogen, a large array of antibodies with discrete fine specificities is synthesized. At the surface of a protein, many discrete regions are recognized by as many distinct antibodies. These regions are called *antigenic determinants*, or epitopes. For a protein of molecular weight 50 kDa, there are 10, 20, or more epitopes that could be identified by distinct antibodies. But antibody heterogeneity is not limited to the mosaic of epitopes. It may be shown that in fact one given epitope may be recognized by slightly different antibodies, and this contributes an extraordinary multiplication of the heterogeneity. This results from the clonal organization of lymphocytes, as originally proposed by Burnet (1). B lymphocytes (and T cells as well) are organized as discrete clones, each of which makes one and only one type of antibody molecule. In humans, the average population of lymphocytes at any given time is of the order of 10^{12}, of which approximately one-fifth are B cells and four-fifths are T cells. These B cells make about 10^{20} molecules of circulating immunoglobulins, a number that can be calculated from the Ig concentration in serum (10 mg/mL). The size of one clone is largely dependent on the immunization state and can vary from one single resting cell to several thousand or more. What happens when an animal is being immunized is that all clones that happen to interact somewhat with any potential epitope of the administered antigen will proliferate, expand, and synthesize as many different antibodies, thereby contributing to a very great heterogeneity. This of course made it very difficult, if not impossible, to study the fine structure of antibody molecules, especially when considering their amino acid sequences. A bias was brought to this by the existence of multiple myeloma in humans, or its equivalent as experimentally induced plasmacytoma in the mouse. These are lymphoproliferative disorders that affect plasma cells. As a result of the malignancy, one clone will expand specifically so that, very rapidly, it will become the major B-cell clone expressed in the body. The corresponding immunoglobulin will be secreted in excessively large amounts, and this provides a homogeneous material available for structural studies. An obvious drawback with this material is that the antibody specificity is generally unknown, which prevents its use for the study of **antigen–antibody interactions**. This difficulty was turned around when Kohler and Milstein (2) succeeded in making somatic hybrids between myeloma cells and normal B lymphocytes from hyperimmunized mice. These hybridomas combined the properties of myeloma cells, which can grow indefinitely in culture or upon transplantation in syngeneic strains of mice, with the clones of immunized lymphocytes that could be selected for a known antigenic specificity, leading to the fantastic expansion of "monoclonal antibodies" (mAbs). Monoclonal antibodies were not only suitable for detailed structural analysis of antibodies, including determination of the three-dimensional protein structure of antibody–antigen complexes. They also allowed access, through the hybridoma cells, to isolation of messenger RNA encoding Ig polypeptide chains and the corresponding complementary DNA, and thus to the complete gene organization of the three main Ig gene loci.

The basic structure of antibodies, elucidated from the pioneer work of Porter in England (3) and Edelman in the United States (4), is given by that of the IgG molecule—known initially as 7S-g-globulin. It is a symmetrical molecule, containing two identical heavy chains (H, 52 kDa) and two identical light chains (L, 23 kDa), which are either **kappa** (k) **or lambda** (l) **chains**. Each H–L pair contains one combining site for the antigen, so the conventional H_2 L_2 IgG molecule is bivalent. The symmetry of the molecule is in agreement with the clonal selection theory, which postulated that each B cell expressed one and only one antibody specificity. This basic model could be extrapolated to other antibody classes, which differ from each other in the nature of their heavy chains and the degree of polymerization of the basic H_2L_2 unit. Five classes have thus been described in higher vertebrates: IgG, IgM, IgA, IgD, and IgE, having the corresponding g, m, a, d, and e heavy chains, respectively. IgM are expressed as H_2L_2 monomers at the cell surface of B cells, but are pentamers in the serum. IgA is mostly a dimer, whether other classes remain as monomers. The diversification of classes allows the antibodies to assume two types of function: (*1*) antigen recognition, common to all classes, and (*2*) biological or effector functions, such as **complement** fixation, active transplacental transfer, or fixation to various cell types, which amplify the action of antibodies and generally favor the elimination of a pathogen.

The functional duality of antibody molecules was clearly established in the late 1950 by Porter (5), who succeeded in cleaving the IgG antibody by papain, a proteinase, which led to the isolation of two identical fragments that were antigen binding, or Fab, and one Fc fragment that did not recognize the antigen but fixed the first component of the complement cascade. Structural support for this organization was clearly demonstrated by Hilschmann in 1965 (6), who reported the first amino acid sequence of two monoclonal human light chains. This is another example of the importance of monoclonal materials in this saga of the determination of the antibody structure. The work was performed on Bence-Jones proteins, which are free light chains isolated from the urine of patients with multiple myeloma. They are the result of a dysbalanced synthesis between the monoclonal heavy and light chains by the malignant plasma cells. Because of their smaller size, they pass the renal barrier and are thus easily isolated in large amounts from patient's urine. The major discovery was that the Bence-Jones light chains, or Ig light chains, were composed of one NH_2-terminal half of 110 amino acid residues that profoundly differed between two patients, whereas the COOH-terminal half, also of 110 residues, was identical. This gave clear evidence for the existence of a huge structural diversity in antibodies, providing a unique basis for antibody specificity. Further extensive work indicated that heavy chains had also a variable region of similar size and a much longer constant region. The antibody combining site could thus be visualized as resulting from a contribution of both the V_H and the V_L regions. A more detailed analysis, computed by Kabat (7), indicated that within the V **variable regions**, subregions of hypervariability could be identified around positions 30, 50, and 100, which were later proven to participate directly in making up the antibody combining site. Three hypervariable regions, also called *complementarity determining regions* (CDR), were identified on each heavy and light chain, and their fine analysis revealed an extraordinary diversity that certainly could account for the expected huge repertoire of antibodies necessary to accommodate the potential repertoire of epitopes of the living world. Direct proof that the CDRs were implicated in antigen recognition came first from affinity labeling experiments, until a final confirmation was provide by X-ray crystallography analysis of crystals of antigen–antibody complexes. In fact, crystals were prepared from the Fab fragment of an antilysozyme antibody, combined with lysozyme, because the complete IgG antibody molecule contains a floppy "hinge" region that prevents crystallization. This structure, obtained by the group of Poljak (8), presented in Figure 1, indicates that about 20 amino acid residues of the antibody participate in binding the antigen, plus a similar number of residues from the antigen. On average, the area of interaction of the two partners is of the order of 600 $Å^2$. Care should be taken in attempts to generalize this model to all other antigen-antibody pairs, because the size and shape of the antibody combining site varies greatly from one system to another. This variation is reflected in the wide variation of the association constants K_A, between 10^5 and 10^{12} M^{-1} . The interactions between antigen and antibody are exclusively non covalent and involve primarily salt bridges, van der Waals interactions, and hydrogen bonds. The contributions of **enthalpy** and **entropy** vary immensely from one system to another, stressing again, if needed, the fantastic diversity potential of antibody molecules.

Figure 1. Three-dimensional structure of a lysozyme–Fab antilysozyme, showing the amino acid contributions from the heavy chain (upper part of Fab) and from the light chain (lower part). The antigen is on the right, and the Fab is on the left. (**a**, **b**) Side views. (**c**) Front view of the interacting residues of the antibody combining site (left) and epitope (right). (From Ref. 1, with permission from R. Poljak.)



Ultimately, the main problem that the immune system has to face is how to generate such a huge diversity with a number of genes that must necessarily be limited. At the time of the first data concerning the amino acid sequences of the light chains, many hypotheses were put forward to account for this diversity. There were two extremes: One considered that the diversity was exclusively the result of somatic hypermutations, whereas the other claimed that everything was encoded at the germline level, arguing that, provided that any light chain might pair with any heavy chain, 10,000 L-chain genes and 10,000 H-chain genes might generate 10^8 antibodies, a number that was already considered reasonable. Besides the fact that 20,000 genes would represent a large portion of the genome, this theory did not account for the conservation of the constant regions, a very serious objection that led Dreyer and Bennet (9) to propose that genes encoding the V and the C regions were separate in the germline. This was shown to be the case when the basic principles of the Ig gene organization were elucidated by the elegant experiments of Tonegawa in 1978 (10). In brief, V and C regions are encoded by separate regions within each of the three H, K, and L Ig loci, with a small number of **C genes** and a large number of V genes (Fig. 2). In addition, the V regions are in fact encoded by a mosaic of two gene segment clusters for the light chains (V_L and J_L) and three for the heavy chains (V_H, D, and J_H). Random combination of these elements takes place exclusively during B-cell differentiation and leads to a large collection of clones expressing various combinations from the basic gene mosaic. Diversity is further amplified greatly by other mechanisms, including somatic hypermutation. As a result, the number of distinct B-cell clones present at any time certainly far exceeds that necessary, especially in view of antigen–antibody recognition being partly degenerate.

Figure 2. Schematic organization of the three Ig gene loci in (**a** mice and (**b**) humans. The IGK, IGL, and IGH loci, codi the k light chain, the l light chain, and the heavy chain, respectively, are located on mouse chromosomes 6, 16, and 12 ar human chromosomes 2, 22, and 14, respectively.

Antibody–Antigen Interactions

Binding of antigens has long been a central paradigm for molecular recognition. In addition, the biological nuances of antigen recognition have such profound ramifications for medicine that the study of antibody–antigen interactions remains a key branch of molecular immunology. In this entry we first describe the structural chemistry of antigen binding, then follow with aspects of antibody–antigen interaction that lead to unique biological phenomena.

1. Chemical Aspects of Antibody–Antigen Interaction

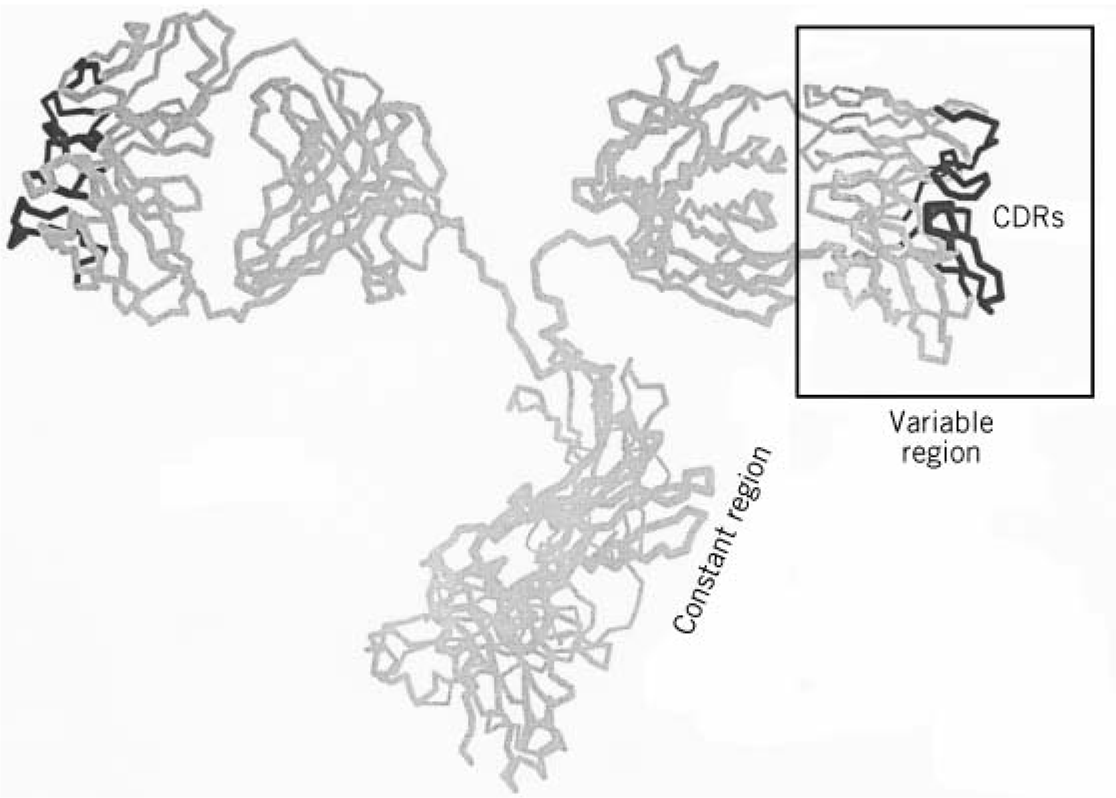
1.1. General Properties

The chemical interactions between antibody and antigen do not differ substantially from other protein–ligand interactions. Hydrogen bonds, van der Waals interactions, and sometimes salt bridges are used to form the antibody-antigen contact. Extremely close steric complementarity between antibody and antigen surfaces seems to be a common characteristic of interfaces (1). Gaps between the opposing antibody and antigen surfaces are sometimes filled by water molecules (2). The association constant for antibody–antigen interactions ranges from 10^5 to 10^{12} M^{-1}, with typical values for protein antigens around 10^8–10^9 M^{-1} (3). Rate constants for binding low molecular weight haptens can be as high as 10^8 $M^{-1}s^{-1}$. Reactions with macromolecular antigens are slower, $\leq 10^6$ $M^{-1}s^{-1}$, except for highly charged antigens, which sometimes enhance the rate through electrostatic interactions (4). In most cases, antigen binding does not cause easily observed changes in the binding site of an antibody. In some cases, conformational changes in the antibody are intrinsic to the binding mechanism. These changes can be caused subsequent to antigen binding, termed an "induced fit" mechanism (5); alternatively, antigen can bind selectively to one of several preexisting antibody conformations (6). Generalizations about the nature of the antibody–antigen interaction are hazardous, as is clear from the observation that the same antibody can bind one ligand through a few strong contacts and another ligand through many weak interactions (7).

1.2. Combining Site Structure and Function

Comparative studies showed that antibody variability was concentrated in three short stretches of sequence within each variable domain (8). These regions were postulated to confer antigenic specificity on an antibody molecule, and were termed "complementarity-determining residues" (CDRs). X-ray crystallographic studies confirmed that the CDRs, although noncontiguous in the antibody primary structure, formed loops that were adjacent to each other in three-dimensional space (9). The position of CDRs within an IgG molecule is shown in Figure 1. Structural studies on antibody–antigen complexes have confirmed that the CDRs form the vast majority of intermolecular contacts. Non-CDR residues can also form contacts, however, and in some cases not all CDRs participate in the interaction with antigen (10). Of the six CDRs, heavy chain CDR3, formed at the genetic level by joining of a D segment to V_H and J_H, is the most structurally diverse, and usually the most energetically significant in binding antigen. (See Immunoglobulin Structure.)

Figure 1. Position of CDRs (dark lines) within an IgG molecule.



1.3. Antigenicity

Antibodies bind to structurally precise surfaces on protein antigens (11). These surface areas can be composed of a contiguous length of polypeptide chain or from several parts of a chain that are separate in primary structure but adjacent in three-dimensional space. The only true prerequisite for a portion of a protein to be recognized as an antigen is surface **accessibility**, although other factors, such as hydrophilicity and mobility, are often considered in predicting antigenicity from protein sequence (12). In the case of peptide–antibody complexes, about 7–10 peptide residues fit in the binding site of the antibody and form an ordered structure, even if the free peptide itself is not strongly ordered in solution (13). Sometimes a bound peptide structure resembles the conformation of the same sequence in an intact protein, a phenomenon that underlies the utility of peptide vaccines (14).

2. Biological Aspects of Antibody–Antigen Interaction

2.1. T-Dependent and T-Independent Immune Responses

"Normal" immune responses depend on the participation of T cells. In outline, antibody-producing B cells capture antigen (protein or protein–hapten conjugate) on their surface, internalize and fragment the antigen, and represent short peptide fragments on the cell surface, embedded in the binding groove of major histocompatibility complex (MHC) molecules. T-cells recognize the peptide–MHC combination and produce signals that cause B cells to enter pathways of proliferation and differentiation (15). Molecular genetic processes activated at the immunoglobulin loci include heavy-chain class switching and somatic hypermutation, leading to production of soluble IgG, IgE, and IgA of high affinity. T-independent antigens include virtually all nonprotein macromolecules. B-cell proliferation and differentiation also occur in a T-independent response, but chain switching and somatic mutation are difficult to detect. Structural attributes of antibodies in a T-independent response are that they are of the IgM isotype, contain germline (unmutated) **variable region** sequences, and show low antigen affinity.

2.2. Maturation of the Immune Response

Antibodies isolated soon after an initial antigen exposure, termed "primary response antibodies", differ from those obtained later in the response or after a second administration of antigen. This transformation of the antibody repertoire, which leads to progressive increases in the affinity for antigen (16), is termed "maturation of the immune response." The structural basis of this phenomenon has been determined from studies of immune responses to haptens, and can be outlined as follows. Contact with antigen induces a process within lymphocytes that introduces point mutations in the variable regions of antibody genes (17). Most mutations have a neutral or deleterious effect on antigen affinity (18). However, some mutations improve the interaction with antigen. Higher affinity confers a selective advantage on lymphocytes that express this mutation, which may be competing with nearby lymphocytes for a limited amount of antigen. Selected lymphocytes proliferate and can undergo further rounds of mutation and selection. Maturation of the immune response leads to improved affinity universally in anti-hapten responses. The same progressive affinity increase is presumed to occur with protein antigens, but unequivocal evidence for this is lacking.

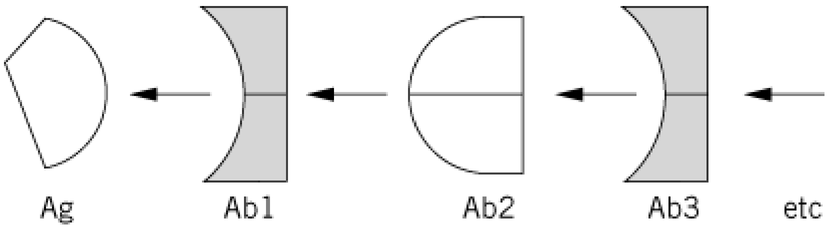
The diversity of the initial repertoire is determined by germline variable gene diversity and processes involved in gene rearrangement. At a structural level, antibody diversity is concentrated around the center of the antigen combining region. Somatic mutation acts to form the mature repertoire, which for protein antigens will show association constants in excess of $10^8\ M^{-1}$. Somatic point mutations can occur anywhere in the variable region, but those selected during maturation are in general located in a band immediately peripheral to the area of diversity expressed in the early repertoire (19).

2.3. Anti-idiotype Antibodies

"Idiotype" is an immunological word that corresponds in structural terms to the unique CDRs of an individual antibody. If an antibody (Ab1) is used to **immunize** an animal, its CDRs can be recognized as a foreign structure, even in an animal of the same species. An antibody that reacts with the CDRs of Ab1 will be made, termed an **anti-idiotype** antibody (Ab2). The anti-idiotype can be used in the same way to generate an anti-anti-idiotype (Ab3). In a theory of immune regulation (20), if Ab1 is complementary to an antigen and Ab2 is complementary to Ab1, then the binding site of

Ab2 should resemble the initiating epitope on the antigen. ***In vivo***, Ab2 is then said to carry an “internal image” of the antigen. This chain of alternating complementary recognition properties is diagrammed in Figure 2).

Figure 2. Chain of complementary binding activities within an idiotype network.



Structural studies have investigated the extent to which the internal image model is accurate. No gross structural similarity between an antigen and Ab2 is necessary for both molecules to bind to Ab1 with high affinity. However, the structure of an antilysozyme (Ab1) complexed with an Ab2 showed that many of the Ab1 residues used for binding lysozyme were also used to bind Ab2 (21). Furthermore, many Ab2 atoms contacting Ab1 occupied positions analogous to contact atoms in lysozyme, and intermolecular hydrogen bonds and even water molecules at the interface were conserved between the Ab1:lysozyme and Ab1:Ab2 complexes. Thus Ab2 can mimic an antigen through close chemical complementarity with Ab1, even in the absence of sequence or structural homology. In the case of Ab3 molecules, structural similarity to Ab1 is unequivocal, although not surprising. CDR sequences are often nearly identical between Ab1 and Ab3, and the structure of an antigen:Ab3 complex shows chemical complementarity as stringent as would be expected at the interface between antigen and an antibody raised directly (22).

2.4. Heterophile Antibodies and Molecular Mimicry

An antibody that reacts with an antigen to which the host has not been exposed is termed a “heterophile antibody” (23). The origin of heterophile antibodies is obscure; no antigen has been unambiguously identified that in a natural situation causes heterophile antibodies to appear. Structurally, heterophile antibodies tend to be low affinity IgM that react with carbohydrate antigens. Some heterophile antibodies, termed “natural antibodies,” appear to arise spontaneously and persist for the lifetime of the organism. The heterophile antibodies that determine ABO blood group compatibility are of this type. In other cases, appearance of heterophile antibodies clearly results from infection. For example, infectious mononucleosis in humans reproducibly induces antibodies specific for an antigen on sheep red blood cells (24). The supposition in such cases is of a process of “molecular mimicry”: a pathogen-specified product is made during infection that possesses sufficient structural similarity to the heterophile antigen that heterophile antibodies are induced (25). When the reactivity induced is to a self-antigen normally subject to immune **tolerance** mechanisms, autoimmune disease may result. For example, streptococcal respiratory infection is the immediate antecedent of rheumatic fever, an autoimmune attack on the heart and vascular tissue. A carbohydrate structure on the bacterial surface is thought to mimic structural glycoproteins in heart valves and vessels (26). Experimental induction of autoimmune diseases by immunization supports this type of antibody–antigen interaction as an initiating mechanism for autoimmunity (27).

2.5. Polyreactive or Polyspecific Antibodies

Polyreactive antibodies do not fit the standard paradigm of one antibody recognizing a single antigen. Instead, a single polyreactive antibody can recognize a panel of many antigens that bear no obvious chemical similarity to each other. Many polyreactive antibodies are IgM, and others are IgG and other isotypes and can bind antigens with high affinity. For example, a set of hybridomas screened for simultaneous reactivity with tubulin, actin, myosin, and single- and double-stranded

DNA showed a median antibody affinity for all five antigens of $10^7\ M^{-1}$ (28). The molecular basis of polyreactivity is unknown. Numerous V genes have appeared in polyreactive antibodies, and there is as yet no characteristic sequence motif that predicts polyreactivity. Nevertheless, sequence studies implicated heavy-chain CDR3 as a major determinant of polyreactivity (29). Structure–function studies comparing a polyreactive and monoreactive anti-insulin with similar sequences confirmed that polyreactivity was associated with heavy-chain CDR3 (30). This CDR loop is presumed to adopt multiple conformations to accommodate different antigens, but crystallographic data on the three-dimensional structure of polyreactive antibodies are lacking.

Antibody-Conjugated Toxins

Soon after the discovery of the high specificity of antibody binding, Paul Ehrlich proposed to exploit such specificity to redirect and restrict the activity of toxins to pathological tissues such as tumors (1-3). Such "magic bullets" could be developed only long after his proposal because of the need of antibodies of well-defined specificity, such as monoclonal antibodies, and to improve the understanding of the biochemistry and mechanism of the action of toxins. Such conjugates have been prepared by linking one of the many available cell-killing plant or bacterial toxins via a **disulfide** or thioether bond to an antibody specific for a cell surface antigen of cancer and noncancer cells. Chimeric toxins have also been prepared by fusing a toxin gene to a gene encoding a hormone, growth factor, or **cytokine** with the intention of depleting receptor-rich cell populations (1-3). In general, it is important that the linkage between the two immunotoxin parts be easily cleaved on or inside cells. Moreover, to restrict immunotoxin binding only to the cells to be intoxicated, the portion of the toxin determining its intrinsic specificity (the B subunit) must be either deleted or inactivated mutationally, and the F_c portion of the antibody must be removed. In this respect, **ribosome**-inactivating plant toxins lacking the B subunit have been frequently used. To avoid unspecific binding to F_c-receptor bearing cells, the toxin can be linked to the $F(\mathrm{ab})_2$ portion of a monoclonal antibody. An additional problem may be presented by the presence of circulating antitoxin antibodies elicited in previous vaccination protocols (eg, anti**diphtheria**) or during the treatment with the immunotoxin. In the latter case, one can use another immunotoxin made with the same antibody and an immunologically unrelated toxin.

Several antibody-conjugated toxins are very effective in killing target cells in culture or in isolated dispersed tissues, ie, bone marrow, but are less effective *in vivo*, because of the lack of accessibility of the cancer cells in solid tumors. However, protocols are being developed to overcome these problems and exploit the potentials of immunotoxins to reach small cancer populations that are undetected by physical and surgical methods (3).

Anticodon

The anticodon of transfer RNA (tRNA) is in the central part of the linear RNA sequence, at positions 34, 35, and 36. This triplet of nucleotides forms transitory base pairs with three nucleotide codons of the **messenger** RNA (mRNA) during **protein biosynthesis**. These codon/anticodon interactions enable the mRNA to direct the order of incorporation of amino acids into the polypeptide chain. These interactions occur on the small subunit of the ribosome. The presence of the anticodon in the seven-membered central loop of tRNA led to the designation of this subdomain as the anticodon loop. The anticodon stem plus the loop constitute the anticodon arm (stem and loop), which contributes to one branch of the L-shaped 3D structure of tRNA. In this structure, the anticodon is about 80 Å from the amino acid acceptor end of the tRNA (see Fig. 1 of Transfer RNA). Besides its fundamental contribution to translation of the genetic information through complementary pairing to the codon, the anticodon of tRNA may contain important identity elements, recognized by cognate aminoacyl-tRNA synthetases, which lead to specific aminoacylation of the tRNA. Besides the anticodon, other members of the loop and of the nearby stem, including modified nucleotides, also contribute both to the efficiency and specificity of aminoacylation.

Codon–anticodon interaction occurs basically through classic **Watson–Crick base pairs**. However, additional types of interactions allow **wobble** to occur between the third base of the codon and the first base of the anticodon (1). The original wobble rules suggested that the first nucleoside of the anticodon can pair with more than one nucleoside at the third position of the codon. Thus, anticodons with a U at the first position could interact with codons having either A or G at the third position. Those presenting a G at position 34 could interact with codons terminating with U or C. More interestingly, tRNA presenting an inosine (deaminated adenosine) at position 34 could recognize codons terminating with either C, U, or A. For example, yeast $tRNA^{Ala}$, anticodon 5′-IGC-3′, interacts with three codons: 5′-GCC-3′, 5′-GCU-3′, and 5′-GCA-3′.

Numerous data accumulated over the years led to revised wobble rules (2, 3), which reflect new possible interactions between classic bases and take into account the vast occurrence of modified nucleosides in the anticodons of tRNA, especially those at the wobble position (residue 34, first position of the anticodon). One minor tRNA, *Escherichia coli*, $tRNA^{Ile}2$, has a methionine anticodon CAU. However, in the mature tRNA, C34 is modified by covalent attachment of lysine on position 2 of the pyrimidine ring, converting it to lysidine or a “k2C” base. Lysidine at the wobble position leads to recognition of the isoleucine-specific codon 5′-AUA-3′ instead of the methionine codon AUG. Interestingly, this modification is also required for specific recognition of the tRNA by isoleucyl-tRNA synthetase (see discussion below). Other examples of modification at position 34 that contribute to the specificity of codon–anticodon recognition have been reported. This is also true for nucleotide 37, at the 3′ side of the anticodon triplet. Many different modified purine nucleosides have been identified at this position, and these modifications contribute to the fidelity of protein synthesis. For example, hypermodification of A to i6A (*N*-6-isopentenyladenosine), t6A (*N*-6-threonylcarbamoyladenosine), and their derivatives, stabilizes the relatively weak A-U and U-A base pairing between the third position of the anticodon and the first position of the codon. The presence of the hypermodified nucleoside ms2i6A (*N*-6-(D-2-isopentenyl)-2-methylthioadenosine), in contrast, prevents codon misreading by *E. coli* $tRNA^{Phe}$. Modifications introduce conformational flexibility or rigidity that restrict or enlarge the number of potential base pairs. Thus the molecular mechanism by which modified bases alter codon recognition are largely structural in nature.

UAG (**amber**), UAA (**ocher**), and UGA (opal) codons do not code for an amino acid, because there are no tRNA with corresponding anticodons. Known as **nonsense codons**, they normally signal termination of translation, but such codons can be created by mutation, when they cause premature termination of protein synthesis. Interestingly, nonsense **suppressor** tRNA, with mutations in the anticodon, can recognize and "suppress" nonsense mutations by inserting a specific amino acid during translation (4). The first suppressor tRNA identified was a tyrosine-specific tRNA in which a single base substitution converted the anticodon from GUA (Tyr) to CUA (amber). Conversion of a classic tRNA to an efficient suppressor RNA may also involve mutations outside the anticodon. Suppressor tRNA have been used as a tool in the search of tRNA identity elements *in vivo* and as a way of inserting desired amino acids at specific sites in proteins.

The anticodon triplet specifies which amino acid the tRNA will insert in response to a codon and is, of course, directly correlated with the amino acid bound to the -CCA end. A simple analysis of the genetic code, however, reveals that the anticodon is not a common signal for synthetase recognition. For example, there are six different serine codons and, consequently, the potential for six different anticodon sequences in serine-specific tRNA. This great variability in isoacceptor tRNA precludes a common signal in the anticodon for recognition by seryl-tRNA synthetase, but it is clear that anticodon nucleotides, as well as other nucleotides within the anticodon loop, are critical for which amino acids are charged by aminoacylation (5-10).

Single-point mutations at any anticodon nucleotide of yeast $tRNA^{Phe}$ or yeast $tRNA^{Asp}$ lead to severe losses in aminoacylation efficiency (11, 12). A simple anticodon switch changes the aminoacylation specificity of methionine and valine tRNA (13). Depending on the tRNA, one, two, or three anticodon nucleotides may be involved in tRNA specificity. Position 35 is required for charging of arginine, both 35 and 36 are important for valine or threonine, and 34, 35, and 36 are involved in specificity for Asn, Asp, Cys, Gln, Ile, Lys, Met, Phe, Trp, and Tyr. In *E. coli* $tRNA^{Gln}$, residue 35 is of greater importance than residues 34 and 36. In yeast $tRNA^{Asp}$, nucleotides 34 and 35 contribute more than do nucleotide 36. Transplantation of anticodons into noncognate tRNA results in increases of four to six orders of magnitude in aminoacylation of the chimeric tRNA with the amino acid corresponding to the transplanted anticodon. Since it does not preclude aminoacylation of the chimeric tRNA with the original amino acid, however, it is clear that additional identity elements elsewhere in the tRNA structure dictate amino acid specificity (see Transfer RNA). The extent and the relative contribution of the different nucleotides of the anticodon to this specificity varies. The losses in specificity for yeast $tRNA^{Asp}$ are about 500-fold, while those for *E. coli* $tRNA^{Val}$ are 100,000-fold.

Other nucleotides within the anticodon domain often contribute to amino acid specificity. Residue 38 is involved in yeast $tRNA^{Asp}$, and both residues A37 and U38 are involved in *E. coli* $tRNA^{Gln}$. An original approach to anticodon domain function uses the *in vitro* synthesis of minihelices (shortened forms of tRNA) mimicking isolated anticodon stem and loop domains. These minihelices possess identity elements and were tested for stimulation of aminoacylation rates of the acceptor stem as substrate and/or for inhibition of full-length tRNA charging (14). Yeast valyl-tRNA (15) and *E. coli* isoleucine-tRNA (16) anticodon minihelices stimulated, up to threefold, the aminoacylation of an acceptor arm minihelix by cognate aminoacyl-tRNA synthetase. The isolated anticodon domain of $tRNA^{fMet}$ binds to *E. coli* methionyl-tRNA synthetase (17).

The anticodon domain is further implicated in discrimination between initiator and elongator forms of tRNA (18) and in alternate functions of tRNA, such as initiation of **reverse transcription** in retroviruses (19) (see Transfer RNA).

Anti Conformation

Anti is used as a prefix to describe the relative orientation of two substituents on adjacent atoms of a molecule when their torsion angle is about 180° (1) (see Conformation). In addition to its formal usage, *anti* has become broadly used to describe the orientation of the **nucleic acid** bases relative to the ribose ring when describing the torsion angle about the glycosidic bond (2). The glycosidic bond torsion is defined by the relative positions of the four atoms surrounding this bond, O4′—*C*1—N9 (1—*C*4(2)) for the purine (pyrimidine) nucleosides (3). When C4 is not over the ribose ring, the conformation is *anti*, corresponding to torsion angles of –80 to –180 and 100 to 180°. Conformations where the purine ring is over the sugar are *syn* and correspond to torsion angles of –80 to 100°. These conformations for adenine are shown in Figure 1.

Figure 1. The *anti* and *syn* conformations of dAMP are shown. The bonds defining the glycosidic torsion angle are darkened for emphasis in both conformers. In the *anti* conformer, the torsion is 110° , and in the *syn* conformer the

torsion angle is +60.

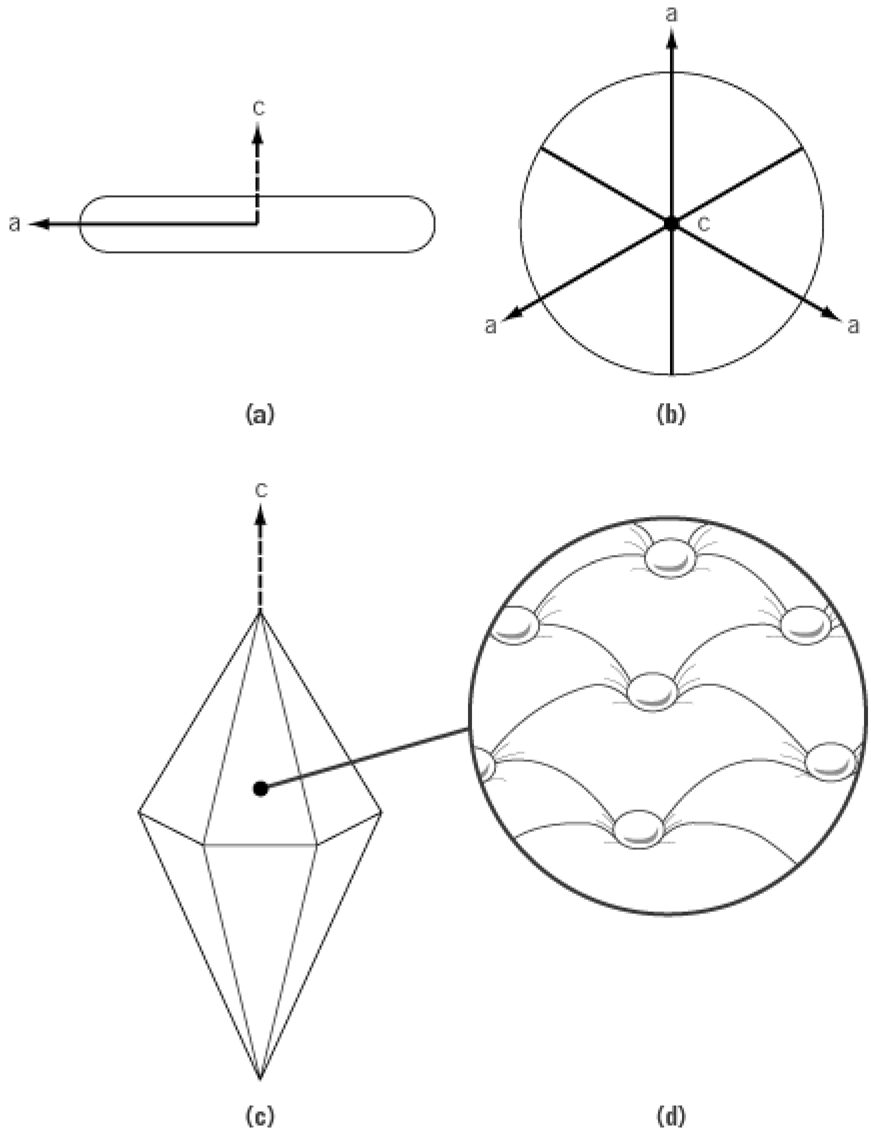
Antifreeze Proteins

Antifreeze proteins (AFPs) adsorb specifically to the surface of ice. By doing so, they inhibit its growth and cause a nonequilibrium depression of the freezing point below the colligative melting/freezing point (1). This depression, which is referred to as thermal hysteresis (°C), helps organisms to avoid or resist freezing when they encounter ice at temperatures below their colligative freezing points. For example, in polar and cold temperate marine environments bony fishes (teleosts) can encounter icy seawater at its freezing point of ≈ –1.9°C, which is over 1°C colder than their colligative freezing point of ≈ –0.7°C. Those fishes that have adapted to this environment produce high concentrations of AFP in their blood (10–25 mg/mL) that can depress their freezing point by the crucial 1°C needed for survival. For practical reasons, AFPs (sometimes known as thermal hysteresis proteins) have been best characterized in fish, but have also been found in insects, plants, and bacteria that encounter subzero conditions. Not all of these organisms resist freezing. In those that do freeze, AFPs may enhance their freeze tolerance by keeping ice crystals from growing (recrystallizing) in the frozen state (2). Recrystallization of ice occurs as the melting temperature is approached and ice becomes more dynamic. It is effectively inhibited by very low AFP concentrations (µg/mL). Although there are reports of AFPs neutralizing ice nucleators (3) and of having protective effects on cells above 0°C (4), the two well-established functions of macromolecular antifreezes, thermal hysteresis and inhibition of ice recrystallization, are related activities that depend on AFP interaction with ice by an absorption-inhibition mechanism.

1. Inhibition of Ice Growth

In ice, each water molecule makes four tetrahedrally oriented hydrogen bonds to neighboring molecules, and the resulting ice lattice has an underlying hexagonal symmetry. When an aqueous solution is cooled in the presence of an ice crystal, water adds preferably to the atomically rough prism surfaces of the crystal much faster than to the two smoother basal planes. At slight undercooling below the freezing point, the prism surfaces are curved, and the ice grows radially as a disk (Fig. 1). Most solutes are swept aside by the expanding ice front. However, AFPs with a specific affinity for an ice surface plane become adsorbed to that surface and cause growth inhibition that further defines the surface plane and typically shapes the ice crystal into a hexagonal bipyramid. The basis for growth inhibition at the surface of ice is that water is forced to add to the lattice between the bound AFP (1, 5). These submicroscopic ice fronts are constrained to grow with a surface curvature that makes it thermodynamically unfavorable for water to join the lattice, which in turn leads to a local depression of the freezing point below that of the bulk solvent. Rather than completely covering the surface, AFPs have been likened to buttons on a mattress (Fig. 1d).

Figure 1. i) In the absence of AFP, a single ice crystal from the melt will grow fastest along the crystallographic *a* axes to form a disk with curved prism surfaces. ii) View of disk perpendicular to i) with *c* axis perpendicular to the page. iii) AFP adsorption to any aspect of the prism surface will force the crystal to become a hexagonal bipyramid. iv) The inset shows a section of the surface illustrating the submicroscopic ice front curvature between bound AFPs.

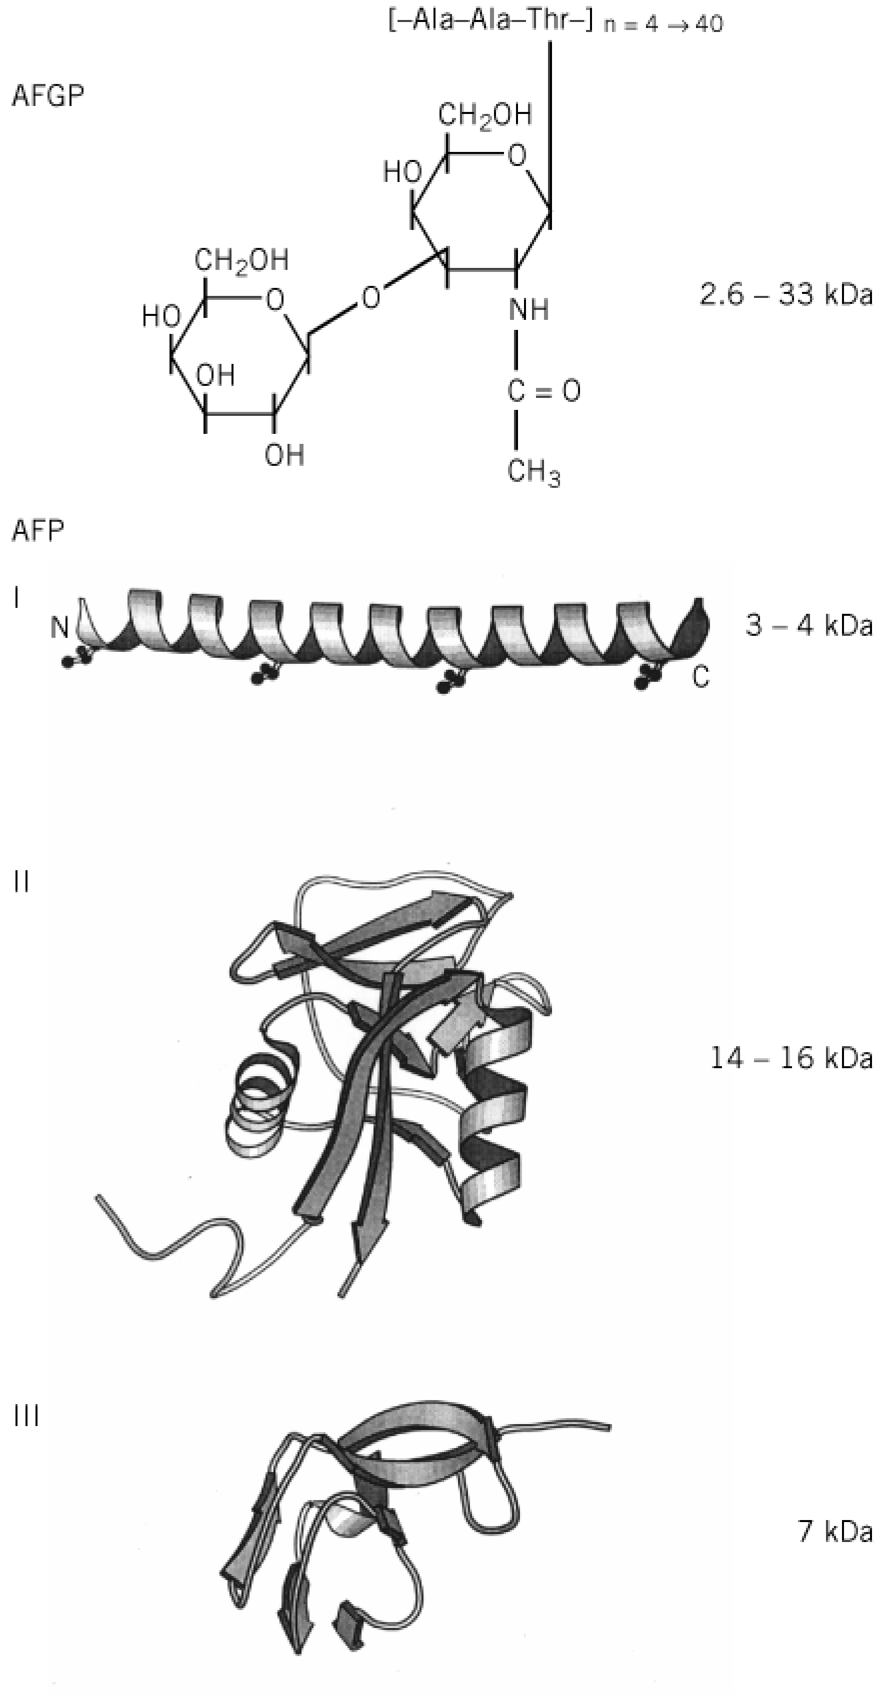


The relationship between thermal hysteresis and AFP concentration is nonlinear. Thermal hysteresis increases hyperbolically with increasing AFP concentration and approaches a plateau value of between 1 and 1.5°C for fish AFPs and 5 to 6°C for insect AFPs. If the temperature falls below the nonequilibrium freezing point at moderate to high AFP concentrations, the ice crystal will grow uncontrollably. At low AFP concentrations and moderate undercooling, the ice front will overgrow bound AFPs. This phenomenon has been used to deduce the ice surface to which AFPs bind by growing ice in a dilute AFP solution and then allowing it to sublime (ice etching) (5). The position of the AFP residue etch on the ice indicates its binding plane and, in some cases, its orientation of binding on that plane.

2. Adsorption of AFPs to Ice

One of the most intriguing features of AFPs is their structural diversity. In fish, there are at least five unrelated types, which are also different from insect AFPs (Fig. 2). It is likely that additional types will be discovered. They are so different that it has not been possible to identify a shared sequence or structural motif that could explain their common ice-binding activity. An added complication is that they bind to different ice surface planes (6). Early models for binding of AFPs to ice relied on a hydrogen-bonding match to the ice lattice (5, 7). However, it has been argued that hydrogen bonding of AFPs to liquid water is energetically favored over binding to ice (8). Also, correct identification of the ice-binding sites now shows them to be more hydrophobic than originally thought (9). One structural feature that AFPs have in common is an extensive region of intimate surface complementarity between the AFP and ice. Thus the energetic contributions to binding could include van der Waals interactions over the AFP–ice interface, some hydrogen bonds, and an entropic component from not having to solvate the AFP and ice surfaces in contact (10)

Figure 2. AFP structures. The 3D structures of Type I AFP from winter flounder (1WFA); Type II AFP from sea raven (2AFP); Type III AFP from ocean pout (1MSI); beetle AFP (1EZG); and moth AFP were solved by X-ray crystallography or nuclear magnetic resonance. The approximate masses of the proteins are indicated in kDa.



3. Evolution of AFPs

Fish AFPs have been classified into five different types. Antifreeze **glycoproteins** (AFGPs) are polymers of the tripeptide repeat Ala-Ala-Thr with a disaccharide (b-D-galactopyranosyl-(1→3)-2-acetamido-2-deoxy-a-D-galactopyranose) attached to the Thr. Type I AFP is an alanine-rich single a-helix. Type II AFP is a globular protein with sequence homology and structural similarity to the carbohydrate recognition domain of calcium-dependent lectins. Type III AFP is a smaller protein with a unique ß-sandwich fold that is homologous to a portion of sialic acid synthase. The most recently discovered (Type IV) AFP has homology to apolipoprotein E and is thought to be a helix-bundle protein.

It is clear that the different AFP types have distinct origins, which suggests that they have been independently co-opted as antifreezes relatively recently in the 175-million-year radiation of the bony fishes (11). Indeed, there are now several examples of very closely related fishes producing different AFP types and at least one clear example of distantly related fishes producing the same type through **convergent** evolution (12). This pattern of recent evolution is reinforced by the observation that AFP gene families show evidence of extensive **amplification**, often with the AFP genes organized as tandem repeats and with substantial variation in gene dosage (13). The diversity of AFP types is also reflected in their expression and processing. AFP genes are either constitutively expressed or are regulated by a variety of cues, including temperature, photoperiod, and hormonal cycles (14). Fish AFPs are typically produced in the liver as pre-proteins for secretion into the serum with or without a pro-sequence. The small antifreeze glycoproteins are produced from a large polyprotein by both **proteolysis** and glycosylation (12). In winter flounder, the external tissues, skin, scales, fins, and gills produce **isoforms** representing a subclass of Type I AFP that appears to lack a signal sequence (15).

Not unexpectedly, plant and insect AFPs are also different. AFPs from winter rye appear to be homologs of three types of extracellular plant pathogenesis-related sequences, namely endochitinases, endoglucanases, and thaumatin-like proteins (16), and carrot AFP is related to polygalacturonase inhibitor (17). These similarities reinforce the links between AFPs and sugar/polysaccharide-binding proteins. Plant AFPs appear to be more active in ice recrystallization inhibition than thermal hysteresis, whereas insect AFPs show considerably more thermal hysteresis activity than fish AFPs. AFPs from moths and beetles have distinct origins, and yet they both form ß-helices with similar threonine-rich ice-binding sites (18, 19). In some terrestrial insects that can resist freezing at temperatures down to –30°C, AFPs may be part of a suite of cryoprotective mechanisms that include elevated polyol levels and the elimination of ice nucleators that would interfere with supercooling.

4. Conclusion

Although adsorption-inhibition is the generally accepted mechanism of AFP action, the energetics of tight binding to ice are not yet fully understood. Other areas of current research include the basis for the hyperactivity of insect AFPs, activities of AFPs other than thermal hysteresis, and applications for AFPs in conferring freeze tolerance/resistance to unprotected organisms.

Antigen

The historical definition of an antigen, given for many years in immunology textbooks, is a rather circular one, because it describes the antigen as a foreign substance that induces upon penetration in an animal (or a human being) the production of an antibody with which it will combine specifically, *in vivo* or *in vitro*. This classical antibody response is a characteristic of vertebrates. Although not basically wrong, this definition necessitates some comments addressing three points: (*1*) antibody, (*2*) induction, and (*3*) foreignness.

1. Antibody

When this definition was proposed, the immune response was characterized solely by the production of antibodies. When it was realized, in the 1960, that the specific functions of the immune system relied on two distinct types of lymphocytes, B cells and T cells, it became clear that the immune response could no longer be limited to the production of antibodies. B and T cells “recognize” the antigen, but in very different ways. B cells express immunoglobulins at their surface, whereas T cells express the so-called T-cell receptor (TCR). By extension, surface immunoglobulins are also given the name of B-cell receptor (BCR), by analogy with the TCR. Once stimulated by an antigen, in combination with other signals (**cytokines**), the B cells differentiate into plasma cells that will express a soluble form of immunoglobulins, also known as *antibodies* or *circulating antibodies*, because they are free in the bloodstream. Immunoglobulins and TCR are constructed on the same general pattern, but are encoded by discrete sets of **genes**. They interact with the antigen in very different manners. The immunoglobulins—or antibodies—interact directly with a nativeform of the antigen, through a small portion of this antigen called the *antigenic determinant* or epitope. The TCR does not recognize the antigen as a whole, but interacts witha fragment of it, which results from **antigen processing** and presentation. This has been well studied for **protein** antigens, which are cleaved into peptides (the processing step) in the so-called antigen-presenting cells (macrophages, dendritic cells, etc.), which will then reexpress these peptides at their surface, in close association with molecules encoded by genes of the major histocompatibility complex (MHC) (presentation step). Finally, the TCR will bind to both the peptide and the MHC-presenting molecule. The peptide derived from the antigen and that interacts with the corresponding TCR is describedas the “T-epitope.”

2. Induction

For a long period of time, in fact until it became possible to work on the chemistry of antibodies in the beginning of the 1960, immunochemists centered their interest on the most accessible partner of the antigen–antibody complex—that is, the antigen, for which simple models of well-defined structure could be worked out. Although somewhat frustrating for a physiologist (this would be like an enzymologist exclusively studying substrates), this approach shed light on the exquisite specificity of recognition by the immune system, thanks mostly to the pioneering work of Landsteiner (1) and the discovery of haptens. Haptens are small molecules that are unable to stimulate the immune system, but may bind to an antibody. To produce this antibody, the hapten had to be conjugated to a protein that served as a carrier, conferring the property of stimulating the immune system. This observation clearly indicated that induction and recognition were two separate properties of an antigen. To clarify this, it was proposed to distinguish antigenicity from immunogenicity and, consequently, an antigen from an immunogen. Antigenicity describes the chemical structures that condition interaction with an antibody or with a TCR, whereas immunogenicity defines the properties of a molecule to induce an immune response. This distinction is far from pure semantics. A protein, considered as a typical “natural” immunogen, has the dual characteristics of a carrier, which is involved in processing and presentation, and of a hapten (in fact a mosaic of haptens) represented by the B epitope. This duality is of central importance for the immune system, in that it implies a close cooperation between B, T, and antigen-presenting cells. In most cases, an antibody response requires cooperation with the T-cell compartment, leading to the distinction of T-dependent antigens, as opposed to T-independent ones, which can stimulate B cells directly without this T-cell “help.”

3. Foreignness

At the end of the nineteenth century, the first antigens that were identified were pathogens: bacteria, **viruses**, parasites, or toxins of various origins. It was soon realized that pathogenicity and immunogenicity were not linked and that a huge variety of cells or molecules could induce an immune response, providing that they were foreign to the animal it was injected into. Furthermore, this requirement of foreignness was strengthened by the famous aphorism “horror autotoxicus” put forward in 1901 by Ehrlich, to indicate that the immune system could not be stimulated by self-components, leading to the concept that it was a master of self–nonself discrimination. Due to independent observations of Grubb, Oudin, and Kunkel (2-4), it became apparent that this distinction between self and nonself was not as clear as initially thought. Oudin described three types of antigenic specificities, termed *isotypy*, *allotypy*, and *idiotypy*. Isotypy refers to those specificities that are characteristic of one molecule of one given animal species, for instance the mouse serum albumin. An antibody raised against albumin of one given mouse will react with the albumin of anymouse. Allotypy defines antigenic specificities that are shared by a group of individuals within a given species, as initially shown by Oudin for the rabbit immunoglobulins. This is the case of the human blood groups, for which people of, say, group A share this specificity. Allotypy simply reflects the existence of epitopes (or allotopes) that are encoded by allelic variants (see Alloantibody, Alloantigen). The last type of specificity, idiotypy, is more subtle, and is inherent to the molecules of the immune system itself. It was initially described by Oudin as the characteristics of one antibody molecule, synthesized by one given animal and specific for one given antigen. So, if a rabbit is given antigen X, it will produce an anti-X antibody (or Ab1). If a second rabbit, expressing the same immunoglobulin allotypes, is immunized against the anti-X antibody, it will produce an anti-anti-X antibody (or Ab2). Ab1 is an idiotype, Ab2 an **anti-idiotype**, and the antigenic specificities recognized on Ab1 by Ab2 are called the *idiotopes*. Because it was later shown that Ab1 and Ab2 could be produced as discrete waves within the same animal, it was clearly realized that the self–nonself distinction was not so obvious. The horror autotoxicus dogma had also to be revisited when it was shown by Avrameas, and extended by Coutinho (5), that a low level of natural autoantibodies was consistently present in every individual, as well as autoreactive T-cell clones. Such natural antibodies have no pathogenic effect,as opposed to those identified in certain autoimmune diseases, for reasons that are still not completely understood.

The term *antigen* covers a huge number of structures, from cells and macromolecular complexes, to relatively small molecules, the lower limit in molecular weight being of the order of a few thousand. Ultimately, and whatever the source of the materials considered, proteins and, to a lesser extent, polysaccharides are the main antigens. Proteins are representative of the T-dependent antigens, which implies processing and presentation. Depending upon their size, the potential number of discrete epitopes of one given antigen may vary from a very small number to several tens, in roughly linear proportion with the exposed area of the molecule. Polysaccharides behave most frequently as T-independent antigens. They are frequently constituents of the bacterial surface and are thus important for the preparation of vaccines against these microorganisms. Another example of polysaccharide antigens is given by the major blood groups in humans. Some macromolecular complexes, such as bacterial lipopolysaccharides, have been studied extensively because they also behave as polyclonal potent mitogenic activators of B cells. Nucleic acids are considered poor immunogens, although they clearly constitute a target for autoantibodies in systemic lupus erythematosus, a severe autoimmune disease. More recently, DNA has been tentatively used as a vaccine, in the form of expression vectors encoding a protein that acted secondarily as an immunizing antigen.

Detailed analysis of the antigenic determinants or epitopes of natural antigens is a difficult task and has necessitated the use of models, among which the most extensively studied in the 1960s and 1970s were polysaccharides by the group of Kabat at Columbia University (6). Based on the binding inhibition of dextran (a polymer of glucose) to anti-dextran antibodies by oligosaccharides of various lengths, the range of size of an epitope, and hence that of the corresponding antibody combining site, was estimated to be between 3 and 6 monosaccharide units. A similar approach was taken by the group of Sela at the Weizmann Institute, with synthetic peptides that mimicked the structure of natural proteins. Direct analysis of natural peptide epitopes with the corresponding antibody was made much later by X-ray crystallography and gave a clear picture of the organization of the antibody combining site. The central message is that there is a huge diversity in size and form of natural epitopes. At the surface of a protein, the number of amino acid residues that interact with the antibody combining site varies from a few to about 20. The variation in both size and number of epitopes at the antigen surface contribute a large part of the heterogeneity of the immune response.

Antigen Processing, Presentation

Antigen processing and presentation are crucial steps for recognition of protein antigens by T cells. The T-cell receptor (TCR) will not bind a protein directly, as do immunoglobulins, but only as peptides derived from the original protein (processing step) and bound to class I or class II molecules of the major histocompatibility complex, or MHC (presentation step). This applies to helper as well as to effector cytotoxic T lymphocytes and therefore condition severy aspect of the T-dependent immune response. These functions strictly condition immunogenicity and correlate well with the dichotomy between carrier and hapten that had indicated long ago that the hapten part of the complex was recognized as such by the B cell, but was unable to initiate an immune response unless conjugated to a carrier protein (see Antigen). Later it was shown that carrier recognition involved the T helper cell but was also strictly dependent on MHC molecules (MHC restriction). Antigen processing and presentation take place in specialized cells and involve a number of molecules, most of which are encoded by genes of the MHC.

The antigen-presenting cells that are most efficient and most extensively studied are the dendritic cells and the epidermal Langerhans cells. They originate from $CD34^+$ bone marrow precursors and migrate to different tissues. They express FcR e I and FcRII, as well as class I and class II molecules of MHC (in humans, HLA-DR). They internalize the antigen by the **endosomal** pathway and, after processing, reexpress at the cell surface antigen-derived peptides associated with class I molecules. Alternatively, they may present peptides associated with class I MHC after macropinocytosis. They may become interdigitated cells and migrate to secondary lymphoid organs, where they present peptides specifically to CD4 T cells. B cells also behave as antigen-presenting cells, and this is of major importance for the antibody response induced by a T-dependent antigen, because it conditions the necessary direct interaction between T and B cells. Finally, macrophages and monocytes also can present antigens, in addition to their other functions.

There are two main pathways for antigen processing and presentation. One involves association with MHC class I molecules and presentation to CD8 T lymphocytes, while the other involves MHC class II molecules and interaction with CD4 lymphocytes.

1. Class I Pathway

MHC Class I molecules are composed of one a polypeptide chain of 43 kDa that forms a heterodimer with the b2 microglobulin. A peptide binding site, which accommodates nonapeptides, is shared by the first two **domains** of the a chain. There is a huge degeneracy in peptide recognition by one such site, as expected from the low number of different MHC molecules expressed in any individual. Class I molecules are specialized in the presentation of endogenous proteins, synthesized *in situ* by a virus or any intracellular bacteria or parasite. Processing starts as a fraction of these cytosolic proteins are hydrolyzed in the proteasome, a **proteinase**-rich complex involved in **protein degradation**. The resulting peptides will be transported by the specialized TAP gene products to class I molecules in the endoplasmic reticulum. The class I peptide complex will pass through the Golgi apparatus, where the a chain becomes glycosylated before being included in a **secretory vesicle** and finally expressed at the plasma membrane. Interaction with the CD8 T cell involves the TCR, which makes contact with amino acid residues of both the peptide and the class I molecule, whereas CD8 binds solely to the MHC molecule. In addition to this specific interaction, many other cell adhesion molecules contribute to this "immunological synapse," as immunologists sometimes call it.

2. Class II Pathway

MHC class II molecules are composed of two chains, a and b, each containing two domains. The peptide binding site is shared by the a1 and b1 domains. The ab heterodimer associates with the Ii (CD74) invariant chain that prevents any association of an endogenous peptide with the class II molecule. After glycosylation during passage through the Golgi, the complex is packed in the class II vesicles that fuse with endosomes, where the invariant Ii chain is hydrolyzed, leaving only the CLIP peptide still associated with the ab heterodimer. The last step, controlled by HLA-DM molecules, involves an exchange between CLIP and a peptide derived from an exogenous protein antigen. The complex of peptide and class II molecules may now be expressed at the cell surface. A fraction of the class II molecules is reinternalized and may bind new peptides, before being reexpressed at the cell surface. The size of peptides that bind to the class II molecule may vary from between 10 and 30 amino acid residues. Interaction with T cells is somewhat similar to the case previously described, except that it involves essentially CD4 T cells.

CD4 T cells are helper cells that will either (a) interact with the T effector compartment and promote the emergence of cytotoxic T cells or (b) interact with B cells that will ultimately produce antibodies. The latter interaction is of particular interest, because the B cell will act as both a presenting cell and an antibody-producing cell. The T-cell–B-cell interaction is initiated because the B cell presents peptides derived from the specific antigen that had been internalized after binding to the surface immunoglobulin. The antigenic peptide–class II complex will trigger the interacting TCR and activate the T-cell CD3 signaling module. Critical molecules are then produced by the T cell, amongst which are soluble cytokines and one membrane ligand, CD40L, which will bind to its receptor, the CD40 molecule, which is constitutively expressed on the B cell. This is the major signal that will ultimately activate the final phase of differentiation of the B cell and provide the key to clonal expansion and antibody production.

Antigenic Variation

Antigenic variation is a sophisticated molecular mechanism that allows parasites, **viruses**, and some bacteria to escape the immune response of the invaded host, by changing the nature of their expressed surface antigens. Classical examples are (a) **trypanosomes** amongst parasites and (b) **influzenza virus**.

Trypanosomes are infectious agents transmitted by glossinas and are responsible for severe tropical diseases, such as sleeping sickness in humans. Trypanosomes express surface **glycoproteins** that induce an immune response in the host. Although at any given time one trypanosome expresses one surface glycoprotein, it may switch to the expression of another one, having a slightly different structure. There are large numbers of these different forms (up to 1000), called **variable surface glycoproteins** (VSG), each being encoded by a distinct **gene**. There are two known mechanisms that account for the successive expression of different VSG genes. One is transposition that brings a gene that was present initially as part of one of several gene clusters, scattered on different chromosomes, to one telomere end. As a consequence of the transposition, that gene is expressed, until another one becomes functional. An alternative mechanism is a change in the control of transcription of expression sites. As the structure varies from one VSG to another, there is a permanent change in antigenicity of the parasite population, thereby ensuring escape from the immune mechanisms of the host. Although a large number of genes are potentially active, only a limited fraction is used, so that the repertoire of different VSGs expressed in one host remains limited; this may explain the appearance of chronic immunity in tropical populations.

Viruses use a different mechanism to escape the immune system. One example is that of influenza A, which expresses two surface antigens, hemagglutinin and neuraminidase. It is well known that new variants always arise, sometimes being highly dangerous as they spread rapidly. New variants are the result of mutations, which induce *antigenic drift*, and exchange of genetic material between different virus strains, leading to *antigenic shift*, which has a more drastic impact on spreading of the virus. Antigenic variation of viruses is a major drawback in preventing infection (see Virus Infection, Animal). One approach is to prepare modified strains by site-directed mutagenesis and thus produce vaccines that might anticipate their natural variation.

A more recent problem of antigenic variation is that by HIV, which mutates rapidly, leading to the rapid accumulation of numerous variants within the same patient and providing a particularly efficient way for the virus to escape the immune system. Added to the fact that lymphocytes themselves area major target for this virus, this stresses the unusual danger of this virus.

Anti-Idiotype Immunoglobulins

Every biologist is familiar with the fact that injection of an antigen into an animal induces an immune response that results, among other things, in the production of specific antibodies. So, if a mouse is given antigen X, it will produce the corresponding anti-X antibody. If we now purify this anti-X antibody and inject it into a mouse of the same strain, (ie, expressing the same **allotypes** as the first mouse), the second mouse will produce an antibody that will react with the anti-X antibody and that represents an anti-anti-X antibody. This defines the idiotypic specificities, which were first described independently in the 1960s by Oudin (1) in the rabbit and by Kunkel (2) in humans. These specificities are located on the **variable regions** of both the heavy and the light chains and are the result of epitope(s) [in this case we use the term of idiotope(s)], related at least in part to the antibody combining site of anti-X. It was shown subsequently that this game could be played one step further: If we now inject a third mouse with the anti-anti-X molecule, the mouse will make anti-anti-anti-X antibodies. Immunologists proposed a simplified nomenclature that reads

$$X \neg Ab1 \neg Ab2 \neg Ab3 \cdots$$

where Ab1 is the idiotype, Ab2 is the anti-idiotype, and Ab3 is the anti-anti-idiotype. This constitutes the so-called idiotypic cascade. One observation of particular interest, independently made by the groups of Oudin in Paris and Urbain (3) in Bruxelles, was that some antibodies in the Ab3 population behaved like Ab1, in that they could interact with antigen X, which the animal had never "seen." This led them to consider that Ab2 had structures resembling X, because it could induce the formation of antibodies (Ab3) that behaved as anti-X. Ab2 was thus considered an "internal image" of the antigen. The observation was generalized by Jerne (4), once it was shown that this cascade could take place spontaneously within the same animal and that the level of expression of each antibody could be modulated (up or down, depending upon the experimental conditions). Jerne proposed that the entire population of antibodies of a given individual were organized as a huge network of interactions, leading to a dynamic equilibrium of B lymphocytes. This was called the *idiotypic network*.

Modulation of the repertoire of B cells expressed at any given time by injection of either partner of the cascade was thoroughly investigated during a number of years. Particular attention was paid to the diverse roles exerted by the Ab2 antibodies, because it was demonstrated that two subpopulations, termed Ab2b and Ab2a, had completely antagonistic regulatory effects, resulting either in the production of Ab3 antibodies that were Ab1-like, or in the down regulation of Ab1. Ab2b are anti-idiotype antibodies that contain a typical internal image and are therefore able to stimulate the production of anti-X antibodies, without disposing of the original antigen. This led to the development of numerous attempts to make "idiotypic vaccines." The second type of population, Ab2a, recognizes idiotopes that are outside the antibody combining site of Ab1, and they appeared quite suitable to repress undesirable antibodies (ie, autoantibodies that have a pathogenic effect in autoimmune diseases).

The theoretical interest of idiotypic vaccines is to function as surrogate for antigens that are difficult to use for immunization, either because they are difficult to isolate, are poorly immunogenic, or present a potential hazard. Many attempts have been made, especially for **viruses**, including HIV, and parasites such as schistosomiasis. Antibodies were generally produced, but it turned out that in most (if not all) cases they were poorly neutralizing, and the protective effect *in vivo* was too low relative to the high efficiency that is expected from an acceptable vaccine.

Down-regulation of pathogenic autoantibodies encountered in autoimmune disease has also been extensively investigated, and it is still currently used in therapeutics. In fact, one uses immunoglobulin preparations assembled from very large pools of donors that are administered intravenously (IVIg). Although experimental arguments are compatible with the presence of anti-idiotypes, many other factors may account for the down regulation of the patient antibodies.

Finally, an interesting application of the internal image is the isolation of cellular receptors by Ab2b that mimic the corresponding ligand. Numerous examples have been reported and successfully used; the first was the Ab2b of the insulin cascade, which was shown to activate the insulin receptor of the b islet of pancreas. Adrenergic receptors or T3 and T4 thyroid hormone receptors are other examples. This could facilitate receptor isolation by the use of immunoadsorbents prepared with these anti-idiotypic internal image antibodies.

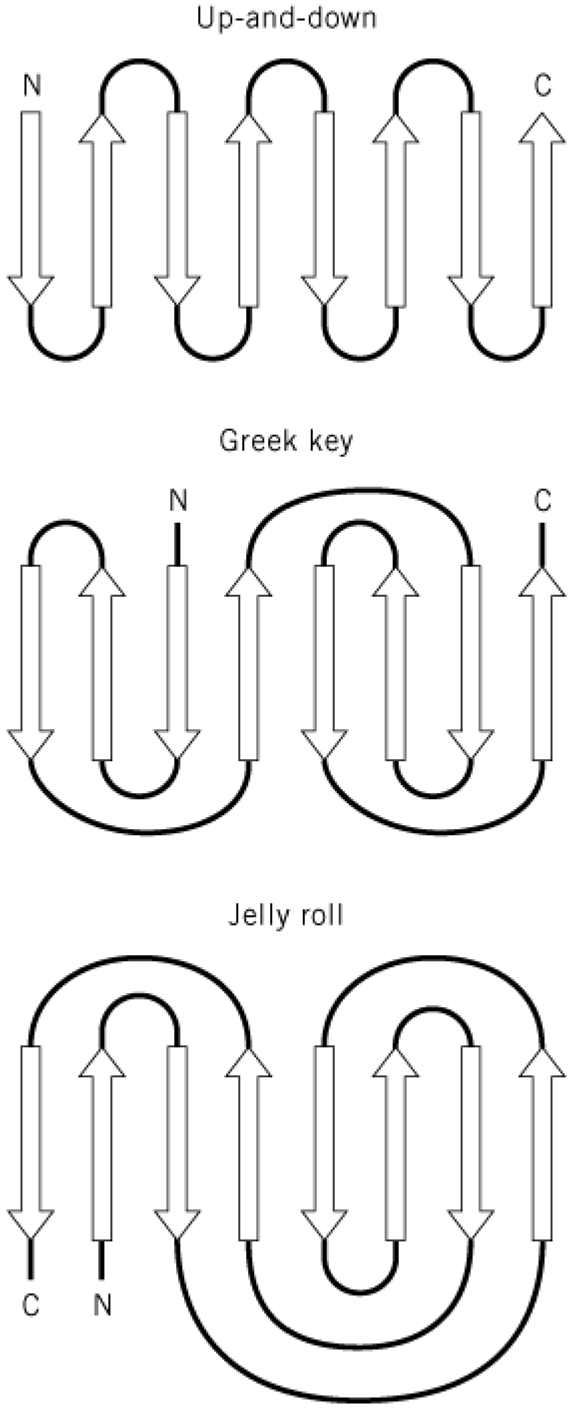
Antiparallel Beta-Barrel Motifs

Antiparallel b-barrel motif is a general term that describes several protein motifs observed in protein structures that have in common a barrel-shaped b-sheet structure formed from antiparallel beta-strands. These include the b-barrel, the **Greek key** barrel (formed from two Greek key motifs), and the **jelly roll** barrel (Fig. 1). The different motifs have different connections between the strands in the barrel. Other types of antiparallel b-barrels include the interleukin-1 motif and the **neuraminidase** superbarrel. All these protein barrels comprise only antiparallel b-strands and are therefore classified as all-b structural **domains**. They therefore differ significantly from the TIM barrel, which is classified as an a/b domain and is formed from a parallel b-barrel surrounded on the exterior by a-helices.

Figure 1. Schematic representation of the up and down (or b-meander), Greek key, and jelly roll topologies.

Antiparallel b-barrels can be formed from each of these three protein motifs, which represent different ways of linking consecutive b-strands together into a b-sheet.



[See also b-Barrel, Greek Key Motif, Jelly Roll Motif, and TIM Barrel.]

Antisense Oligonucleotides

Antisense oligonucleotides are used to **hybridize** to a specific **RNA** molecule *in vivo* and thereby to inhibit its subsequent use. In most cases, the target RNA is a messenger RNA (mRNA), which cannot then be translated into a protein. All that is required is knowledge of the gene's nucleotide sequence, so that an antisense oligonucleotide with the complementary sequence can be synthesized. In this way, the expression of one **gene** can be blocked, and the consequent observed effects help to elucidate the physiological role of the gene and its product.

Selection of the sites in a RNA molecule at which optimal antisense activity may be induced is complex, dependent on the terminating mechanism and influenced by the chemical class of the oligonucleotide. Each RNA displays a unique pattern of sites of sensitivity. Within the phosphorothioate oligodeoxynucleotide class, studies have shown that antisense activity can vary from undetectable to 100% by shifting an oligonucleotide by just a few bases in the RNA target (1, 2). Significant progress has been made in developing general rules that help to define potentially optimal sites in RNA species, but to a large extent this must be determined empirically for each RNA target and every new chemical class of oligonucleotides.

1. Therapeutic Uses

Besides being useful for characterizing the roles of genes, antisense oligonucleotides have the potential for therapeutic use to regulate the expression of certain genes or to block an infection by a pathogenic **bacterium** or **virus**. The therapeutic use of oligonucleotides represents a new paradigm for drug discovery, because oligonucleotides have not been studied before as potential drugs and they are being used to intervene in processes that have not been considered sites at which drugs might act. The affinity and the specificity of binding derive from the hybridization of two oligonucleotides and therefore are theoretically much greater than can be achieved with small molecules. Furthermore, the rational design of the nucleotide sequence of antisense oligonucleotide is much more straightforward than the design of small molecules interacting with proteins. Finally, it is possible to consider the design of antisense drugs to treat a very broad range of disorders, including those not amenable to other types of treatment.

This use of antisense oligonucleotides is still in its infancy, and the initial enthusiasm must be tempered by appropriate reservations concerning practical aspects. To be useful as a drug, an antisense oligonucleotide must be much more stable than ordinary nucleic acids, and it must be able to reach its desired site of action, the interior of a cell. Questions about the technology reduce to, can oligonucleotide analogs be created that have appropriate properties to be drugs? Specifically, what are the pharmacokinetic, pharmacological, and toxicological properties of these compounds and what are the scope and potential of the medicinal chemistry of oligonucleotides? Answers to many of these questions are available now.

2. Phosphorothioate oligodeoxynucleotides

To address the problem of stability, nonconventional oligonucleotides not susceptible to degradation or to hydrolysis by nucleases have been designed. Of the first generation of oligonucleotide analogs, the phosphorothioate class is best understood and has produced the broadest range of activities (3). Phosphorothioate oligonucleotides differ from normal in that one of the nonbridging oxygens in the phosphate group is replaced by a sulfur. The resulting compound is negatively charged, chiral at each phosphorothioate, and much more resistant to nucleases than a phosphodiester bridge.

2.1. Hybridization

The hybridization of phosphorothioate oligonucleotides to DNA and RNA has been thoroughly characterized. The melting temperature (T_m) of a phosphorothioate oligodeoxynucleotide bound to RNA is lower than for a corresponding phosphodiester oligodeoxynucleotide by approximately 0.5° C per nucleotide. Compared to RNA duplex formation, a phosphorothioate oligodeoxynucleotide has a T_m approximately 2.2°C lower per nucleotide. This means that, to be effective *in vitro*, phosphorothioate oligodeoxynucleotides must be relatively long, typically at least 17 to 20 nucleotides, and invasion of double-stranded regions of the target RNA is difficult (4-7).

2.1.1. Interactions with Proteins

Phosphorothioate oligonucleotides bind to proteins. These interactions can be (3) nonspecific, sequence-specific, or structure-specific, each of which may have different characteristics and effects. Nonspecific binding to a wide variety of proteins has been demonstrated, most thoroughly with serum albumin. The affinity of such interactions is low. The **dissociation constant** (K_d) for albumin is approximately 200 µM, about the same as for its binding of aspirin or penicillin (8-10). Phosphorothioates also interact with **nucleases** and **DNA polymerases**; they are slowly metabolized by both endo and **exonucleases** and are **competitive inhibitors** of these enzymes (11). In an RNA–DNA duplex, phosphorothioates are substrates for ribonuclease H (RNaseH) (12). At higher concentrations, phosphorothioates inhibit the enzyme, presumably by binding as a single strand (11). Again, the oligonucleotides are competitive antagonists for the DNA–RNA substrate.

Phosphorothioates are competitive inhibitors of DNA polymerase a and b with respect to the DNA template and **noncompetitive inhibitors** of DNA polymerases g and d (12). They are also competitive inhibitors for the **reverse transcriptase** of HIV and inhibit its associated RNase H activity (13, 14). They bind to the cell surface protein CD4 and to protein kinase C (15). Phosphorothioates inhibit various viral polymerases (16), and they also cause potent, nonsequence-specific inhibition of RNA splicing (17).

2.1.2. In Vivo Pharmacokinetics

Binding of phosphorothioate oligonucleotides to serum albumin and alpha-2 macroglobulin provides a repository for these drugs in the serum and prevents their rapid renal excretion. Because serum protein binding is saturable, however, intact oligomer may be found in urine with high doses (18, 19), eg, 15 to 20 mg kg^{-1} administered intravenously to rats. Phosphorothioate oligonucleotides are rapidly and extensively absorbed after parenteral administration, as much as 70% within 4 h (20, 21). Distribution of phosphorothioate oligonucleotides from blood after absorption or intravenous administration is extremely rapid. Distribution **half-lives** are less than one hour (18-20, 22). Clearance from the blood and plasma exhibits complex kinetics, with a terminal elimination half-life of 40 to 60 h in all species except man, where it may be somewhat longer (21). Phosphorothioates distribute broadly to all peripheral tissues, although no evidence for significant penetration of the blood brain barrier has been reported. Liver, kidney, bone marrow, skeletal muscle, and skin accumulate the highest amounts (20, 22). Liver accumulates the drug most rapidly (20% of a dose within 1 to 2 hours) and also eliminates it most rapidly (eg, the terminal half-life from liver is 62 h and from renal medulla 156 h). Within the kidney (23), oligonucleotides are probably filtered by the glomerulus, then reabsorbed by the proximal convoluted tubule epithelial cells, perhaps mediated by interactions with specific proteins in the brush border membranes. At relatively low doses, clearance of phosphorothioate oligonucleotides is caused primarily by metabolism (19, 20, 22), mediated by exo- and endonucleases.

2.1.3. Pharmacological Activities

Phosphorothioates also have effects inconsistent with the antisense mechanism for which they were designed. Some of these effects are sequence- or structure-specific. Others result from nonspecific interactions with proteins. These effects are particularly prominent in *in vitro* tests for antiviral activity, when high concentrations of cells, viruses, and oligonucleotides are often incubated together (24, 25). Human immune deficiency virus (HIV) is particularly problematic, because many oligonucleotides bind to the gp120 protein (26). Moreover, uncertainty as to the mode of action of antisense oligonucleotides is certainly not limited to antiviral or just *in vitro* tests (27-29). These observations indicate that, before drawing conclusions, careful analysis of dose-response curves, direct analysis of target protein or RNA, and inclusion of appropriate controls are required. In addition to interactions with proteins, other factors can contribute to unexpected results, such as overrepresented sequences of RNA and unusual structures that may be adopted by oligonucleotides

(26).

A relatively large number of reports of *in vivo* activities of phosphorothioate oligonucleotides have now appeared documenting activities after both local and systemic administration (30). However, for only a few of these reports have sufficient studies been performed to draw relatively firm conclusions concerning the mechanism of action by directly examining target RNA levels, target protein levels, and pharmacological effects, using a wide range of control oligonucleotides and examining the effects on closely related isotypes (31-34). Thus, there is a growing body of evidence that phosphorothioate oligonucleotides induce potent systemic and local effects *in vivo*, suggesting highly specific effects difficult to explain via any mechanism other than antisense.

2.1.4. Toxicological Properties

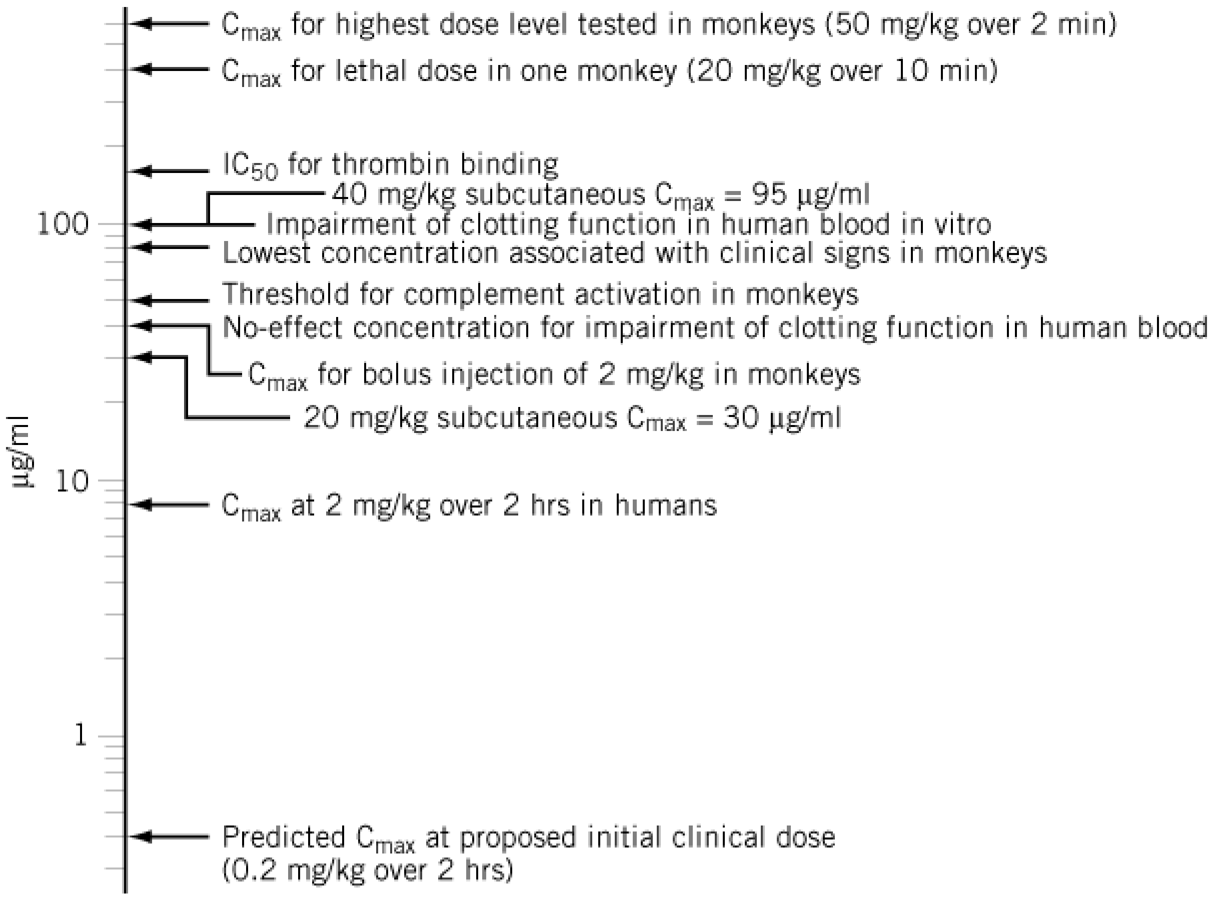
Phosphorothioate oligonucleotides are not toxic in themselves, but their use is limited by side effects. In rodents, this is immune stimulation (35, 36). In monkeys, it is sporadic reductions in blood pressure associated with bradycardia, which is often associated with activation of C-5 **complement** involving activation of the alternative complement pathway (37). All phosphorothioate oligonucleotides tested to date induce these effects, although there are slight variations in potency depending on their sequence and/or length (36, 38, 39). A second prominent toxicological effect in the monkey is on blood clotting. The mechanisms responsible for these effects are probably very complex, but preliminary data suggest that direct interactions with thrombin are at least partially responsible (40).

In man, the toxicological profile differs. When ISIS 2922 is administered intravitreally to patients with cytomegalovirus retinitis, the most common adverse event is anterior chamber inflammation, which is easily managed with steroids. A relatively rare and dose-related adverse event is morphological changes in the retina associated with loss in peripheral vision (41). ISIS 2105, a 20-mer phosphorothioate designed to inhibit the replication of human papilloma viruses that cause genital warts, has been administered intradermally at doses as high as 3 mg/wart weekly for three weeks. Essentially no toxicities have been observed (42).

2.1.5. Therapeutic Index

An attempt to put the toxicities and their dose-response relationships into a therapeutic context is shown in Fig. 1. This is particularly important because considerable confusion has arisen concerning the potential utility of phosphorothioate oligonucleotides for selected therapeutic purposes as a result of unsophisticated interpretation of toxicological data. As can be readily seen, the immune stimulation induced by these compounds is particularly prominent in rodents and unlikely to be dose-limiting in humans. Nor have hypotensive events in humans been observed to date. This toxicity occurs at lower doses in monkeys than in man and certainly is not dose-limiting in man. On the basis of present experience, the dose-limiting toxicity in man is likely to result from blood clotting abnormalities, associated with peak plasma concentrations well in excess of 10 μg/ml. Thus, it phosphorothioate oligonucleotides have a therapeutic index that supports their evaluation for a number of therapies.

Figure 1. Plasma concentrations of ISIS 2302 at which various activities are observed. These concentrations are those of intact ISIS 23902 and were determined by extracting and analyzing plasma by capillary zone electrophoresis.



2.1.6. Clinical Activities

Significant therapeutic benefit has been reported in patients with cytomegalovirus retinitis treated locally with fomivirsen (43). ISIS 2302 administered every other day for one month also resulted in statistically significant improvement for five to six months in patients with steroid-dependent Crohn's disease in a randomized, double-blind placebo, controlled trial (44).

2.2. Medicinal Chemistry of Oligonucleotides

The core of any rational drug discovery program is medicinal chemistry. Although the synthesis of modified **nucleic acids** has been a subject of interest for some time (see DNA Synthesis), the intense focus on the medicinal chemistry of oligonucleotides dates perhaps no more than the past five years. Modifications have been made to the base, sugar, and phosphate moieties of oligonucleotides (Fig. 2). The subjects of medicinal chemical programs include approaches to (3) create enhanced and more selective affinities for RNA or duplex structures, the ability to cleave nucleic acid targets, enhanced nuclease stability, (4) cellular uptake and distribution, and *in vivo* tissue distribution, metabolism, and clearance. Arguably, the most interesting modifications to date are those that alter the sugar moiety (45) and the backbon. Modifications such as 2′ methoxyethoxy enhance affinity for RNA, potency *in vivo*, provide a dramatic increase in stability, and reduce the potency for blood clotting and inflammatory effects. Also of interest are a number of modifications that replace the phosphate or the entire phosphate sugar backbone. Several novel chemical classes are being evaluated in animals and will shortly be studied in man, so it seems likely that a variety of chemical classes with differing properties will be available in the near future.

Figure 2. Isis oligonucleotide modifications.

Antisera

Antisera have long been the major reagent in immunology, and this field was for years known as serology. An antiserum is the serum of an animal that has been **immunized** against an antigen, or more commonly hyperimmunized, to get the highest possible titer of the desired antibodies. Very clearly, vaccination and serotherapy were the first great miracle in fighting against pathogens, long before the discovery of antibiotics. From a medical standpoint, antisera were used to fight quickly against a pathogen or a toxin, because vaccination takes a long time to generate a host immune response. There are several concerns regarding the use of antisera for therapy in humans or in animals. First, one has to be certain that protection is indeed ensured by antibodies and not exclusively by cell-mediated immunity. This is not a trivial matter, because there are only a limited number of instances in which protection is due primarily to antibodies. Second, the use of antisera from a foreign animal species (heterologous antisera) will induce a strong immunization of the host against all the injected antigens. This results in the appearance, within a week or two, of a local and generalized syndrome, called *serum sickness*, that may include urticaria, local edema, rashes, arthralgia, fever, lymphadenopathy, and, ultimately, severe glomerulonephritis resulting from the formation of immune complexes. This was observed when serotherapy with horse serum was extensively used in humans, especially against **diphtheria** or tetanus. Diphtheria, a bacterial disease, can now be cured with antibiotics, and children undergo a regular schedule of vaccination that actively prevents the disease. Tetanus remains a very severe disease, with an elevated rate of mortality. Serotherapy is still used because antibodies are extremely effective against the toxin; nevertheless, everyone should be revaccinated every 10 years, because this provides the best and safest protection.

Heterologous antisera should be used only in very exceptional occasions—for example, after bites from highly dangerous snakes. Heterologous antisera are being systematically replaced, when appropriate, by purified immunoglobulins, preferentially of human origin. Intravenous immunoglobulins (IVIgs) are used to correct severe immunodeficiencies of the B-cell compartment. For example, this is the case with X-linked agammaglobulinemia (Bruton disease), which is transmitted genetically through the mother and occurs in young boys. This disease is due to a variety of mutations of the BTK gene (for Bruton tyrosine kinase) that result in an early blockage of B-cell differentiation. IVIgs are also used to help patients with chronic or transient hypoglobulinemia. Whenever the deficiency is severe and would necessitate a lifelong treatment, an allogenic bone marrow graft is performed, which restores the immune system of the patient. IVIgs are also used in therapy of autoimmune diseases, although the mechanisms are not absolutely understood, but may be due in part to a reequilibration of the idiotype network. Specific purified antibody of human origin can be prepared in some selected cases. The most popular preparation is the anti-D (Rhesus) immunoglobulins that are used worldwide for prevention of the hemolytic disease of the newborn (see Alloantibody, Alloantigen).

With the start of organ transplantations, many attempts were made to prevent rejection by blocking the immune system of the recipient. Antilymphocyte serum, prepared in rabbits or in horses, has been used but had the usual limitation linked to the induction of serum sickness mentioned above. It could, however, help for a transient difficult acute period of rejection. It has been replaced by a monoclonal antibody, prepared in the mouse and directed against the CD3 (signaling module) of the T-cell receptor. Used for a short period of time, it proved efficient in down-modulating the immune response of the host, with limited risk of immunization against the heterologous immunoglobulin. Genetic engineering has also been proposed to minimize immunization against heterologous determinants. One classical approach is to insert the six specific hypervariable regions of a murine monoclonal antibody in place of the corresponding regions of a human antibody framework, using protein engineering. This engineered antibody is certainly less immunogenic, but it still is, because of the idiotype determinants that cannot be avoided. Fully engineered human monoclonal antibodies would certainly be ideal for human use. This goal is being worked on actively by pharmaceutical companies. Its is not yet practical, and no one has yet succeeded in making stable “natural” human monoclonal antibodies.

Besides the roles in human therapy mentioned above, antisera remain of course reagents of choice for experimental purposes. They may be used to identify new molecules and to purify them with techniques like immunoaffinity chromatography or **immunoprecipitation**, which are powerful tools to isolate rare components, such as membrane proteins, receptors, hormones, or diverse ligands. Monoclonal antibodies have tended to replace antisera, which is partly unfortunate and sometimes a mistake, because conventional antisera can be exquisitely specific and are very efficient, potent tools, with a mosaic of specificities that may of great help to the molecular biologist.

Antitermination Control of Gene Expression

Bacteria have evolved many different complex mechanisms to control both transcription and translation of **genes** in response to environmental changes. In many cases, transcription is controlled at the level of initiation by DNA-binding proteins that either inhibit (repressors) or stimulate (activators) initiation. In addition, transcription can be regulated at the level of elongation. In some cases, transcription of a gene or operon will terminate prematurely in the absence of the action of a positive regulatory molecule. In these cases, antitermination factors allow transcription to read through termination signals and to generate full-length transcripts.

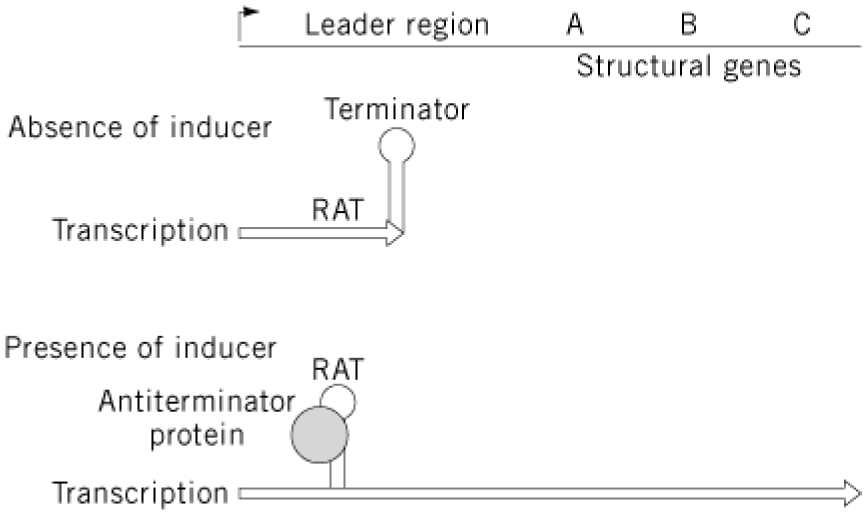
Two fundamentally different mechanisms for antitermination have been described. In one case, RNA polymerase is modified so as to allow it to read through transcription terminators. This type of mechanism controls phage development (1) and expression of rRNA operons (2). The second mechanism, covered in this chapter, involves trans-**acting factors** that interact with **RNA** and prevent formation of the terminator structure. This mechanism is very similar to **attenuation**, but antitermination can be distinguished from attenuation in that the action of the regulatory molecule results in transcription readthrough, with the default pathway being premature termination. In attenuation, the action of the regulatory molecule induces transcription termination, and the default pathway is readthrough.

Three distinct mechanisms that regulate gene expression by antitermination will be reviewed here. These mechanisms differ primarily in the type of biomolecule used as the regulator. The first mechanism uses antiterminator proteins that are activated to bind RNA targets in response to environmental stimuli. In the second mechanism, transfer RNA is used as the regulator. In this case, the degree of aminoacylation (or charging) of the tRNA is used to sense the availability of the cognate amino acid within the cell, to induce expression of genes involved in metabolism of this amino acid. Finally, in the case of the **Escherichia coli** tryptophanase operon, it appears that ribosomes are used as the regulatory molecule. Thus, bacteria have evolved a large number of mechanisms to use different biomolecules to all perform the same task—that is, to alter the conformation of the nascent mRNA to signal RNA polymerase whether it should terminate prematurely or continue transcription of the particular structural gene(s).

1. RNA-Binding Protein-Mediated Antitermination: The Sac/Bgl Family of Antiterminator Proteins

Expression of several catabolic operons in bacteria is regulated by antitermination involving RNA-binding proteins. These proteins prevent formation of Rho-independent transcription terminators in the nascent mRNA upstream of the regulated gene(s) (3). One such system in *E. coli* and several in *Bacillus subtilis*, appear to be highly related based on similarities of their antiterminator proteins as well as their RNA targets. In addition, several other systems function similarly but appear to have arisen independently. A general model for this mechanism is shown in Figure 1.

Figure 1. A general model for antitermination control by the Sac/Bgl family of antiterminator proteins. Under noninducing conditions, transcription starts at the promoter (designated by the arrow) and terminates prematurely, often in a leader region prior to the structural genes. In the presence of inducer, the antiterminator protein is activated to bind to the RAT (ribonucleic antiterminator) RNA. This binding stabilizes an RNA secondary structure involving the RAT, which prevents formation of the overlapping terminator, and transcription continues into the structural genes.



1.1. The *E. coli bgl* Operon

The *E. coli bglGFB* operon encodes all the functions necessary for the regulated uptake and utilization of aromatic b-glucosides. The operon is cryptic in wild-type strains but can become functional through spontaneous mutations. When functional, expression of this operon is regulated by antitermination mediated by the BglG protein in response to the levels of b-glucosides (4). In the absence of inducer, BglG does not bind RNA, and most transcripts terminate at one of two Rho-independent transcription terminators present in the leader region upstream of *bglG* and between *bglG* and *bglF*. When b-glucoside levels are high, BglG binds to an RNA target, named RAT for ribonucleic antiterminator, just upstream of the terminators. This binding stabilizes an alternative antiterminator RNA structure, which prevents formation of the terminator, thus allowing transcription to continue and the operon to be expressed.

The RNA-binding activity of BglG is regulated by **phosphorylation** mediated by BglF. In the absence of b-glucosides, BglF phosphorylates BglG, which prevents it from dimerizing and binding to the RAT (5). In the presence of b-glucosides, BglF dephosphorylates BglG, which now dimerizes and binds to the RAT. Phosphorylation of both b-glucosides and BglG is accomplished by transfer of the phosphate group from the same phosphorylated residue, Cys24, in BglF (6). These results suggest that, under conditions in which b-glucoside levels are high, the phosphate group can be transferred from BglG back to Cys24 in BglF. A model has been proposed in which unliganded BglF phosphorylates BglG, and b-glucoside binding induces BglF to undergo a conformational change that activates it to dephosphorylate BglG.

A similar system for b-glucoside utilization exists in the related **Gram-negative** enteric bacterium *Erwinia chrystanthemi*, although in this case the *arb* operon is not cryptic (7). ArbG shows high sequence similarity to BglG, suggesting that it functions analogously in antitermination control of the *E. chrystanthemi arb* genes. Antitermination also appears to control b-glucoside operons in several Gram-Positive Bacteria as well. A putative b-glucoside (*bgl*) operon has also been identified in *B. subtilis* and may be regulated by a similar antitermination mechanism (8). In addition, a protein, BglR, with homology to BglG also controls b-glucoside usage in *Lactococcus lactis* (9).

1.2. The *B. subtilis sac* Genes

Expression of two sucrose utilization operons in *B. subtilis*, *sacPA* (10) and *sacB* (11), is induced by sucrose via transcription antitermination mediated by the RNA-binding proteins SacT and SacY, respectively. SacT and SacY show extensive sequence similarity to each other, as well as to BglG from *E. coli*. The antitermination mechanisms that control these genes also appear to be quite similar to that described above for the *E. coli bgl* operon. Rho-independent transcription terminators exist in leader regions upstream of both *sacPA* and *sacB* and prevent transcription of the structural genes in the absence of the inducer, which is sucrose. In the presence of sucrose, SacT and SacY are activated to bind RAT sequences in the *sacPA* and *sacB* leader transcripts, respectively, and allow transcription to read through into the structural genes (12). Like BglG in *E. coli*, both of these antiterminator proteins are phosphorylated. In the case of SacY, phosphorylation negatively regulates RNA-binding activity and appears to be mediated by SacX (13). SacT is phosphorylated by HPr, a component of the phosphoenolpyruvate **phosphotransferase system**, but the role of this phosphorylation in sucrose-mediated antitermination is less clear (12).

Recently, the protein structure of the RNA-binding domain of SacY has been determined by both NMR (14) and X-ray crystallography (15). The domain exists as a dimer, with each monomer consisting of a four-stranded antiparallel beta-sheet. Several amino acid residues have been identified through genetic, biochemical, and preliminary NMR studies as being important for RNA binding. These residues are clustered on the surface of one side of the protein structure (15).

1.3. Other Examples of Bgl/Sac Type Antiterminators

In addition to the *bgl* and *sac* systems described above, several other operons are regulated by RNA-binding antiterminator proteins with homology to BglG, SacY, and SacT. LicT regulates the *licS* gene, which is involved in b-glucan utilization in *B. subtilis* (16). There is also a RAT sequence overlapping a potential Rho-independent terminator upstream of *licS*.

In *Lactobacillus casei*, the lactose (*lac*) operon is regulated in response to lactose levels by LacT, which shows sequence homology to the other members of the Bgl/Sac family of antiterminators (17). The 5′-leader region of the *lac* mRNA contains a region with sequence similarity to the RAT sequence, as well as a potential stem-loop structure resembling a Rho-independent terminator.

1.4. Antiterminators with No Similarity to the Bgl/Sac Family

Several other systems are regulated by RNA-binding antiterminator proteins that are unrelated to those of the Bgl/Sac family; furthermore, these proteins do not appear to be related to each other. These regulatory systems thus appear to have arisen independently.

In *B. subtilis*, both the *glp* regulon, which is involved in usage of glycerol-3-phosphate, and a histidine-utilization (*hut*) operon are regulated by RNA-binding antiterminator proteins; GlpP (18) and HutP (19), respectively. The amino acid sequences of these antiterminator proteins are not similar to any other antiterminator proteins. Further, the mechanisms by which these antiterminator proteins function appear to be different from those described above, because there are no clear antiterminator RNA secondary structures near the terminators in these operons.

The amidase (*ami*) operon of *Pseudomonas aeruginosa* is regulated by antitermination in response to short-chain aliphatic amides, such as acetamide. The *amiR* gene encodes an antiterminator protein (AmiR), which is negatively regulated by AmiC, apparently through formation of an AmiC-AmiR complex (20). Acetamide destabilizes the AmiC-AmiR complex, leading to antitermination and expression of the operon. AmiR interacts with an RNA target in the 5-leader region of the *ami* mRNA that contains a Rho-independent terminator. However, no clear antiterminator RNA secondary structure is predicted. AmiR binding has been suggested to function in antitermination by interfering directly with formation of the terminator stem-loop structure (20).

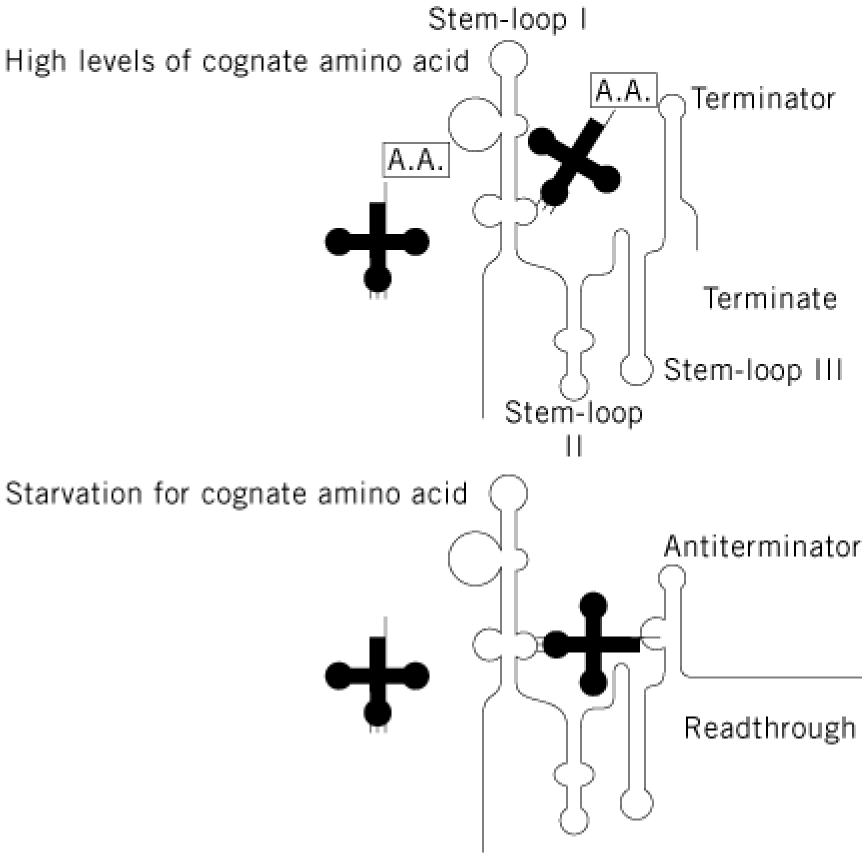
In addition to all the catabolic operons described above, one anabolic operon has been shown to be regulated by antitermination. Expression of the *nas* operon of *Klebsiella pneumoniae*, which encodes enzymes required for nitrate assimilation in this bacterium, is induced by nitrate or nitrite. The NasR protein mediates transcription antitermination through a terminator in the leader region of the operon (21). This protein shows weak homology with AmiR in the carboxyl-terminal region.

2. Transfer RNA-Mediated Antitermination

An interesting variation on the antitermination mechanism involves the use of tRNA as the regulatory molecule. This mechanism regulates a large number of aminoacyl-tRNA synthetase genes in Gram-Positive Bacteria (22, 23) and several amino acid biosynthetic operons, including the *ilv-leu*, in *B. subtilis* (24, 25), and the *his* and *trp* operons in *Lactococcus lactis* (26). Expression of these genes is induced specifically by starvation for the corresponding amino acid. In the case of the amino acid operons, insufficient levels of the amino acid leads to increased expression of the corresponding biosynthetic operon. For the aminoacyl-tRNA synthetase genes, increasing the level of the synthetase is thought to allow more efficient charging of the cognate tRNA when the corresponding amino acid pool is low.

A long (approx. 300-nucleotide) untranslated leader region exists upstream of the structural gene(s) of these operons that contains several conserved features, including three stem-loop structures preceding a Rho-independent transcription terminator. Hence, in the absence of the inducing signal, transcription terminates prematurely in the leader region prior to the coding sequences. In addition to the conserved secondary structures, there is an important conserved 14-nucleotide sequence known as the T-box present in each leader region; hence these genes are known as the T-box family. An alternate arrangement of the leader region involving base-pairing between a portion of the T-box and a conserved sequence in the 5′ side of the terminator stem has been proposed to form an antiterminator structure that allows transcription to read through into the structural genes (Fig. 2) (27).

Figure 2. Model for antitermination control by tRNA. Under conditions with adequate levels of the cognate amino acid (aa), the charged tRNA does not interact with the leader region, and the terminator forms. Under conditions of starvation for the appropriate amino acid, the uncharged tRNA interacts with the leader region via base-pairing between the anticodon and the specifier sequence, and by base-pairing between the CCA sequence at the acceptor end of the tRNA with the side bulge of the antiterminator in the leader. These interactions stabilize formation of the antiterminator conformation of the leader transcript, resulting in induction of expression of the gene. The tRNA is shown as the shaded cloverleaf structure, and a boxed “A.A.” attached to the tRNA indicates it is aminoacylated. Adapted from T. M. Henkin (1996) *Annu. Rev. Gen*. **30**, 35–57.



Another important conserved feature of the leader region of these genes is the presence of a triplet sequence corresponding to a codon for the appropriate amino acid for each operon. For example, in *tyrS*, which encodes tyrosyl-tRNA synthetase, the leader contains a UAC tyrosine codon, while the ilv-leu operon leader contains a CUC leucine codon. This triplet is always present in a bulged sequence in Stem-loop I (Fig. 2) and has been shown to be critical for induction in several systems. It was the presence of these triplets that led to the hypothesis that tRNAs play a role in this regulatory mechanism. This triplet was designated the "specifier sequence" because, in the case of the *B. subtilis tyrS* gene, altering the sequence to correspond to a codon for another amino acid switched induction to respond to starvation for the new amino acid (27). Other experiments demonstrated that translation of this codon was not involved in induction and that uncharged tRNA was the inducer (27). In addition, a second interaction between the CCA sequence at the 3′ end of the uncharged tRNA and the complementary UGG sequence in the T-box have been shown to be important (28).

A model for tRNA-regulated antitermination regulation is presented in Fig. 2. Under starvation conditions for the corresponding amino acid, the cognate uncharged tRNA interacts with two sites in the leader region, to induce formation of the antiterminator structure and allow transcription to read through into the coding region. Aminoacylation of this tRNA is predicted to interfere with the interaction at the CCA end and prevent the charged tRNA from binding; the leader transcript then folds into the conformation with the terminator, halting transcription. It is not known if factors in addition to tRNA are required for antitermination. To date, however, it has not been possible to reconstitute tRNA-mediated antitermination in vitro, and several other lines of evidence also suggest that other factors may be involved in this mechanism (23).

In addition to the antitermination mechanism described above, processing of the leader RNA has been shown to play a role in regulating expression of the *B. subtilis thrS* gene (29). Cleavage occurs in the loop of the antiterminator near the T-box sequence and is more efficient under threonine starvation conditions, suggesting that bound tRNA induces both antitermination and RNA processing. This processing increases the stability of the mRNA, which would allow for increased translation and production of the threonyl-tRNA synthetase. Thus induction of expression of this gene in response to threonine starvation occurs at both the level of transcription antitermination and mRNA stability.

3. The *E. coli* Tryptophanase Operon

E. coli and several other microorganisms have the capacity to degrade tryptophan as a source of carbon, nitrogen, and/or energy (30). The degradative tryptophanase operon (*tnaCAB*) of *E. coli* is regulated by catabolite repression (31) and by an antitermination mechanism. Antitermination involves translation of a ***cis***-*acting* 24-residue leader peptide (*tnaC*) containing a critical Trp codon (32, 33), one or more RNA polymerase pause sites between *tnaC* and *tnaA* (34), and Rho termination factor (34). While the precise antitermination mechanism responsible for controlling the *tna* operon is not firmly established, all of the data are consistent with the following model (Fig. 3) (35). During growth in a medium lacking both tryptophan and a catabolite-repressing carbon source, transcription initiation is efficient. As transcription proceeds, translation of the leader peptide occurs as soon as the coding sequence becomes available. Once the translating ribosome reaches the UGA stop codon, ribosome release exposes a *rut* (Rho utilization) site that immediately follows the stop codon. Rho then binds to the *rut* site and begins to translocate in the 3′-direction, until it encounters paused RNA polymerase, ultimately leading to transcription termination upstream of *tnaA*. When cells are growing with inducing levels of tryptophan, TnaC, or a complex of TnaC with an unidentified protein, prevents ribosome release at the *tnaC* stop codon, thereby masking the *rut* site and, hence, blocking Rho interaction with the transcript. Eventually RNA polymerase would overcome the pause signal and transcribe the structural genes encoding tryptophanase (*tnaA*) and a tryptophan **permease** (*tnaB*). This model assumes that there is a fundamental difference between the TnaC peptide, or the TnaC peptide-protein complex, in cells growing with or without tryptophan. It was proposed that such a complex under inducing conditions would prevent ribosome release (35), reminiscent of characterized translation attenuation mechanisms (36). The tryptophanase operon of *Proteus vulgaris* is thought to be regulated by a mechanism essentially identical to that of *E. coli* (37).

Figure 3. Model of *E. coli tna* operon regulation. Under noninducing conditions (no extracellular tryptophan), ribosome dissociation at the *tnaC* stop codon exposes a *rut* site, allowing Rho binding. Rho translocates to the paused RNA polymerase, leading to transcription termination. Under inducing conditions (extracellular tryptophan), ribosome stalling at the *tnaC* stop codon prevents Rho association, leading to transcription readthrough. See text for details. Adapted from C. Yanofsky, K. V. Konan and J. P. Sarsero (30).

Antithrombin

Antithrombin is a proteinase inhibitor of the serpin family that is the principal anticoagulant in human plasma; it is also known as antithrombin-III. It is composed of a single polypeptide chain of 432 amino acid residues, with four carbohydrate side chains (see N-Glycosylation). It has a reactive-center peptide bond between Arg393 and Ser394 that provides a specific target for thrombin, factor Xa, and other proteinases of the blood clotting system. Antithrombin is present in plasma at a concentration of nearly 100 mg/L and circulates in a relatively inactive form, being activated conformationally by the binding of heparin. Genetic deficiency or dysfunction of antithrombin is a significant cause of familial thromboembolic disease.

a_1-Antitrypsin

a_1-Antitrypsin is a proteinase inhibitor of the **serpin family** that consists of a single polypeptide chain of 294 amino acid residues and four carbohydrate side chains (see N-Glycosylation). It also known as a_1-proteinase inhibitor. Present at a concentration of 1 g/L, it is the predominant proteinase inhibitor in human plasma in terms of concentration. Its reactive-center peptide bond between Met358 and Ser359 specifically targets the elastases that are involved in connective tissue remodeling. Genetic deficiency of a_1-antitrypsin is relatively common and predisposes to the development of the lung disease emphysema, with an associated risk of liver cirrhosis (see Serpins).

AP Endonucleases

AP endonucleases are enzymes that cleave the phosphodiester bond on either side of an AP site in DNA and are involved in base excision repair. Enzymes that cleave the phosphodiester bond to the 3′

side are referred to as type I AP endonucleases, and those that cleave the phosphodiester bond 5′ to the AP site are type II AP endonucleases. Whether or not a bona fide type I AP endonuclease exists that is not associated with DNA glycosylase activity is not known. However, type II AP endonucleases, which cleave AP sites by hydrolysis, have been found in many organisms and have been characterized.

1. AP Lyases (Class I AP Endonucleases)

Type I AP endonucleases are also DNA glycosylases, and it appears that the same active site is involved in both the glycosylase and AP endonuclease activities. However, it has also been demonstrated that cleavage of AP site occurs by b-elimination, which involves abstraction of a hydrogen from the C2′ position of the deoxyribose. Because this is a lyase reaction, and not a hydrolyase reaction, the type I AP endonucleases are referred to as AP lyases (1).

Endonuclease III and 8-oxoguanine glycosylase are examples of this class of enzymes (1, 2). The a-NH_2 group of the *N*-terminal amino acid residue forms a Schiff base with the ring-opened form of the deoxyribose, eventually leading to cleavage of the deoxyribose–phosphate bond without water addition. Following elimination of the base by glycosylase action, the enzyme remains attached to DNA through a protonated Schiff base intermediate where the C1′ of the sugar is covalently bound to the nitrogen of the *N*-terminal a-amino group of the protein (3). b-Elimination of this intermediate, followed by hydrolysis of the Schiff base, results in cleavage of the phosphodiester bond and generation of a *trans* a–b-unsaturated aldehyde on the 5′ side, and a 5′-phosphate on the 3′ side, of the cleavage, which is concomitant with the release of the enzyme. When the AP lyase activity is associated with a glycosylase activity, the two reactions are, for the most part, coupled (2). In these instances, it is natural to assign a physiological role to the AP lyase. However, cleavage of an AP site on the 3′ side occurs readily even in the absence of enzymes and can be accelerated by alkaline pH and by basic proteins such as histones and cytochrome *c*. Hence the assignment of AP lyase activity to a protein in the absence of an associated glycosylase activity is virtually impossible.

2. AP Endonucleases (Class II AP Endonucleases)

These enzymes hydrolyze the phosphodiester bond 5′ to an AP site. AP endonuclease IV in *E. coli*, which has a **homologue** in yeast and humans, is the only example of a "pure" AP endonuclease—that is, an endonuclease with only hydrolysis activity 5′ to an AP site and with no significant activity on any other substrate. However, the best-characterized AP endonuclease is the *E. coli* exonuclease III and its homologues in eukaryotes, including yeast, Drosophila, and mammals. In contrast to the pure AP nuclease endonuclease IV, the exonuclease III, as the name implies, has exonuclease activity as well.

2.1. Exonuclease III/Rrp1/APE

The prototype of this group of enzymes, exonuclease III, has several activities, including **ribonuclease** H, 3′ to 5′ exonuclease, and type II AP endonuclease. The enzyme is specific for double-stranded DNA. It is a simple polypeptide chain of 30 kDa with no cofactor. The X-ray crystallography structure of an enzyme–substrate complex demonstrates that the base is flipped out of the double helix, into the active site of the enzyme (4). The *E. coli* enzyme is a potent 3′ to 5′ exonuclease. The exonuclease activity has a preference for blunt double-stranded termini, but it can initiate exonuclease action from a nick as well. An activity related to the 3′ to 5′ exonuclease function is the ability of the enzyme to remove deoxyribose fragments, including 3′-phosphoglycolate esters and 3′-phosphate, from the 3′ termini of DNA strand breaks generated by attack of reactive oxygen species on DNA. Exonuclease III-defective mutants are extremely sensitive to H_2O_2 and ionizing radiation, which most probably kills cells through the strand breaks introduced by reactive oxygen species. As a rule, these are not clean breaks with 3′-OH and 5′-P termini. Instead, they most often contain either 3′-phosphate or fragmented deoxyribose, which must be processed further before they can be utilized by **DNA polymerases** to fill in the gap created by the DNA damage. These structures are removed efficiently by exonuclease III, but not by endonuclease IV.

The *Drosophila* exonuclease III homologue is a monomer of 75 kDa. The 250-amino-acid-residue *C*-terminal region of the protein is homologous to the exonuclease III family of AP endonucleases. However, the *N*-terminal 400 residues are not related to any known sequence, and the function of this putative **domain** is unknown at present. The *Drosophila* enzyme was initially isolated as an activity that catalyzes strand transfer and was thought to perform a **RecA**-like function in this organism, hence the name Rrp1 (Recombination related protein 1). However, later work has not confirmed a role for this protein in recombination. The enzyme has a potent type II AP endonuclease activity, but its 3′ to 5′ exonuclease activity is rather modest compared to the *E. coli* enzyme and is only 10^{-2} to 10^{-3} of the AP endonuclease activity. Whether the *N*-terminal 400 residues play any role in recombination or in DNA repair is not known at present.

The human AP endonuclease (APE/HAP1/APEX) is highly homologous (90% to 95% sequence identity) to the enzymes from bovine and rodent sources. These enzymes are 35-kDa monomers and are clearly related to *E. coli* exonuclease III. The mammalian enzymes have potent type II AP endonuclease and 3′-phosphoglycol aldehyde esterase activities necessary for denuding a “jagged” 3′ terminus caused by direct attack of reactive oxygen species or by direct hit by ionizing radiation. In contrast to exonuclease III, however, the 3′ to 5′ exonuclease activity of mammalian type II AP endonucleases is rather weak and undetectable with certain 3′ sequences. The structure of human AP endonuclease indicates that it flips out the deoxyribose moiety into the active site (5), as is observed also in the *E. coli* exonuclease III.

A unique property of mammalian APE proteins is their capacity to reduce critical cysteine residues in certain transcription factors and by doing so activate these transcription factors. In fact, the human APE was also purified as a factor that activates the AP-1(Jun/Fos) transcription factor and was named Ref (for reducing factor 1) before the realization that it is identical to APE. The APE cysteine residue involved in this reduction reaction is located in the NH_2-terminal region and plays no role in the AP endonuclease activity of this protein. In addition to Jun and Fos, other transcription factors, including USF, NF-kB, c-Myb, and v-Rel, are activated by reduction of an oxidized cysteine by APE *in vitro* (5). However, the physiological role of these *in vitro* activities is currently not known.

Mouse APE **knockout** mutants are lethal at the embryonic stage. This could be due to either (a) the importance of base excision repair for survival of the organism or (b) disruption of an activating mechanism for important transcription factors.

2.2. Endonuclease IV

The *E. coli* endonuclease IV, Nfo, is a monomer of 30 kDa that cleaves 5′ to AP sites in a reaction that is independent of divalent metal ions such as Mg^{2+} . It also has potent 3′-PGA diesterase and 3′-phosphatase activities but does not have exonuclease function. Although Nfo^{-} mutants are not especially sensitive to H_2O_2, they are hypersensitive to killing by the oxidative agents bleomycin and *t*-butylhydroperoxide, indicating that endonuclease IV acts on a subclass of oxidative DNA lesions that are not processed efficiently by exonuclease III. The importance of Nfo in cellular defense against oxidative stress is underscored by the fact that this is the only DNA repair enzyme that is induced by oxidative stress as part of the SoxRS regulon.

The Nfo homologue in yeast, Apn1, is the major AP endonuclease in this organism. Apn1 is a monomer of 40 kDa with 31% sequence identity with the *E. coli* Nfo endonuclease. The biochemical properties of Apn1 are very similar to those of Nfo, and indeed the expression of Apn1 in *E. coli* corrects the oxidant-sensitive phenotype of *nfo* mutants, but not the H_2O_2 sensitivity.

AP Sites (Apurinic/Apyrimidinic Sites)

AP (apurinic/apyrimidinic) sites are deoxyribose residues in the DNA that have lost the purine or pyrimidine bases.

1. Occurrence

AP sites are generated by a variety of mechanisms:

1.1. Spontaneous Base Loss

The glycosylic bond joining the base to the deoxyribose in the DNA backbone is relatively unstable and is cleaved, even under physiological conditions, at a rate incompatible with life. It is estimated that at normal pH and temperature there are base losses at rates of about 10^{-12} s^{-1} for double-stranded DNA and 10^{-10} s^{-1} for single-stranded DNA. This means that humans (with about 1.2×10^{10} bp per diploid cell) lose about 1 base per minute per cell, or, taking into account that there are about 10^{13} cells in the human body, lose 1.5×10^{16} bases from their DNA daily. The rate of base loss is greatly accelerated by heat and low pH. Because of higher susceptibility of their N9 atom to nucleophilic attack, the purine bases are hydrolyzed at a rate about 100-fold faster than are pyrimidines (1). In fact, because of this unique property of purines, one of the procedures for chemical DNA sequencing reactions consists of heating the DNA at acidic pH, followed by cleavage of the resulting AP site by alkali treatment.

1.2. Ionizing Radiation

Ionizing radiation most often causes base reduction, oxidation, or fragmentation. In particular, a urea residue attached to the deoxyribose is a relatively common product of ionizing radiation and, for all practical purposes, may be considered an AP site. Such radiation causes base loss by either (a) generating reactive oxygen species that attack and destroy bases or (b) direct hits by ionizing radiation.

1.3. Glycosylases

There are about a dozen DNA glycosylases with varying degrees of specificity for bases with minor modifications: uracil glycosylase, 3-methyladenine DNA glycosylase, 8-oxoguanine DNA glycosylase, and glycosylases that act on mismatches, such as T-G glycosylase, specific for the T residue, and A-G glycosylase, specific for the A residue. These enzymes release the modified, abnormal, or mismatched bases by hydrolyzing the glycosylic bond linking the base to the deoxyribose. Most of the glycosylases have dual enzymatic activities in that, after cleaving the glycosylic bond, they also cleave the phosphodiester bond by b-elimination. However, some, such as uracil glycosylase, are “pure” glycosylases with no such associated AP lyase activity.

2. Consequences

AP sites in DNA are, in fact, very unstable. Even at physiological pH and temperature, the abasic sugar can be eliminated by b–d elimination. The presence of the divalent metal ions that would be expected in biological fluids greatly accelerates the cleavage reaction. The reaction may be further accelerated by basic proteins, such as cytochrome *c*. Consequently, AP sites as such do not constitute an important lesion interfering with cell survival. In contrast to b-elimination, however, which occurs readily under a variety of conditions, the d-elimination reaction, which in combination with b-elimination would release the abasic deoxyribose from DNA, does not occur at physiologically relevant rates. AP endonucleases hydrolyze the phosphodiester bond 5 to the AP site, and *Escherichia coli* cells that lack this enzyme are sensitive to agents that generate AP sites or fragmented deoxyribose residues.

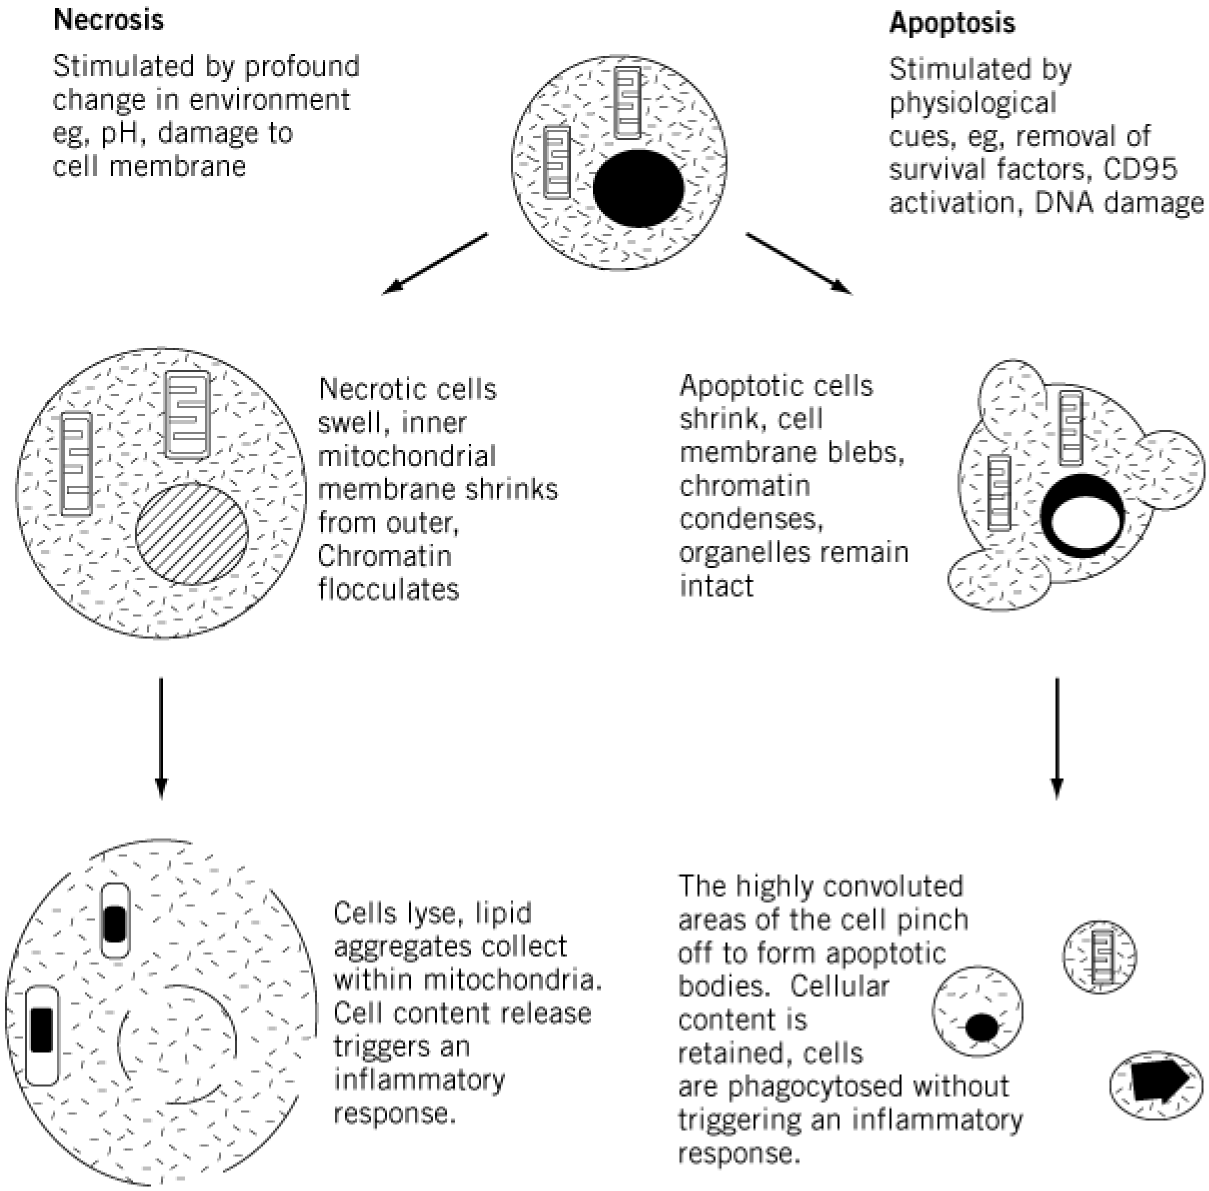
Apoptosis

Wyllie et al. initially used the term “apoptosis” in a paper in 1972 to describe a newly observed form of cell death (1). The discovery of apoptosis has revolutionized many areas of modern biology, especially those areas concerned with disease development (2). This is primarily because apoptosis is an active form of cell death that, unlike necrosis, is critical for the maintenance of tissue homeostasis (3, 4). Thus, cell populations are numerically controlled through not only differentiation and proliferation, but also the physiological loss of cells through apoptosis. Critically, this implies that a cell which loses the capacity to apoptose, or a cell which becomes inappropriately sensitive to death stimuli, can lead to perturbations in cell number regulation and, ultimately, disease development.

Cells undergoing apoptosis are evident in all tissues in response to diverse stimuli. In healthy tissues, apoptosis accounts for all the cell deaths occurring in response to normal physiological signals. Apoptosis (often referred to as programmed cell death in a developmental context) occurs at many stages of embryonic development, eg, during the formation of digits from a solid limb paddle, where interdigital cells between the digits die (5). Single apoptotic cells are evident in healthy proliferating tissues such as small gut crypts and the dermis of the skin (4). Moreover, apoptosis is also seen during endocrine-induced atrophy of tissues, in cell-mediated immunity, in development of the nervous system, and in the "necrotic" oxygen-starved cores of solid tumors (6).

Morphologically, an apoptotic cell is very different from a necrotic cell (1, 6, 7); see Figure 1. One of the most prominent and easily identifiable stages of apoptosis involves the nucleus. Chromatin condenses and forms aggregates near the nuclear membrane, which becomes convoluted, whereas the nucleolus becomes enlarged and appears abnormally granular. The chromatin is also subject to the actions of an activated **endonuclease** that cleaves the DNA into 300- to 50-kbp fragments initially, and 180-bp fragments subsequently (8). Changes in the cytoplasm are also evident at this time; the cell shrinks visibly, adherent cells round up, and distinct protuberances or membrane blebs are discernible. **Organelles** within the shrunken cytoplasm still look normal, except for dilation of the endoplasmic reticulum. These "blebbing" cells exclude vital dyes, indicating no structural failure in the cell membrane. It is at this point in the apoptotic process, which may only take 10 to 30 minutes, that apoptotic cells *in vivo* are **phagocytosed**, by either their nearest neighbors or professional macrophages (9). Thus, apoptosis occurring in single cells *in vivo* is very easily overlooked due to its rapid progression. Cells in the later stages of apoptosis, especially those *in vitro*, form apoptotic bodies as a result of pinching off of the highly convoluted blebbing areas of the cell. These apoptotic bodies are phagocytosed or, in situations where there is much cell death, the unphagocytosed apoptotic cells undergo secondary necrosis, characteristically swelling and loosing membrane integrity.

Figure 1. A comparison of apoptosis and necrosis.



1. Removal of Apoptotic Cells

A critical part of the apoptotic pathway is the efficient recognition and phagocytosis of apoptotic cells. The rapid disposal of apoptotic cells does not elicit an immune response, consistent with apoptosis being the “no-nonsense” pathway for the disposal of unwanted cells. A breakdown in either the communication between macrophage and apoptotic cell or in the pathway of apoptosis itself may be two of the mechanisms through which chronic inflammatory disorders occur. Recognition of apoptotic cells by professional macrophages is mediated partly by $a_v b_3$ integrin (the *vitronectin* receptor) and the CD36 ligand. Between these two molecules on the external surface of the cell sits a **glycoprotein** containing the sequence -R-G-D- (-Arg-Gly-Asp-), *thrombospondin*, which acts as a molecular bridge to bind to an unknown anionic site on the apoptotic cell (10-12). Apoptotic cells also express surface phosphatidylserine, which binds to an as yet uncharacterized macrophage **receptor** (13, 14). The recognition of apoptotic cells mediated by the vitronectin receptor, CD36 ligand, and thrombospondin is confined to monocyte-derived macrophages. Recognition of apoptotic cells through the expression of phosphatidylserine, which is flipped onto the cellular surface due to the inactivation of an ATP-dependent flipase, is utilized primarily by inflammatory macrophages (9, 15). Four other molecules have been implicated in apoptotic cell recognition systems: (1) the 61D3-antigen found on human macrophages, (2) ICAM-3, found on the surface of human B cells (16), (3) the ABC1 transporter (17), and (4) the macrophage scavenger receptor (18). As mentioned previously, the interaction between apoptotic cells and macrophages does not elicit an inflammatory response, unless the apoptotic cells start to undergo secondary necrosis. Under these circumstances, other macrophage receptors are employed, and inflammatory **cytokines** are released (19). This change from "silent" death to one that activates the immune system may be a method of recruiting more phagocytes to the site of cell death to cope with the increasing number of corpses.

2. Regulation of Apoptosis and Cell Viability

The discovery that apoptosis is an active form of cell death which is transiently suppressable by both inhibitors of protein and RNA synthesis suggested that the cell needed to synthesize new proteins prior to its death [reviewed in (20)]. This sparked an enthusiastic hunt for a critical cell death gene that had to be translated prior to death. No such gene has been found, but many genes that regulate apoptosis have been identified as a result.

A cell can be triggered to undergo apoptosis in response to diverse stimuli, with each stimulus activating different pathways involving **gene expression**, as well as post-translational modification. The discovery that apoptosis can be suppressed by the presence of specific survival factors, either cytokines or proteins expressed within the cell, suggested that regulation of cell viability was paramount to the function of the cell (21). Indeed, it appears that apoptosis represents a default pathway in all cells (22). If a cell does not receive the correct survival stimulus, it will die; consequently, cells within multicellular organisms are maintained in a viable state by a constant supply of survival factors.

Once a cell is triggered to apoptose, activation of a common set of destruction proteins, irrespective of the stimulus involved, precipitates the morphological changes that we call apoptosis. Overall, the apoptotic pathway can be divided into three phases:

1. The *decision phase*, in which the cell receives a stimulus and, depending on both its internal and external environments, may or may not be triggered to die.
2. The *commitment phase*, in which the cell is committed to death and cannot recover.
3. The *execution phase*, in which the decision to die has been made and the activated apoptotic machinery leads to the morphological changes that define an apoptotic cell.

3. The Decision Phase of Apoptosis

The decision phase can be compared to that of a judge hearing the evidence during a trial. The evidence presented comes from many different sources: genes, cytokines, toxic chemicals, DNA damage, and the presence of viral and bacterial infection. Only once all the evidence is heard will the sentence be passed. The genes that modulate the decision phase are many and varied. Some are more commonly associated with the regulation of the cell cycle, such as *c*-**myc**, *cdc25*, *c-fos*, p53 and *rb* (**retinoblastoma**), whereas others are members of recently identified gene families, such as the *bcl-2* family. **Cytokines** can either trigger or delay apoptosis. Tumor necrosis factor a (TNFa) and CD95 ligand (CD95L, FasL, Apo-1L) are two examples of cytokines that trigger apoptosis upon binding to their receptors (23), whereas the addition of factors such as **interleukin**-3 (IL-3) (24) or ***insulin**-like growth factor 1* (IGF-1) suppresses death (25). Conversely, removal of anti-apoptotic cytokines also induces cell death (26, 27). Both viruses and bacteria trigger apoptosis upon infection of a cell, suggesting that the cell commits suicide to prevent the invading pathogen from spreading. However, both viruses and bacteria have evolved mechanisms that manipulate this response. Adenovirus, eg, has three genes required for productive infection: E1A, E1Bp19, and p55. E1A stimulates the infected cell to proliferate; however, this stimulus concomitantly triggers apoptosis. E1Bp19 and p55 delay the host cell from triggering cell death, thereby facilitating virus production (28, 29).

Alternatively, some bacteria such as *Shigella flexneri* actively promote the death of the cell by triggering the execution machinery (30-32). This allows the early release of the bacteria and triggers an immune response, which damages the surrounding tissue and aids the passage of the bacteria into its target cells.

3.1. Oncogenes, Tumor Suppressor Genes, and Apoptosis

In terms of suppressing tumorigenesis, long-lived organisms like humans need to limit the chances of their component cells acquiring mutations that lead to increased proliferative capacity and eventual clonogenic outgrowth. This is, in part, limited by restricting the types of cells with proliferative capacity. Many adult cell lineages exist in a senescent or postreplicative state. Moreover, for those cells that must retain the capacity to divide, apoptosis provides a “safety net.” Genes that are involved in proliferation are also involved in cell death; in fact, the two processes appear inexorably linked. This paradoxical coupling of two opposing biological processes was first realized through work on the pervasive oncogene *c-myc* (33) but has since been confirmed for several mitotic genes (34).

3.2. *c-myc* and Apoptosis

The protein product of the *c*-**myc** gene, c-Myc, is both necessary and sufficient to ensure fibroblast proliferation; in the presence of **mitogen**, all cells in cycle express c-Myc. Fibroblasts remain in cycle as long as mitogens and c-Myc are present, but only remain viable in the presence of additional survival factors. In the absence of such survival factors, cycling cells expressing deregulated Myc undergo apoptosis. This response to oncogene deregulation is thought to protect the organism against cells that acquire mutations in c-Myc. Mutant cells that continuously express c-Myc will proliferate, but since the survival factor *in vivo* is thought to be limiting, the mutant cells will die once the supply of factor is exhausted (25, 35). Thus, small proto-tumors may well arise *in vivo*, but they should regress due to lack of survival signals. If, however, another mutation has occurred producing a cooperating anti-apoptotic lesion, the mutated cells will survive. Several genes that cooperate with *myc* during tumorigenesis are anti-apoptotic. For example, v-Abl, which is a very good suppressor of apoptosis in response to many stimuli, will render haemopoietic cells cytokine-independent for growth and survival (36, 37). *bcl-2*, a gene initially identified through its translocation in the t(14:18) mutation found in follicular lymphoma (38), will cooperate with *myc*, suppressing the apoptotic signal induced through Myc expression (39, 40). The outcome of this cooperation *in vivo* is lymphoma, as seen in both double *bcl-2/Eμ-myc* **transgenic** mice (41, 42) and in human patients with the t(14:18) translocation (43, 44).

3.3. Bcl-2, an Anti-apoptotic Oncogene

The potent ability of Bcl-2 to suppress apoptosis triggered in response to a number of diverse stimuli prompted much research into its biochemical function. This function is still relatively obscure, but several members of the Bcl-2 family of proteins have been identified as a result (45-47). Bcl-2's form and functionality have been conserved throughout multicellular evolution, as exemplified by Ced-9, its counterpart in the nematode *C. elegans*, and the Adenovirus E1Bp19 protein (48). Ten or so members of this family now exist, and all share defined regions of homology, although not all act to suppress apoptosis (Table 1). The pro-apoptotic members of the family (Bax, Bak, and Bcl-x_S (49-53)) share three regions of homology, BH-1, -2, -3, whereas the anti-apoptotic members (Bcl-2 and Bcl-x_L) have a fourth region of homology, known as BH-4 (54, 55). Removal of the BH-4 **domain** from either Bcl-2 or Bcl-x_L results in a loss of protective function. Family members can dimerize with themselves and with one another, and these interactions are important for their function (56, 57). For example, Bcl-2 preferentially binds to the pro-apoptotic family member Bax, whereas Bcl-x_L binds to Bak. If the number of Bax homodimers in the cell exceeds the number of Bcl-2 homodimers or Bax/Bcl-2 heterodimers, then the cell is more likely to undergo apoptosis (47). However, it is not clear which forms of these proteins are dominant for determining life or death. A second set of Bcl-2-associated proteins has been identified that influences cell survival through interaction with Bcl-2 family members, but whose members do not have all, if any, of the BH regions (Table 2) (45, 46). Bag-1, eg, has no homology to Bcl-2, but binds to it and augments the protective function of Bcl-2 (58). Bad, on the other hand, has homology to the family and binds Bcl-2, an interaction that disrupts Bcl-2's binding with Bax, leading to cell death (59, 60).

Table 1. Pro-apoptotic and Anti-apoptotic Members of the Bcl-2 Family[a]

Bcl-2 Family Inhibitors	Bcl-2 Family Promotors
Bcl-2 (mammalian)	Bax (mammalian)
Bcl-xL (mammalian)	Bak (mammalian)
Bcl-w (mammalian)	Bcl-xS (mammalian)
Mcl-1 (mammalian)	
A1 (mammalian)	
NR-13 (mammalian)	
E1B p19 (viral)	
BHRF1 (viral)	

[a] Anti-apoptotic members contain up to 4 Bcl-2 homology (BH) domains and the transmembrane (TM) domain, whereas pro-apoptotic members contain only BH 1-3 and the TM domain, except for Bcl-x_s that contains only BH4, BH3, and the TM domain. Members of this gene family have been conserved throughout evolution with homologues existing in nematodes, mammals, and viruses (46, 47, and references therein].

Table 2. Proteins That Bind to Bcl-2 Family Members and Regulate Their Function[a]

Bcl-2-like Inhibitors of Apoptosis	Bcl-2-like Promotors of Apoptosis
Bag-1 (no BH domains)	Hrk (BH 3, TM domain)
Bra (BH 2 and BH 3)	Bik (BH 3, TM domain)
Raf-1 (no BH domains)	Bid (BH 3)
	Bim (BH 3, TM domain
	Bad (BH 1, 2, 3, no hydrophobic tail)

[a] A variety of proteins interact with Bcl-2 proteins. Some contain the BH domains that influence their function, such as Bid, Bim, Bik, whereas others have no homology with Bcl-2, but still bind and influence its function (46, 47, and references therein].

Both Bcl-x_L and Bcl-2 have effects on cell-cycle transition (61). Cells expressing either gene exhibit a longer-than-average time to reenter the cell cycle after arresting in G_0, suggesting that Bcl-x_L and Bcl-2 interact with components of the cell-cycle machinery.

3.4. Tumor Suppressor Genes and Apoptosis

Tumor suppressor gene products suppress unrestrained cell proliferation through their specific inhibitory effects on the cell cycle and are implicated in the development of neoplasia following their loss or functional inactivation. One tumor suppressor gene product, p53, induces apoptosis in some tumor cell lines. p53 is a short-lived protein that is stabilized in the presence of DNA damage and triggers cell-cycle arrest, presumably to facilitate DNA repair (62). If the DNA damage is too great to repair, apoptosis is triggered, earning p53 the title "guardian of the genome" (63). At present, it is unclear if p53's induction of apoptosis is effected through its upregulation of $p21^{Waf\text{-}1/Cip\text{-}1}$, leading to cell-cycle arrest (64), through some other p53-regulated gene, or is independent of p53 transcriptional activity (65). Bax, the pro-apoptotic Bcl-2 homologue, is transcriptionally regulated by p53, but not all apoptotic cell deaths induced by p53 stabilization require Bax expression (66). The role of p53 as a sensor of DNA damage was neatly illustrated by examining apoptosis in thymocytes from p53-knockout mice (67, 68). p53 null thymocytes undergo death by apoptosis as normal, except when treated with agents that damage DNA, such as etoposide or irradiation. Therefore, in the absence of p53, the cell is neither instructed to leave the cell cycle and repair the damaged DNA, nor to die. Cells therefore progress through subsequent cycles with damaged and mutated DNA. The role of p53 in inducing apoptosis in circumstances in which DNA damage is not evident is at present unclear, although in p53 knockout mice there is no evidence of a defect in tissue homeostasis due to ineffective cell death when cytokines become limiting (67, 68).

A second tumor suppressor gene implicated in control of apoptosis is the **retinoblastoma** (*rb*) gene (69-71). The absence of the functional gene product, Rb, results in massive apoptosis in the haemopoietic and nervous system possibly due to the cells being constantly in cycle and unable to arrest or terminally differentiate. This makes it impossible for cells to establish appropriate survival signals and cell:cell contacts. Loss of both p53 and Rb function results in rapid tumor progression (72), suggesting that cells which have overcome restraints upon cell-cycle progression can also escape apoptosis, underlining the link between cell proliferation and cell death.

3.5. Cytokine Signaling Pathways and Apoptosis

Although a wealth of information is available about the signal transduction pathways activated by cytokines and growth factors in many cell types, surprisingly little is known about how apoptosis (and conversely cell viability) is modulated. Initially, many of the factors now referred to as *survival factors* were considered solely to stimulate cells to proliferate. Thus, many of the identified signal transduction pathways are involved in proliferation but not necessarily survival. For survival signals, two pathways can exist. Cells can be stimulated to survive by one specific pathway. Loss of this signal upon removal of the cytokine may simply trigger cell death due to negation of the first signal. However, removal of the cytokine may trigger another independent signaling pathway. Only now are these different possibilities being investigated.

3.5.1. Survival Signals

Cytokines with very different actions activate substantially overlapping signaling circuits, many of which appear to be required, but are not solely responsible, for regulating cell survival. However, even with these complex signaling networks, it is possible to gather some information about survival signals. For example, apoptosis stimulated by the withdrawal of **nerve growth factor** (NGF) in phaeochromocytoma (PC12) cells involves the induction of the AP-1 transcription factor c-Jun proximal to the time when neurons become committed to apoptosis. Activation of c-Jun requires phosphorylation by the protein kinase JNK (MKK4) that is, in turn, activated by MAP kinase (73) (see Phosphorylation, Protein). In contrast, the suppression of apoptosis by NGF in the same cells may involve a discrete survival signaling pathway routed through **Ras** (74), Raf, and MAP kinase (73). Hence, in this case, the induction of apoptosis and promotion of survival may be independent informational processes, rather than mere negation of one other.

In some documented cases, the ability of anti-apoptotic cytokines to suppress apoptosis does not depend on the synthesis of new genes or proteins, indicating that survival is mediated by posttranslational mechanisms. IGF-1 (25), a potent inhibitor of apoptosis in many cell types, and epidermal growth factor (EGF) (75) are reported to suppress apoptosis effectively in cells treated with inhibitors of RNA and protein synthesis. The suppression of apoptosis in such instances must be effected by means of preexisting molecular machinery. One possible candidate signal is the activation of PI-3 kinase (PI3-K) through Ras, whose inhibition blocks the ability of NGF to mitigate apoptosis (76). However, specificity is absent, since PI3-K is activated in many signaling pathways in response to signals that do not suppress apoptosis. IGF-1 also signals via PI3-K, and the pro- and anti-apoptotic signaling pathways for this cytokine have been identified. PI3-K can be activated by its upstream effector Ras, and it can activate several downstream pathways, including the ribosomal protein $p70^{S6K}$, the **Rho** family polypeptide Rac, and the serine/threonine protein kinase PKB/Akt. Of these downstream effectors, PKB/Akt is anti-apoptotic in fibroblasts expressing c-Myc and in other cell types in the absence of survival factors, whereas the Ras-mediated Raf signaling pathway is pro-apoptotic (77-79). These findings underscore the pleiotropic nature of intracellular signaling. Signals emanating from GTP-Ras trigger a plethora of potential biological outcomes, some of which promote apoptosis and some of which suppress it. The net outcome for Ras activation is presumably dictated by downstream interactions that potentiate or mitigate other signals.

3.5.2. Killer Cytokines

Apoptosis can also be triggered by certain **cytokines**, such as TNFa and CD95 ligand. These two pathways represent the best understood triggers of apoptosis, since their activation pathways are essentially mapped. CD95 ligand and TNFa bind and activate their specific receptors on the surface of the cell (80). The TNF type 1 and CD95 (Fas, Apo-1) receptors are functionally similar; both are transmembrane receptors that contain a region within their cytoplasmic tail which is necessary for the initiation of the apoptotic response (81-83). This region of homology is called the *death domain* (DD). Several adaptor proteins bind to this domain and can trigger apoptosis by directly linking to the downstream effector caspase machinery (23). Alternatively, in the case of TNFR1, the adaptor proteins can also activate NFkB signaling pathways (84). CD95-induced cell death, eg, results in the association of the ***d**eath-**i**nduced* ***s**ignaling **c*** *omplex* (DISC) (80). Upon binding of its ligand, the CD95 receptor trimerizes and binds to its death domain the protein *Fas-associated death domain* (FADD), also known as MORT1 (85, 86). FADD contains a C-terminal DD and, at its N-terminus, a *death effector domain* (DED), so called because the expression of this domain is required to trigger CD-95-induced apoptosis. The DED domain of FADD binds to the DED in caspase-8, a protein also called FLICE (FADD-like ICE, where ICE is "interleukin converting enzyme") (87, 88). The thiol proteinase domain of FLICE, located at its C-terminus, is activated upon binding FADD, and FLICE then activates the *caspase cascade* by cleaving downstream caspases (89) (see Caspases). CD95-triggered apoptosis can be suppressed by expression of the anti-apoptotic proteins Bcl-2 and Bcl-x_L (90) or by proteins that inhibit the interaction of FLICE with FADD (91). Thus, the binding of CD95 ligand to the receptor and recruitment of FADD occur within the decision phase of apoptosis. The commitment of cells to CD95-induced apoptosis does not appear to occur until FLICE is recruited to the DISC, cleaved, and therefore activated. TNFR1 exhibits a similar pathway involving an overlapping set of adaptor proteins (23).

4. The Commitment Phase of Apoptosis

As yet, it is unclear what commits a cell to undergo apoptosis. To a certain degree, the final trigger must be cell autonomous, because cells that have received the same stimulus do not all enter apoptosis at the same time; cells may die within 10 minutes of the signal or within 3 days. Initially, the caspases were proposed to act at this point, with their activation leading to certain death (92-94) Although exogenous expression of pro-caspases leads to cell death, this death is again stochastic and can be suppressed by the addition of IGF-1 (95) or thiol proteinase inhibitors such as the poxvirus protein CrmA and **baculovirus** inhibitor p35 (96, 97). Surprisingly though, not all caspase inhibitors suppress cell death. In the case of c-Myc-induced or Bax-induced apoptosis, the addition of tetrapeptide caspase inhibitors based on the pro-IL-1b cleavage site does not prevent cells from becoming committed to die (98, 99). Thus, even when caspases are inhibited, the cell still undergoes commitment, but it takes much longer to progress through the morphological changes of apoptosis (99). This result suggests caspases are required for the rapid execution phase of apoptosis, but not necessarily for commitment.

The unknown entity in mammalian cells is the putative homologue of the *cell death gene 4* (Ced-4) (see Programmed Cell Death). Ced-4 is required for cell death in *C. Elegans* and appears to function upstream of Ced-3, suggesting that Ced-4 may be involved in commitment (100). Recent data have shown that Ced-9, Ced-3, and Ced-4 bind one another, with Ced-4 being the critical intermediate (101-104). Without Ced-4 expression, Ced-9 does not interact with Ced-3. The expression of Ced-4 in mammalian cells produces a similar reaction between Bcl-x_L and the Ced-3 homologue, FLICE (caspase-8) (101). Whether Ced-4 is a killer of mammalian cells is also not clear, but Ced-4 expression is toxic to yeast (104). In the fission **yeast** *Schizosaccharomyces pombe*, Ced-4 localizes to condensed chromatin and induces caspase-independent death in this apoptotically naïve cell model. Cell death is suppressed upon the expression of Ced-9, which causes relocalization of Ced-4 to the membrane of the nucleus and to the endoplasmic reticulum. These data strongly suggest that Ced-9 suppresses Ced-4-induced death by binding to it. This, in turn, implies that the disruption of the Bcl-x_L/ Ced-4-“like protein” and FLICE interaction in mammalian cells may commit the cell to death.

5. The Execution Phase of Apoptosis

The execution phase describes the stage where the cells morphologically change and exhibit all the characteristics of apoptosis. Not all the agents responsible for these changes have been identified, but activation of the endonuclease occurs at this stage, as does activation of the *ced-3* homologues, the caspases. Overall, the caspase pathway can be thought of as a packaging process that carries out the rapid dismantling of the cell. Cells still die in the absence of caspase activity, but death is significantly prolonged (99). The cleavage of caspase substrates such as Poly-(ADP ribose) polymerase (PARP), the catalytic subunit of DNA protein kinase, and nuclear lamins [reviewed in (105)], in concert with an endonuclease, allow the nucleus and chromatin to be degraded efficiently. This saves the dying cell energy and facilitates the maintenance of membrane integrity, which in turn prevents release of the cell contents, which would stimulate an immune response.

Other effectors of the execution phase are not so well documented. Both ceramide and reactive oxygen species are found in apoptotic cells, but their exact roles are not clear (110-114): They may well be a consequence of death, rather than an effector. Changes in mitochondria also occur within apoptotic cells (115-117). Selective release of **cytochrome *c*** from the mitochondria appears to trigger apoptosis through activation of the caspases. A membrane permeability transition also occurs where the pores that regulate traffic between the mitochondrial outer and inner membranes become disrupted (117). However, it is unclear exactly when this change occurs within an individual cell undergoing apoptosis, making it difficult to assign these changes to a particular phase within the apoptotic pathway.

Overall, the execution phase is one where caspases and endonucleases are active and the cell is dismantled, progressing through the series of morphological changes that originally defined the process of apoptosis. Execution ends with the efficient and rapid phagocytosis of the corpse.

6. Summary

Apoptosis is an active form of cell death indistinguishable from programmed cell death that occurs during invertebrate and vertebrate development. Apoptosis is thought to be the default state of all cells; hence, cells must receive a survival signal in order to remain viable. Apoptosis is triggered in response to a diverse set of stimuli and plays a critical role in the maintenance of tissue homeostasis. Mutations that disrupt the apoptotic pathway are pivotal in the development of many diseases, including degenerative brain disorders and cancer.

ara Operon

The pentose sugar L-arabinose is distributed widely as a component of **plant** polysaccharides in pectins, gums, and cell walls. It is also present in smaller amounts in the cell walls of some **bacteria**. Thus it is likely that, in its natural environment in the vertebrate intestine, the bacterium *Escherichia coli* periodically encounters arabinose released through degradation of these polymers (1). Not surprisingly, *E. coli*, like many other bacteria and fungi, has *ara* **genes** that encode the enzymes and **transport** proteins necessary to utilize L-arabinose as a source of carbon and energy.

The *ara* genes of *E. coli* have been of exceptional importance to biology for several reasons. If the lac operon is the exemplar of regulation of **gene expression** by **repression of expression**, the *ara* operon is the counterpart as the model for positive control of gene expression, even though more complete analysis has revealed that each has both positive and negative features. (An operon is one gene or a linear sequence of related genes that are transcribed as one unit from a common initiation point [see Transcription]. The transcript is then **translated** into protein products corresponding to the separate genes.) The first clear example of DNA looping as a feature of transcription control was the *ara* operon. The hypothesis of positive control of the *ara* operon was a challenge to establishment scientists, and its validation was the end of a fascinating story in the history of science. Moreover, the details of the operon are complex and interesting in themselves.

1. *ara* Operon of *Escherichia coli*

The classical *ara* operon of the bacterium *Escherichia coli* comprises three genes, *araBAD* (Fig. 1). This and four other operons, *araC, araE, araFGH*, and *araJ*, are uniquely associated with metabolism of L-arabinose (Table 1). Each set of genes is under control of the activator protein AraC, the product of the *araC* gene. The function of each gene is known, except for *araJ*, which may encode a protein that processes or transports an arabinose-containing polymer, or pumps potentially toxic arabinosides from the cell.

Figure 1. The positions of the *araBAD* operon and the *araC* regulatory gene on the *E. coli* chromosome. Transcription o

Table 1. *ara* Genes and Gene Products

Gene	Location on the *E. coli* chromosome (minutes)[a]	Size of gene (amino acid codons)	Activity of product
araA	1.4	500	L-arabinose isomerase
araB	1.5	566	L-ribulokinase
araC	1.5	292	AraC regulatory protein
araD	1.4	231	L-ribulose-5-phosphate-4-epimerase
araE	64.2	472	L-arabinose transport, low affinity
araF	42.8	329	L-arabinose transport, high affinity
araG	42.7	504	L-arabinose transport,

			high affinity
araH	42.6	329	L-arabinose transport, high affinity
araJ	8.5	394	Transport or processing of polymer? Efflux of toxic arabinosides?

[a] Location is based on a 100 minute circular chromosome.

1.1. Uptake and Utilization of Arabinose

Two independent systems deliver arabinose from the environment across the cell membrane into the cell. *araE* encodes a membrane protein that mediates arabinose uptake via proton **symport** and is the lower affinity transporter (K_M = 50 µM) (2). The *araFGH* operon encodes a **periplasmic** arabinose-binding protein (*araF*), a probable ATPase subunit (*araG*), and a membrane protein (*araH*), which together mediate ATP-driven arabinose transport. This transporter shows higher affinity for arabinose (K_M = 1 µM) than AraE, but lower capacity (2, 3).

Internal arabinose is converted in three steps to D-xylulose-5-phosphate, a metabolyte in the pentose-phosphate shunt pathway and one that is not unique to arabinose metabolism. The enzyme mediating the first step, L-arabinose isomerase, has a low affinity for arabinose with a KM (Michaelis constant) of 60 mM (4); this suggests that cells growing on arabinose have a very high internal arabinose concentration (5). The glucose-specific phosphotransferase enzyme IIA^{Glc} when unphosphorylated inhibits the isomerase (unpublished results cited in 6) This inhibition may be one of the causes of the preferential use of glucose when both arabinose and glucose are in the environment.

The product of isomerase activity, L-ribulose, is converted to L-ribulose-5-phosphate by L-ribulokinase, and the phosphorylated compound is converted in turn to xylulose phosphate by the epimerase encoded by *araD*. Arabinose inhibits growth of *araD* mutants on other nutrients, presumably because accumulation of a high concentration of ribulose phosphate is toxic. Thus secondary mutants lacking isomerase or kinase activity as the result of *araA, araB*, or *araC* mutation, and therefore not forming ribulose phosphate, can be selected by plating an *araD* population on broth plates containing arabinose (7).

1.2. Regulation of *ara* Operon Expression

In the absence of arabinose, the *ara* genes are essentially not expressed, except for the regulatory gene, *araC*. On exposure to L-arabinose, all of the *ara* genes are activated, transcription of *araBAD* begins within five seconds, and the Ara proteins appear within several minutes, allowing growth on the sugar (5). The true inducer has been shown by X-ray crystallography of the inducer-AraC protein complex to be -L-arabinose (8). L-lyxose also induces the *ara* genes (9). However induction of the *ara* genes by lyxose is unlikely to occur in nature because L-lyxose is rare. *araC* mutants have been obtained that are inducible by D-fucose or by -methyl-L-arabinoside, normally inhibitors of induction (1, 10, 11).

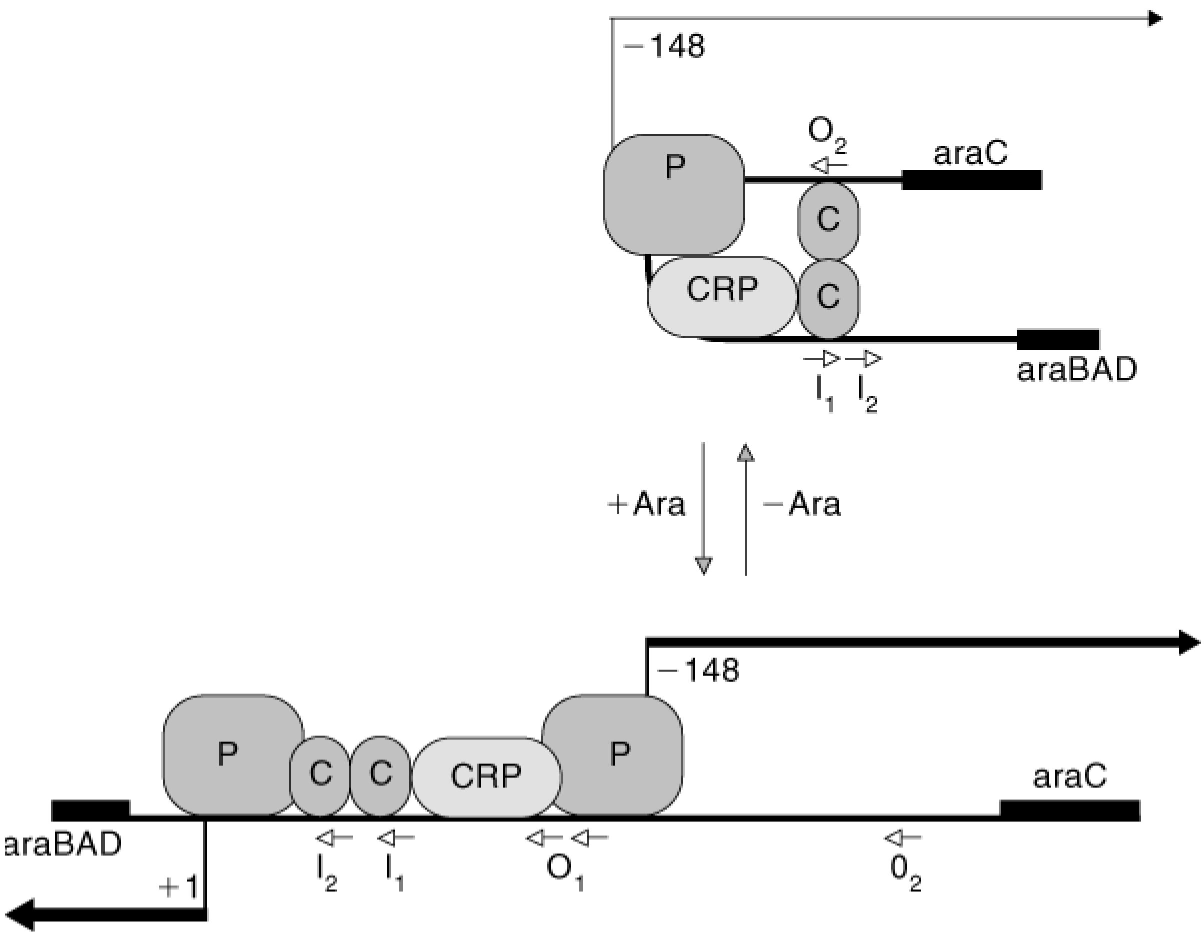
In vivo studies using cells lacking both arabinose transport systems showed the K_M for induction by arabinose to be unexpectedly high, nearly 10 mM (11), although, as noted above, the internal arabinose concentration is likely to be higher than this during growth on arabinose because of the low affinity of the isomerase for the pentose. The high concentration-dependence of induction suggests that there might be natural selection against a mutant isomerase with a better affinity for arabinose.

Complementation studies showed that the *presence* of AraC protein is necessary for *araBAD* gene expression (12, 13), a discovery unanticipated by those who believed all gene activation resulted from *removal* of repressors. Later, AraC was shown to be required for expression of the other *ara* operons as well (except for *araC*). *araC* is the prototype for a large family of regulatory genes that share sequence similarity in the DNA binding region and are homologous and presumably related through evolution (14).

Cyclic AMP (3¢,5¢-cyclic AMP, cAMP) bound to cyclic AMP receptor protein (CRP) is also a positive regulator for all the *ara* operons. Expression of many genes is controlled by availability of CRP-cAMP; lack of expression due to low CRP-cAMP is referred to as catabolite repression. *In vitro* transcription of *araBAD* mimics that *in vivo* in that it requires both the AraC and CRP regulatory proteins with their bound ligands. Analysis of transcription *in vitro*, and further *in vivo* studies, have given a broad understanding at the molecular level of control of *araBAD* transcription although details remain to be determined (5).

The AraC protein structure has two domains connected by a flexible polypeptide linker. The *N*-terminal domain binds arabinose and is responsible for formation of the active dimeric form of the protein. The *C*-terminal domain binds DNA at specific sites, with similar sequences, upstream of each *ara* operon. In the regulatory region between the divergently transcribed *araBAD* and *araC* operons (Fig. 1), there are five sites at which AraC can bind (Fig. 2).

Figure 2. Activation of transcription of the *araBAD* operon by arabinose. CRP refers to CRP-cAMP, and P refers to RNA polymerase. AraC protein is shown as a dimer bound to $I_1$and O_2in the absence of arabinose and to $I_1$and I_2in the presence of arabinose. I_1, I_2, O_1 (a double site), and $O_2$are all potential binding sites for the AraC protein and conform to the consensus sequence 5¢;-TAGCN$_7$TCCATA-3¢ (reading in the direction of the arrows) (16) although there is considerable variation among sites. Note how the mode of pairing of the dimers differs depending on the presence of arabinose (5, 8). On addition of arabinose, transcription of *araBAD* is initiated and expression of *araC* is increased (bottom). After a few minutes AraC-arabinose dimers are thought to bind to O_1 and O_2 so as to form a new DNA loop and reduce *araC* transcription to that characteristic of cells in the absence of arabinose (not shown).



In the absence of arabinose, the two DNA-binding domains of the AraC dimer are oriented so that they can not readily bind both of the adjacent I sites at the same time. Instead, the AraC dimer contacts I_1 and O_2, thereby forming a DNA loop within the region between *araB* and *araC* (Fig. 2) (15). On addition of arabinose, the dimer undergoes a conformational shift such that the two DNA-binding domains preferentially bind I_2I_1 (Fig. 2) (16). The presence of AraC at I_2 stimulates addition of **RNA polymerase** and open complex formation, and transcription of *araBAD* commences, if CRP-cAMP is present (5). Although this model was proposed and refined before detailed structural information was available, X-ray crystallographic studies of the AraC *N*-terminal domain and linker support the model (8).

Addition of arabinose also affects expression of *araC*. When the I_1-O_2 loop is opened, transcription of *araC* is accelerated (Fig. 2). After a few minutes, AraC-arabinose dimers are thought to reform DNA loops, this time by bridging O_1 and O_2 (17, 18). O_1-O_2 looping does not regulate *araBAD* transcription, but interferes with RNA polymerase binding and initiation at the *araC* promoter; this reduces the rate of *araC* transcription to that characteristic of cells in the absence of arabinose (5).

araC is controlled by CRP-cAMP as well. CRP-cAMP binding increases, but is not essential for, *araC* transcription; it is necessary for substantial expression of the other *ara* operons.

The mechanism by which AraC-arabinose, CRP-cAMP, and RNA polymerase interact to trigger transcription is not clear. Bound CRP-cAMP helps to open the I_1I_2 repression loop on addition of arabinose, but it probably activates RNA polymerase binding or initiation as well, either by direct contact or indirectly through contact with AraC (5). (CRP-cAMP does not aid AraC binding.)

Several kinds of CRP-cAMP-independent mutants have been obtained. One class (*rpoD*) has an altered RNA polymerase **sigma factor**-70 subunit (19), while another (*araC*) is altered in AraC itself (20). Other mutants (*araI*) are transcribed by RNA polymerase independently of the AraC or CRP proteins, and they result from changes at the RNA polymerase binding site in the *araBAD* promoter (21).

2. Other Mechanisms for Arabinose Degradation

The pathway for arabinose degradation that is common to *E. coli* and many other bacteria is not the sole means for utilizing L-arabinose in the biological world, nor is the regulatory model described above the only means for control of *ara* enzyme synthesis. At least five different pathways exist (1), and different regulatory systems are found even among organisms using the same pathway. Although the work on other organisms is still at an early stage, it is known that the **gram-positive** bacterium, ***Bacillus*** *subtilus*, utilizes the same degradatory pathway for arabinose utilization as *E. coli* but appears to use a simple repressor as the means of control of *ara* gene expression (22). The fungus ***Aspergillus*** uses a completely different pathway for arabinose utilization and, not surprisingly, appears to have different control systems as well (23). It will be remarkable if the *ara* genes in these other organisms are regulated by the simple repressors once hypothesized for the *ara* genes in *E. coli*.

Arabidopsis

Arabidopsis thaliana (L.) Heynh is a dicotyledonous plant that is ideally suited for molecular-genetic studies. It is generally accepted as a model for unraveling the molecular mechanisms involved in plant growth and development, biochemical pathways, cell biology, physiology, and pathogenic interactions. Minimal genomic DNA content, few repetitive DNA sequences, and small gene families account for its technical and biological simplicity. *Arabidopsis* is a natural diploid amenable to laboratory-scale genetic experiments. It is small (15 cm to 30 cm) and is grown at high density (100 plants per 0.5 m^2) without seed contamination. It has a short life cycle (6 weeks to 3 months), high seed production by self-fertilization (up to 10,000 seeds per plant), is mutagenized easily, and with its 200 different ecotypes is a natural source of genetic variation. International coordination of *Arabidopsis* research has resulted in fast exchange of material, methodology, and information and in the creation of large-scale research programs, such as the genome-sequencing and expressed-sequence tag (EST) projects. The completion of the entire genome sequence was a milestone in plant biology because for the first time a molecular overview has been obtained of common and different pathways between plants and other eukaryotes. Moreover, every plant gene is now accessible for functional analysis. In the post-genomic era *Arabidopsis* research maintains its pioneering position in the field of plant science.

1. History

The first botanical description of *Arabidopsis* by Johannes Thal goes back to 1577. In 1907, Laibach studied the continuity of the chromosomes (5 per haploid genome) by using the plant, and he was the first to emphasize the advantages of the species for genetic analyses (1). In 1976, Bennett and Smith showed that *Arabidopsis* has the smallest nuclear DNA content of the angiosperms analyzed. In that period, extensive chemical and irradiation mutagenesis of the plant was performed (2). Koornneef *et* *al.* (3) published the first genetic map containing 76 morphological markers. In the mid eigthies, Meyerowitz and coworkers demonstrated the small size and low complexity of the genome, which provoked a general interest in using the plant as an experimental model (4). In 1988, efficient transformation methods opened the potential of transgenic research in the species (5). At the same time, saturation mutagenesis of the genome by insertion of heterologous DNA was initiated and resulted in large collections that became available to the scientific community (6). In 1989, the US National Science Foundation launched the 'Multinational Coordinated Long Range Plan for Arabidopsis Genome Research', steered by an international board of scientists, with the aim of promoting *Arabidopsis* as a model system for plants, in analogy to other models such as *Drosophila melanogaster* and *Caenorhabditis elegans*. The major achievements of this initiative were a seed and DNA stock centers (The Arabidopsis Biological Resource Center [Ohio State University, Colombus, OH, USA] and the Nottingham Arabidopsis Stock Centre [University of Nottingham, Loughborough, UK]), a database, and joint efforts for physical mapping and sequencing of the genome and for gene identification. The *Arabidopsis* genome sequencing project was initiated in Europe at the end of 1993, followed by an American and a Japanese initiative. This international consortium, the Arabidopsis Genome Initiative completed the entire sequence by the end of 2000 (7).

2. Classification, Geographical Distribution, and Ecotypes

Arabidopsis thaliana is an annual herb of the mustard family (Brassicaceae, previously named Cruciferae), has bisexual flowers, and is typified by a cross-shaped corolla, tetradynamous stamen (four long and two short ones), and capsular fruit (siliques). The genus *Arabidopsis* consists of 27 species and has been classified under a new tribe, the Arabidae, based on classical morphological and molecular phylogenetic studies. *Arabidopsis* is a facultative long-day plant, meaning that long days accelerate the initiation of flowering. It originated from Eurasia and North Africa, but is now a common weed in the temperate regions of the Northern Hemisphere. Its broad geographical distribution resulted in natural variation. Approximately 200 ecotypes (wild populations) have been registered. These ecotypes represent a natural source of heritable variation: for instance, differences are observed in flowering time, response to cold, fresh weight production, and pathogen resistance. Among ecotypes, a DNA sequence polymorphism of up to 1.4% in low-copy DNA has been measured. Deletions, insertions, and substitutions have occurred. Frequently used ecotypes are Columbia, Niederzenz, Wassilewskija, and the laboratory strain Landsberg *erecta*. The Columbia ecotype was used as standard for the genome sequence, whereas other ecotypes are preferred for mutagenization. DNA polymorphisms are exploited in F2 populations for mapping and quantitative trait locus (QTL) analyses.

3. Genome Structure and Organization

The size of the nuclear genome of *Arabidopsis* was estimated to be between 50 to 150 Mb as determined by reassociation kinetics (see C-Value), flow cytometry, or electron microscopy. From recent physical mapping data, this size was refined to 100 to 140 Mb, which is 3- to 400-fold smaller than that of other members of the angiosperms.

In 2000, the genome sequence of *Arabidopsis* was published, covering 115.4 megabases of the 125-megabases genome (7). A whole genome duplication as well as lateral gene transfer from a cyanobacterial-like ancestor appears to be part of the evolution of the *Arabidopsis* genome. The *Arabidopsis* genome consists for 80% of single- and low-copy DNA. Four classes of highly repeated DNA have been identified, which represent only 10% of the genome and are located mainly at the telomeres and around the centromeres. Ribosomal DNA accounts for 6% of the genome and is localized at the top of chromosomes 2 and 4. In addition to the genomic sequencing, more than 30,000 redundant *Arabidopsis* ESTs have been sequenced and submitted to public databases. Comparison of EST data with data of the genome sequencing program indicates that approximately 60% of the genes are represented by an EST.

From the sequence data, several conclusions can be drawn on gene organization and DNA composition: the gene density is one gene every 4.5 kb, the average gene length is 2 kb, genes have between 0 to 30 introns, 25,498 predicted transcripts encode proteins of approximately 11,000 families, and roughly 30% of the genes could not be assigned to functional categories. The gene families are either dispersed or in tandem arrays; long stretches (approximately 120 kb) of unique or low-copy DNA are interspersed with short stretches of a few kb of moderately repeated DNA; the GC content of the DNA is 35%, and methylation occurs in 6% of the cytosine bases.

The availability of the genome sequences of *Arabidopsis* and several other organisms allows comparisons at the genome level. For example, *Arabidopsis*, *Drosophila* and *C. elegans* have a similar amount of approximately 11,000 to 15,000 different protein types, indicating that this is the minimal number of proteins needed for a functional multicellular organism. Basic processes, such as translation, appear to be conserved across kingdoms, whereas more specialized processes use proteins that differ between plants and animals. These include membrane channels and transporters, components of signal transduction pathways, and transcription factors (8). Plants contain roughly 150 unique protein families (7).

Information on the genome project and on research in general on *Arabidopsis* is centralized in "The Arabidopsis Information Resource" (TAIR) database. A home-page on the Internet (`http://www.arabidopsis.org/home.html`) provides a lot of information on ongoing research (genetic and physical maps, genome sequence information, links to public databases, seed and DNA stock centers, etc.).

4. Genetics and Physical Mapping

Based on metaphase staining and genetic linkage group analyses, the haploid chromosome number is 5, ranging in size from 13.4 Mb to 25.4 Mb. The genetic map comprises more than 460 loci. The ratio of physical to genetic distance between markers on average is 200 kb per cM. However, from the physical map construction of chromosome 4, recombination hot spots (30–50 kb/cM) and low spots (≥550 kb/cM) were found (9). Many tools are available to map a mutation, for example, recessive visible markers, codominant embryo-lethal markers, dominant selectable markers on the located T-DNA and *Activation/Dissociation* insertions, restriction fragment length polymorphism (RFLP)-derived or PCR-based molecular markers, such as microsatellites, insertion/deletions (INDEL), and single nucleotide polymorphisms (SNP). Several molecular marker maps have been constructed based on RFLP, rapid amplified polymorphic DNA, or amplified fragment length polymorphism (AFLP) as well as on different mapping populations. A combined map, made by statistical integration, gives an approximate position and order for the markers. Recombinant inbred (RI) lines, derived from a cross between Columbia and Landsberg *erecta* (10), have been used to locate 1265 molecular markers to date. The physical map consists of contigs of DNA clones that are correlated with the mapped markers. Currently, YAC, bacterial artificial chromosome (BAC), and phage P1 artificial chromosome (PAC) contig maps are available that cover the entire genome.

5. Scientific Advances and Applications

The molecular-genetic approach in *Arabidopsis* research together with cell biology tools, such as confocal microscopy, laser cell ablation, and dye-loading have led to major breakthroughs in plant developmental biology (11-13). Tremendous progress has been made in understanding the molecular control of meristem identity in vegetative meristems, during flower initiation and flower organ formation, embryo development, and pattern formation during embryogenesis, root development, epidermal cell fate specification in root hair, and trichome formation. Genes have been identified that are involved in hormone perception, biosynthesis, and signal transduction. The first hormone receptor for plants has been characterized in *Arabidopsis* (14). Much of the molecular insights into light perception and signal transduction, cell cycle regulation, and in disease resistance in higher plants comes from studies in *Arabidopsis* (15-17). Biochemical items, such as cell wall biology, are being explored. Within the next 10 years, the function of every gene will be determined. This will be achieved by reverse genetics techniques, such as knockouts and targeting-induced local lesions in genomes (TILLING) (18), to create allelic diversity and by implementation of genome-wide methods, such as transcript profiling and microarrays. In general, biological processes will be analyzed by genomics and bioinformatics tools in order to identify all the molecular components involved.

The *Arabidopsis* genes and mutants are resources that are exploited to isolate orthologs from other species and to test their functional conservation (19), or that are used for the genetic modification of even distantly related crop plants (20). The molecular markers within contigs in *Arabidopsis* have been used for comparative mapping with *Brassica* spp. Colinearity in 5- to 10-cM regions has been demonstrated between the *Arabidopsis* genome and that of *Brassica nigra* (21). This implies that information and markers obtained from the physical mapping in *Arabidopsis* can be applied to syntenic genomic regions in mustard crops to analyze important traits in breeding programs. Microarrays of *Arabidopsis* have proven to be useful for the analysis of transcription profiles of developing seeds in related species, such as *Brassica* (22), and will be a great help in the study of seed biology in engineered plants. It is to be predicted that *Arabidopsis* will be used as a reference system to accelerate knowledge accumulation in crop species. DNA sequence analysis showed the presence of genes in the *Arabidopsis* genome that suggest the existence of secondary metabolism pathway in this plant (7). Hence, *Arabidopsis* might be a helpful tool to unravel these pathways in medicinal plants.

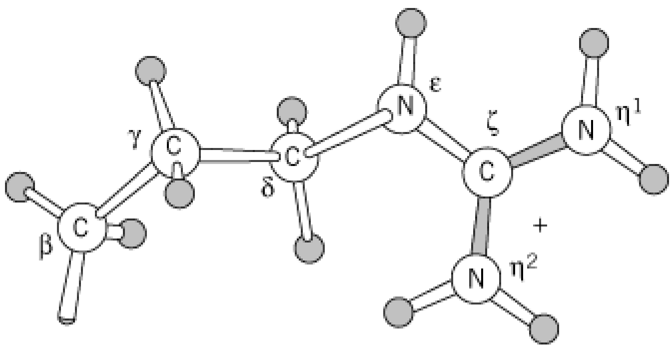
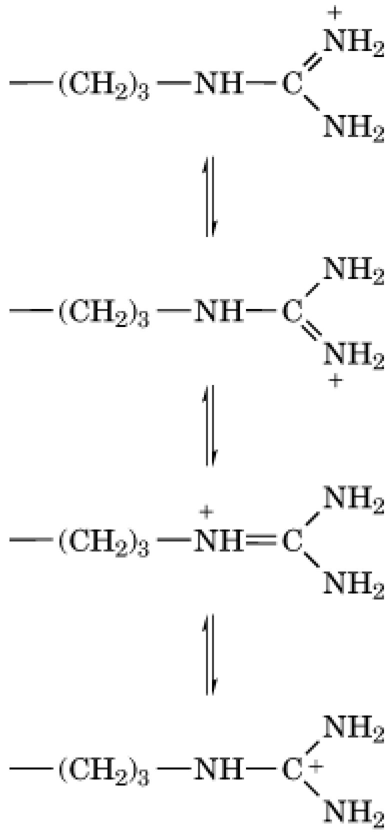
Arginine (Arg, R)

The amino acid arginine is incorporated into the nascent polypeptide chain during **protein biosynthesis** in response to six **codons**—CGU, CGC, CGA, CGG, AGA, and AGG—and represents approximately 5.7% of the residues of the proteins that have been characterized. The arginyl residue incorporated has a mass of 156.19 Da, a **van der Waals volume** of 148 Å^3, and an accessible surface area of 241 Å^2. Arg residues have average conservation during divergent evolution; they are interchanged most frequently in **homologous** proteins with lysine, the other basic residue.

The Arg side chain consists of three nonpolar methylene groups and the strongly basic d-guanido group:



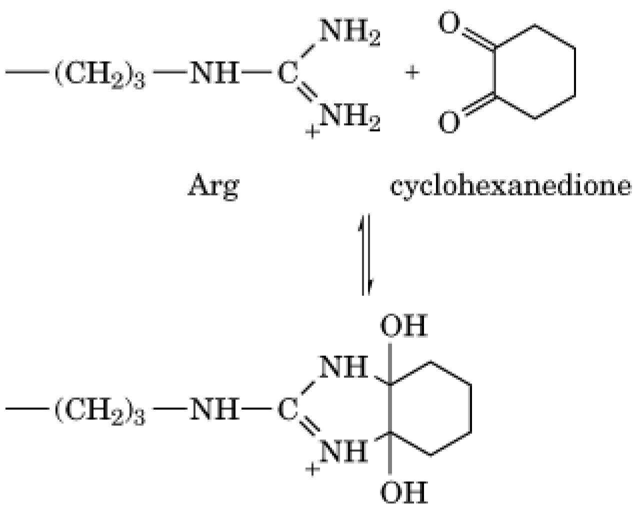
With a pK_a value usually of about 12, the guanido group is ionized over the entire pH range in which proteins exist naturally. The ionized guanido group is planar as a result of resonance:



and the positive charge is effectively distributed over the entire group. In the protonated form, the guanido group is unreactive, and only very small fractions of the nonionized form are present at physiological pH values. The guanido groups of Arg residues are almost invariably at the surfaces of native protein structures, and virtually no Arg residues are fully buried, but the nonpolar part of the side chain, and the adjoining polypeptide backbone, are frequently buried within the interior. Arg residues favor the *alpha*-**helical** conformation in model peptides and also occur most frequently in that **secondary structure** in folded protein structures.

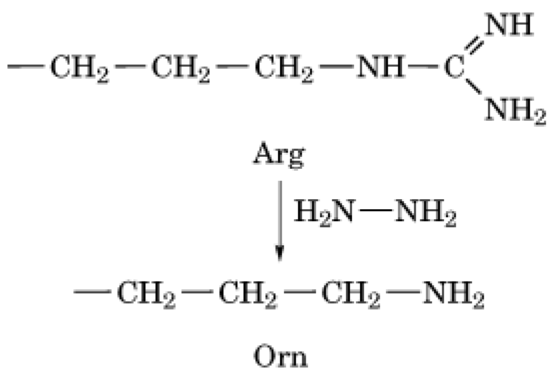
Proteinases frequently cleave polypeptide chains adjacent to Arg residues, as in the processing of pro-hormones, such as pro-**insulin**, at pairs of basic residues.

The guanido group can form heterocyclic condensation products with 1,2- and 1,3-dicarbonyl compounds, such as phenylglyoxal, 2,3-butanedione, and 1,2-cyclohexanedione:



These reactions occur readily because the distance between the two carbonyl groups of the reagents closely matches that between the two unsubstituted nitrogen atoms of the guanido group. The adduct formed can be stabilized further by the presence of borate, which complexes with the adjacent hydroxyl groups.

The guanido group can be cleaved by hydrazine (H_2NNH_2) to produce the side chain of ornithine:



This reaction is, however, often accompanied by cleavage of the polypeptide backbone.

Ascaris

Ascaris is a genus of large animal parasitic nematodes. Common species include *Ascaris equorum*, a horse parasite, *Ascaris suum*, a pig parasite, and *Ascaris lumbricoides*, which parasitizes humans. Adult ascarid nematodes, which reside in the host intestine, range from several inches to several feet in length, and females can produce more than 2 million eggs per day. Fertilized eggs are released into the environment by defecation, where they remain dormant until ingested by another host. The acidic environment of the stomach and the increase in temperature trigger resumption of embryonic development, resulting in first-stage (L1) juveniles (often termed *larvae*) inside the egg shell. After molting once, the larvae hatch from the egg as second-stage (L2) juveniles. Like all nematodes (*q.v.*), Ascaris molts through three more juvenile stages (L3–L4) and then to a sexually mature adult. Stages in the parasitic life cycle are tissue-specific: The L2 burrows through the wall of the small intestine and is carried via the bloodstream or lymphatic system to the lungs, bronchi, and trachea. It molts to L3 and migrates up the trachea and down the esophagus, returning to the small intestine where it molts to L4 and then, about two to three months after the initial infection, to a mature adult that begins producing eggs. About 25% of the human population is infected by *Ascaris lumbricoides*, primarily in developing countries. Ascaris infections are generally debilitating but not life-threatening, although heavy infections can cause severe complications resulting from intestinal obstruction, peritonitis, or allergic reaction.

As an experimental organism, Ascaris was important to early embryologists and cytologists such as Theodor Boveri and Otto zur Strassen in the 1890s, who took advantage of several favorable properties of the early embryos that are still exploited by present-day researchers. The embryos are obtainable in large numbers from gravid females; they are transparent, facilitating observation by light microscopy; they can be stored in their original dormant state and their development initiated synchronously by high temperature or acid shock; and the pattern and timing of their embryonic cleavages, like those of most nematodes (*q.v.*), are invariant from embryo to embryo, with many cell fates apparently determined as the cells are born. The species studied most extensively by Boveri, *Ascaris megalocephala*, has the additional advantage of having only one large chromosome, which was convenient for cytological studies. Ascaris also has the peculiarity that there is chromosome fragmentation and diminution in all of the **somatic** precursor cells as they separate from the **germ line** in the early embryo. Although later work has shown that most of the discarded DNA does not include coding sequences, this feature allowed Boveri to demonstrate that cytoplasmic components specific to the germ line were responsible for maintaining chromosomal integrity in these cells, which supported the view that nonrandomly segregating cytoplasmic determinants were responsible for dictating early cell fates.

In the modern era, Ascaris has also become an important system for research in neurobiology. Part of the rationale behind Sydney Brenner's choice of the small free-living soil nematode *Caenorhabditis elegans* (see Caenorhabditis) for genetic and ultrastructural analysis of a simple nervous system and its development was the hope that Ascaris, only distantly related but much more suitable for electrophysiology because of its larger size, would allow functional analysis of a homologous nervous system. This hope has been largely realized: The two nervous systems appear to be very similar in both structure and function, and information from each has been valuable in understanding the other.

Asexual

The term “asexual” means without sex; it is an adjective applied to multicellular organisms with missing or atrophied sexual organs and to forms of reproduction that do not involve the fusion of male and female gametes (see Asexual Reproduction).

The initial concept of sex referred to diploid, multicellular species in which new individuals are produced by the fusion of two haploid gametes, a sperm and an ovum (sexual reproduction). Individuals of many of these species may be classified into two sexes, *male* and *female*, depending on whether they are able to produce sperm or ova (eggs), respectively. This is the situation in most animals and in dioecious plants. The sex of an individual may be determined genetically or by the environment. Individuals are *asexual* if the organs that produce gametes are missing or atrophied; *intersexual* if their sexual organs are intermediate or ambiguous; or ***hermaphrodite*** if they have both kinds of sexual organs, whether they are functional or not. Hermaphroditism is prevalent in many species of plants, whether both pollen and ova are produced in the same *hermaphrodite* flowers, or in separate flowers of the same plant (*monoecious* plants).

These concepts cannot be transferred to unicellular organisms without some modifications. The haploid cells that predominate in the life cycles of many unicellular eukaryotes can often be classified into different **mating types**, sometimes more than two, with the criterion that only those of different mating type are able to fuse and form diploids. This situation is called *heterothallism*. The mating types of the lower eukaryotes are sometimes called sexes, even though cells of different mating types are not homologous to sperm and ova of the animals.

In the situation called *homothallism*, diploid cells may be formed by the fusion of two genetically identical haploid cells. This would happen if there were a single mating type or if haploid cells change their mating type when they find no partner of the opposite one, as occurs in the homothallic strains of the yeast *Saccharomyces*.

Asexual bacteria are unable to transfer or receive DNA via conjugation (see Hfr'S And F-Primes; F Plasmid).

Asexual Reproduction

Asexual reproduction includes all forms of reproduction that do not involve the fusion of male and female gametes. The asexual reproduction of a cell consists in the formation of genetically identical daughter cells; in the eukaryotes, this implies nuclear division via mitosis. Multicellular organisms are formed through repeated cycles of asexual reproduction from an initial zygote (see Development and Embryology). The daughter cells need not be completely identical, because cells with the same genotypes may differ in the quantitative distribution of transcription factors (see Differentiation). The genotypes of the daughter cells may differ because of mutation, mitotic recombination, chromosomal nondisjunction, and other infrequent events.

There are two kinds of *asexual* reproduction of multicellular organisms, namely, parthenogenesis and vegetative reproduction. Parthenogenesis imitates sexual reproduction, in that embryogenesis is apparently normal, but without participation of a male gamete. Haploid individuals are produced through the parthenogenetic development of a normal female gamete. **Diploid** individuals are produced through the fusion of the haploid nuclei of a female gamete and a neighboring haploid cell, such as the synergids of plants and the polar bodies of animals. Other diploid individuals are produced through the parthenogenetic development of a diploid cell after failure of meiosis. In vegetative reproduction, individuals are derived from one or many somatic cells. It is a common natural process in many plants and lower animals, and it is the only multiplication mechanism in some of them.

Artificial interventions permit new forms of asexual reproduction. These include (a) the production of haploid plants from the culture of anthers and (b) the production of diploid animals through the replacement of the nucleus of the ovum by a somatic nucleus. Vegetative reproduction and ameiotic parthenogenesis lead to the formation of *clones*, which are sets of individuals with identical genotype. Clonal propagation is usually carried out through vegetative reproduction from a single cell or a group of identical cells.

The parasexual cycle may be seen as a form of asexual reproduction in the lower eukaryotes and in cultured cells of multicellular organisms. Haploid cells, not necessarily of different **mating type**, fuse to form heterokaryons, and the nuclei of the heterokaryon fuse to produce diploid nuclei; these revert to haploidy, not by meiosis, but by random chromosome losses during mitosis, accompanied by mitotic recombination.

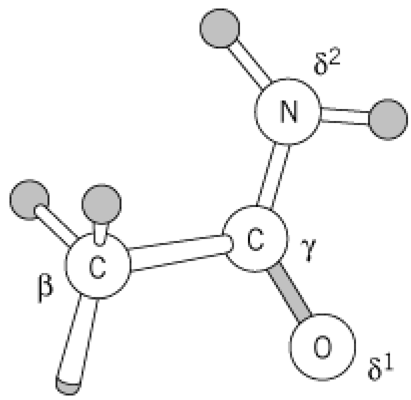
The sexual processes of bacteria imply the conjugation of two compatible cells and the transfer of part of the genetic information of one to the other (see Hfr'S And F-Primes; F Plasmid). Formally similar are asexual processes in which some genetic information from a cell is transferred to another via a **virus** or via naked DNA (see Transformation). These processes are not exclusive to the prokaryotes.

In evolutionary terms and in comparison with the various sexual processes, asexual reproduction has advantages of speed, economy, and the conservation of certain genotypes that may be lost or made less frequent after meiosis (see Heterosis, and Aneuploidy). The main drawback of asexual reproduction is the limited creation of new genetic variation (see Genetic Diversity).

Asparagine (Asn, N)

The amino acid asparagine is incorporated into the nascent polypeptide chain during **protein biosynthesis** in response to six **codons**—CGU, CGC, CGA, CGG, AGA, and AGG—and represents approximately 4.4% of the residues of the proteins that have been characterized. The asparaginyl residue incorporated has a mass of 114.11 Da, a **van der Waals volume** of 96 $Å^3$, and an accessible surface area of 158 $Å^2$. Asn residues are those most variable during divergent evolution; they are interchanged frequently in **homologous** proteins with serine, aspartic acid, lysine, and histidine residues.

The side-chain of Asn residues is the same as that of aspartic acid, except that the carboxyl group has been converted to the amide:



Both amino acids occur naturally and are incorporated directly into proteins during their biosynthesis; Asn residues do not arise from amidation of Asp in proteins. The amide side chain does not ionize and is not very reactive chemically. It is polar, however, because it is both a hydrogen bond donor and acceptor. The amide group is labile at extremes of pH and at high temperatures, and Asn residues can **deamidate** to Asp. The Asn residue is especially labile at alkaline pH because its side chain is sterically suited to interact with the —NH— group of the following residue in the polypeptide chain, to form transiently a cyclic succinimidyl derivative (see Deamidation). This derivative can undergo racemization and hydrolysis to cleave the polypeptide chain or to produce a mixture of D and L isomers of Asp and isoAsp residues. In an isoAsp residue, the normal backbone peptide bond is through the side-chain carboxyl group rather than the usual a-carboxyl. The deamidation reaction of Asn residues occurs 30–50 times more rapidly if the following residue is **Gly**, because the absence of a side chain there favors succinimide formation, and —Asn—Gly— sequences are especially prone to deamidation. The rate depends on the polypeptide conformation, however, because only some conformations permit succinimide formation. If the succinimide ring reacts with hydroxylamine instead of water, peptide cleavage results. Therefore, Asn—Gly peptide bonds are readily cleaved by incubation with hydroxylamine.

Asn residues are the site of N-glycosylation of proteins, one of the most prevalent post-translational modifications. The Asn residue that is so glycosylated always occurs in a characteristic sequence: —Asn—Xaa—Ser—, —Asn—Xaa—, Thr—, or —Asn—Xaa—Cys—, where Xaa can be any residue except **Pro**, which also cannot immediately follow the tripeptide sequence.

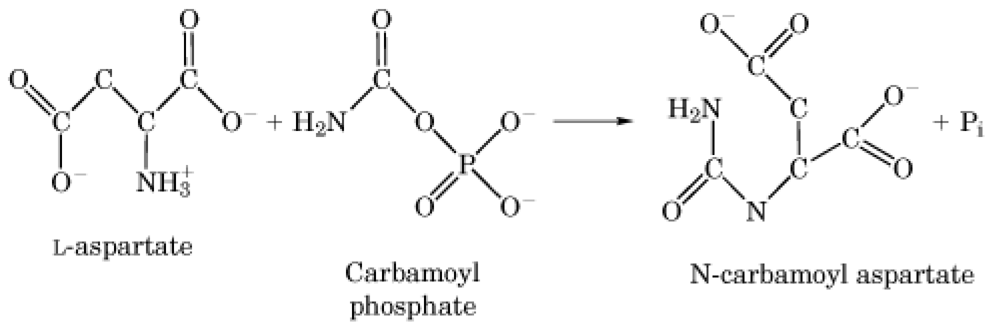
Aspartate Transcarbamoylase

Aspartate transcarbamoylase (carbamoylphosphate:L-aspartate carbamoyl-transferase, ATCase, EC 2.1.3.2) is a ubiquitous enzyme of **pyrimidine** biosynthesis in which it catalyzes the first unique step in the *de novo* synthetic pathway:



1. The *Escherichia coli* Paradigm

Although the enzyme exists in a variety of oligomeric and multifunctional complexes in various organisms, the most studied ATCase is that of *Escherichia coli*. It is a structurally complex, **allosterically** regulated enzyme containing two catalytic trimers associated with three regulatory dimers, $2(c_3){:}3(r_2)$ (Fig. 1). The catalytic polypeptide chain is encoded by the *pyrB* **gene**, whereas *pyrI* encodes the regulatory polypeptide. These genes are preceded by two tandem **promoters**, designated P_1 and P_2, and an open reading frame encoding a 44-residue leader polypeptide, *pyrL*. Promoter P_2 has been identified as the physiologically significant promoter (see Fig. 2).

Figure 1. Structure of the intact *E. coli* ATCase viewed along the 3-fold axis (**a**) and along the approximate 2-fold axis (

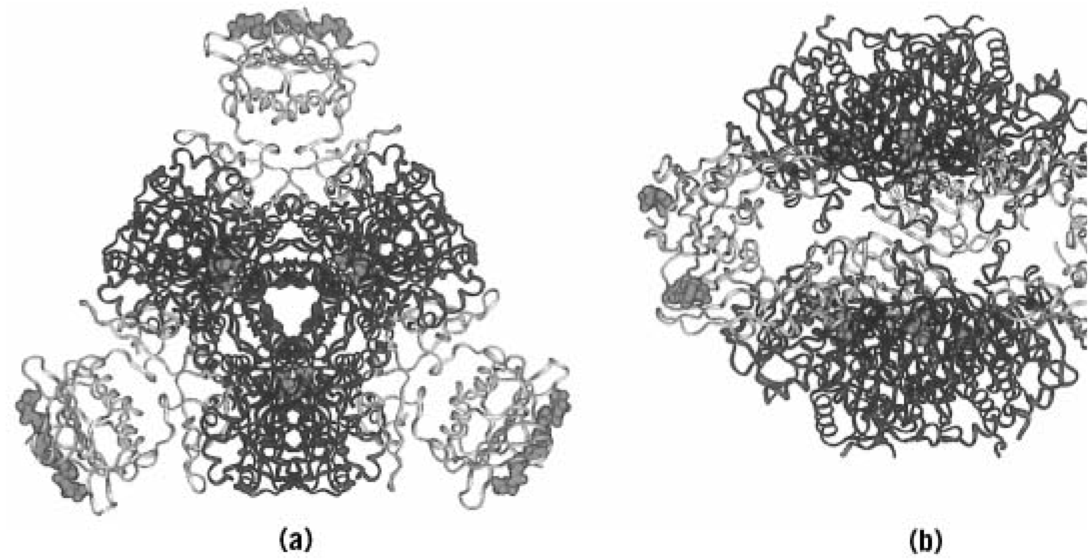

Figure 2. Genetic organization of the *E. coli pyrLBI* operon. The position of the three cistrons on the chromosome is sho positions of three hairpin structures adopted by the messenger RNA. The sequence around the first two is shown below. *pause hairpin*, flanked on each side by uridine-rich sequences. The second is the *terminator hairpin*, encoded by the atte

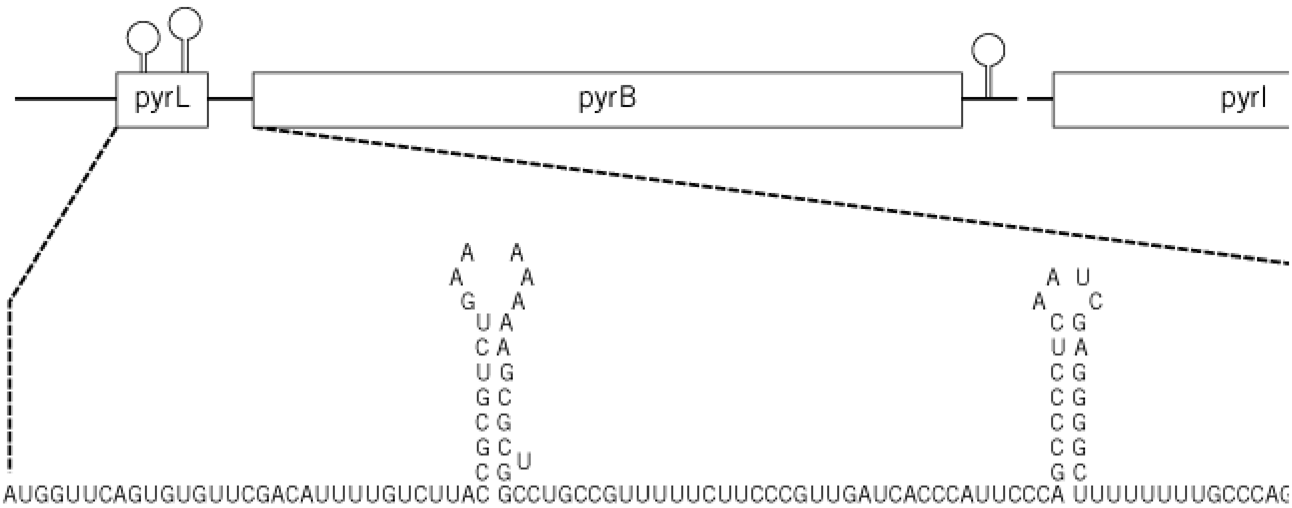

The *pyrLBI* operon is located on the linkage map of *E. coli* at 97 minutes and unlinked to any of the genes or small operons of the other six enzymes involved in pyrimidine biosynthesis. The expression of these genes is noncoordinately regulated by the intracellular levels of uridine or cytidine nucleotides, with the expression of the *pyrBI* operon negatively regulated over 300-fold. Most of this regulation (50-fold) occurs through a UTP-sensitive **attenuation** control mechanism, whereas attenuator-independent mechanisms are responsible for approximately a 6.5-fold range of regulation, including a pyrimidine-sensitive **transcriptional** initiation mechanism, and **stringent** control by ppGpp (1). According to the current model for attenuation control, transcriptional termination at the *pyrBI* attenuator (a **rho**-independent transcriptional terminator) is regulated by the relative rates of transcription and translation within the *pyrBI* leader region. Low intracellular levels of UTP cause **RNA polymerase** to pause at the uridine-rich region in the leader transcript (this pausing is enhanced by NusA, a general transcription factor that increases the efficiency of termination). This allows time for a ribosome to initiate translation and catch up to the stalled RNA polymerase before it transcribes the attenuator region. As RNA polymerase eventually makes its way through the attenuator, the adjacent translating ribosome blocks formation of the *terminator hairpin*. This permits RNA polymerase to read through into the *pyrBI* structural genes, with translation terminating before the *pyrB* initiation codon. When intracellular levels of UTP are high, RNA polymerase does not pause during the transcription of *pyrL*. Without this pausing, the ribosomes cannot catch up to RNA polymerase before it transcribes the attenuator. This allows formation of the RNA hairpin, thus terminating transcription prior to the structural genes.

In addition to the genetic regulation of *pyrLBI*, the gene product ATCase also exerts significant control over the rate of pyrimidine biosynthesis (2). This is achieved by allosteric modification of the enzymatic activity in response to substrate concentration (**homotropic** cooperativity) and the nucleotide end products of both the purine and pyrimidine pathways (**heterotropic** regulation; see Tables 1 and 2). In the oligomeric complete enzyme, catalysis proceeds by a preferred order mechanism, with carbamoyl phosphate binding before aspartate and N-carbamoyl-L-aspartate leaving before inorganic phosphate. Homotropic cooperativity is induced by aspartate in the presence of a saturating concentration of carbamoyl phosphate and involves a structural transition of the enzyme consistent with a two-state, **concerted model**. As aspartate is bound, the enzyme shifts from the **T-state**, characterized by low activity and low affinity for substrates, to the **R-state** with high activity and high affinity for substrates. The kinetic consequence of this positive cooperativity is a sigmoidal substrate saturation curve (Fig. 3). Heterotropic activation is caused by the purine ATP, whereas the pyrimidine end products CTP and UTP **feedback inhibit** the enzyme. The pattern of inhibition exhibited by pyrimidine nucleotides is synergistic: CTP inhibits ATCase activity approximately 60% and UTP has minimal effect, while CTP in combination with UTP inhibits ATCase activity >95% (3). CTP, ATP, and UTP bind competitively, with different affinities, to a common allosteric site. CTP binds the most tightly with a pattern consistent with two classes of three sites each, whose **dissociation constants** differ by a factor of 20 ($K_{d\text{-CTP}}$: 5 to 20 µM). The binding of ATP follows a pattern similar to that of CTP with two classes of affinity sites, except that ATP binding is an order of magnitude weaker than that of CTP ($K_{d\text{-ATP}}$: 60 to 100 µM). The binding of UTP appears to be limited to three sites ($K_{d\text{-UTP}}$: 800 µM), although there may be a second class of sites too weak to be measured. Interestingly, the binding of CTP to three sites appears to enhance the binding of UTP to the remaining three sites almost 100-fold, resulting in a predicted K_d for UTP in the presence of CTP of 10 µM (4). These biochemical binding characteristics are well suited to the physiological requirements of the pathway: Although the intracellular concentration of CTP (500 µM) and UTP (900 µM) is 3- to 6-fold lower than that of ATP (3 to 5 *mM*), their stronger binding can effectively displace ATP at the allosteric sites of the enzyme.

Physiological Significance of Catalytic Characteristics of the *E. coli* Aspartate Transcarbamoy

Catalytic Characteristic	Functional Consequence
• Ordered substrate binding (CP→Asp)	• Places catalytic emphasis on aspartate
• Cooperative aspartate binding	• Allows large changes in catalytic activity with onl of physiological substrate concentrations
• Distinct regulatory and catalytic subunits	• Increased sophistication in the allosteric modulatic activity
• Presence of shared active sites and catalytictrimers	• Facilitates modulation of catalytic activity with sul movements
• T→R structural transition	• Provides for dramatic differences in aspartate bind modulation of catalytic capacity at physiological lev

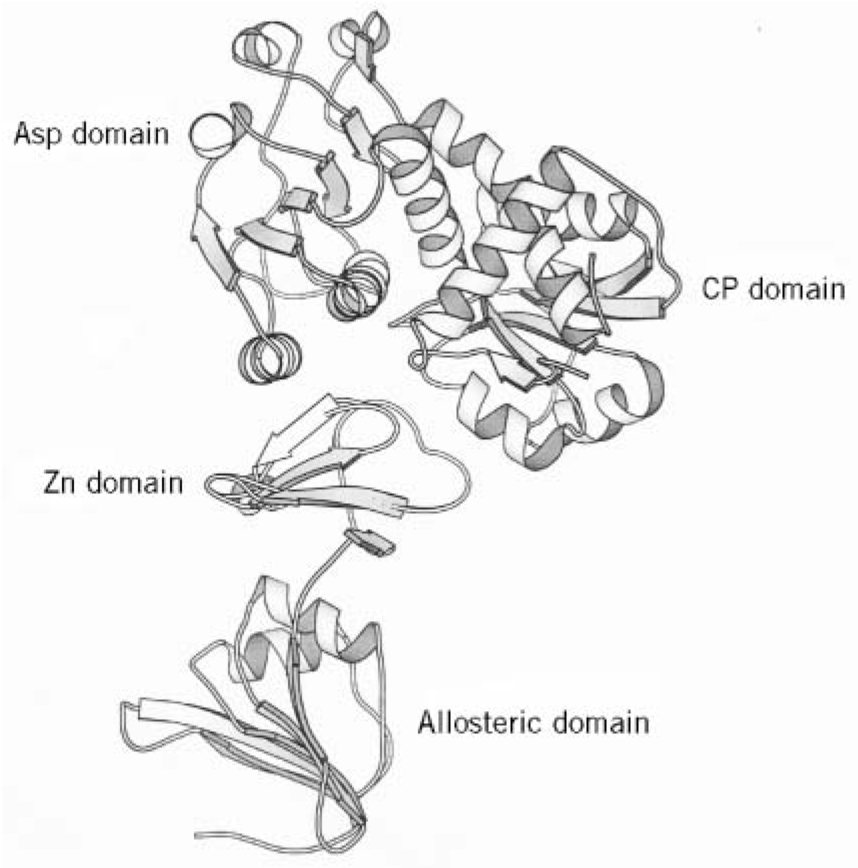
Table 2. Physiological Significance of Allosteric Characteristics of the *E. coli* Aspartat

Allosteric Characteristic	Functional Consequence
• Allosteric inhibition by CTP	• 50–70% inhibition of activity by nucleotide balance new synthesis with utilization
• Synergistic inhibition by UTP and CTP	• UTP and CTP are both end-products of the b pathway and the synergism provides 90–95% activity
• Competitive allosteric activation by ATP	• ATP competes with CTP and UTP for the sa thus balancing intracellular purine and pyrimi pools
• Competitive allosteric inhibition by	• Allows for displacement of ATP (activation)

CTP and CTP + UTP	(CTP or CTP + UTP)
• Negative cooperativity in binding CTP	• Permits modulation of enzymatic activity ov of inhibitor concentration
• Communication of allosteric signals across protein–protein interfaces	• Facilitates modulation of allosteric signal
• Asymmetry of the holoenzyme	• Provides two distinct classes of allosteric bir a single enzyme

Comparison of the X-ray crystallography structures of the enzyme has revealed that each of the catal independently folding structural **domains**: the carbamoyl phosphate (CP) domain and aspartate (Asp sites are located at the interface between the CP and Asp domains of one catalytic chain and the CP chain. Likewise, the regulatory chains are composed of two structural domains: the zinc-binding (Zn domain. Differences between the two states of the enzyme have been identified by comparison of the inhibitor (CTP) and the R-state structure binding a bisubstrate analogue [N-(phosphonacetyl)-L-aspa change in quaternary structure involves substantial conformational rearrangements as the catalytic tr mutually reorient 10° around the 3-fold axis, while each regulatory dimer rotates 15° around the 2-fc binding, the two domains of each catalytic chain (Asp and CP) undergo domain closure, whereas the chain (Allo and Zn) undergo domain separation. Site-directed mutagenesis studies have shown that c domains is important for the formation of the high-affinity, high-activity R-state, which is required t conformation needed for catalysis, and for homotropic cooperativity.

Figure 4. Domain organization of the *E. coli* ATCase illustrated with one catalytic chain (C1) and its associated regulat composed of two independently folding domains: the aspartate-binding (Asp) domain and carbamoyl phosphate-bindin regulatory chain is composed of the zinc-binding (Zn) domain and nucleotide-binding (allosteric) domain. This R1:C1 u MOLSCRIPT programs.



In addition to these studies, well over 100 site- and region-specific mutations have been created in th studies, along with the many structural and biochemical analyses, have contributed to our understanc active-site and allosteric site locations, identifying interactions important to the stabilization of the T catalytically significant residues. More recently, site-directed mutagenesis studies have been directec mechanism. Mutations have been created that can effectively separate the homotropic from the heter from inhibition, and CTP inhibition from CTP + UTP synergism. Although the mechanism of alloste current mutagenesis and structural studies are attempting to identify and differentiate between possit discreet pathways for each nucleotide signal, (2) complex and multiple interlocking pathways, or (3) energy changes.

2. Diversity of Aspartate Transcarbamoylase

2.1. Prokaryotes

With the exception of some anaerobic protozoan parasites, all examined organisms are capable of *de* and have been found to possess the enzyme aspartate transcarbamoylase. The earliest classification c and Jones in 1969 (16), based on enzyme size and response to nucleotides, partitioned the enzyme in ATCases are the largest ATCases found in bacteria and were initially described for the pseudomona ATCases of *E. coli* and other members of the *Enterobacteriaceae*; whereas (3) class C is the class w until recently was restricted to **Gram-positive** bacteria such as *Bacillus* (Fig. 5). The class A ATCas in size, and the intact enzyme exists as two catalytic trimers of 35 kDa in dodecameric association w chains ($2A_3$:$3D_2$). In *P. putida*, this 45-kDa chain has been shown to be a nonfunctional homologue the third enzyme in *de novo* pyrimidine biosynthesis immediately following ATCase in the biosynth

Figure 5. Organization of the first three enzymes and genes of pyrimidine biosynthesis: glutamine amidotransferase (G

2.2. Eukaryotes

The ability to form chimeric proteins opens the possibility that intragenic fusions could provide a me development of new proteins by the fusion of domain modules. Among the biosynthetic pathways of examples of single polypeptides that carry multiple enzymatic activities. Eukaryotic ATCases provic examples of a multienzymatic protein. In lower eukaryotes, such as **yeast**, the first enzyme in the pat *synthetase* (CPSase), and ATCase are physically linked, forming the CD*A protein fusion complex. *cerevisiae* and *S. pombe*, the enzyme architecture includes four domains; three functional domains c *amidotransferase* (GLNase), CPSase, ATCase activities, and one dihydrorotase-like (D*; DHOase) c the third enzymatic activity of the pyrimidine biosynthetic pathway just following ATCase. This stru the architecture previously discussed for the class A prokaryotic enzymes, which possess a domain v DHOase. The regulation of this complex includes the feedback inhibition of both CPSase and ATCa though the carbamoylphosphate produced by GLNase/CPSase is tightly channeled to ATCase and a the GLNase/CPSase alone should be sufficient to regulate pyrimidine metabolism.

In higher eukaryotes, the CA complex is associated with a functional DHOase domain producing a n (physically arranged in a CDA sequence). This complex provides the central metabolic control for p CPSase subjected to allosteric inhibition by UTP and activation by 5-phosphoribosyl 1-pyrophospha regulatory and catalytic functions involve a single polypeptide chain, the multifunctional complex m structure. A series of **proteolytic** and genetic truncation studies over the last 15 years have provided structure of CAD is well-defined and simple: Each enzymatic domain is separated from the others by polypeptide linker, and each domain can function in the absence of the other activities.

There are a number of proposals regarding the evolutionary role of the multienzymatic architecture. channeling occurs between CPSase and ATCase of the bifunctional CD*A complex. Channeling of s successive enzymatic activities are carried out on the same protein complex and could conceivably p advantage by limiting the loss of intermediate products. However, this is not always the case, as the freely releases the products of CPSase and ATCase, whereas ATCase and DHOase can readily utiliz outside the enzymatic complex. In the case of CAD and similar enzymatic complexes, coordinate **ge** alternative regulatory advantage for the evolution and maintenance of large enzymatic complexes. T complexes would provide for a smaller number of independent genes to regulate and simplify the co subcellular localization of multiple enzymatic activities.

In summary, the *de novo* biosynthetic pathway involves the set of reactions that supplies UMP from metabolic pathways: aspartate, glutamine, ATP, PRPP and carbon dioxide. The *de novo* pyrimidine enzymatic steps from carbamoyl phosphate synthetase (CPSase) to orotidylate decarboxylase (OMP evolution has developed a variety of regulatory controls and genetic organizations. Independent of it ATCase provides an important regulatory component of *de novo* pyrimidine biosynthesis in all free- maintaining homeostasis in intracellular nucleotide pools is an essential consideration for metabolisr enzymological regulation mechanisms are critical for balancing the nucleotide precursors of DNA/R

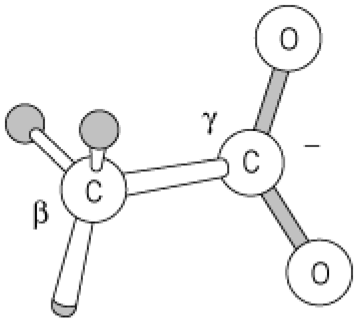
Aspartic Acid (Asp, D)

The amino acid aspartic acid is incorporated into the nascent polypeptide chain during **protein biosynthesis** in response to only two **codons**—GAU and GAG—and represents approximately 5.3% of the residues of the proteins that have been characterized. The aspartyl residue incorporated has a mass of 115.09 Da, a **van der Waals volume** of 91 $Å^3$, and an accessible surface area of 151 $Å^2$. Asp residues are frequently changed during divergent evolution; they are interchanged in **homologous** proteins most frequently with asparagine and glutamic acid residues.

The side chain of Asp residues is dominated by its carboxyl group:



This carboxyl group is normally no more reactive than are those of corresponding organic molecules, such as acetic acid. Its intrinsic pK_a value is close to 3.9, so Asp residues are ionized and very polar under physiological conditions; consequently, very few Asp residues are buried in folded protein structures, and nearly all have at least the carboxyl group on the surface. The pK_a can be shifted in folded proteins, however, and either the ionized or nonionized form can be used in the protein's function. For example, carboxyl proteinases have one active-site carboxyl group function in the ionized form, and another when nonionized. Asp carboxyl groups have a weak intrinsic affinity for Ca^{2+} ions, and they are used in many calcium-binding proteins.

Asp residues differ from Glu only in having one methylene group, rather than two, so it might be thought that they would be very similar chemically and functionally in proteins, but this is not so. The slight difference in length of the side chains causes them to have different tendencies in their chemical interactions with the peptide backbone, so they have markedly different effects on the conformation and chemical reactivity of the peptide backbone. For example, Asp residues favor the *alpha*-**helical** conformation much less than Glu residues. In folded protein structures, Asp residues occur most frequently in reverse turns, whereas Glu residues are most frequently found in a-helices. The polypeptide chain can be cleaved relatively easily at Asp residues, because the side-chain carboxyl group participates in the reaction. —Asp—Pro— peptide bonds are especially labile in acid, because the carboxyl group interacts with the unique tertiary N atom of the Pro residue.

Aspartyl Proteinase Inhibitors, Protein

The synthetic peptide aspartyl proteinase inhibitors [see Proteinase Inhibitors, Protein] are among the most intensively designed molecules. The principal recent reason for this is that HIV proteinase inhibitors turned out to be successful drugs for fighting AIDS. In contrast, the protein inhibitors of aspartyl proteinases are very little studied. It is difficult to believe that this neglect is a result of the rare occurrence of such inhibitors in nature. The activation of zymogens of aspartyl proteinases (pepsinogen) has been a problem of long-standing interest. The propeptide is clearly a pepsin inhibitor. Much more potent and typical is the pepsin inhibitor from the roundworm (*Ascaris lumbricoides*). The determination of the three-dimensional structure of its complex with pepsin is now in progress and may awaken this long-dormant field. A large number of reports deal with cathepsin D inhibitors classified as members of the soybean trypsin inhibitor (Kunitz), or STI family, [see Soybean Trypsin Inhibitor (Kunitz), STI, (Kunitz)]. Many of the cathepsin D inhibitors are also said to inhibit trypsin, but the details of their interaction either with cathepsin D or with trypsin have been little studied.

Asymmetric Unit

The asymmetric unit is the fundamental structure that is repeated in crystals of macromolecules (see Crystallography**;** X-Ray Crystallography). Depending on the symmetry of the crystallographic lattice, each particle is present in multiple copies in the unit cell of the crystal. Only if symmetry is absent (space group P1) is a single copy present in the unit cell. In this case, the entire unit cell is an asymmetric unit. But if the unit cell has symmetry elements, it can be divided into identical parts related by this symmetry. Such a part, called the asymmetric unit, does not contain any crystallographic symmetry element. In Fig. 1, a projection of the unit cell in space group P2 is drawn. The twofold axes are perpendicular to the plane of the drawing. This unit cell has two asymmetric units. If the structure of the asymmetric unit is known, the structure of the entire crystal can be reproduced by applying the crystallographic symmetry.

Figure 1. Projection of a unit cell in space group P2 that has twofold axes (black ellipses) perpendicular to the plane of the drawing. The circles are particles related by the symmetry. The symmetry divides the unit cell into two exactly equal parts. Therefore, this cell has two asymmetric units.

Atomic Force Microscopy

Binnig, Quate, and Gerber developed a scanning probe technique known as atomic force microscopy (AFM) and as *scanning force microscopy*. Unlike its predecessor, scanning tunneling microscope (STM), AFM also images nonconducting samples, such as biological specimens, in a liquid environment at molecular and even atomic resolution. Currently, structural information about biological materials at the molecular level is obtained from other **microscopic** techniques, including electron microscopy, electron crystallography, X-ray crystallography, nuclear magnetic resonance (NMR) spectroscopy, and vibrational spectroscopy. These techniques require extensive sample preparation and unfavorable operating environments, and they are unsuitable for providing real-time functional information. Molecular function is studied by various molecular biological, biochemical, and electrophysiological techniques, but it is difficult to combine both structural and functional studies in one technique. Moreover, these techniques provide incomplete information about the surfaces of biological macromolecules, the very sites of their interactions with other molecules. In contrast, AFM images the surfaces of biological specimens, where most of the regulatory biochemical and other signals are directed. Other microscopic techniques also image surfaces, for example, the **scanning electron microscope** (SEM), but AFM images living cells and molecules in a liquid environment at comparable and often greater resolution.

1. Principle of Operation

AFM is based on the general physical principle that the interactive force between two bodies is inversely proportional to some power of the distance separating them and on the physicochemical natures of the interacting bodies. A tip that is sharp on the molecular scale is attached to a cantilevered spring: As it is moved across the surface of the specimen, it is deflected by the interactive forces between the atoms of the tip and those of the specimen (see Fig. 1 of Scanning Probe Techniques). Because the spring constant of the commonly used cantilevers (10^{-1} to 10^{-2} N/m) is much smaller than the intermolecular vibrational spring constant of the atoms in the specimen (10 N/m), the cantilever senses exquisitely small forces exerted by the individual sample atoms. The tip's deflection is a measure of the forces sensed by the cantilever, which are transduced to generate molecular images.

In practice, a microfabricated cantilevered tip is pressed against a sample surface by a small tracking (loading) force. The tip is raster-scanned in the x-y plane over the specimen by moving the sample beneath the tip or by moving the tip over the sample. The sample's vertical position (z) is also monitored. The three planes of movement are controlled by a piezoelectric xyz scanner, and the information about the three coordinates is used to create the image (Fig. 1). The cantilevered tip is brought sufficiently close to touch the sample (known as “contact” mode), or it oscillates at a finite distance (>a few nanometers) from the surface (“noncontact” mode). A noncontact mode microscope has the advantage that it does not perturb the sample, but the lateral resolution in these microscopes is poor, and hence they are not commonly used for biological imaging.

Figure 1. Schematic illustration of the operating principle of multimodal atomic force microscopes. (**a**) Schematic of the combined scanning ion conductance and atomic force microscope. A pipette serves as the probe: A laser beam reflecting from a mirror glued to the back of the pipette provides the deflection signal for the topographic image as the pipette is moved across the surface. The electrode has a nanometer-sized hole. Electrodes within the pipette and in the bath measure electrical currents (R. A. Proksch, R. Lal, P. K. Hansma, G. Morse, and G. Stucky (1996) *Biophys. J.* **71**, 2155–2157). (**b**) A combined light and atomic force microscope. The first focal point is located inside the upper portion of the piezoelectric scanner. After the positions of the lenses are adjusted, the scanning focused spot accurately tracks the cantilever, and the zero-deflection signal from the four-segment photodiode is independent of the position within the scan area. One of the key advantages of this new AFM is that there is optical access to the sample from above and below. Thus, the new AFM can be combined with an optical microscope of high numerical aperture. The other key advantage is that the sample is stationary during scanning and can be large, so that techniques for on-line perturbations and recordings are easily incorporated. For details, see P. K. Hansma, B. Drake, D. Grigg, C. B. Prater, F. Yasher, G. Gurley, V. Elings, S. Feinstein, and R. Lal (1994) *J. Appl. Phys*. **76**, 796–799; R. Lal and S. A. John (1994) *Am. J. (b)

The deflective force is translated into a detectable signal in several ways. The most common is by an optical lever system (Fig. 1). A monochromatic laser beam reflects from the upper face of the cantilever, the angular direction of which changes as the cantilevered tip undergoes deflections. The reflected beams are captured and converted into electrical signals by position-sensitive multisegmented photodetectors. Such an optical lever amplifies the cantilever's deflection as much as a thousandfold, so deflections even less than a nanometer are measured.

1.1. Modes of Operation

Using an appropriate feedback system, the cantilever's deflection is kept constant or left to respond freely to the sensed forces. In the constant deflection mode (also called "constant force mode"), the feedback loop changes the height of the sample (to maintain the constant deflection) by adjusting the voltage applied to the z portion of the xyz piezoelectric scanner. The amount of z change corresponds to the sample's topological height at each point in the x-y raster. Combining the information from the three coordinates generates the 3-D image.

In the variable deflection mode ("constant height mode"), the feedback loop is open so that the cantilever deflection is proportional to the change in the tip–sample interaction, that is the force sensed by the cantilever. The surface image is constructed from the deflection information. It is called the constant height mode because the z component of the piezoelectric scanner does not change appreciably. This is usually unsuitable for a sample with large surface corrugation (e.g., cells), because the force fluctuations, and thus the cantilever's deflections, are enormous and often result in disengagement of the tip from the sample.

"Error mode" imaging relies on the imperfection in the feedback loop to operate in the constant-deflection mode. The error signal is amplified to yield contour information in the z plane. In the error mode, the feedback loop gathers high-frequency information that is normally not acquired in the constant deflection mode. This high-frequency information provides details of sharp contour changes (edges) in the sample. Measurements of actual height in error mode imaging are not accurate, however, in contrast to the other modes of operation. The main advantage of error mode operation is that imaging occurs without exerting high forces on the sample.

In "tapping mode" imaging, the cantilever is oscillated at very high frequency, normally near its resonance frequency, as it scans the sample. As the tip approaches the sample surface, its oscillatory amplitude decreases because of energy loss when the tip "taps" the surface. The amplitude of the cantilever oscillation is detected and used by the feedback system to adjust the tip–sample distance for constant amplitude. This ensures a much shorter tip–sample contact time, and smaller lateral forces are exerted on the cantilever. In this way, this mode has been successfully used for imaging delicate and individual macromolecules. The disadvantage of this mode of operation is that the vertical imaging force can be large, thus increasing the possibility of sample damage.

1.2. Sample Preparation

AFM is used to image specimens in aqueous, semiaqueous, or dry conditions. The imaging condition is normally chosen to maintain the specimen in as near a lifelike condition as possible. Where resolution takes priority over the physiological condition, however, the investigator is not as constrained. Imaging conditions also influence the choice of substrate, the stability of the specimen with respect to the tip interaction, and the preservation of the specimen with respect to its physiological or biochemical functions. At present, investigators rely on an empirical approach to find a suitable method, and probably will for some time to come. When it "works", the search stops for the "ideal support" or buffer.

The physicochemical characteristics of the sample determine or suggest ways under which it can be imaged. Problems encountered are as simple as getting the sample to attach to the support. Techniques for sample support include drying down of samples and adsorption to specially prepared surfaces. For example, imaging of **plasmid** DNA is vastly improved in to both resolution and consistency, under propanol, which increases the humidity and produces a more hydrated condition. This allows reducing the tip-tracking force exerted on the sample to <1 nN , thus decreasing sample deformation.

The interaction of the sample with the support determines the magnitude of the imaging force. If the sample does not adhere tightly to the support, low tracking forces must be used for imaging, or the tip literally sweeps the sample from the support. Originally, graphite (**hydrophobic** and uncharged), mica (hydrophilic and negatively charged), and glass (usually negatively-charged) were the supports most routinely used. These supports can also be modified chemically to adjust their hydropathy, charge density, and polarity. Today the repertoire has expanded greatly, and examples include gold treated with a variety of agents for DNA imaging. Gold supports maintained under potential (voltage) control have been used for DNA imaging with the **scanning transmission microscope**, and they may also prove useful for AFM.

The specimen support can also be modified or coated chemically so that it acts as a **ligand** for the sample and thus orients the specimen in a defined way. It is also possible to use artificial systems to generate constraints where there were none before. Examples include imaging isolated **cholera toxin** molecules incorporated into synthetic phospholipid bilayers, followed by covalent cross-linking or imaging the vaccinia virus protrusion out of living cells held by a suction pipette.

1.3. Forces in AFM
Interactive forces that deflect the cantilevered-tip are attractive or repulsive, and they vary depending on the mode of operation and the conditions used for imaging.

In contact mode imaging, the tip is deflected mainly by the repulsive forces from the overlapping electron orbitals of the atoms of the tip and sample. The dominant attractive force is a van der Waals interaction due primarily to the nonlocalized dipole–dipole interactions among atoms of the tip and specimen. When imaging in air, (attractive) surface tension is also present because of adsorbed water layers. For imaging in fluids, electrostatic interactions between charges on the specimen and the tip (occurring either naturally or induced by to polarization), osmotic pressure due to charge movements and rearrangements, and structural forces due to hydration, solvation, or adhesion enable a reduction in the net imaging force although both the meniscus and surface tension forces are abolished.

The interplay of local forces determines the stability of the specimen and the resolution. Theoretically the force should be $\leq 10^{-10}$ N for nonperturbed biological imaging. The sensitivity of AFM is sufficient to record small interactive forces, including the breaking of hydrogen bonds. Imaging in contact mode under liquid, but with a net attractive rather than repulsive force, increases the resolution significantly and has produced true atomic resolution, even with an imaging force of 10^{-11} N. As explained below, however, successful imaging of cells, membranes, and isolated proteins has been obtained with forces as large as 10^{-7} N.

In principle, any movement of the tip caused by its interaction with the sample in the x, y, or z directions provides information about the specimen's topography. To date, most information has been obtained from z deflections. Improvements in hardware and software have, however, allowed recording movements in the zy or zx planes and measurement of lateral forces for image generation. The contribution of lateral forces to image contrast generation can be substantial.

1.4. Resolution in AFM
1.4.1. Spatial Resolution
The limit of spatial resolution for AFM is not well defined because, unlike conventional microscopies, the images are formed by reconstructing the contours of interacting forces between the specimen and tip. The operating resolution in AFM is defined as the minimum size of two adjacent features that can be distinguished clearly. By selecting a small scan size and suitable operating conditions, one can distinguish two structures that are less than a nanometer apart. Image processing

tools used to define resolution in X-ray crystallography and electron microscopy studies may not give correct results for AFM. The operating resolution can be divided into three categories:

1. Instrumental resolution: The lateral resolution is about 1 Å and is determined by the limitations of the hardware. The vertical resolution is 0.1 Å, and hence molecular perturbations on a sample surface can be imaged.
2. Target resolution: The lateral resolution achieved depends on the characteristics of the tip, the operating environment, and the nature of the specimen. For crystalline solid specimens and many inorganic materials, atomic resolution of 1 to 2 Å has been achieved.
3. Resolution in biological specimens: The nature of the biological samples and their preparation play a key role in determining the resolution limits. For the surface of a living cell, the resolution is relatively poor (~10 nm) but greater than that by light microscopy and comparable to that by scanning electron microscopy. In a biological specimen whose the density of particles is high and mobility is limited (e.g., proteins in a membrane), the resolution is comparable to that of a crystalline specimen.

1.4.2. Temporal Resolution

Temporal resolution is limited by the maximum speed at which a specimen can be scanned and still have the tip accurately track surface features. Preliminary studies suggest that the scan speed should be ≤2.2 μm/s for 1 nm spatial resolution on soft and deformable biological materials imaged in aqueous solution. Thus, membrane macromolecules whose dimensions are 10 nm × 10 nm (such as **channels** and **receptors**) divided into 10 × 10 pixels (with pixel size ~1 nm) require about 45 to 50 ms to image. However, if only a single line is scanned, the image can be repeated every 4 to 5 ms. Measuring at a single point, rather than scanning, increases the temporal resolution significantly, and hence it is possible to obtain spatial information at very short time intervals. The temporal resolution also depends on the mode of operation (constant deflection or constant height mode), operating environment (solvents, pH, viscosity, elasticity), and the nature of the interactions between tip and sample. In the constant-height mode, the scan speed is limited by the speed with which the deflection of the cantilever changes in reacting to surface features. In the constant deflection mode, the scan speed is limited by how the speed with which the piezo scanner changes its z component. There is ultimately a limit to the temporal resolution imposed by the low-pass filter used to eliminate sampling noise. These filters typically have a cutoff frequency of ~15 kHz , corresponding to a time resolution of 67 μs.

Temporal resolution also depends on the material being imaged. Individual molecules at molecular resolution require faster scan speeds than cells at lower resolution. Molecular movements of biological macromolecules can be correlated with their lateral diffusion constant. Lipids in a bilayer have a typical diffusion constant of 10^{-8} cm^2/s , corresponding to a mean velocity of ~2 μm/s. The proteins embedded in natural biomembranes have diffusion constants many orders of magnitude lower (e.g., the acetylcholine receptor in myoblast patches has a diffusion constant <3.0×10^{-12} cm^2/s. Thus it is quite possible to obtain images at molecular resolution of proteins and other macromolecules that are properly anchored in a lipid bilayer or immobilized on a substrate.

1.5. Identity of Imaged Structure

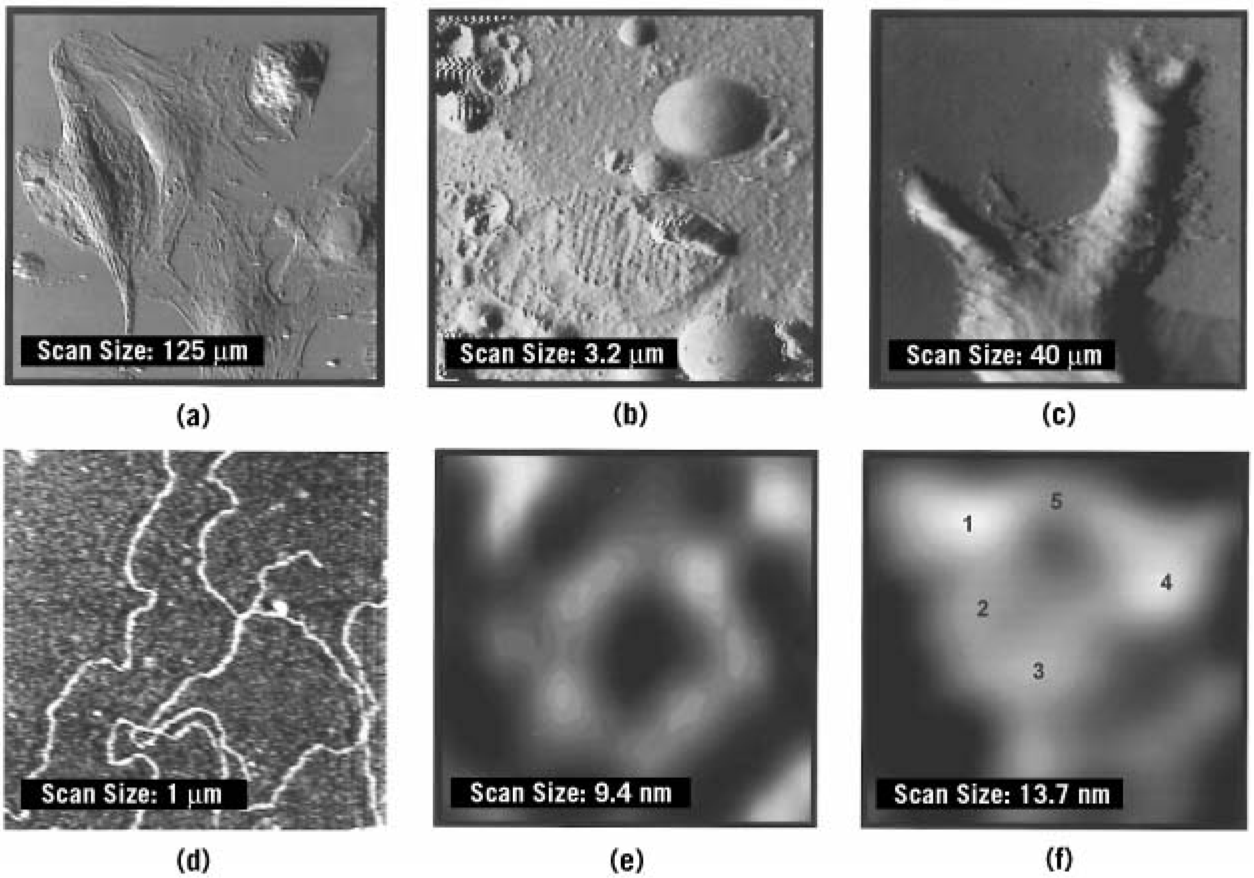
Although AFM provides molecular-resolution surface information for crystalline and amorphous materials, it is often difficult to define the nature of individual components, especially if the specimen contains a heterogeneous population of structures. This is the case with most biological systems, except in favorable systems like membranes that contain a crystalline patch of similar protein molecules. For mixed macromolecules, it is essential to compare the information obtained from AFM with that from alternative or complementary techniques, such as structural probes of electron microscopy and X-ray crystallography, biochemical and immunological binding assays, pharmacological labeling, and electrophysiological measurements.

1.6. Examples of AFM Imaging

1.6.1. Cells and Cellular Processes

AFM images cellular and subcellular structures in physiological conditions at a resolution far exceeding that of optical microscopes. Living cells have been imaged in aqueous conditions with a resolution as small as 10 nm. By applying a larger imaging force, intracellular **organelles** and cytoskeleton networks have also been examined (Fig. 2). The ability to view structures beneath the plasma membrane is puzzling. Two possible mechanisms are (1) the tip penetrates the bilayer and images the substructure or (2) the plasma membrane drapes around the cytoskeletal fibers and the tip images the contour of the plasma membrane. If the "drape" model is correct, these observations give wonderful demonstrations of the flexibility of biological membranes and a potential tool for measuring the "drape characteristics" of natural and synthetic membranes.

Figure 2. Images obtained with AFM. (**a**) Error-mode AFM image of a fixed atrial cell. The cytoskeletal network and ce nucleus are visible. [S. Shroff, D. Saner, and R. Lal (1995) *Am. J. Physiol*. **269**, C286–292.] (**b**) AFM error mode image a freeze-fracture replica of atrial tissue. Details can be identified in the mitochondrion and in the atrial granules and vesicles. Scale Bar: 1 mm. [L. Kordylewsky, D. Saner, and R. Lal (1994) *J. Microsc*. **173**, 173–181.] (**c**) Error-mode AF image of a neurite outgrowth in PC-12 cells treated with **nerve growth factor** and dibutyryl cyclic AMP. For details, se R. Lal, B. Drake, D. Blumberg, D. Saner, P. K. Hansma, S. Feinstein (1995) *Am. J. Physiol*. **269**, C275–C285. (**d**) Lamb DNA under propanol using a regular silicon nitride tip. Note the sharp bends in the strands and a fairly regular series of lumps along the strands, 6 to 8 nm apart. The strand width is 7 to 9 nm, greater than expected, which may result from the relatively large size of the tip. Scan size is 1000 nm × 1000 nm (courtesy H. Hansma, H. G. Hansma, R. L. Sinsheimer, M Q. Li, and P. K. Hansma (1992) *Nucleic Acids Res*. **20**, 3585–3590). (**e**) AFM height mode image of a single connexon (gap junction hemichannel) imaged on its cytoplasmic face. The subunit structure, a central pore, and the spacing betwee connections are apparent [S. A. John, D. Saner, J. Pitts, M. Finbow, and R. Lal (1997) *J. Struct. Biol*. **120**, 22–31).] (**f**) High-resolution AFM imaging of a single acetylcholine receptor expressed in *Xenopus* oocytes. The channel has a diameter of ~10.5 nm , and the five subunits (~1 to 1.5 nm in diameter) that have a central pore-like structure are shown. The protrusion of one unit is not apparent in the image [R. Lal (1998) *Scanning Microsc*. **10**, 81–96].



In AFM imaging, the scan area can be varied from the micron to nanometer range, and hence it is possible to image features ranging from whole cells to individual macromolecules, such as **ion channels** and receptors (Fig. 2). In air-dried, hydrated Xenopus oocytes in which acetylcholine receptor proteins are expressed, the characteristic pentameric subunit structure of the expressed receptor has been observed after removing of the follicle layer. This technique of imaging expressed proteins on or in the surface of the plasma membrane of oocytes will shortly enable the characterization of a myriad of ion channels and receptors expressed in an appropriate expression system.

The major factor limiting resolution in imaging a cell surface is the mobility of the upper plasma membrane, plus the mobility of the macromolecules within the plasma membrane: the lower membrane is anchored to the substrate. Improvements in resolution may be made by (1) increasing the surface rigidity (e.g., suction of cells onto patch pipettes and thus reducing the lateral mobility of proteins); (2) by imaging with low forces (e.g., attractive force mode imaging or magnetic tapping imaging).

1.6.2. Membranes and Membrane Proteins

Imaging membranes, both native and reconstituted, has received wide attention because of their flattened 2-D sheet-like structure and the ease in preparing them. Purified membrane proteins, such as bacteriorhodopsin, gap junctions, acetylcholine receptor, and the hexagonally packed intermediate (HPI) layer from *Drosophila radiodurans*, have been imaged in aqueous conditions without fixation (Fig. 2). These membrane proteins have been characterized extensively by alternative techniques, such as electron microscopy and electron and X-ray crystallography. The results from AFM studies agree remarkably with those from other techniques. In addition, AFM images provide a direct observation of membrane polarity. For example, extracellular and cytoplasmic surfaces of gap junctions are distinguished unambiguously. The thickness measurement in AFM study is also direct and often very precise.

Synthetic membranes (Langmuir–Blodgett) and reconstituted vesicles have been imaged at molecular resolution. Images of Langmuir–Blodgett films provide direct measurement of lipid membrane thickness, obtained previously by indirect methods and theoretical extrapolations, because the height resolution in AFM is subnanometer. AFM images of Langmuir–Blodgett films show individual polar head groups and their molecular arrangement, including their long-range packing. An advantage of studying these membranes with AFM is that one can change the lipid composition on-line and study lipid–lipid interactions, lipid fluidity, and lipid–protein interactions. AFM images of proteins that are naturally embedded within membranes and form 2-D crystalline arrays and images of LB films provide some of the best evidence that the imaging of biological specimens generally agrees with that by electron microscopy, with the advantage, of course, that AFM imaging occurs in nearly physiological environments. It is also worth noting that such a correlation adds weight to the interpretation of images gathered by electron microscopy.

Proteins immobilized by synthetic membranes have also been imaged. Bacterial porins are one of the best-studied channel-forming membrane proteins. Porins reconstituted as 2-D crystals in lipid vesicles have been imaged in a liquid environment. AFM images at molecular resolution show the trimeric structure of porins illustrated by X-ray crystallography and electron microscopic single-particle reconstruction. In addition, recent studies show that molecular resolution can be obtained on noncrystalline specimens in liquid media. This opens a new avenue for studying the molecular structure of biological macromolecules (e.g., ion channels, receptors) that are easily expressed in an appropriate expression systems, such as the *Xenopus* oocyte, or simply isolated and anchored properly on suitable substrates. For example, purified **cholera toxin** molecules incorporated into synthetic phospholipid bilayers by covalent cross-linking, observed at molecular resolution, have the expected pentameric structure. Other membrane proteins imaged by AFM include the hexagonally packed intermediate (HPI) layer of *Drosophila radiodurans*, Na^+, K^+-**ATPase**, vacuolar **proton**

pumps (V-H^+-ATPase), and Ca^{2+}-ATPase.

As mentioned before, AFM imaging of whole cell membranes has also been achieved. Acetylcholine receptor expressed in *Xenopus* oocytes has been observed. **Calcium channels** have been localized on the calyx-type nerve terminal of fixed chick ciliary ganglion in culture by imaging **avidin**-coated 30-nm gold particles incubated with w-**conotoxin** GVIA linked to biotin, although the molecular structure of individual calcium channels was not reported. The interchannel spacing of 40 nm was noticed, which may reflect the spatial limitation due to tagging with 30-nm gold particles. Individual calcium channels have much smaller diameters. Other membrane channels, such as **sodium channels**, **potassium channels**, and gap junctions, are 6 to 10 nm in diameter. Isolated cellular organelles have been imaged with AFM, including nuclear pore complexes, ~134 nm in outer diameter, with a central pore-like trough.

1.6.3. Isolated Macromolecules, such as DNA, Amino Acids, and Proteins
Imaging isolated macromolecules is challenging because it is difficult to find suitable surfaces to which to anchor the molecules for repeatable and reliable imaging. The recent development of cryo-AFM shows good promise for obtaining high-resolution images of isolated macromolecules. Images at molecular resolution have been obtained of DNA at the **plasmid** and **chromosomal** levels, polyamino acids, isolated proteins, and ligand–receptor complexes. Large protein fibers, such as actin and microtubules, have also been imaged at molecular resolution, and it was possible to discern individual actin molecules. Isolated protein molecules show dynamic changes while imaging with the AFM. For example, when glycogen phosphorylase *b* binds to phosphorylase kinase, the dimensions and shapes of the proteins change noticeably.

Imaging DNA and nucleic acids has been appealing for many reasons. Given their well-known geometry and easy availability, they are readily identified and hence used for calibration and for studies of the interaction between tip and sample. Intriguingly, this may also open a door for structure-based sequencing and mapping of DNA AFM. However, DNA sequencing AFM will require an order-of-magnitude improvement in resolution (to ~2 to 3 Å). This increase may come from improvements in hardware and software, but methods to prepare DNA in extended conformations will probably be just as important in improving resolution.

Images of double-stranded DNA at molecular resolution (2 to 3 nm), in which the helical pitch and turns could be deciphered, have been obtained in air and liquid. Occasional images at higher resolution showing individual base pairs have also been obtained. Single-stranded DNA, though, has proven more intractable to image at any molecular resolution.

Images of complexes of DNA and protein A deposited onto mica show single proteins bound to the end of the DNA strands. In addition some single protein molecules bind to up to four DNA strands per protein molecule. When **RNA polymerase** binds to DNA, AFM images show that the modified DNA is bent at marked angles where the polymerase binds. One appeal of these approaches is in searching for DNA-binding proteins and, intriguingly, perhaps to image the effects of **topoisomerase** on DNA.

1.6.4. Imaging Dynamic Processes
AFM, unlike other molecular level imaging systems, allows imaging in an aqueous environment. In an elegant set of studies, AFM was used to visualize real-time surface processes on vaccinia virus *pox viridae*-infected monkey kidney cells. Real-time changes in surface morphology and the exocytosis of enveloped virus and proteins were observed over a period of 19 hours. In contrast, cells not infected with virus showed no appreciable change in surface morphology. The real-time contractile activity of cultured atrial myocytes was also imaged. As the concentration of calcium increased, cells underwent rapid contraction, and a corresponding shortening in cytoplasmic fibers (perhaps cross-bridges) was observed.

Dynamic studies have been conducted on isolated proteins, such as formation of glycogen phosphorylase-phosphorylase kinase complexes, antibody–antigen interactions, dynamics of immunoglobulin adsorption, and binding of streptavidin to a biotinylated lipid bilayer. Real-time polymerization of **fibrin**, a protein important in blood clotting, shows that the polymer chain grows by the fusion of many short chains, rather than by successive addition of monomers to a few long chains. A change in Langmuir–Blodgett film morphology has been observed as trace amounts of a fluorescent dye are added, suggesting that the perturbation of molecular conformation by the tracer molecules may not be as insignificant as is commonly believed.

AFM can be used for *in situ* studies of the growth of protein 3-D crystals in their native solution environment and of the role of nucleation centers, lattice defects, and saturation level. These studies may provide clues for growing the 3-D crystals essential for high-resolution X-ray crystallography.

1.7. Structure-Function Studies

AFM can be combined with other techniques, which opens the possibility, as various biochemical, pharmacological, and other perturbations are introduced on-line, of real-time dynamic studies for direct structure–function correlations at the molecular level. For example, "single cell" experiments have been reported where electrical activity and AFM images were obtained from *Xenopus* oocytes expressing acetylcholine receptor. Electrical recording of acetylcholine-sensitive current and labeling by specific binding of **a-bungarotoxin** were also conducted in parallel. The receptor density calculated from the AFM studies correlates well with that from electrical measurements and toxin binding, but the clustering of acetylcholine receptor differs from the uniform distribution of the expressed receptors that is commonly assumed in electrophysiological studies. A correlation between patch-clamp electrical recording and AFM of transcription factor IID (TFIID) interactions with the nuclear pore complex has also been reported, showing unplugging of the nuclear pore complex accompanied by prolonged electrical current through the channel, perhaps reflecting the reopening of the channels. A combined AFM and patch-clamp study measured the electrical current in the membrane patches excised from *Xenopus* oocytes and attached to the pipette tip, while imaging the surface topology with AFM. Although the resolution of such a study is limited, it nevertheless shows the promise of direct structure-function studies of membrane macromolecules. Another study simultaneously measured images of bacteriorhodopsin in purple membranes adsorbed onto a lipid monolayer, ion transport through the membrane, and the electrical properties of the membrane. A recent study simultaneously measured the surface structure of nuclear pore filters and electrical current passing across the filter through pores of different diameters. For such a study, a scanning ion-conductance microscope was developed that records electrical activity, while imaging the 3D-structures of various membranes (Fig. 1).

Imaging force can be varied considerably during experiments. Such a feature has been used to nanomanipulate protein and membrane structures, and two different conformations of membrane proteins have been reported.

As already mentioned, action is at biological surfaces. The potential for rapidly characterizing and cataloguing the structures of synthetic peptides opens vistas for synthesizing drugs that can interact with "similar surfaces" within the body. Because AFM measures the force of an interaction between substrate and cells, interactions of a ligand or agonist should be measurable if well-defined molecules are placed on the tip of the AFM. Then it may be possible to use this ligand as a probe to determine the presence or absence of a receptor in impure, natural preparations. Perhaps more importantly, it may be possible to measure the interactive forces between agonist and receptor. This information will prove useful in designing of drug inhibitors or mimics.

1.8. Analysis of Micro-mechanical Properties

Contrast mechanism and image formation in AFM reflect a sum of many local forces and the micromechanical properties of the specimen. As the choice of specimen is shifted from rigid and hard materials (such as mica, graphite, tungsten) to soft and deformable biological materials, the dominating micro-mechanical properties shift from pure frictional to viscoelastic. Frictional forces on the atomic scale have been measured between two silica surfaces, two thin films, and between tungsten and graphite. By using local frictional force contours, fluorinated and hydrocarbon regions were distinguished in a Langmuir–Blodgett film. The hydrocarbons and fluorocarbons had separate domain structures: hydrocarbons as circular domains, fluorocarbons as the surrounding flat films. The frictional force was higher in the fluorinated region than in the hydrocarbon region. Such compositional studies provide a mechanism to identify individual components in a multicomponent sample like a cell membrane.

The viscoelastic properties of several soft, deformable biological materials, including cells, has also been obtained by a technique called *force mapping*. Such a study can be undertaken during on-line pharmacological and biochemical perturbations. In each imaging pixel, the tip is brought into proximity with the surface until a preset deflection is reached. The tip then retracts to its original position, and this process is repeated in every pixel. A height image is obtained from the amount of vertical piezo movement necessary at each point to obtain the preset deflection of the cantilever. For each pixel, a deflection versus distance curve is stored, which can be fitted to different models to obtain properties, such as the elastic modulus of the sample surface. Usually, the tip apex is approximated by a semisphere or a cone and the specimen by a spherical or planar model, depending on the shape of the features on the surface.

Thus, AFM is an imaging tool and also a system for analyzing micromechanical properties of cells, subcellular organelles, and macromolecules. It may be possible to study localized viscoelastic properties of molecular motor units, the distribution and propagation of contraction waves in a muscle cell, and the correlation between the calcium concentration wave and electrical propagation. One can also induce local shearing (frictional) force or pressure to assess the effects on the vascular system (mimicking the role of blood flow-induced shearing on vasorelaxation) or to distinguish pressure- or shear-sensitive ion channels in plasma membranes.

1.9. Simultaneous Multimodal Imaging

The simple design of AFM allows integrating it with other techniques, such as light fluorescence microscopy, laser confocal microscopy, and near-field scanning optical microscopies. Such integrated systems permit simultaneous multimodal imaging and provide independent verification with appropriately labeled markers. For example, using appropriately labeled **fluorescent** signals, one can identify specific areas and then use AFM to obtain high-resolution details.

1.9.1. Combined AFM and Light Fluorescence Microscope

Although conventional AFMs are ideal for high-resolution imaging, they could not be combined with large-aperture optical microscopes. In a few AFMs, however, the cantilever moves and the sample is stationary, permitting the addition of optical microscopes that have high numerical apertures. The most promising of these AFMs has the scanned-cantilever mode in which the cantilever position is accurately tracked by a scanned focused spot (Fig. 1) and is incorporated into an inverted fluorescence microscope. This combined fluorescence and force microscope has been used to image **immunolabeled** membranes and whole cells (Fig. 2). Fluorescent labels show remarkable correspondence among AFM images and the specificity of the molecules: such correspondence that one can obtain structural information at molecular resolution on biological macromolecules present individually or in small clusters, long as they have detectable fluorescent signals.

1.9.2. Combined Atomic Force Microscope and Confocal Microscope

Early combined AFM and laser-scanning confocal microscopes (LSCM) included features like a stationary sample stage, an AFM with an optical tracking system for the scanned cantilever, and either a scanned-beam or tandem design confocal microscope. The limitations of such systems include a limited scan range of both the AFM and confocal images. The scan range of the independently scanned confocal spot is limited to the size of the field of view of the objective and off-axis optical aberrations, and the scanned-cantilever AFMs with optical level detection require optical tracking of the cantilever for a large scan range. The latter constraint was overcome by the scanned-cantilever (tip) design with an optical tracking feature (the features explained previously in the combined AFM-fluorescence microscope), where the sample is scanned by a piezo system and the AFM tip and objective remain stationary. The AFM registers the topography of the sample surface, and the LSCM laser scans the surface to obtain fluorescent data on the same scan area. Although the AFM scan size is increased in this improved design, the confocal scan size is still limited by the objective. Moreover, although the AFM images are of the sample surface, the confocal image plane may not be the sample surface, but anywhere within the confocal slice, which could be no more than 100 nm thick.

A new combined AFM and LSCM allows simultaneous imaging of the sample surface in both modes, in addition to the conventional confocal imaging through the sample thickness. The salient features of such a combined microscope include a scanned-sample approach wherein the specimen is scanned above an inverted microscope objective with a fixed optical path for fluorescent LSCM imaging. An AFM positioned directly above the sample simultaneously measures the surface topography. Therefore, in this design the confocal spot and AFM cantilever remain stationary. Optical cantilever tracking is not required, and the confocal spot can be centered in the microscope's objective. The AFM feedback system ensures that the focal point is on or near the surface of the specimen, so that when the cantilever is positioned at the confocal spot, the LSCM and AFM images are acquired in direct registration, allowing image features to be easily correlated.

In this combined multimodal system, the confocal plane can be selected from the topmost region on a specimen surface or anywhere through its depth, so it is quite possible to follow, for example, cytoplasmic signal transduction processes leading to changes in the cellular plasma membrane surface conformations.

1.9.3. Combined Atomic Force Microscopy and Electrophysiological Recording

A combined tapping-mode AFM and a scanning ion-conductance microscope have been developed recently (Fig. 1). One of the salient features of this combined microscope is a bent glass pipette used as both the force sensor and the conductance probe. The force-sensing capability allows measuring of the pipette deflection, which then is used to create surface images in both regular contact mode and tapping mode. The conductance-measuring capability allows recording the electrical current flow across pores in a suitable specimen. Using such a microscope, it is possible to image the structures of channels and receptors and to measure their functional states (conducting vs. non-conducting) (Fig. 3).

Figure 3. Examples of AFM multimodal imaging. (**a**) and (**b**) Simultaneous immunofluorescence and atomic force microscopy of amyloid b peptide (AbP) reconstituted into liposomes. All liposomes, with or without AbP, were imaged with AFM (**a**), a few are shown at higher magnification in the inset. The liposomes were treated with anti-AbP antibody and subsequently identified with fluorescein-conjugated second antibody. The AbP-carrying liposomes showed strong fluorescence signals (**b**). [S. K. Rhee, A. P. Quist, and R. Lal (1998) *J. Biol. Chem.* **273**, 13379–13382]. (**c**), (**d**) and (**e**) Adhesion sites between a *Xenopus* retinal glial cell (XR1 cell line) and extracellular matrix material in a cell culture. The fluorescent images show the location of b-**integrin** (**c**) and f-actin (**d**) fibers detected by immunofluorescence, and the tapping mode AFM image (**e**) reveals the 3-D architecture of the focal point after removing of the cell body [R. Lal and R. Proksch (1997) *Int. J. Imaging Syst. Technol.* **8**, 293–300]. (**f**) and (**g**): Simultaneously combined AFM and fluorescence-confocal microscopic images. The sample was a suspension of fluorescently labeled latex beads that were dried into a gel on a plastic diffraction grating. The lines of the grating are visible in the topographic AFM image (**f**) but not in the confocal fluorescent image (**g**). The two images allow distinguishing a nonfluorescent particle (left arrow) from a fluorescent particle (right arrow), although both appear as raised bumps in the AFM image. [P. E. Hillner, D. A. Walters, R. Lal, H. G. Hansma, and P. K. Hansma (1995) *J. Micro. Soc. Am*. **1**, 123–126]. (**h**) and (**i**): Simultaneously combined AFM and scanning ion-conductance microscope (SICM) electrophysiology. (**h**) shows a tapping mode AFM image of a nucleopore membrane, and (**i**) shows the associated ionic conductivity image obtained by tapping mode SICM. Note that there are some differences in the pores detected by the two procedures. For example, the area circled in white shows a groups of pores that appear to be deep in the AFM image and highly conductive in the SICM image. The area circled in grey contains a large pore that appears deep in the AFM image but is nonconductive in the SICM image. The scale bars at the bottom are intensity-coded. Brighter is a greater height in the AFM image and a greater conductance in the SICM image. [R. A. Proksch, R. Lal, P. K. Hansma, G. Morse, and G. Stucky (1996) *Biophys. J.* **71**, 2155–2157.]

Another approach is combining AFM with the patch-clamp technique in the same experiment. Such a combined technique records electrical current in the excised membrane patches from *Xenopus* oocytes that are attached to the patch pipette tip, while simultaneously observing the surface topology with AFM. Also, The membrane surface is also deformed by applying pressure through the patch pipette and observing the lateral displacement of features. However, the resolution is limited to about 10 nm.

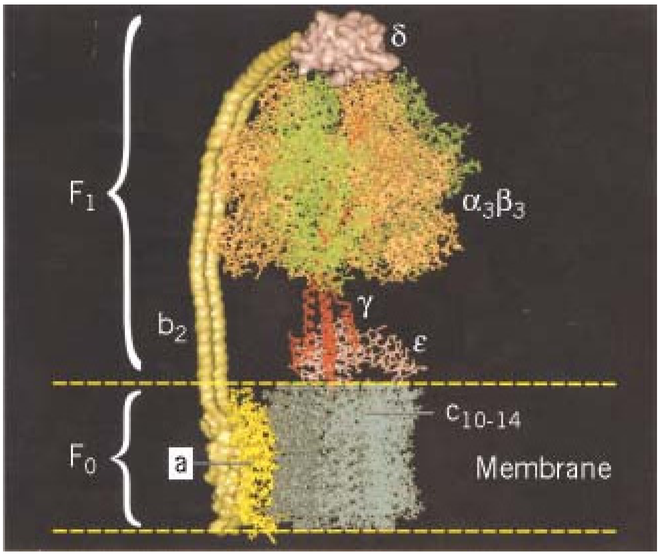
ATP Synthase

ATP synthase, also called F_0F_1 ATPase, or simply F-ATPase, is the universal protein that terminates oxidative phosphorylation by synthesizing ATP from ADP and phosphate. Nearly identical proteins are found in eukaryotic mitochondria and bacteria, and they all operate on the same principle. Electron-driven ion **pumps** set up concentration and electrical gradients across a membrane (see Chemiosmotic Coupling and Proton Motive Force). ATP synthase utilizes the energy stored in this electrochemical gradient to drive nucleotide synthesis. It does this in a surprising way by converting the electromotive force into a rotary torque that promotes phosphate binding and liberates ATP from the catalytic site where it was formed. Remarkably, this process can be reversed in certain circumstances. ATP hydrolysis can drive the engine in reverse, so that F-ATPase functions as a proton pump. Indeed, the vacuolar V-ATPases, the most ubiquitous intracellular proton pumps, are structurally similar to ATP synthase and operate according to the same principles.

ATP synthase is composed of at least eight subunit types, whose stoichiometries are denoted by the subscripts (a_3, b_3, g, d, ε, a, b_2, c_{12}), that combine into two distinct regions. The geometric arrangement of the subunits is shown schematically in Fig. 1(a). The soluble F_1 portion consists of a hexamer, a_3b_3. This hexamer is arranged in an annulus about a central shaft consisting of the coiled-coil g subunit. Subunits d and ε are also generally isolated with F_1. The F_0 portion consists of three transmembrane subunits, a, b_2, and c_{12}. The 12 copies of the c-subunit form a disk into which the g and ε subunits insert. The remainder of F_0 consists of the transmembrane subunits a and b_2. The latter is attached by the d subunit to an a subunit, so that it anchors the a subunit to F_1. Thus there are two "stalks" connecting F_0 to F_1, gε and b_2d.

Figure 1. Schematic diagram of the subunit organization of ATP synthase (1). (**a**) The a_3b_3 hexamer and a portion of the g shaft. The lower part of g has not been resolved. The c-subunit consists of 12 pairs of transmembrane a-helices, and the a subunit consists of six transmembrane a-helices. The ε subunit abuts c and g and interacts with the DELSEED region of b. The a subunit is attached to an a subunit via the b and d subunits. (**b**) The proton motive force at the a–c interface leads to the functional subdivision into two counterrotating assemblies, usually denoted as the "rotor" and "stator." The rotor consists of subunits c_{12}-g-ε, and the stator consists of subunits a-b_2-d-a_3b_3.



The key to understanding how ATP synthase carries out its catalytic and synthetic roles lies in this geometric organization. The entire protein can be divided into two operational regions denoted suggestively as the "rotor" and the "stator" for reasons that derive from the rotary mechanism by which the protein operates (Fig. 1b). Indeed, it turns out that ATP synthase has two rotary engines in one. The F_0 motor converts transmembrane electrochemical energy into a rotary torque on the g shaft, and F_1 uses ATP hydrolysis to turn the g shaft in the opposite direction. Because they are connected, one drives the other in reverse. When F_0 dominates, the rotor turns clockwise (looking upward in Fig. 1), so that F_1 synthesizes ATP. When F_1 dominates, so that F_0 is driven counterclockwise, it can pump protons against an electrochemical gradient. Deciphering how this remarkable dual energy transduction works is one of the great triumphs of modern chemistry.

1. ATP Synthesis in F_1 is Driven by Rotation of the g-Shaft

We begin with the F_1 motor, because we now know precisely what it looks like. This is due to John Walker and the X-ray crystallography group at Cambridge, who worked out the exact structure of the a_3b_3 hexamer and most of the g shaft (1). A stereo view of the structure is shown in Fig. 2. Walker was awarded the Nobel Prize in 1997 because his structure revealed essential asymmetries in the molecule's structure that were the key to understanding how it worked. In the early 1980's, Paul Boyer at UCLA proposed the surprising theory that, in the catalytic sites of F_1, ATP is in chemical equilibrium with its reactants, ADP and phosphate (2). So the formation of ATP is essentially without cost energetically. However, because each ATP hydrolyzed under cellular conditions liberates about 12 kcal/mol, this energetic price must be paid at some point. Boyer proposed that F_1 pays this price in the mechanical work necessary to liberate the nucleotide from the catalytic site. Further, release of product (ATP) proceeds sequentially and cyclically around the a_3b_3 hexamer because the synthetic reactions are synchronized in a fixed-phase relationship by rotation of the g shaft and cooperative coupling between the three catalytic sites. Boyer's “binding change” mechanism neatly fits the Walker structure, and Boyer shared the 1997 Nobel Prize. A schematic diagram of the binding change mechanism is shown in Fig. 3.

Figure 2. Stereo pair showing the molecular structure of the F_1 subunit run through center, coils extending out from mid in light gray, and the two coils of the g subunit medium gray. Its asymmetrical structure is evident. In the b subunit: the s is in dark gray, and the lower hinge segment is medium gray. The structure of the ε subunit (not shown) is known, but it the g and c subunits.

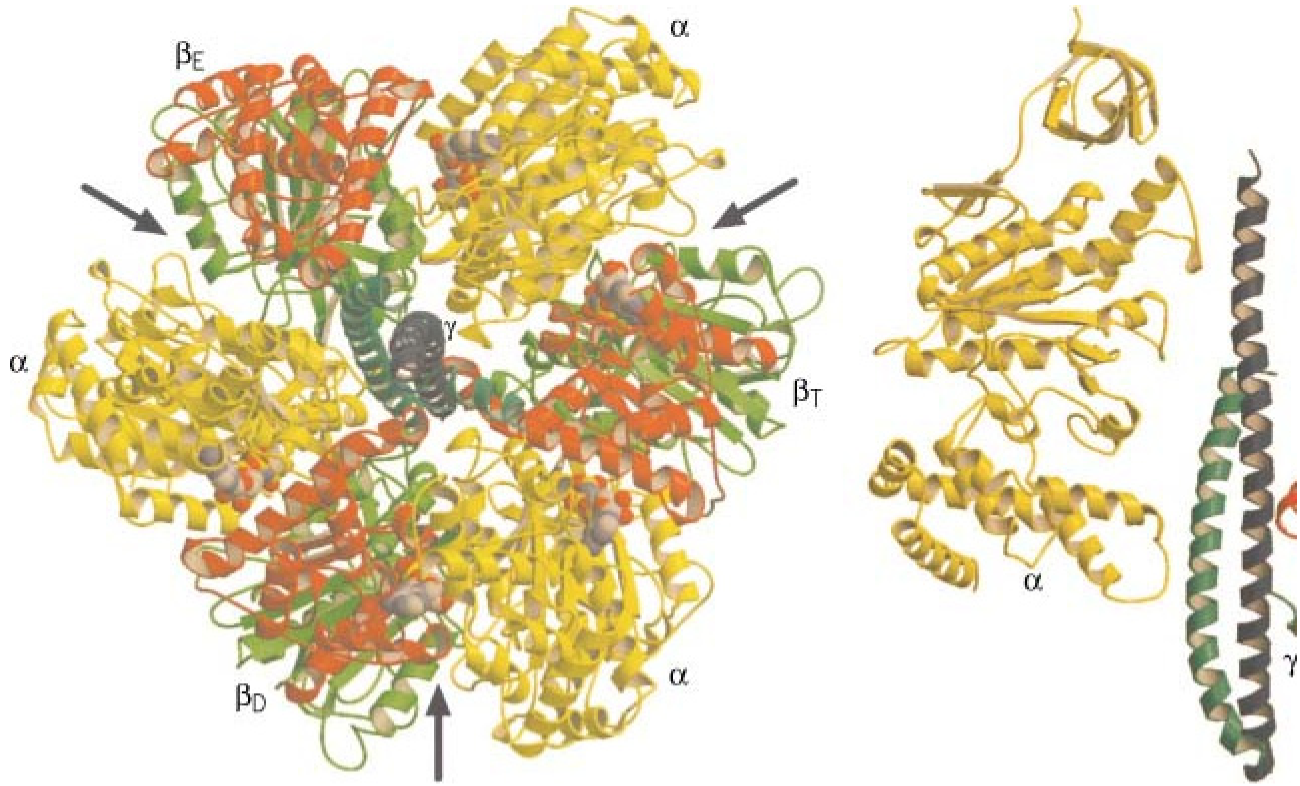


Figure 3. The binding change mechanism. Notation for site occupancies: T = ATP bound, DP = ADP • P_i bound, D = A] numbered clockwise. The lengths of the arrows indicate the relative binding affinities. (**a**) The system starts with either ((b_1, b_2, b_3) = (D, T • D • P, D). (**b**) Clockwise rotation of g increases the binding affinity of ADP in b_1, traps ATP in b_2, a (**c**) Further rotation of g traps ADP and allows P_i binding in b_1, releases the tightly bound ATP and allows ADP binding

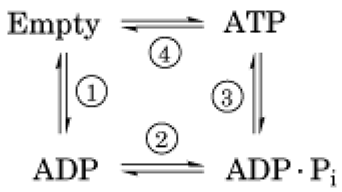
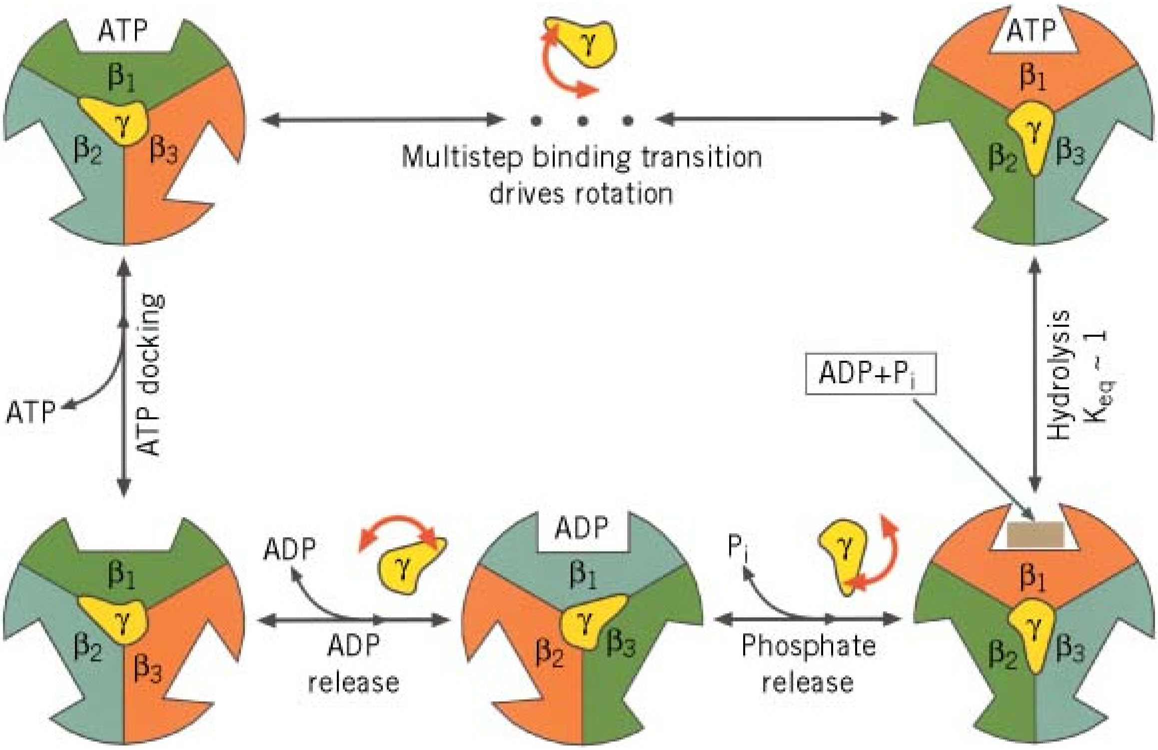
There are actually six nucleotide-binding sites on the a_3b_3 hexamer. All lie at the interfaces between the a and b subunits. The catalytic sites lie mostly in the b subunit, whereas the noncatalytic sites lie mostly in the a subunit. The role of the noncatalytic sites is uncertain, but they may help to hold the hexamer together. Each catalytic site traverses the synthetic cycle sequentially:



In steps 1 and 2, a site binds ADP and phosphate (not necessarily in that order). While trapped in the catalytic site in step 3, the reactants (ADP and P_i) and product (ATP) are in chemical equilibrium. Step 4 requires the input of mechanical torque from F_0 on g to trap the reactants in the ATP state and to pry open the site, releasing the tightly bound ATP. Most of the 12 kcal/mol price of synthesis is paid in step 4. The way in which this works is found in the shape of the a_3b_3 hexamer and the g shaft.

The g subunit is asymmetric and bowed. It fits into a central annulus in a_3b_3, which is itself asymmetric (Fig. 4). At the top of the a_3b_3 hexamer is a **hydrophobic** "sleeve" in which the g shaft rotates. Further down, however, the annulus is offset from the center, so that as g rotates clockwise, it sequentially pushes outward on each catalytic site. In addition, the ε subunit is located eccentrically and attached to the g and c subunits, so that as g rotates, it comes into contact sequentially with each b subunit in a conserved region called the DELSEED sequence (named for the single-letter abbreviation of its constituent amino acid residues). Together, this asymmetrical rotation exerts stress on the catalytic site, loosening its grip on ATP, so that thermal fluctuations can free it into solution.

Figure 4. Cross section of F_1 showing the conformational changes in the b subunits that drive rotation of g. The a subunit is on the left and the stationary barrel region of b is on the right. During the hydrolytic cycle, the lower segment of b undergoes a hinge-bending motion that rotates it about 30° inward. This motion pushes on the eccentric g coiled coil, causing it to rotate within the barrel bearing. During synthesis, the rotation of g pushes on each catalytic site. The panels show three snapshots of the motion during a 180° rotation. Movies of the rotational sequence can be downloaded from the authors' World Wide Web site: (site currently unavailable)



(3). These interactions may mediate phosphate- and nucleotide-binding, the necessary precursors to synthesis. In addition, the catalytic sites are elastically coupled, so that the occupancy of one site affects the affinity of the other two sites. The consequence of this coupling is that when ATP concentrations are low enough so that only one site is occupied, hydrolysis proceeds much more slowly than when more than one site is occupied.

Together with the F_1 molecular structure, the binding change model strongly supports the idea that catalysis involves rotation of the g subunit. However, dramatic visual confirmation was provided by *in vitro* experiments in which the a_3b_3g subunits were isolated and attached to a bead. A fluorescently tagged actin filament was attached to the g shaft, and when ATP was supplied, the filament could be clearly seen rotating. In fact, a complete revolution takes place in three steps and consumes a single ATP per step (4).

The viscous drag on the actin filament was estimated, which allowed computing the torque developed by the F_1 motor and comparing it with the **free energy** available from ATP hydrolysis. The startling result was that the motor generates an average torque of more than 40 piconewton nanometers (40×10^{-12} N $\times$ 10^{-9} m), more than six times the maximum force developed by kinesin or myosin. More impressively, the motor operates near 100% mechanical efficiency, this precludes any sort of heat engine, which would be limited by the Carnot efficiency (4). Several models have been proposed that address the issue of torque generation and efficiency (4-6).

The energy to drive this motion derives from the hydrolytic cycle of ATP at the catalytic site. Moreover, the conformational change that drives the hydrolysis motor must be nearly the reverse of the motion that frees ATP from the catalytic site during synthesis. Examination of the structure reveals that the major conformational change is a hinge-bending motion in the b subunits. The bottom portion of each b subunit below the nucleotide-binding site rotates inward approximately 30°, during which it pushes on the bowed g subunit, turning it much like one cranks an automobile jack (Fig. 4).

2. F_0 Converts Proton Motive Force into Rotary Torque

Currently, there have been no direct observations of rotation in the F_0 portion of ATP synthase (7). However, current thinking is that the F_0 assembly converts the energy contained in the transmembrane proton motive force into a rotary torque at the interface of the a and c subunits (Fig. 1). This torque turns the rotor (the c, g, and ε subunits), which couples to the F_1 synthetic machine.

The c assembly consists of 12 subunits, each consisting of two transmembrane alpha-helices (8). There is one essential acidic amino acid (Asp61 in the *Escherichia coli* ATP synthase) which binds protons. Because variants of ATP synthase can operate on sodium rather than protons, the interaction between the c subunit and the translocated ion has the property of an electrostatic carrier mechanism (9).

The a subunit consists of six transmembrane a-helices that contain at least one essential basic residue (Arg210 in *E. coli*) (8, 10). The electrostatic interaction of these rotor and stator charges is essential for torque generation, and several proposals have been put forward for the way this could work (11-14). Whatever the mechanism, the F_0 motor must generate a torque sufficient to liberate three ATP's from the three catalytic sites in F_1 for each revolution. If the proton flux through the stator is tightly coupled to the rotation of the c subunit, then a rotation of 2p/3 carries four protons down the electromotive potential of 230 mV typical of the mitochondrial inner membrane (14). This is sufficient to account for the mechanical energy required for synthesis of one ATP.

Under anaerobic conditions, the ATP synthase of the bacteria *E. coli* can reverse its operation, hydrolyzing ATP and turning the c subunit backward so that it functions as a proton pump. This is not surprising because the F-ATPases are structurally similar to the most common proton pumps, the vacuolar, or V-ATPases (7). These pumps may have been the **evolutionary** precursors of ATP synthase (15). A striking difference between the two is that the F-ATPases have 12 acidic rotor charges, whereas the V-ATPases have six. It can be shown that this enables the V-ATPases to function more efficiently as ion pumps at the expense of relinquishing their capability to synthesize ATP.

3. Summary

Both the F_1 and F_0 motors can operate in both directions. F_1 is a hydrolytically driven three-piston engine that can be driven in reverse to synthesize ATP from ADP and phosphate. F_0 is an ion-driven rotary engine that can be driven in reverse to function as an ion pump. The F-ATPases are structurally similar to and presumably evolutionarily related to the V-ATPase ion pumps (15). It is thought that most ion pumps function by an “alternating access” mechanism, whereby an ion is first bound strongly on the dilute side, then energy is supplied to move the ion so that it communicates with the concentrated side and weakens its binding affinity (16). In contrast with other ion pumps, however, the F and V-ATPases accomplish this by a rotary mechanism that is driven indirectly by nucleotide hydrolysis, rather than by direct phosphorylation (17). It is thought that the F_0 motor is also related to the bacterial **flagellar** motor. Both can operate on sodium, although the flagellar motor has eight or more “stators” and develops far more torque than F_0 (18, 19).

The mechanism driving the F_1 hydrolytic motor may carry hints for other nucleotide hydrolytically fueled motors, such as kinesin, myosin, and dynein. However, important structural differences may make the comparison difficult (4). For example, the motors previously mentioned all “walk” along a polymer track to which they bind tightly during a portion of their mechanochemical cycle. The power stroke of the F_1 motor is driven by the b subunit, which pushes on the g shaft, but does not bind tightly to it, that is, it does not “walk” around the g shaft. Moreover, no other motor operates with nearly the efficiency of the F_1 motor, implying that there are important entropic steps in other motors that are absent in the F_1 motor.

ATP-Binding Motif

The ATP-binding motif, also called the *Walker motif*, is a structural protein motif that is frequently found in proteins that bind ATP or GTP. It can usually be identified from just the primary structure of a protein using a fingerprint sequence that characterizes proteins as ATP or GTP-binding (see GTP-Binding Proteins). Walker et al. (1) identified two regions of sequence conservation: the A region has a stretch of small **hydrophobic** residues followed by [Gly/Ala]━X━X━Gly━X━Gly━Lys━Thr/Ser, where X is any residue. The second region of sequence conservation also has a stretch of small hydrophobic residues, this time ending in a conserved **aspartate** residue. In the three-dimensional structures of proteins having the ATP-binding motif, such as adenylate kinase, the hydrophobic residues of the A-region form a buried b-strand, and the glycine-rich region forms a loop, called the P-loop, that interacts with the phosphate of the bound nucleotide. The second conserved region codes for another hydrophobic b-strand, and the conserved aspartate is required for binding the magnesium ion that usually accompanies nucleotides bound to proteins.

The ATP-binding motif represents a common, but not the only, mode of interaction between proteins and ATP/GTP. For example, it is structurally distinct from the actin fold of proteins such as actin, hsp70, and hexokinase, which bind and hydrolyze ATP or GTP and where a conformational change is implicated in nucleotide binding (2).

ATPase

Any enzyme that catalyzes the hydrolysis of ATP to ADP and inorganic phosphate (P_i) is classified as an ATPase. In some cases, the phosphate is transiently transferred to the protein before its release as a product. The hydrolysis of ATP liberates much energy, so this reaction is usually coupled to another, energetically unfavorable reaction. Three major types of ATPase are associated with membranes that couple ATP hydrolysis to the translocation of specific ions across a membrane: P-, V-, and F-ATPases.

P-ATPases have a relatively simple polypeptide composition (one or two subunits) and are phosphorylated as part of their catalytic cycle. Examples of P-ATPases are (*1*) the Na^+, K^+ – ATPase of the plasma membrane of animal cells; (*2*) the H^+ – ATPase of the plasma membranes of **yeast**, **fungi**, and plants; and (*3*) the Ca^{2+} – ATPase of the sarcoplasmic reticulum (the endoplasmic reticulum of muscle). The plasma membrane Na^+, K^+ – ATPase and H^+ – ATPase function to generate and maintain the plasma membrane electrical potential difference (inside negative), as well as the ionic disequilibria across that membrane. Ca^{2+} – ATPases function in Ca^{2+} homeostasis (see Calcium Signaling).

V-ATPases have a much more complicated polypeptide composition than do P-ATPases and are not phosphorylated during catalysis. V-ATPases are found on the membranes within the interiors of **eukaryotic** cells (endomembranes), including membranes from vacuoles (from which the “V” is derived), **lysosomes**, **Golgi**, **secretory vesicles**, **clathrin**-coated vesicles, and, in some instances, plasma membranes. V-ATPases are H^+ – ATPases that show some similarity to the proton-linked ATP synthases. The function of V-ATPases is to catalyze proton transport into the endomembrane interior compartments at the expense of ATP hydrolysis. Acidification of the interior of endomembranes is required for some of their functions. In **archaebacteria**, an enzyme with similarity to V-ATPases functions as an ATP synthase.

F-ATPases (also known as "F_1–F_0") have a complex polypeptide composition and, as in V-ATPases, there is no phosphorylated intermediate in the reaction mechanism. In non**photosynthetic** eukaryotes, the F-ATPase is found exclusively on the inner membrane of mitochondria, whereas in green plants and algae there are two distinct F-ATPases; one in mitochondria and the other on the thylakoid membrane of chloroplasts. In bacteria, F-ATPase is present in the plasma membrane. ATPases couple the flow of protons (or Na^+ in some cases) to ATP hydrolysis and synthesis. The activity of the F-ATPases is very tightly regulated. Several mechanisms combine to prevent wasteful ATP hydrolysis by F-ATPase, but to allow rapid ATP synthesis at the expense of electrochemical proton (or Na^+) potentials generated by proton translocation linked to electron transport (see Chemiosmotic Coupling). F-ATPases operate *in vivo* as ATP synthases; consequently, the term *ATP synthase* is preferred to *F-ATPase* when referring to the entire enzyme. The catalytic portion of the ATP synthase may be readily removed from coupling membranes and purified as a large 400-kDa water-soluble protein. Such preparations may have high ATPase activity and are called "F_1" or "F_1-ATPase" (see ATP Synthase).

Attenuation Of Transcription

The ability to modulate **gene** expression in response to changing environmental signals is crucial for the survival of all organisms. Virtually every stage involved in the synthesis, function, and degradation of macromolecules is a potential target for one or more regulatory events (1). Regulatory mechanisms have been identified for all three stages of transcription (initiation, elongation, and termination). Several postinitiation regulatory mechanisms have been categorized as transcription attenuation mechanisms. Transcription attenuation can be defined as any mechanism that utilizes transcription pausing or transcription termination to modulate expression of downstream genes. For the purpose of this article, however, the definition will be restricted to situations in which the action of the regulatory molecule promotes transcription termination, with the default situation being transcriptional readthrough. There are also related **antitermination** mechanisms in which the action of the regulatory molecule promotes transcriptional readthrough.

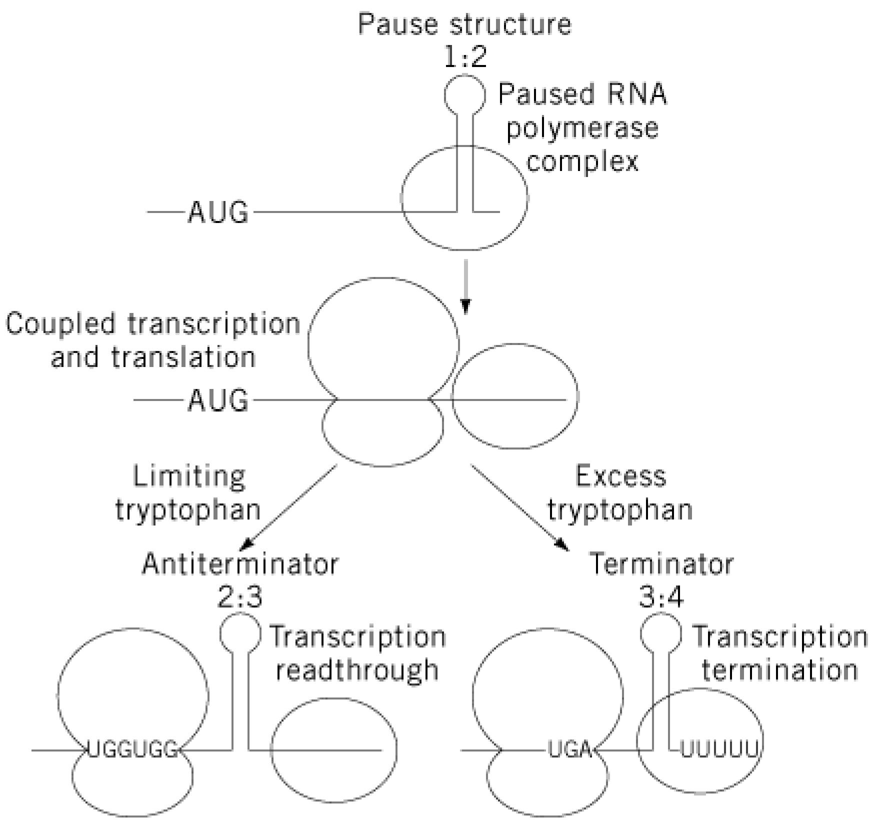
Once transcription of a gene is initiated, the transcription elongation complex and its nascent transcript are potential targets for regulation. As transcription proceeds, the nascent transcript may fold into specific secondary and tertiary structures that signal the transcribing **RNA polymerase** to pause or terminate transcription before reaching the structural genes (1). Transcription attenuation mechanisms allow the organism to modulate the extent of transcriptional readthrough past the terminator structure in response to changing environmental signals, thereby regulating expression of the downstream genes. As will be seen, several different transcription attenuation mechanisms have been identified.

1. Transcription Attenuation of Biosynthetic Operons of Enteric Bacteria

Transcription attenuation was the first demonstration that organisms can exploit RNA structure to modulate gene expression. The first attenuation mechanism was elucidated by Charles Yanofsky and his coworkers for the *Escherichia coli* tryptophan biosynthetic operon (*trpEDCBA*; see TRP Operon) (2). In addition, many other amino-acid biosynthetic operons in enteric bacteria are regulated by transcription attenuation (eg, *his*, *leu*, *ilv*, *pheA*). In each case, the genetic information required for transcription attenuation is encoded within a 150–300-bp leader region located between the **promoter** and the first structural gene of the operon (1). Because the salient features of transcription attenuation are conserved in each system, the *E. coli trp* operon will be discussed, and the key differences with respect to other operons will be pointed out where appropriate.

Transcription initiation of the *E. coli trp* operon is regulated by TrpR, a **DNA-binding** repressor protein. Once transcription starts, the elongating transcription complex is subject to control by transcription attenuation (1). The combined actions of repression (80-fold) and transcription attenuation (eight-fold) result in approximately 600-fold regulation in response to changing concentrations of intracellular tryptophan (3). A simplified model of the *E. coli trp* operon transcription attenuation mechanism is depicted in Figure 1 (4). The 141-nucleotide leader transcript can form three overlapping RNA secondary structures, referred to as the pause structure, the antiterminator, and a Rho-independent terminator. In addition, the nascent *trp* leader transcript contains a small open reading frame that encodes a 14-amino acid residue leader peptide. Soon after transcription of the *trp* operon is initiated, a secondary structure (structure1:2) forms in the nascent transcript that signals RNA polymerase to pause. The paused RNA polymerase complex allows sufficient time for a ribosome to initiate translation of the leader peptide. The translating ribosome then disrupts the paused RNA polymerase complex, and transcription resumes, with the ribosome closely following the molecule of RNA polymerase, thereby coupling transcription and translation. At this point, two different outcomes can occur, depending on the level of tryptophan in the cell. Under conditions of limiting tryptophan, the level of charged transfer RNA $tRNA^{Trp}$ is low. As a result of the low tryptophanyl-$tRNA^{Trp}$ concentration, the translating ribosome stalls at one of two tandem Trp **codons** strategically placed within the leader peptide coding sequence. Ribosome stalling at the Trp codons effectively uncouples transcription and translation. As transcription proceeds, therefore, the antiterminator structure (structure 2:3) forms and prevents formation of the overlapping Rho-independent terminator (structure 3:4), resulting in transcriptional readthrough into the *trp* structural genes. Under conditions of tryptophan excess, the level of charged $tRNA^{Trp}$ is sufficiently high to allow efficient translation of the tandem Trp codons, and the ribosome continues to the end of the leader peptide. When the ribosome reaches the leader peptide stop codon, it physically blocks formation of the antiterminator structure, thereby promoting terminator formation and, hence, termination of transcription, before RNA polymerase reaches the *trp* structural genes. Thus, expression of the *trp* operon is decreased when the cell has an adequate supply of tryptophan. As can be seen by the above example, the regulatory signal is charged $tRNA^{Trp}$, and the sensory event is the capacity to translate a short peptide-coding sequence (1). The transcription attenuation mechanisms for several other amino acid biosynthetic operons, such as the *his*, *phe*, and *leu* operons, are essentially identical to that for the *trp* operon, except that the leader peptides contain seven His (5), seven Phe, and four Leu codons (6), respectively.

Figure 1. Model of transcription attenuation for the *E. coli trp* operon. RNA polymerase pauses following formation of the pause structure provides time for a ribosome to initiate translation of the leader peptide. Under tryptophan-limiting conditions, the ribosome stalls at the tandem Trp codons, resulting in transcription readthrough. Under conditions of tryptophan excess, the ribosome reaches the leader peptide stop codon. This ribosome position blocks formation of the antiterminator, leading to terminator formation and transcription termination. (See text for details.) Adapted from Landick and Yanofsky (4).



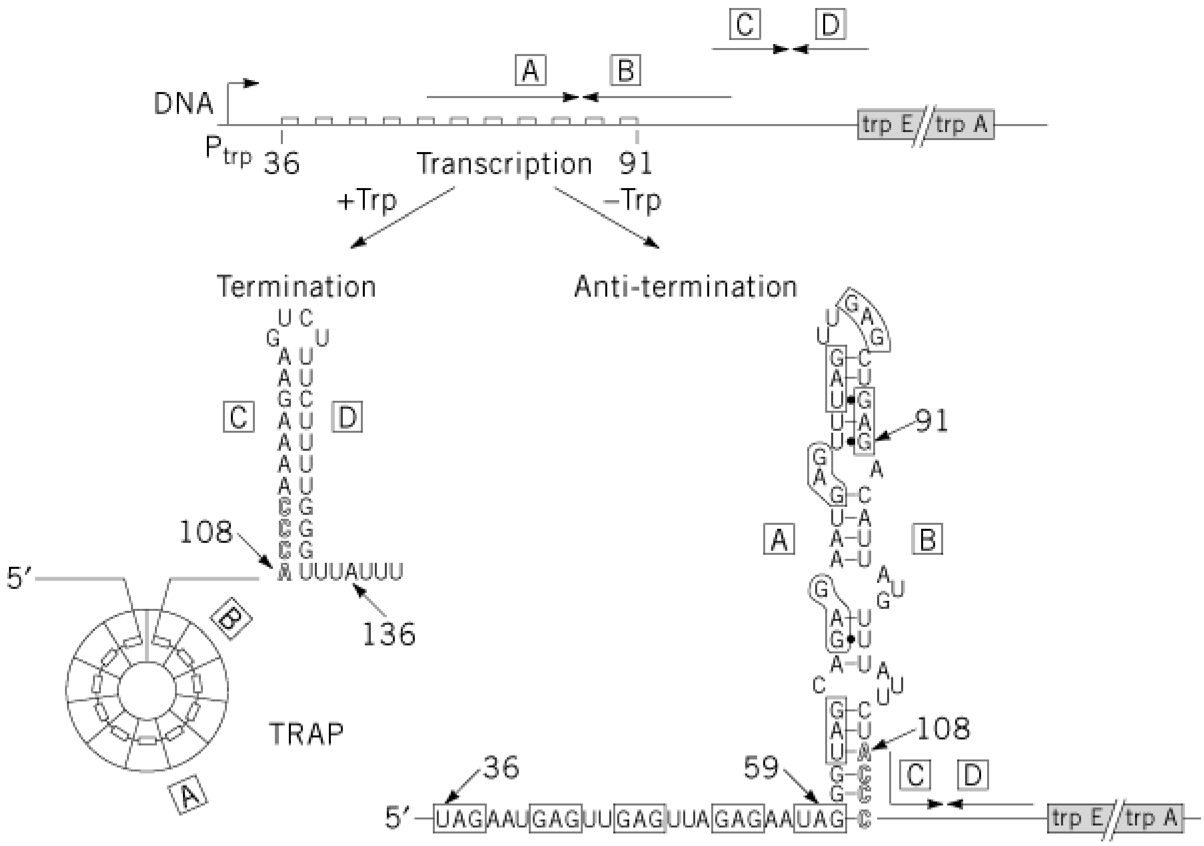
Expression of the *E. coli* pyrimidine biosynthetic operon, *pyrBI*, is also regulated by transcription attenuation (7, 8). In this case, the concentration of UTP serves as the regulatory signal, in conjunction with a UTP-dependent pause signal consisting of an RNA hairpin and several U residues just after the hairpin. A transcription terminator exists approximately 60 nucleotides downstream of the pause structure, but the leader transcript does not have the potential to form an antiterminator structure. Finally, there is a 44-residue leader peptide encoded by an open reading frame beginning prior to the pause signal and extending past the terminator. The model for this attenuation mechanism is as follows: When there is a deficiency of UTP, the transcribing RNA polymerase pauses at the leader pause site. This provides time for a ribosome to initiate translation of the leader peptide, which results in coupled transcription and translation. As transcription proceeds, the translating ribosome prevents formation of the transcription terminator, allowing transcription of the structural genes. However, pausing is inefficient when the cell contains an adequate supply of UTP. In this case, RNA polymerase transcribes and recognizes the terminator before the ribosome reaches this segment of the leader transcript, thus halting transcription in the leader region prior to the structural genes.

2. Transcription Attenuation of Gram-Positive Biosynthetic Operons

The transcription attenuation mechanisms that have been identified for the *trp* and *pyr* operons in the **Gram-positive bacterium** *Bacillus subtilis* differ dramatically from those described for the enteric bacteria. Most notably, ribosomes and tRNA molecules are not involved. Instead, sequence-specific RNA-binding proteins are responsible both for sensing the level of tryptophan or UMP in the cell and, ultimately, for the decision to terminate transcription or to readthrough into the structural genes.

Expression of the *trpEDCFBA* operon of *B. subtilis* is regulated by TRAP, the *trp* RNA-binding attenuation protein (9, 10). TRAP is composed of 11 identical subunits arranged in a single ring (11). Tryptophan binding between each adjacent subunit in a cooperative manner activates TRAP to bind RNA (11). Transcription initiation of the *trp* operon appears to be constitutive, occurring 203 nucleotides upstream of the first structural gene. A transcription attenuation model for the *B. subtilis trp* operon is depicted in Figure 2. The *B. subtilis trp* leader transcript contains inverted repeats that can form mutually exclusive antiterminator and Rho-independent terminator structures (12), although there is no apparent transcription pause signal in this case. When cells are growing in excess tryptophan, tryptophan-activated TRAP binds to 11 closely spaced (G/U)AG repeats present in the *trp* leader transcript (11, 13). Recent studies have shown that TRAP binds to these repeats by wrapping the RNA around the protein ring, with the bases of the (G/U)AG repeats interacting with several amino acid residues on adjacent subunits in the protein (14). TRAP binding blocks formation of the antiterminator, which allows formation of the overlapping terminator structure. Thus, transcription halts in the leader region prior to the *trp* structural genes. Under conditions of limited tryptophan, TRAP is not activated and does not bind to the *trp* leader transcript. Thus, as transcription proceeds, the antiterminator forms, allowing transcription readthrough into the *trp* structural genes (9, 12).

Figure 2. Model of transcription attenuation of the *B. subtilis trp* operon. The large boxed letters designate the complementary strands of the terminator and antiterminator RNA structures. Small rectangles represent the GAG and UAG repeats involved in TRAP binding; these triplet repeats are also outlined in the sequence of the antiterminator structure. Numbers indicate the residue positions relative to the start of transcription. Nucleotides 108 to 111 overlap between the antiterminator and terminator structures and are shown as outlined letters. The TRAP protein is represented as an 11-subunit ring, and the bound RNA is shown forming a matching circle on binding to TRAP, with each triplet repeat interacting with one subunit. From Antson et al. (11).



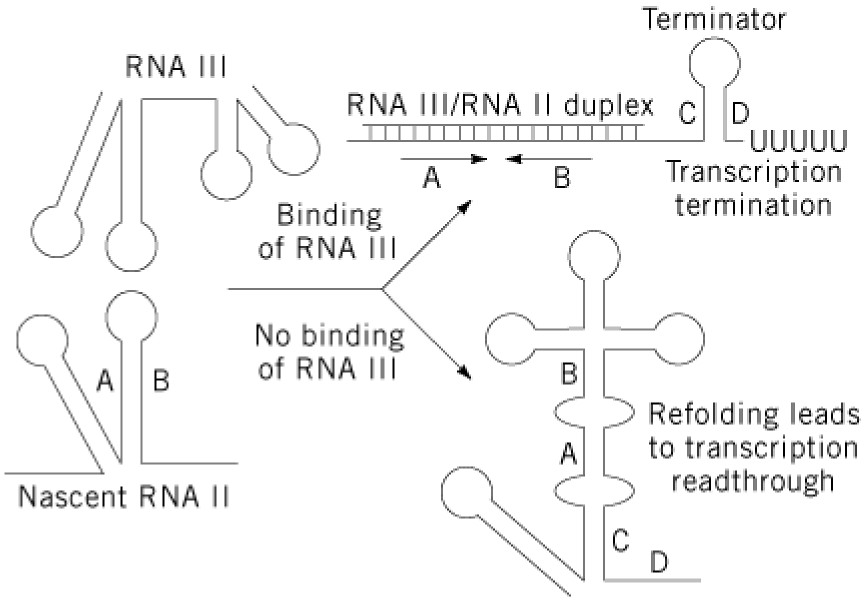
Expression of the *B. subtilis pyr* operon is also controlled by transcription attenuation mediated by an RNA-binding protein. This operon encodes 10 polypeptide chains involved in de novo synthesis of pyrimidines (15, 16). Transcription attenuation occurs in response to UMP levels through the action of PyrR, which is encoded by the first gene of the operon (17). There are several novel features of the attenuation mechanism that controls this operon. In contrast to the systems described previously, the *pyr* operon contains three attenuators: one located in the 5′-untranslated leader region, the second between the first and second genes, and the third between the second and third genes of the operon. Each attenuator can form three alternative RNA secondary structures. In addition to terminator and antiterminator structures similar to those described previously, a structure called the anti-antiterminator can form upstream of, and overlapping, the antiterminator. In the presence of UMP, PyrR is activated to act at each of the three attenuators to promote transcription termination and downregulate expression of the operon. In contrast to the mechanism by which TRAP controls attenuation in the *trp* operon, PyrR binding does not interfere directly with formation of the antiterminator structure, but rather functions by stabilizing the anti-antiterminator, which thereby indirectly stabilizes the terminator (18). The nature of the binding sites for PyrR and TRAP reflects the different effects these proteins have on RNA structure when they bind. TRAP binds to an entirely single-stranded site (19, 20), whereas PyrR binds to a stem-loop structure (21).

Another novel feature of this system is that PyrR is not only an RNA-binding regulatory protein, it is also an enzyme, uracil phosphoribosyltransferase (UPRTase), which catalyzes formation of UMP from uracil and 5-phosphoribosyl-1-pyrophosphate. The physiological role of this enzyme is not clear, as *B. subtilis* has an additional UPRTase that has been shown to be more important for UMP synthesis. The structure of PyrR in the absence of UMP shows two oligomeric forms of the protein, one as a dimer and the other as a hexamer (21). Both forms appear to exist in solution, but PyrR is thought to bind RNA as a dimer. Neither the amino acid sequence nor the structure of PyrR show significant similarity to TRAP. Thus it appears that these two similar attenuation mechanisms evolved independently.

3. Antisense RNA-Mediated Transcription Attenuation

Antisense RNA control of gene expression has been documented for many prokaryotic genes, some of which involve an interesting form of transcription attenuation (22-24). For example, the copy number of the *Streptococcus agalactiae* plasmid pIP501 is regulated by antisense RNA-mediated transcription attenuation (23, 24). The antisense RNA (RNA III) inhibits expression of *repR*, the gene encoding the essential RepR initiator protein, by binding to the nascent *repR* leader transcript (RNA II). This interaction promotes formation of a Rho-independent terminator upstream of the *repR* coding sequence. Interaction of RNA III with RNA II is initiated by the formation of a “kissing complex” between single-stranded loops of both molecules, followed by propagation of the RNA helix. In the absence of RNA III interaction, formation of the transcriptional terminator is prevented, and expression of *repR* can proceed normally. A model illustrating this mechanism is depicted in Figure 3.

Figure 3. Model of plasmid-encoded *repR* transcription attenuation. Interaction of RNA III with the nascent RNA II (*repR*) transcript promotes terminator formation and transcription termination. In the absence of RNA III interaction, refolding of the nascent transcript blocks formation of the terminator, leading to transcription readthrough. (See text for details.) Adapted from Brantl and Wagner (24).



4. Transcription Attenuation of Eukaryotic Genes

Expression of many eukaryotic genes is also regulated at the level of elongation of transcription by processes similar to attenuation (for reviews see 25, 26). In many cases, the action of an inducer protein is required to release the stalled RNA polymerase II elongation complex. In several systems, including *c-myc* (27-31), *N-myc* (32), *c-fos* (33), and adenosine deaminase (34), potential stem-loop structures, similar to prokaryotic transcription terminators, have been identified near the sites of attenuation. However, the precise transcription attenuation mechanisms of these systems are not known.

The best-characterized eukaryotic system involving control of transcription elongation is transcriptional activation of **HIV**-1 by the transactivator protein Tat (35). In this system, transcription initiates at the HIV-1 promoter in the viral long terminal repeat (LTR). In the absence of Tat, transcription terminates prematurely prior to the structural genes. Tat recognizes an RNA target called TAR, located near the 5′-end of the viral transcript (36, 37)). After binding to TAR, Tat interacts with several host cell proteins to enhance the processivity of RNA polymerase II and allow expression of the HIV-1 genes. Transcriptional pausing of RNA polymerase II just downstream of the TAR RNA structure was recently demonstrated. This could allow time for Tat to interact with TAR before RNA polymerase terminates prematurely (38). Interestingly, the pause signal is an RNA stem-loop similar to those seen in attenuation control in enteric bacterial systems.

Autoantibody

Autoantibody is a very misleading term for certain antibodies, because it covers very different situations. This probably is largely due to Ehrlich's initial proposals, formulated at the beginning of the twentieth century, of the *horror autotoxicus* dogma, leading later to the discrimination between self and nonself (1). If one sticks to this view, one must consider that autoantibodies escape from the dogma and produce a pathological situation, as is the case for autoimmune diseases. Two main observations have led us to revisit this view: one is the existence of idiotypes and **anti-idiotypes**, and the other is the presence of the so-called natural autoantibodies.

It was proposed by Jerne (2) that immunoglobulins are organized as a large idiotypic network in which Ig molecules regulate each other by their interactions. Another, more pragmatic approach would be to consider that the millions of different Ig molecules present at any given time in one individual provide a sufficient number of different specificities to recognize any potential epitope, including those expressed by the immunoglobulins themselves, and more generally by any self-**epitope**, unless subject to strict negative selection during differentiation, leading to an absolute tolerance state, which would be in agreement with Ehrlich's concept. Is this the case? During B-cell differentiation, before leaving bone marrow as immature B lymphocytes, newly formed cells are screened against the local environment, and self-aggressive cells are eliminated, providing the major basis for B-cell tolerance. But this is not an all-or-none phenomenon. It is believed to be relatively flexible, based on the average affinity of IgM molecules expressed at the surface of immature B cells. This view leaves open the possibility that immature B cells circulating in the periphery have retained some autoreactive potential against a possible self antigen.

The next question is, Are there natural immunoglobulins endowed with properties of recognition of self molecules? The answer is undoubtedly yes and is supported by many observations, especially those from the groups of Avrameas and Coutinho (3). Natural antibodies in whole serum were first described as having the essential characteristic of being polyreactive, a conclusion that was not *a priori* surprising because of their polyclonality. When analysis at the **monoclonal** level was made possible with the hybridoma technology, it was realized that most natural antibodies had a wide recognition spectrum, as observed from their patterns of binding to many different molecules used for systematic screening. Most natural antibodies were IgM, and complementary DNA sequencing of their V_H and V_L regions revealed that they contained very few mutations, indicating that they reflected transcription of germline **genes**. Affinity measurements revealed moderate but significant association constants. Natural monoclonal autoantibodies thus seem best defined as primarily germline-encoded and polyreactive. Polyreactivity contains in itself the possibility of having both anti-self and anti-nonself specificities. Presumably due to their relatively modest affinities, low concentration, and, of course, the fact that they passed the screen for potentially aggressive anti-self specificities, these antibodies qualify as harmless and may be regarded as the pool of basic circulating immunoglobulins of wide spectrum, endowed with a high connectivity, and constituting the primary germline idiotypic network. By contrast, aggressive autoantibodies found in the serum of patients suffering autoimmune diseases generally contain mutated sequences and are often of isotypes other than IgM.

One may thus consider active immunization as bringing a transient perturbation of the background of the natural equilibrium, leading to the emergence of clones that acquire a greater affinity and an increased specificity through the occurrence of somatic hypermutations.

Autoimmune Diseases

Autoimmunity is not pathologic *per se* because natural autoantibodies, natural autoreactive T-cell clones, and the connected idiotypes and **anti-idiotypes** are part of the basic organization of the immune system. Autoimmune diseases (AIDS) are the consequence of a major failure in the regulation of the immune system, as the emergence of self-reactivity becomes aggressive and harmful to the organism. They represent a major cause of morbidity, and their incidence increases with aging.

The primary causes of autoimmune diseases (AIDS) are still very poorly understood, and the precise target of the autoimmune reactions is not always known. In some cases, one organ, and eventually one target molecule, can be identified. Examples of these are myasthenia gravis, in which antibodies directed against the acetylcholine receptor have been identified, or autoimmune thyroiditis, where the presence of autoantibodies directed against receptors for thyroid stimulating hormone have been documented. Such antibodies may have very different impacts upon binding. Some may act as a mimic of the hormone and therefore activate thyrocytes, thereby inducing hyperthyroidism, which is characteristic of Graves' disease. Conversely, others will block receptor activation, leading to a hypothyroidism state, as seen in Hashimoto's disease. Another example of an organ-specific AID is insulin-dependent diabetes mellitus, in which the cellular target is the b islets of the endocrine pancreas. Some AIDs appear to be not organ-specific, such as systemic lupus erythematosous, when a number of autoantibodies are directed against a large variety of antigens, including DNA and nucleoproteins.

Several characteristics generally underline the occurrence of AIDs: (a) In most cases there is a genetic predisposition, with a frequent linkage to certain major histocompatibility complex (MHC) haplotypes; (b) they are chronic diseases that persist for years; and (c) although the molecular target of autoantibodies or autoreactive T-cell clones may be identified, this does not clarify the nature of the initial antigen, if any.

Linkage to an MHC haplotype is indicated by the increase of the relative risk for a given AID to occur. The most spectacular example is that of ankylosing spondylitis, a very severe arthritis that most frequently affects hips, for which 95% of patients are HLA-B27. This indicates a relative risk of about 70 (ie a $B27^+$ individual has 70 times greater chance to have the disease than the average population). This AID is also particularly interesting because it has been observed that microorganisms such as *Klebsiella* share an identical sequence of six amino acid residues, Gln—Thr

—Asp—Arg—Glu—Asp (QTDRED), with an epitope of the HLA27 molecule. It was postulated that this AID might be the consequence of an epitope mimicry, an infection with *Klebsiella* inducing an immune response that subsequently would cross-react with the HLA epitope of the host. A similar hypothesis was proposed for rheumatoid arthritis, a very common rheumatological disorder that may develop for years, because it was found to be associated with certain DR4 alleles expressing the Gln —Lys—Arg—Ala—Ala (QKRAA) sequence. A similar sequence was found in Hsp 70, which might provide another example of epitope mimicry as the starter for the initial immunization.

The V_H and V_L regions of autoantibodies isolated from AID patients have been sequenced extensively, with the hope of detecting significant differences from natural, nonaggressive autoantibodies. Frequently, dominant expression of some V_H and/or V_L is observed, as in the case of anti-DNA autoantibodies isolated from lupus patients. In most occasions, but not always, these antibodies have mutated **variable regions**, as opposed to the germline sequences generally found in natural antibodies. The significance of this remains unclear, however, primarily because the autoantibodies developed by a rather large number of AID patients seem to be only passive witnesses of an autoimmune response, rather than being involved in pathogenesis, which is frequently attributed to cytotoxic T lymphocytes.

Numerous animal models have been defined and extensively studied. Many have stressed the importance of the genetic background, such as the obese strain of chickens that develop a hereditary spontaneous autoimmune thyroiditis that is quite similar to Hashimoto's disease. Another example is the nonobese diabetic (NOD) mice that develop an autoimmune diabetes, which spontaneously develops an insulitis that becomes full insulin-dependent diabetes mellitus at 7 months of age. New Zealand black (NZB) mice and other strains that spontaneously develop a systemic lupus erythematosous-like syndrome are another example. These models are interesting because they provide a possible key to understanding the genetic basis for the equivalent human diseases. Other approaches are centered more on attempts to isolate antigens that might induce an AID-like syndrome. An example of this is experimental autoimmune encephalomyelitis, which is a possible model for multiple sclerosis; it can be induced upon injection of myelin basic protein, from which encephalitogenic peptides and precise epitopes have been described. This disease can also be transferred with lymphocytes but not by serum, pointing to the role of cell-mediated immunity in this AID. Interestingly, T cells with a suppressive activity have also been identified, offering the possibility of modulating the immune system negatively by this approach. Such a treatment is eagerly awaited for most AIDs, particularly multiple sclerosis. Thus far, primarily nonspecific immunosuppressive agents are used, with the obvious problem of generating severe secondary effects.

Autoimmunity

The immune system is able to discriminate between self and nonself, but there are often ambiguities with this formulation. First, it certainly is intended to stress the fact that the immune system is designed for the important role of fighting against external pathogens, whereas it should be harmless for the components of the organism. There are two ways to be harmless. One is simply not to "show off," the second is to be present, but silent. Immunologists long lived with the idea originally put forward by Ehrlich in 1901 of the *horror autotoxicus*, thus considering that autoantibodies, and more generally autoimmunity, could not exist. This was even strengthened by Burnet, when he proposed the clonal selection theory, based on the elimination of autoreactive lymphocytes (the so-called "forbidden clones"), leading to immune **tolerance**. On these bases, autoimmunity may only be considered to be a pathological deviation, with the emergence of autoimmune diseases. Discovery of the interactions between idiotype and **anti-idiotype** and of the existence of natural antibodies endowed with auto reactivity made it necessary to reconsider the problem.

A long debate has taken place for years between immunologists, first on the existence, and then on the nature, of natural antibodies and their possible autoimmune properties. Identification of "natural" monoclonal antibodies that were polyspecific clarified the situation, because it was demonstrated that these antibodies contained **variable (V) regions** of both the heavy and the light chains that were mostly not mutated, and like the germline gene from which they were derived. As a result, these antibodies could be considered the first circle of antibody defense, with some polyspecificity that is the best witness of a certain degeneracy of recognition by the immune system. Deliberate immunization will stimulate clones that have the best affinity for the antigen, and this affinity will be amplified by the mechanism of somatic hypermutation, as the specificity becomes more precise. To be polyspecific immediately implies that both auto- and xenospecificities may be found, as was shown using a large panel of random antigens for screening. Autoimmunity has also been described in the T-cell population and is subject to the same comments, with the exception that T cells do not mutate upon antigenic stimulation.

The entire repertoire expressed at a given time by the immune system is probably best visualized as a large network of interacting molecules that regulate each other. Deliberate immunization would result in transient perturbation of this equilibrium. Deviation to the production of aggressive B- and T-cell clones would thus be a central alteration of this equilibrium, ensuring some leakiness for the negative selection of potentially aggressive clones.

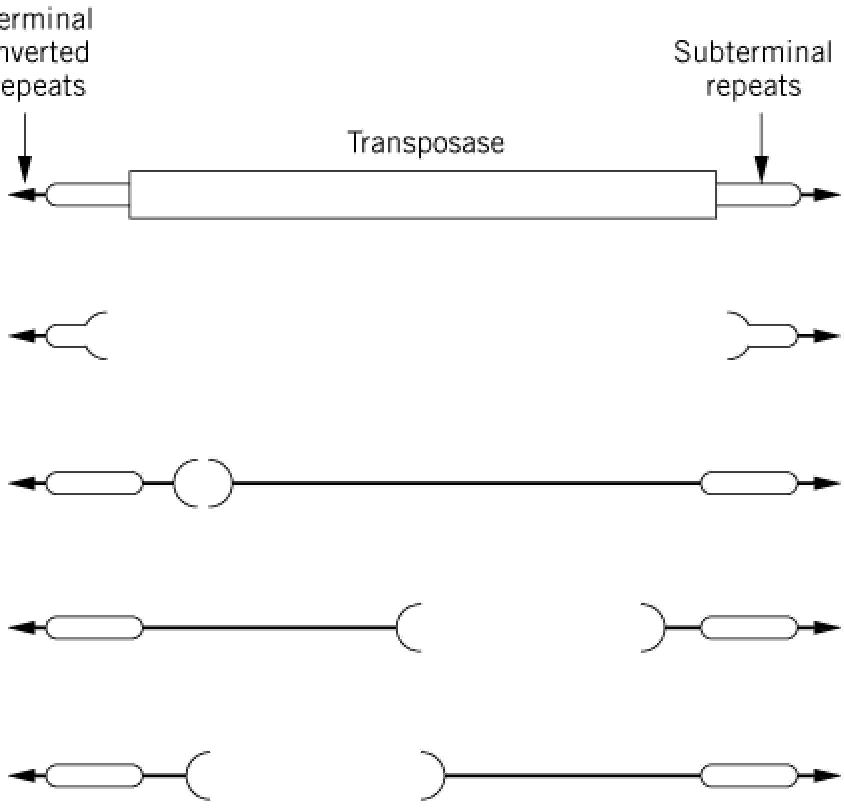
Autonomous Controlling Elements

Transposable elements are discrete pieces of DNA that can move between nonhomologous positions in the genome. When Barbara McClintock discovered transposable elements in maize, she called them controlling elements, emphasizing that they could affect gene expression, in addition to being able to move from place to place within the genome (1). She discovered two classes of elements; one she termed *activator* (Ac), which could itself translocate within the genome. She also determined that Ac encoded a product that could promote the movement of a second class of elements called *dissociation* (Ds). In the presence of Ac, Ds could move and cause chromosome breaks that altered the expression of nearby genes, but was unable to move in the absence of Ac. Ds elements are so-named because their translocation could be associated with chromosome breakage.

We now know that Ac is an intact transposable element encoding a recombinase, a transposase, that promotes element translocation and has special sequences at the termini of the element upon which the transposase acts to promote translocation. Such intact elements are said to be “autonomous” because they can translocate without the assistance of another element. Ds, by contrast, is a nonautonomous element. It doesn't encode a transposase itself and is thus dependent on the presence of other Ac elements to supply a transposase to promote its transposition. Ds is actually an Ac element that has undergone internal deletions that have removed the transposase gene but have left intact the special terminal sequences on which transposase acts intact (Fig. 1). Thus the terminal sequences of Ds are the same as the terminal sequences of Ac, so that the Ac transposase can promote the translocation of Ds (2); there are several different Ds elements that contain different extents of the internal, nonterminal sequences. The deletions are thought to result from abortive repair of the gapped donor site after element excision (2-4).

Figure 1. Autonomous and nonautonomous elements. A schematic representation on an intact (autonomous) Ac element is shown (top line). It encodes a transposase formed from several exons (not shown) and special recombination sequences at the ends of the element. The arrows represent short perfect inverted repeats and the oval other repeated sequences; these are not shown to scale. Only some of the subterminal repeats are necessary for transposition. Various deletion derivatives of Ac are shown (lines 2–5); these internal deletions make the element dependent on an intact Ac for transposase and hence for translocation.



Ds Elements

Virtually all bacterial elements that have been observed are autonomous; that is, encode a transposase and have cognate terminal sequences. Nonautonomous and autonomous elements are frequently observed in other organisms such as *Drosophila*, Caenorhabditis *elegans*, and plants (5).

Autonomously Replicating Sequences

The chromosomes of **yeast** contain many genomic segments at which DNA replication is ordinarily initiated. On average, one is found every 40 kb in the *Saccharomyces cerevisiae* genome. These regions can act as the **origin of replication** for a circular **plasmid**. When such a segment is linked to a nonreplicative DNA fragment, it can confer on that fragment the ability to replicate autonomously as a plasmid in a yeast cell in the S-phase of the cell cycle. This construction is called an *autonomously replicating fragment* (ARS).

An ARS-containing DNA fragment can **transform** yeast cells at much higher frequencies than a fragment without an ARS, because it can replicate autonomously without undergoing a rare homologous recombination before its **genes** can be expressed. In contrast to the latter transformants, however, those formed with an ARS-containing DNA are extremely unstable and lose the transforming DNA even under selective conditions. For unknown reasons, they tend to remain associated with the mother cell without being evenly distributed to the daughter cell upon division.

ARS have been found in *Saccharomyces cerevisiae* and but also in other yeasts, such as *Candida maltosa*, *Hansenula polymorpha*, *Kluyveromyces lactis*, and *Schizosaccharomyces pombe*. They are not restricted to yeasts and have also been described in other lower **eukaryotes**, such as *Aspergillus nidulans* and *Entamoeba histolytica*, and even in at or near potential replicative origins from *Drosophila*, Chinese hamster, and humans.

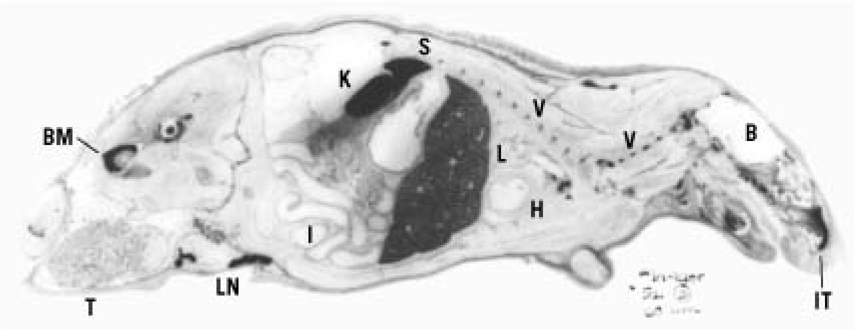
Autoradiography

Autoradiography is the technique of recording an image of a preparation containing beta-particle emitting radioactivity, using photographic film, X-ray-sensitive film, an emulsion, or other radiation-sensitive medium. The samples are placed directly against the film for a period of time to allow radioactive emissions from the sample to interact with the film emulsion and create an image. A photographic emulsion is a suspension of crystals of silver bromide embedded in gelatin. When crystals of silver bromide are struck by charged-particle or photon radiation, the silver atoms are ionized and form an invisible latent image. After exposure to the sample, the photographic grains in the emulsion are fixed using standard photographic developing, which removes silver bromide that has not been ionized. After the emulsion is developed, each small aggregate of reduced silver atoms becomes a visible dark spot on the emulsion; collectively, they make up the photographic image.

Production of a visible silver grain requires a number of ionization events, so the photographic response is not exactly linear to the amount of radiation present. Preflashing the film with a uniform low intensity of light “primes” each grain of silver to become reduced and visible after absorbing just one or a very few additional beta particles from the sample. This increases substantially the sensitivity of the film and also makes the photographic response more directly proportional to the amount of radiation in the sample. The signal-to-noise ratio is often increased by exposing the film to low temperatures. The sensitivity can also be enhanced by using scintillation screens that emit visible light on encountering a beta particle; the light is recorded by the film (see Fluorography).

Autoradiography has a large number of practical applications in the biological, chemical, and physical sciences, because it provides both qualitative and quantitative information (eg., images and amounts present). It may be used to image large, small, and microscopic specimens, including sectioned whole organisms, organs, tissues, cellular structures, and nucleic acids that contain some radiolabeled compound. An example of a whole-animal autoradiograph is shown in Figure 1. Cells may be autoradiographed either in culture as a monolayer, on a glass slide, or on thinly sectioned living tissues from an animal organ or tumor. Microautoradioagraphy involves coating the sample directly with a radiation-sensitive emulsion; cellular constituents that have incorporated the radiolabel can be clearly identified. Autoradiography is used with electrophoresis or chromatography to image radiolabeled macromolecules and other separated chemicals for quantitative analysis. For example, autoradiography is useful for indicating the position of hybridized nucleic acids on Southern blots and **Northern blots**, and of proteins on **Western blots.**

Figure 1. Whole-body autoradiograph of a rat that had been injected with indium-111 chloride. Courtesy of B. Anders Jönsson, Lund University, Sweden.



1. Historical Development

The first autoradiograph, or **autoradiogram**, was made in 1859 by Crookes, who placed uranium rocks on photographic plates (1). Crookes would not understand the process by which the images were created until 37 years later when he visited the laboratory of Henri Becquerel. Bequerel discovered gamma rays from naturally radioactive uranium salts in 1896 when he placed uranium together with photographic plates that had been placed inside black paper to protect them from sunlight (1). This discovery closely followed the discovery of X rays by Wilhelm Roentgen in 1895 using a Crookes electron tube.

The French photographer Nicéphore Niepce had observed the darkening of silver grains on photographic plates by uranium in 1867, but he did not recognize any practical applications of this phenomenon (2). Although George de Hevesy, the pioneer of radioactive tracers, had used bismuth isotopes in animals in 1923, the first autoradiographs of radioactively labeled animal tissues were made in 1924 by Lacassagne in France (1-3). Lacassagne fed polonium-210 to rabbits and later placed thin sections of rabbit kidney tissues in paraffin blocks against photographic plates. Gettler made the first autoradiographs of human tissues from deceased persons who had ingested radium chloride in 1933 (1).

The earliest images were of poor quality. Autoradiographic techniques were improved by Leblond, who, in 1943, showed the microdistribution of iodine-131 in cells (1, 2). In 1946, Bélanger and Leblond (4) developed a method for locating radioactive elements in tissues by covering histological sections with a photographic emulsion. In 1954, Gabriel introduced techniques for identifying radioiodine using human serum albumin zone paper electrophoresis (1). In 1953, techniques were developed for labeling nucleic acids and studying kinetics of cell mitosis and division (5). High resolution techniques have more recently been employed for study of other metabolic and pharmacokinetic processes in molecular biology.

2. Film-Less Autoradiography

Modern trends in autoradiography involve replacing high speed X-ray film with radiation detector systems, laser scanners, and computer-based imaging systems. A variety of radiation-detecting crystals and phosphors have been developed for this purpose. Storage phosphor screens are more sensitive, by a factor of about 20–100 for beta-emitting radionuclides (2), and they are reusable. The exposure time is also much less, by a factor of about 10, over conventional X-ray film, and samples may be processed at room temperature and without a darkroom or chemicals for film developing. Applications of filmless autoradiography include **two-dimensional gels**, Southern blots, **Northern**

blots, immunoblots, and quantitative polymerase chain reaction (**PCR**) (2).

Microchannel array detectors have been introduced to replace both X-ray films and phosphor screens (8). The new instruments are faster (by a factor of ~10) and have greater image resolution than do phosphor screens for detecting latent images from hybridization studies using macromolecules labeled with carbon-14, sulfur-35, phosphorus-32, and iodine-125 from flat gels, blots, membranes, tissue slices, and other flat specimens.

Autosome

An autosome is any chromosome other than the sex chromosomes. For example, the human genome has 24 chromosomes, including 22 autosomes plus the X- and the Y-chromosomes. This is described as the haploid set. If a cell contains a complete haploid set of chromosomes, it is described as euploid. If the chromosome set is altered by duplication or deletion then the cell is **aneuploid**. If a cell contains two sets of genomes per nucleus, it is **diploid**, and if it contains more than two, it is described as polyploid.

Organisms that have a largely vegetative existence, such as some **fungi** and **algae**, have mainly haploid cells. In metazoans the **gametes**, such as the **spermatozoa** and **oocytes** in humans, are haploid. Sexual **reproduction** involves the fusion of two haploid gametes to form a diploid egg in an animal. The vast majority of the cells in an animal that develop from an egg are diploid. Thus there are two active copies of each autosome in most animal cells. In **plants**, a polyploid state is common where the number of genomic copies in somatic cells may range from 3 to 10 (1). The number of genomic copies can actually be **polymorphic** within a particular species (2). Thus plants are relatively insensitive to the number of copies of a particular **gene** in a given cell. This is not the case with animals, where somatic cells are almost always diploid. The only exceptions are those animals with **parthenogenetic** life styles in which either males or females develop as a default state from an unfertilized egg. In general, animal cells cannot accommodate more than two copies of a particular chromosomal region.

Aneuploidy occurs when parts of chromosomes or whole chromosomes are absent from the genome. In humans the nondisjunction of homologous chromosomes during **meiosis** or of sister chromatids during **mitosis** can lead to aneuploidy. When a chromosome is in excess of the normal euploid number, the condition is called hyperploidy. For example, a hyperploid state in humans occurs when there are three copies of a particular chromosome, a condition known as trisomy. All human autosomes except chromosome 1 have been found as trisomies (3). Most trisomic embryos are spontaneously aborted, but live births occur with trisomies of chromosomes 13, 18, and 21 (4). The most common human trisomy to reach term is that of chromosome 21, resulting in Down's syndrome. These children are mentally retarded, predisposed to cancer and have a shortened life span. Presumably the deleterious effects of three copies of chromosome 21 follow from an imbalance in the expression of one or several sets of genes on chromosome 21 relative to the other genes on the other chromosomes in the cell.

Experiments in *Drosophila melanogaster* indicate that changes in the dosage of a single gene might be tolerated, but a deletion that includes several genes or a large section of a chromosome is likely to cause sterility (5). Surprisingly in trisomies of *D. melanogaster* involving whole chromosome arms, many of the duplicated autosomal genes express only diploid levels of gene product. The expression of genes outside the duplicated region is also affected, however, indicating the pleiotropic effects of altering gene copy number. An interesting aspect of sexual reproduction requiring the use of two distinct haploid gametes is that there are two copies of each autosome in a diploid cell, whereas there are be one or two copies of each sex chromosome. **Dosage compensation** is the phenomenon whereby the **transcriptional** activity of genes on the sex chromosome is adjusted to similar levels independent of the number of copies, so that it is constant relative to the activity of a gene on an autosome (see X-Chromosome Inactivation).

Humans, again have two X-chromosomes in one sex (female) and one X-chromosome in the other (male). To achieve dosage compensation, an entire X-chromosome is silenced in female diploid cells. This process is called X-chromosome inactivation and results in the formation of the Barr body. The capacity to monitor the activity of genes on autosomes relative to the sex chromosomes has facilitated the discovery of novel mechanisms of regulating genes at the level of whole chromosomes.

Auxins

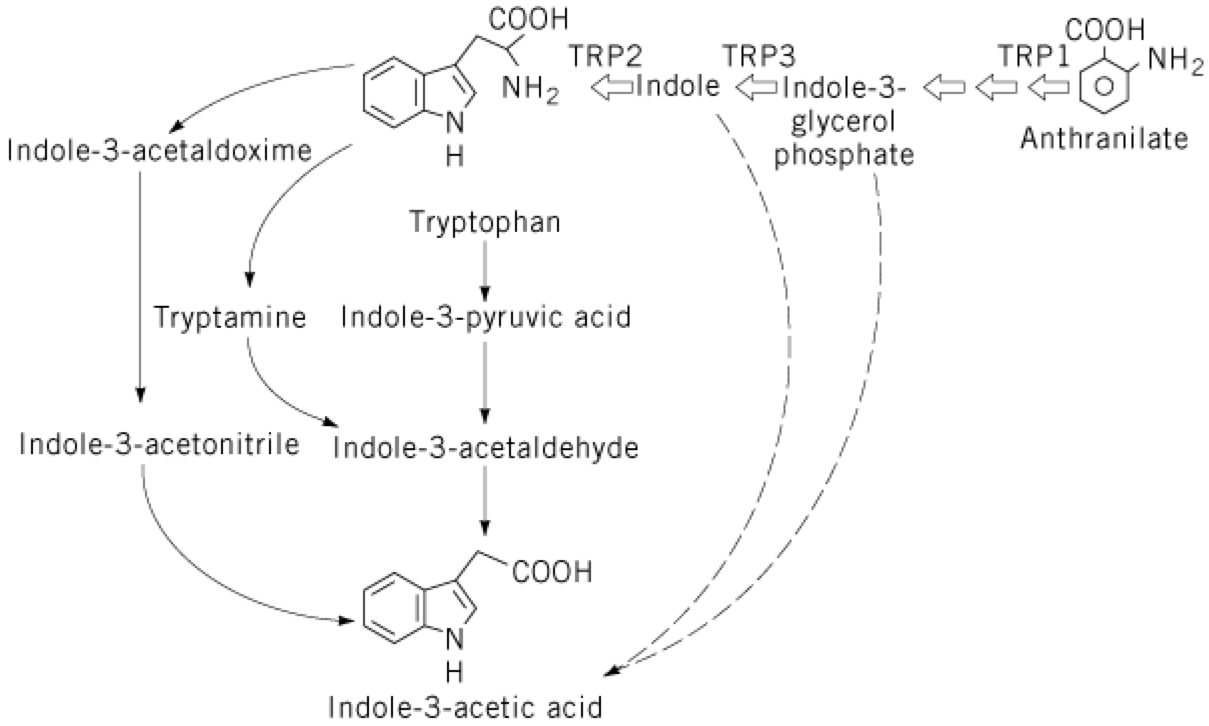
1. History

Auxins were the first class of plant hormones to be discovered. Initial observations by Charles Darwin and his son Francis on the phenomenon of bending of canary grass coleoptiles toward a unilateral source of light (known as phototropism) led the foundation for a series of experiments that culminated in the discovery of the first phytohormone (1). The active substance was isolated from oat coleoptiles by Went in 1926 (2) and later identified and named auxin (from the Greek "to increase"). By analogy with the animal hormone concept from Bayliss and Starling (3), plant physiologists interpreted auxin as a phytohormone.

2. Biosynthesis and Metabolism

The most abundant natural auxin is indole-3-acetic acid (IAA). It is mainly synthesized in the shoot apex and in young leaves. Other substances with auxin activity that are found in plants are indole-3-butyric acid, 4-chloro-indole-acetic acid, and phenyl acetic acid (4, 5); these compounds are active only at higher concentrations, and their roles in development remain largely unknown. Multiple pathways exist for auxin biosynthesis; some of these are dependent on tryptophan, while others are independent (Fig. 1). In certain species, different routes are operational (6), whereas in others, essentially all of the IAA is derived from tryptophan (7). Three possible routes for tryptophan-dependent IAA synthesis have been proposed (4, 5), which include indole-3-acetonitrile, tryptamine, and indole-3-pyruvic acid as the respective intermediates. Genes encoding tryptophan decarboxylase (which catalyzes the conversion of tryptophan to tryptamine) and nitrilase (forming IAA from indole-3-acetonitrile) have been cloned (8-10). The route via indole-3-acetonitrile has been found primarily in Brassicaceae. Likewise, the tryptamine pathway is not supposed to be of general importance, because tryptamine is not universally present in plants. A unique tryptophan-dependent pathway via indole-3-acetamide is used by bacteria and by plant cells that are transformed with ***Agrobacterium*** *tumefaciens*. The corresponding genes have been used to alter the IAA levels in **transgenic** plants (11).

Figure 1. Auxin biosynthesis in higher plants. (Based on Ref. 4.)



Tryptophan-auxotroph mutants have revealed the existence of a tryptophan-independent pathway for IAA biosynthesis. Both maize (12) and Arabidopsis (13) tryptophan mutants overproduce IAA or IAA conjugates, respectively. On the other hand, mutants that block tryptophan biosynthesis before indole-3-glycerol phosphate have a **phenotype** suggestive of auxin deficiency (14). Based on these observations, IAA was proposed to be synthesized through a tryptophan precursor, either indole or indole-glycerol phosphate, thereby bypassing tryptophan (4). An auxin-overproducing mutant that accumulates both free and conjugated auxins has been isolated (15, 16). The wild-type gene product might inhibit auxin biosynthesis and shows similarity to aminotransferases (17).

Of all the auxin present in plant tissues, 95% resides in conjugated form, coupled to amino acids, **peptides**, or proteins via amide bonds, or to sugars via ester linkages (18). The role of these conjugates is diverse: the storage of free IAA (released by hydrolysis), its transport, and eventually its catabolism. A genetic approach was used to characterize a hydrolase that catalyzes the formation of free IAA from IAA-Leu (10). The *ILR1* (*IAA-leucine resistant 1*) **gene** encodes a protein with similarity to a bacterial aminoacylase that catalyzes amide cleavage.

3. Transport

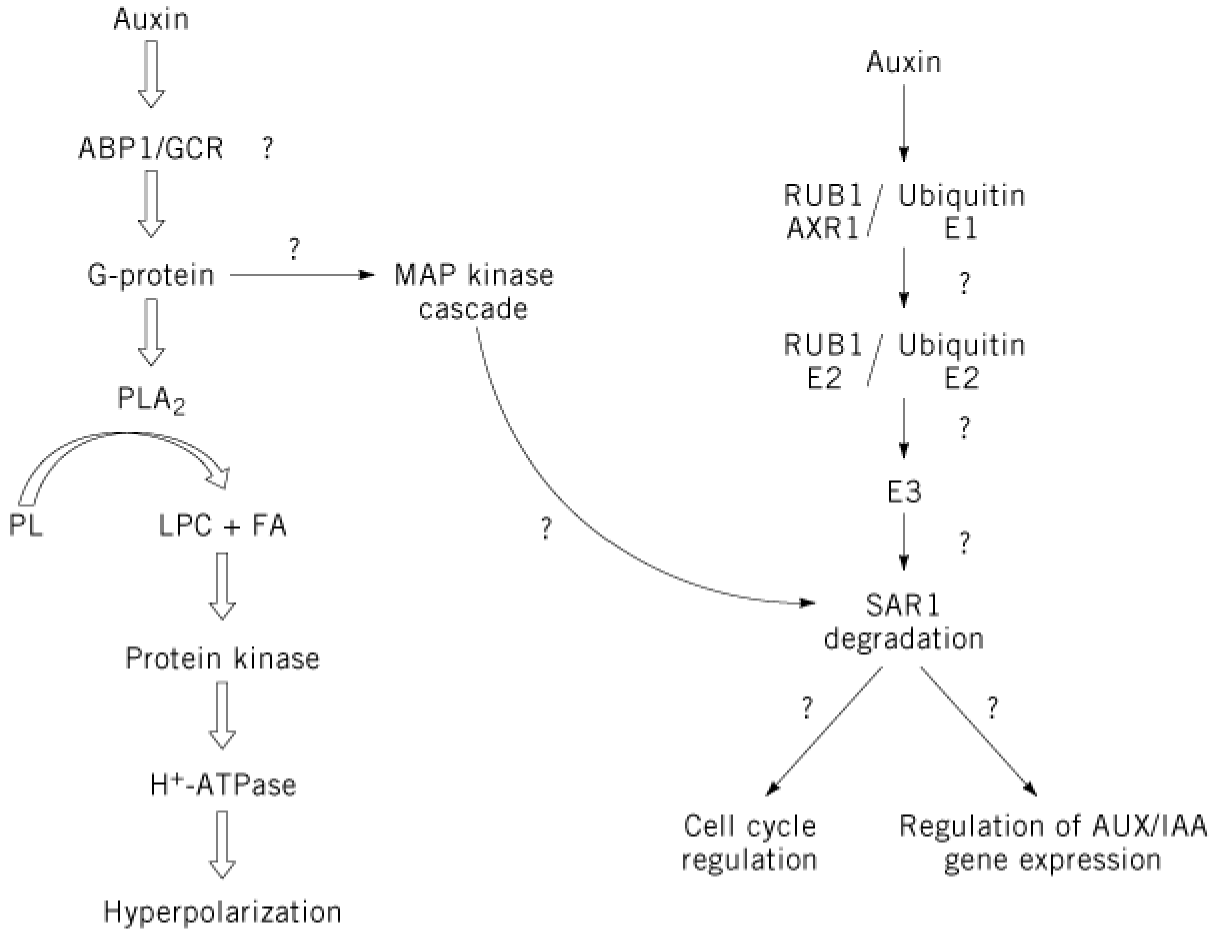
Another important aspect determining auxin levels is transport of the hormone. Auxin transport can be either (a) polar, basipetally directed, and active or (b) nonpolar and inactive (19). The latter occurs through phloem tissue. Polar transport is probably involved specifically in processes of apical dominance, vascular differentiation, and shoot–root communication. Evidence exists for the presence of influx and efflux carriers, although protonated auxin can enter cells by simple diffusion. Proton–auxin **symport**, energized by the plasma membrane **proton pump**, allows a more rapid uptake than by diffusion. The AUX1 protein has been suggested to represent an auxin uptake carrier (20), based on its similarity to amino acid uptake carriers, which also function as symporters. Although several mutants have been characterized that show growth defects similar to those upon treatment with polar transport inhibitors (21), only one of them appears to be a candidate for the auxin efflux carrier. The PIN1 (*pin formed 1*) gene product shows the characteristics of a transmembrane protein (22). The corresponding mutant displays abnormal cotyledon development, together with twisted, narrow leaves with branching midveins. Auxin transport is reduced at all stages of development (23).

Recently, factors that may modulate auxin transport have been characterized (24, 25). Both the loci *RCN1* (*ROOT CURLING on NPA1*) (coding for a protein phosphatase A regulatory subunit) and *MP1* (*MONOPTEROS1*) (coding for a homologue of the auxin response factor ARF1) (26) (see text below) have been isolated based on their altered response to auxin transport inhibitors. Mutations in the *MP1* gene interfere with vascular strand formation and with initiation of the body axis in the embryo (27).

4. Signal Perception and Transduction

The perception and transduction of the auxin signal remains largely enigmatic (Fig. 2). Two different approaches have been followed toward the identification of putative auxin receptors: (a) the characterization of auxin-resistant mutants and (b) the isolation of auxin-binding proteins (28, 29). Because auxin is present both intra- and extracellularly, a site of perception may be needed on both sides of the membrane. Although many auxin-binding proteins have been identified, none has been proven to function as an internal receptor at the molecular level. In contrast, an external receptor has been characterized. There is evidence that auxin causes changes in the plasma membrane potential via stimulation of the proton ATPase and modulation of **ion channels**. These rapid responses result from auxin binding to a protein named ABP1 (auxin-binding protein 1). Thus far, it is unknown whether ABP1 mediates cell growth. Although ABP1 possesses a *C*-terminal signal for retention in the endoplasmic reticulum (ER) and largely resides in the ER, it does not seem to bind auxin in this cellular compartment. Instead, ABP1 can reach the cell surface by a yet unknown mechanism, as demonstrated by immunolocalization experiments (30). It is hypothesized that ABP1 is retained at the membrane periphery by interaction with a docking protein, because ABP1 does not contain a potential membrane-spanning domain. The nature of the docking protein is undefined, but biochemical evidence supports the concept of a **G-protein**-coupled receptor (GCR) (31). These receptors contain seven transmembrane domains and are directly coupled to heterotrimeric G proteins. A possible effector could be phospholipase A_2, which produces lysophospholipids and free fatty acids. The former have been proposed to act as second messengers that can activate the plasma membrane proton ATPase (32, 33). However, G-protein-coupled receptors may activate different G proteins in different cell types, as has been shown in animal cells (34), and therefore may control a downstream branched transduction pathway. At least one report suggests the involvement of a MAP kinase cascade in the initiation of cell division by auxin in cell cultures (35).

Figure 2. A model for auxin signal transduction. PL, phospholipids; PLA_2, phospholipase A_2; LPC, lysophospholipids; FA, fatty acids. (Modified from Refs. 29 and 39.)



The second approach to molecular characterization of auxin signal transduction involves the isolation and characterization of auxin-resistant mutants. At least seven loci were identified by screening for resistance to auxin-induced root growth inhibition (21). AXR1 (auxin resistant 1) probably plays a role at an early stage in the signaling chain, because the recessive *axr1* mutant cannot respond to auxin in all the assays tested. The *AXR1* gene encodes a protein with homology to the amino-terminal half of the **ubiquitin**-activating enzyme E1 (36). Thus, a central part of the mechanism of auxin action appears to play a regulatory role in protein degradation. Recently, two genes of *Saccharomyces cerevisiae* were found to be similar to *AXR1* (37). One of these regulates the stability of key components of cell cycle regulation, such as the **cyclin**-dependent kinase inhibitor Sic1p, through conjugation of the ubiquitin-like protein RUB1 to CDC53p, a component of a E3 ubiquitin—protein ligase complex (37). The speculation that *AXR1* plays a role in cell cycle control is considerably strengthened by the characterization of the *tir1* (*transport inhibitor response 1*) locus, a semidominant mutation that also confers auxin resistance (38). Sequence analysis revealed similarity between TIR1 and F-box proteins found in E3 ubiquitin-protein ligase complexes in yeast. The product of the *SAR1* (*suppressor of auxin resistance*) gene has been proposed as a candidate target for AXR1-dependent ubiquitin degradation (39). The *sar1* mutant was identified as a suppressor of the Axr1 phenotype (40). SAR1 may function as a repressor of *AUX/IAA* genes, or it may be involved in cell cycle regulation (40). The mostly root-specific *axr4* mutation probably defines an AXR1-independent path. Double-mutant analysis indicates that at least two interacting pathways exist, in which AXR4 and AUX1 define a first route while AXR1 defines a second one (41).

5. Downstream Targets

Ultimately, the auxin signal leads to induction or repression of a series of target genes, some of which are responsive in a few minutes (42, 43). The products of these primary response genes are likely candidates to play a role in auxin-stimulated growth. The induction of the early genes is independent of *de novo* **protein biosynthesis**, implying that **post-translational processes** control the activity of factors that affect their expression. The transcriptional activation of early genes is based on the presence of auxin-responsive, cis-acting, response elements (AuxREs). Two auxin response-element domains were defined in the *Pisum sativum IAA4* and *IAA5* genes, one of which acts as an auxin switch while the other acts as an enhancer element. The former AuxRE is present in the promoter of *AUX/IAA*, *SAUR* (*small auxin-upregulated mRNAs*, and auxin-inducible 1-aminocyclopropane-1-carboxylate synthase genes. An alternative AuxRE is found in the promoter of the *GH2* and *GH4* genes. Essentially, this element consists of a G-box motif, binds bZIP factors, and is generally responsive to stress signals. The biological role of most of the auxin early-response gene products remains to be elucidated. Nevertheless, based on similarities with proteins of known functions, it is proposed that *GH2* and *GH4* genes are **glutathione-*S*-transferases**. *AUX/IAA* polypeptide chains are short-lived nuclear proteins that probably function as an auxin switch in a secondary phase of signal transduction (42), implying that their target gene products probably mediate auxin responses. Thus, the *AUX/IAA* polypeptides might be involved in homo- and heterodimerization with auxin response factors, such as ARF1, that bind to AuxREs (26, 44). The *IAA17* and *AXR3* genes are identical (44). *Axr3* is a dominant auxin-resistant mutant with extremely resistant roots, although the general phenotype of the mutant resembles auxin hypersensitivity (45).

6. Effects

Depending on temporal and spatial factors, a particular subset of downstream target genes is activated and results in one of many described effects. Auxin has been implicated in a variety of growth and developmental processes, such as cell division, stem and root elongation, leaf expansion, formation of adventitious and lateral roots, induction of vascular tissue, apical dominance, tropisms, flowering, and fertility (46).

Auxotroph

An auxotroph is a mutant that requires a factor for growth that is not required by the **wild-type**. The opposite of an auxotroph is a **prototroph**, an organism that grows in minimal medium containing only inorganic salts and a carbon source (plus an additional energy source if the organism is an

autotroph). Typical auxotrophic mutations are in genes encoding biosynthetic enzymes for amino acids, vitamins, and **nucleotides**. Some organisms are natural auxotrophs. For example, humans require that all vitamins and several amino acids be supplied in their food. In contrast many, but not all, free-living **microorganisms**, such as *Escherichia coli*, are prototrophs. A specific auxotrophic **phenotype** is called an auxotrophy, eg, an arginine auxotrophy, and the mutant is called an arginine auxotroph.

Avidin

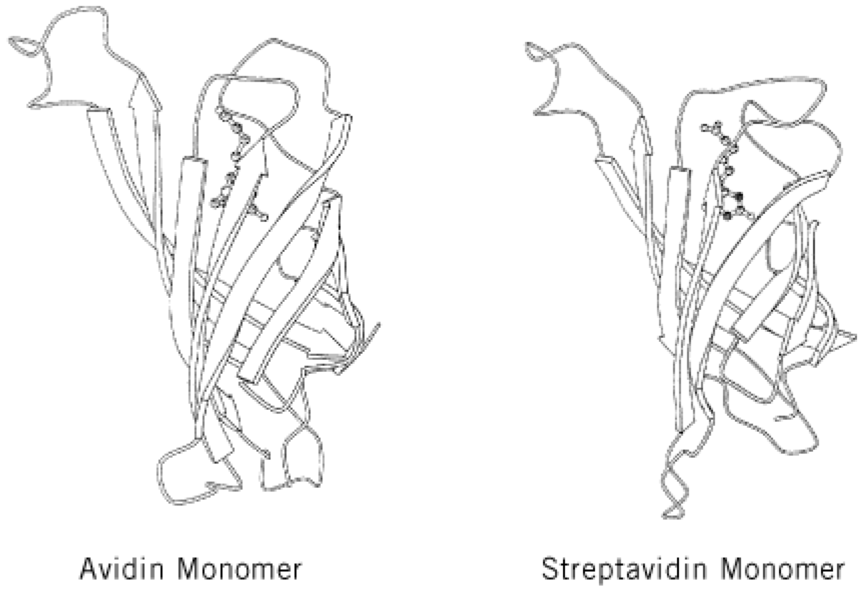
Avidin is a minor **glycoprotein** component of egg white that binds the vitamin biotin with the largest **association constant** known ($\mathbf{K_a} \sim 10^{15}\ M^{-1}$) for a **ligand**–protein interaction (1). Its function in egg white is not known precisely, although protective or antibiotic activities have been suggested. It gained importance not because of its natural functionality, but because of its utility as a tool in molecular biology [see Avidin-Biotin System]. Together with its bacterial relative streptavidin and in complex with biotin, avidin has become one of the most important tools in molecular biology because of its myriad of applications in many fields of biology, biotechnology, and even chemistry (2). Originally, the avidin-biotin complex was introduced to localize, detect, and isolate biologically active molecules (3, 4), but over the years it has became a standard system for replacing radioactivity in immunoassays, for DNA probes, and for various clinical and medical applications (5, 6).

The avidin molecule forms a very stable tetramer that consists of four identical monomers. The monomer is glycosylated at asparagine-17 and is strongly basic (isoelectric point of about 10.5) due to a surplus of arginine and lysine residues. The relatively high molar **absorption** ($A^{1\%}_{[280\ nm]} = 1.54$) reflects the four tryptophan and one tyrosine residue per monomer. The molecular mass of the glycosylated tetramer is about 62,400 Da. When the oligosaccharide residue is removed, the estimated mass is 57,120 Da.

Each avidin monomer binds one molecule of biotin. The binding is considered to be kinetically noncooperative among the subunits (7), although one of the tryptophan residues from a neighboring monomer is inserted physically into the binding site and thus contributes to binding biotin and to the enhanced stability of the tetrameric structure (8). Avidin also binds to the dye HABA (4′-hydroxyazobenzene-2-carboxylic acid), but the association constant (ca. $10^6\ M^{-1}$) is considerably lower than that of the avidin-biotin complex.

The unusually strong binding and the many uses of the system caused scientists to try to understand the molecular basis for this interaction. Moreover, since its inception, many groups have sought to improve various components of the system or the system as a whole. Concurrently, structure-function studies have been implemented, in which early results show the importance of aromatic amino acids in the biotin-binding sites of both avidin and streptavidin. The final structural proof is the determination of the crystal structure of both proteins (Fig. 1), which shows that their overall fold, organization into the tetramer, and content and position of amino acids in the binding sites are all similar (8-10).

Figure 1. Ribbon diagrams of the avidin–and streptavidin–biotin monomers, showing the eight strands of the b-barrel. The biotin molecule is shown in a ball-and-stick model.



The avidin monomer forms a b-barrel, composed of eight antiparallel b-strands, connected sequentially by loops. The biotin-binding site is a **hydrophobic** pocket that, in the absence of biotin, contains five molecules of structured water. The combined structure of these water molecules emulates that of biotin itself, and as a consequence, they prevent the binding pocket from collapsing. The water molecules are expelled upon binding of biotin. Because no conformational change occurs during complex formation, the binding has a gain of **free energy**. In fact, the avidin-biotin system can be considered a natural host–guest complex. It is clear that any change of this “ideal system” leads to reduced affinity. Indeed, site-directed mutagenesis or chemical modification of residues in the binding site have reduced the affinity constant. An example is the nitration of the essential binding-site tyrosine (11), which decreases the association constant to ~10^{10} M^{-1} , and renders the binding reversible at alkaline pH. Another example is the site-directed modification of tryptophan 120 in streptavidin to phenylalanine, which is also accompanied by a loss in affinity (12).

Different modifications of avidin were introduced over the years, including Extravidin, Neutralite avidin, and Lite avidin (13). Extravidin and Neutralite avidin are avidins in which the arginine residues were modified, whereas the oligosaccharide moieties were removed from Lite and Neutralite avidins. These derivatives are useful in many applications, because avidin, being a basic glycoprotein, is subject to a variety of extraneous nonspecific or undesired binding, particularly to DNA. Similar qualities of genetically engineered forms of avidin are possible because avidin was successfully expressed in a eukaryotic host (14, 15). This should enable preparation of different derivatives of avidin with high affinities, provided that the binding site residues are preserved. It seems that the nonbinding-site residues can be altered extensively.

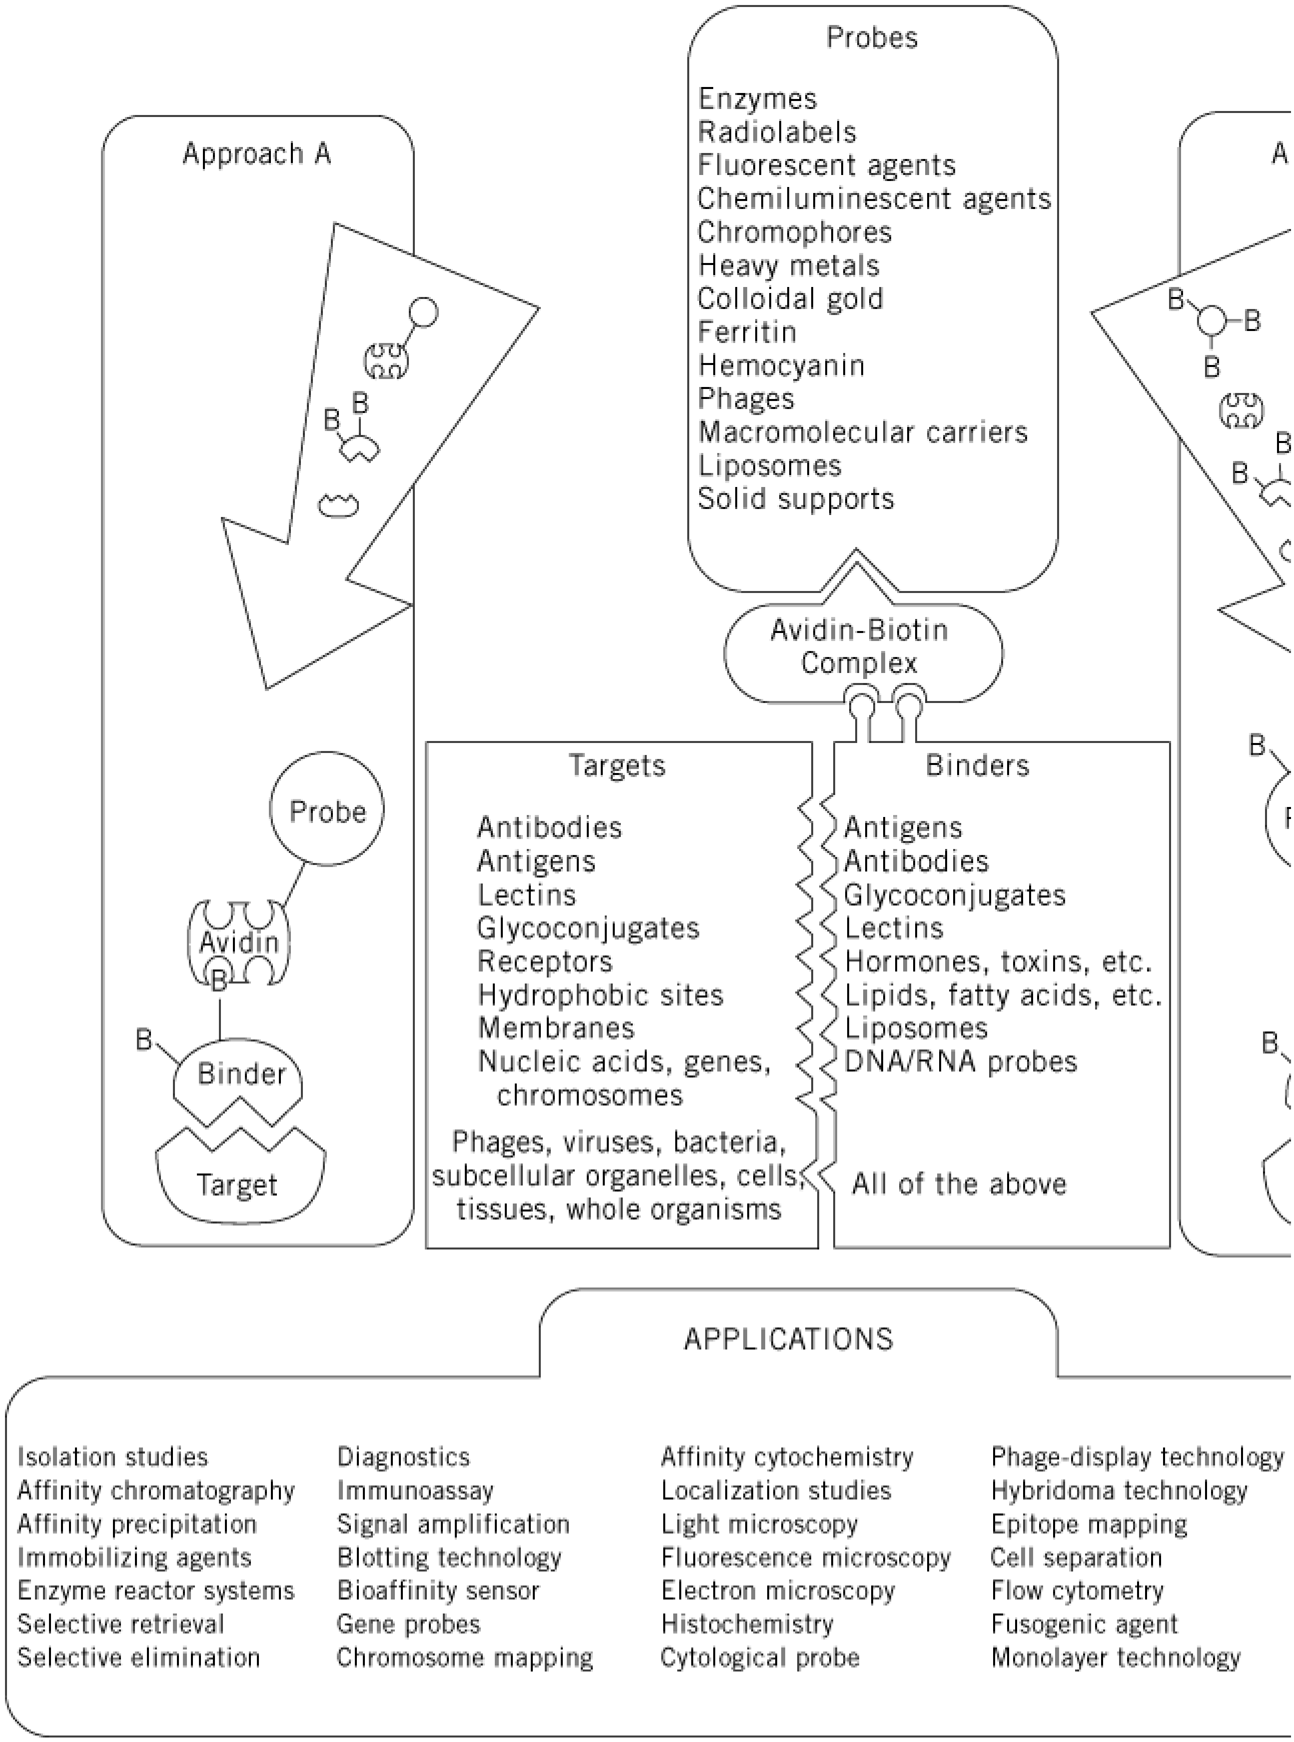
Avidin-Biotin System

The avidin-biotin system has become one of the major mainstays in biochemical analysis and has far-reaching application in biotechnology, industry, and clinical medicine (1). The general idea of the avidin-biotin system is that biotin, a low molecular weight vitamin, can be chemically coupled to other low or high molecular weight molecules (e.g., proteins, hormones, **DNA** molecules, etc.). The biotin moiety is still recognized by avidin or streptavidin, either as the native protein or in derivatized form containing any one of a number of reporter groups or probes. The principle of this system is illustrated in Fig. 1.

Figure 1. Overview of the avidin-biotin system and the two major strategies for the various applications. In both approa desired experimental system is combined with a biotinylated binder molecule. Approach A involves direct interaction wi probe. In approach B, avidin is a sandwich between the biotinylated binder and the biotinylated probe. Various targets, b the applications are listed.



The avidin-biotin system has become a “universal” tool in most of the fields of the biological sciences, because of studies that commenced in the mid 1970s and the constant development that has continued until today (2-6). The system has been applied for a wide variety of purposes (Fig. 1) and has recently been adapted for clinical use for the localization, imaging, and therapy of cancer (7). The binder and the target can be any of the components listed in Figure 1. What is required for this system is the capacity to biotinylate a binding entity so that the specificity and activity of the binding function is retained. For different approaches to biotinylation and the reagents used for binding to different functional groups, see Biotin. As can be seen, most of the functional groups on biological molecules can be modified with biotin.

Because of its charge neutrality and lack of **glycosylation**, streptavidin is generally preferred over egg-white avidin in many applications, although new derivatives of avidin (e.g., Neutravidin) may prove advantageous and less expensive [see Avidin and Streptavidin). The final component added to the system is the probe. The various probes and their potential uses are shown in Fig. 1. The probes are prepared in two ways. They are chemically conjugated directly to avidin or streptavidin (Fig. 1, Approach A) and are **fluorescent**, **radioactive**, or other types of macromolecules (proteins, polysaccharides, etc.). A second approach is to biotinylate the probes and to interact them with streptavidin under subsaturating ratios, thus leaving extra binding sites vacant (Fig. 1, Approach B). More recently, **fusion proteins** have been prepared of streptavidin with different enzymes and native fluorescent proteins.

In many cases, such as **affinity chromatographic** applications, more reversible binding of biotin to avidin would be a distinct advantage. In this context, streptavidin has a critical disadvantage in that the interaction between its subunits is very strong, and it cannot be used when reversibility of the interaction is desired. This is in contrast to avidin, from which an immobilized monovalent form can be produced (8), and the immobilized avidin monomer binds biotinylated compounds reversibly (9).

Site-directed mutagenesis and chemical modification studies are currently being performed on both avidin and streptavidin to understand better their interaction with biotin, the interaction between their subunits, and, perhaps eventually, for better application in the previously-mentioned systems (10, 11). In this regard, the single, critical tyrosine residue of the binding sites of avidin and streptavidin was **nitrated**, and the tetrameric structures of the resultant “nitro avidin” and “nitro streptavidin” were retained (12). The biotin-binding property also had sufficiently high affinity for a variety of applications, including affinity chromatography, enzyme immobilization, and **phage-display** technology (13, 14). The major difference between the nitro avidins and the native molecules is that biotinylated compounds are released by competition with free biotin, and then the latter is liberated by treating the column with basic solutions (pH 10), thereby regenerating the original biotin-binding capacity of the nitro avidin affinity column. Reduced or altered binding characteristics are also conferred on the binding sites of avidin or streptavidin by site-directed mutagenesis of selected binding site residues, such as tryptophans.

Today, the avidin/streptavidin-biotin system is a real necessity in most fields of biological study.

Azurin

Azurins are proteins of bacterial origin that belong to the family of cupredoxins (ie, blue single-copper proteins) as is plastocyanin (1). Azurins consist of a single polypeptide chain that contains ca. 128 amino acid residues (~14 kDa molecular weight) (2). Several X-ray crystallography studies of azurins isolated from various bacteria, as well as of single-site mutated forms, have yielded high-resolution, three-dimensional protein structures (Fig. 1) (1, 3-6). The protein consists of eight b-strands that form a b-sandwich (barrel) structure. A segment between b-strands 4 and 5 lies outside this barrel and contains a short **a-helix** (residues 55 to 67). The copper ion is bound about 7 Å below the protein's surface and is coordinated by five ligands: three equatorial ones [a cysteine(112) thiolate and two imidazoles (His46 and His117)] and two weak ligands in axial positions (the carbonyl O atoms of Gly45 and Met121). This configuration (the carbonyl O atom in Gly45 excepted), is conserved in all known structures of "blue" type 1 (T1) copper sites determined thus far (1).

Figure 1. The three-dimensional structure of azurin. The copper center with its ligands is seen near the top of the molecule. The disulfide bond is found at the opposite end of the molecule.

These protein–metal interactions yield a copper site that has a distorted, trigonal bipyramidal geometry, which may explain the stabilization of the Cu(I) state relative to Cu(II) (7) (see Redox Enzymes). Structure-imposed Cu → L p-backbonding has been proposed to account further for stabilization of the cuprous state, because strong p-interaction with the d_p orbitals results in an increase of the ligand field strength. The oxidation/reduction potentials of the Cu(II)/Cu(I) in azurins (~310 mV) are higher than is generally observed for copper complexes. Studies of several mutant forms in which Met121 is replaced, demonstrated that large **hydrophobic** residues raise the Cu(II)/(I) potential, whereas negatively charged ones lower it (8): The span in reduction potential going from Glu121 to Leu121 azurin is 300 mV, or about half the range of the potentials for the naturally occurring T1 sites. The large increase in reduction potentials caused by substitutions involving bulky hydrophobic side chains at position 121 is rationalized by exclusion by such side chains of water from the metal site or simply by providing a low dielectric environment for the copper ion. In contrast, negatively charged hydrophilic residues or water are expected to stabilize the copper ion in the more positively charged +2 state and thus lower the potential, as is indeed observed. Smaller effects on the reduction potential were observed when mutations were made in other positions. It should be emphasized, however, that a thiolate copper ligand *per se* is not a prerequisite for high reduction potentials (8).

As with all other cupredoxins, azurins are also spectroscopically characterized by an intense blue color and a uniquely narrow hyperfine coupling in the electron paramagnetic resonance (EPR) spectrum (see Electron Paramagnetic Resonance). The intense blue color is due to a

$\pi S \rightarrow Cu(d_{x^2-y^2})$ligand-to-metal charge transfer involving the thiolate ligand as the electron donor; it has a molar extinction coefficient of 4000 to 6000 $M^{-1}cm^{-1}$ (9). This is more than 100 times larger than what is found for simple Cu(II) complexes. A second characteristic property associated with the blue (T1) Cu (II) is an EPR spectrum displaying a hyperfine splitting in the $g_{||}$ region, due to interaction of the Cu(II) nuclear and electron spins, which is unusually narrow (~0.008 cm^{-1}), or approximately 50% smaller than those of inorganic copper complexes. This is attributed to delocalization of the unpaired $Cu(d_{x^2-y^2})$electron onto the Cys(S) *p*p orbital, thus reducing the nuclear–electron interaction (10). The unique spectroscopic properties of the T1 site are most likely related to the electron-mediating function of cupredoxins, and this relationship is a central issue in studies of biological electron transfer proteins (11).

Recent experimental investigations of the electron transfer mechanism by azurin have in part been directed toward the intramolecular process in single-site mutated forms of the proteins (12-14). This was motivated by the finding that azurin provides a useful model system for studies of long-range, intraprotein electron transfer (LRET). One way by which this reaction can be induced is from the half-reduced disulfide bond to the Cu(II) ion (12, 14). Another one is by attaching an extraneous redox center to the protein (11, 13). Results of these studies yielded insights into the mechanisms of intramolecular electron transfer in proteins and the parameters that determine the degree of electronic coupling between electron donor and acceptor. Effective electron transfer in proteins requires minimal reorganization of the redox centers as a result of the process. As described above, the metal ion in the blue copper proteins is coordinated to a site that is intermediate between the preferred geometries for Cu(II) (tetragonal planar) and Cu(I) (tetrahedral) (6). Furthermore, the relatively high reduction potentials provides an increased driving force. Finally, the tightly knit, antiparallel b-sheet structure of azurin probably improves the electronic coupling between the reaction partners through the protein matrix.

B Cell

Specific recognition by the immune system is mediated fundamentally by B and T lymphocytes. These cells derive from the hematopoietic stem cells through discrete differentiation pathways, although both originate in the bone marrow (and in the liver during embryonic and fetal life) (see Hematopoiesis). T cells mature in the thymus, whereas B cells continue to differentiate in the bone marrow itself. B cells express immunoglobulins that directly interact with native epitopes—that is, subregions of an antigen with a well-defined three-dimensional structure. Surface immunoglobulins are associated with a signaling module made of a Iga-Igb heterodimer to form the B-cell receptor (BCR). In contrast to the BCR, T-cell receptors (TCRs) do not interact directly with native epitopes, but they identify peptides derived from the original antigen as presented by molecules encoded by genes of the major histocompatibility complex (MHC).

Both the B and the T cells have to face the repertoire problem—that is, how to generate extremely large number of different immunoglobulins and TCRs to meet the requirements of recognizing an extraordinary large number of discrete epitopes. A theoretical approach suggests that this number might be as large as 10^{17}. Because the total number of lymphocytes in a human adult averages 10^{12} (roughly divided into one-fifth B cells and four-fifths T cells), and taking into account that they are clonally organized, the number of BCRs and/or TCRs expressed at one given time appears much less than 10^{17}, which implies some basic degeneracy in the immune recognition system. Nevertheless, the number of different structures must still be quite large, which therefore raises the problem of how to generate such a large repertoire with, necessarily, a limited number of genes. This is the main challenge for B cells (and T cells as well), to which the way they differentiate brings the answer.

During fetal life, B lymphocytes differentiate in the liver and then in the bone marrow, which remains active throughout life. The first steps of B-cell differentiation take place in the bone marrow, which is a primary lymphoid organ, and drives precursors derived from the hematopoietic stem cells to the immature B lymphocytes. This period of differentiation is antigen-independent and is essentially devoted to generation of the basic immunoglobulin repertoire, which is the result of a complex sequence of events that involve multiple gene rearrangements. Immature B lymphocytes migrate to secondary lymphoid organs, namely spleen, lymph nodes, tonsils, and gut-associated lymphoid tissues, including Peyer's patches. Further differentiation necessitates antigen encounter and a number of complex cellular interactions, among which cooperation between the B and T cells plays a major role. A second round of diversity is then generated, which results mostly from somatic mutations, and the final steps of differentiation, including isotype switching, lead to the emergence of plasma cells and memory B cells. Two discrete lineages of B cells have been well-characterized in the mouse and are designated B1 and B2. B1 cells express the CD5 marker, have a low level of surface IgD, and are mostly encountered in peritoneal and pleural cavities. They seem preferentially responsible for autoantibody synthesis. B2 cells represent the major and conventional B-cell population.

1. From the Hematopoietic Stem Cell to the Immature B Cell

All differentiation events that drive the emergence of the various lineages (granulocytes, erythrocytes, monocytes, megakaryocytes, **lymphocytes**) derive from a common hematopoietic stem cell that originates in the bone marrow. The B lineage presumably initiates from a precursor common to the B and the T lymphocytes. The main features of the molecular and cellular events that take place in the bone marrow and lead to B cell commitment are indicated in Figure 1. Three major subpopulations define the B lineage: proB, preB, and immature B cells. The successive steps of differentiation proceed from the periphery toward the center of the bone marrow and may be followed in several ways: (a) acquisition and/or loss of surface antigens (especially CD markers) identified by monoclonal antibodies, (b) identification of cytoplasmic proteins and/or messenger RNA transcripts, and (c) analysis of the gene rearrangement status for each of the three Ig gene loci: H, L, and K.

Figure 1. B-cell differentiation in humans. Early steps of B-cell differentiation take place in the bone marrow and are an

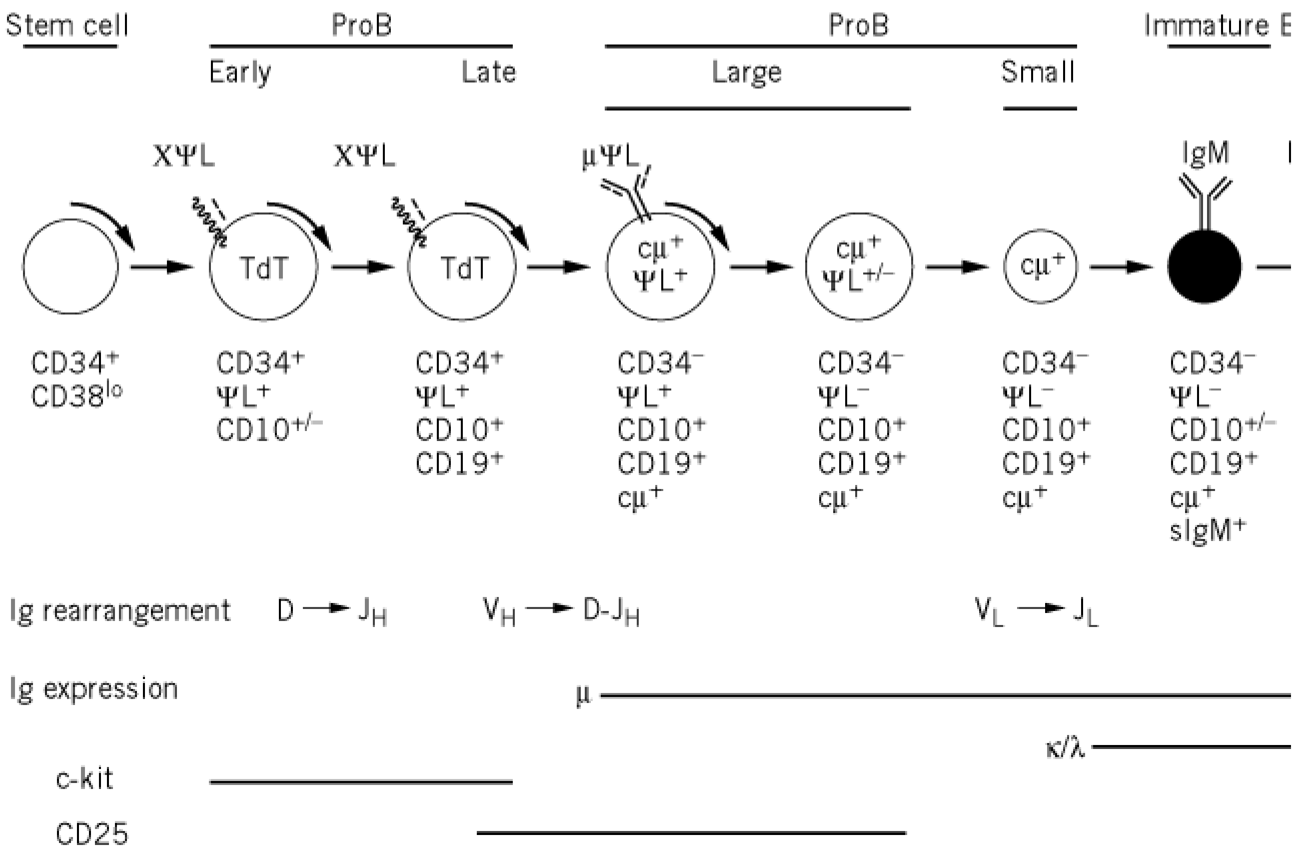
organization plays a key role in mounting a T-dependent B-cell response, during which affinity is tuned upon the acquisi
mutations and the biological functions of the antibodies are adapted by isotype switching. Ultimately, this differentiation
cells that secrete antibodies and in memory B cells that are involved in secondary responses. Each step of differentiation
by various CD surface markers, as indicated.



The first steps of differentiation involve a sequence of direct interactions of the precursors with the stromal cells, ensured by various sets of **cellular adhesion molecule**s (CAMs). The VLA4 integrin expressed at the cell surface of the precursors interacts with stromal VCAM1, and the resulting early proB cells now express Kit, a receptor that binds the stem cell factor of stromal cells. This interaction triggers proliferation of the proB cells, which will continue to differentiate through other stimuli. Late proB cells are stimulated by a soluble growth factor also of stromal origin, **interleukin-**7 (IL-7), which drives proliferation of preB cells. As these steps of differentiation proceed, the cells are dividing, and Ig gene rearrangements that generate the basic repertoire take place in a sequential fashion. CD marker characterization indicates that CD34, which is already expressed in the hematopoietic stem cells, remains present at the surface of precursors and proB cells. Late proB cells can be characterized by the coexpression of CD34 with CD19, which is a very specific marker of the

B lineage because it is found on all subsequent stages, with the exception of the plasma cells. CD10, also known as the common acute lymphocytic leukemia antigen (CALLA), is expressed up to the immature B-cell stage a seems expressed slightly before CD19. Other markers are expressed as differentiation proceeds, such as CD20, CD21, CD22, CD23, and CD24.

2. The Basic Ig Repertoire Develops in the Bone Marrow as B Cells Differentiate

As already stated, the main feature of B-cell differentiation is the acquisition of the basic repertoire of immunoglobulins that becomes expressed as IgM on immature B cells. IgM has the classical H_2L_2 organization, and both the H and L chains have variable and constant regions. The variable regions of the heavy and light chains interact in the antibody combining site, which is responsible for specific antigen recognition. Heavy and light chains are encoded by genes that are localized on three discrete gene clusters, H, k and l, located on chromosomes 14, 2, and 22, respectively. The unique feature of Ig gene organization is that they must be rearranged by the specific recombinases RAG1 and RAG2 (for recombinase activating genes) before becoming functional. The first recombination event, DH to JH, takes place in the early proB cells (see Fig. 1) and is rapidly followed by the rearrangement of one of the V_H segments to D-J. Another enzyme, terminal deoxynucleotidyl-transferase, is also active in proB cells, for which it represents an additional cytoplasmic marker. This enzyme adds nucleotides in a random fashion during the joining of D to J and of V to D-J rearrangements. ProB cells that have rearranged the IgV_H locus must “make” two decisions. One is to remain monoclonal with respect to H-chain production, the second is to activate rearrangement of the light chains. Both events are regulated by the m chain itself, which must be in its membrane form. Once the first allele of the IgH locus has completed the rearrangement process, the resulting gene may be functional or not, depending upon whether the recombination has generated a sequence of nucleotides with an open reading frame. Because of the triplet organization of the genetic code, this happens only once every three rearrangements. If the first rearrangement is out of frame, the second allele will recombine, with the same probability of success. A second failure will lead to cell death. Conversely, once a functional gene has been generated, the resulting heavy chain will exert a negative feedback on a further rearrangement of the IgH locus, ensuring monoclonal expression of the m chain. Much evidence suggests that the heavy chain must be expressed at the cell surface to regulate these events. Expression of the m chain at the cell surface requires that it associate with another partner, which resembles the light chain, and for this reason it is named YL or surrogate light chain. First described in the mouse and then identified in humans, the surrogate light chain is composed of two polypeptide chains, encoded by the l-like (or l5 in the mouse) and the VpreB genes, part of the regular IgL locus. The m-YL complex becomes expressed at the surface of what is now a large preB cell, which also expresses CD10 and CD19, but no longer CD34. The cell is able to undertake light-chain gene rearrangements, which occur in the order k→l. The recombination process is regulated in the same manner as that of the heavy chains, so there is only one light chain that is expressed in any given cell, either k or l (see l) Light Chains). The negative feedback on further rearrangements of the light chain genes is exerted by the complete IgM, which is now expressed at the surface of the immature B cell and has replaced the mYL complex. At this point, the Iga–Igb module is associated with the preB cell complex, strongly suggesting that the mYL complex might be considered a “preB” receptor.

3. Immature B Cells are Selected Before Leaving the Bone Marrow

Before leaving the bone marrow, immature B cells that express surface IgM are confronted with the local “self” antigenic environment. They are particularly sensitive to triggering by multivalent antigens, resulting in their clonal deletion by apoptosis. Alternatively, soluble self antigens do not cause the immature B cells to die, but instead induce an anergic state that does not seem to prevent the cells migrating to the periphery. It should be noted, however, that this negative selection has a threshold that leaves a fraction of autoreactive cells going to the periphery. These cells are responsible for the presence in the bloodstream of natural autoantibodies that must be of some physiological relevance. Once validated by this “quality control,” immature B cells circulate to the periphery through blood vessels and lymphatic system, colonize the secondary lymphoid organs, and actively recirculate. They now have become mature B cells, expressing both IgM and IgD isotypes at their surface.

4. Final Steps of B-Cell Differentiation Take Place in the Periphery and are Antigen-Dependent

The B lymphocytes that are now circulating in the periphery are nondividing, short-lived cells. To achieve their ultimate differentiation, they must be triggered by an antigen, most often T-cell-dependent (Fig. 1). Within the first days after antigenic stimulation and T-cell help, activated B cells may mature to plasma cells that have an abundant endoplasmic reticulum and secrete immunoglobulins. Activated B cells may also evolve to colonize the primary follicle of a lymph node and generate a germinal center, where they interact with follicular dendritic cells, divide rapidly, switch to another isotype, most frequently IgG, and start to accumulate somatic hypermutations that considerably amplify diversity and affinity. Clones of high affinity will be positively selected by antigen and can now progress toward plasma cell differentiation or become long-lived B memory cells.

5. Conclusions

Differentiation of B cells is a highly sophisticated process that takes place continuously in the bone marrow and results in the constant emergence of a very large repertoire of immunoglobulins, expressed both as membrane B-cell receptors (BCRs) and soluble antibodies. The numerous molecular events that lead from the hematopoietic stem cell to the mature B cell are under constant selective pressure, implying a high level of cell death. Therefore, the available repertoire appears, at any given time, to be a compromise between the necessary economy in the gene number, compensated by the recombination processes, and an unavoidable wastage due to the stochastic aspects of gene rearrangements and to the negative selection of clones having a high affinity for self components.

B_{12} (Cobalamin)

Cobalamins are complex organometallic cofactors containing a central cobalt atom that is coordinated equatorially to four nitrogen atoms provided by the corrin ring. The two cofactor forms of this vitamin are *adenosylcobalamin* (AdoCbl) and *methylcobalamin* (MeCbl). A variety of other forms have been described in which the upper ligand is a water, *glutathione*, or cyano group, but the physiological significance of these forms is unknown. In nature, this cofactor is found in association with two enzyme subfamilies, the AdoCbl-dependent *isomerases* that catalyze 1,2 rearrangement reactions and the MeCbl-dependent *methyltransferases* that catalyze transmethylation reactions. Members of both subfamilies are fairly prevalent in the bacterial world, where the isomerases are involved in fermentative pathways, and the methyltransferases are involved in pathways leading to methionine, acetate, or methane. In mammals, only two B_{12}-dependent enzymes are known, the cytoplasmic *methionine synthase* and the mitochondrial *methylmalonyl-CoA mutase*. In this review, the molecular biological aspects of B_{12} biosynthesis, enzymology and diseases will be discussed briefly.

1. B_{12} Biosynthesis

The structural cousins, vitamin B_{12}, heme, and chlorophyll, are constructed from a common template that is derived from the precursor, 5-aminolevulinic acid. Methylation at C2 converts the common intermediate, uroporphyrinogen III, to precorrin-1 and commits it to B_{12} biosynthesis. Thereafter, a biosynthetic assembly line, which includes a series of methylations, ring contraction (between rings A and D), cobalt insertion, alkylation, amidations, and nucleotide loop assembly reactions, takes the cofactor to its final form. Two separate pathways lead to corrin ring biosynthesis in the aerobic and anaerobic worlds (for reviews, see Refs. 1-4). They run parallel at some steps and diverge at others. A unique structural feature of B_{12} is the presence of a nucleotide loop that terminates in dimethylbenzimidazole, which can serve as the lower axial ligand to cobalt. The pathways leading to the assembly of dimethylbenzimidaole in aerobic and anaerobic organisms are distinct, but their details remain to be elucidated (5). The **genes** encoding corrin biosynthesis functions have been **cloned** from *Pseudomonas denitrificans*, where they are organized in clusters scattered along the genome (reviewed in Ref. 3) and from *Salmonella typhimurium*, where they are clustered at 41 min (reviewed in Ref. 2). The transcription factor PocR regulates the transcription of the cobalamin biosynthetic and propanediol utilization (dependent on a B_{12} enzyme) genes in *S. typhimurium* (6, 7).

2. B_{12} Enzymes

The cofactor role of AdoCbl was first described by Barker and co-workers in glutamate mutase (8), followed a few years later by the discovery of MeCbl in methionine synthase (9). B_{12}-dependent enzymes catalyze chemically difficult reactions and manipulate the reactive cobalt–carbon bond in radically different ways (reviewed in Ref. 10). In the methyltransferase subfamily, cobalamin is the initial acceptor of the methyl group donated from substrates such as methyltetrahydrofolate and methanol, and alkyltransfer to and from the cobalamin occurs *via* heterolytic cleavage of the cobalt–carbon bond. In the isomerases, the cobalt–carbon bond is broken homolytically, as the enzymes catalyze 1,2 rearrangement reactions. The migration of a diversity of groups, ranging from carbon (in methylmalonyl-CoA mutase, glutamate mutase, and methylene glutarate mutase) to nitrogen (in ethanolamine ammonia lyase and b-lysine mutase) and oxygen (in diol dehydrase), is catalyzed by the isomerases. The genes encoding a number of methyltransferases and isomerases have been cloned and the structures of the B_{12}-binding domain of the *Escherichia coli* methionine synthase (11) and of the *Propionibacterium shermanii* methylmalonyl-CoA mutase (12) have been determined. In both enzymes, the cofactor is bound in an extended conformation in which the intramolecular base, dimethylbenzimidazole, is removed from the cobalt and replaced by a **histidine** residue donated by the protein. Another important member of the B_{12} family of enzymes is ribonucleotide reductase, which converts ribonucleotides to deoxyribonucleotides (13). The reaction mechanisms of B_{12}-dependent enzymes are discussed in a number of reviews (10, 14-18).

3. B_{12}-Related Diseases

Functional B_{12} deficiency can result from either nutritional insufficiency or from genetic defects (19, 20). It is manifested clinically by a combination of symptoms including hematological and neurological abnormalities, methylmalonic aciduria and homocystinuria, depending on whether one or both B_{12}-dependent enzymes is affected. The genetic defects or inborn errors of cobalamin metabolism can result from impairments in uptake, transport, or enzymatic function and are inherited as autosomal recessive traits. Cobalamin absorption and transport abnormalities resulting from impairments in intrinsic factor, its receptor, or in transcobalamin (TC) II have been described. The cDNA encoding human intrinsic factor (21) and TC II (22) have been cloned and mapped, and genetic defects in TC-II in patient cell lines have been identified (23).

Intracellular cobalamin metabolism is complex, compartmentalized, and dependent on several enzymes. Defects in the early steps following internalization of TC II/cobalamin affect both MeCbl and AdoCbl syntheses and fall into the *cbl* C, D, and F genetic complementation groups. The identities of the proteins encoded by these loci and their precise functions are unknown. MeCbl synthesis is specifically compromised in *cbl*G and *cbl*E patients. Cloning of the cDNA encoding methionine synthase (24-26) and identification of mutations correlated with the *cbl*G phenotype (25, 27) indicate that this locus represents methionine synthase. AdoCbl synthesis is specifically impaired in *cbl*A, B, and *mut* patients. The defect in *cbl*B and *mut* patients is in cobalamin adenosyltransferase and methylmalonyl-CoA mutase, respectively. The cDNA encoding methylmalonyl-CoA mutase has been cloned (28), and a number of pathogenic mutations have been described (29).

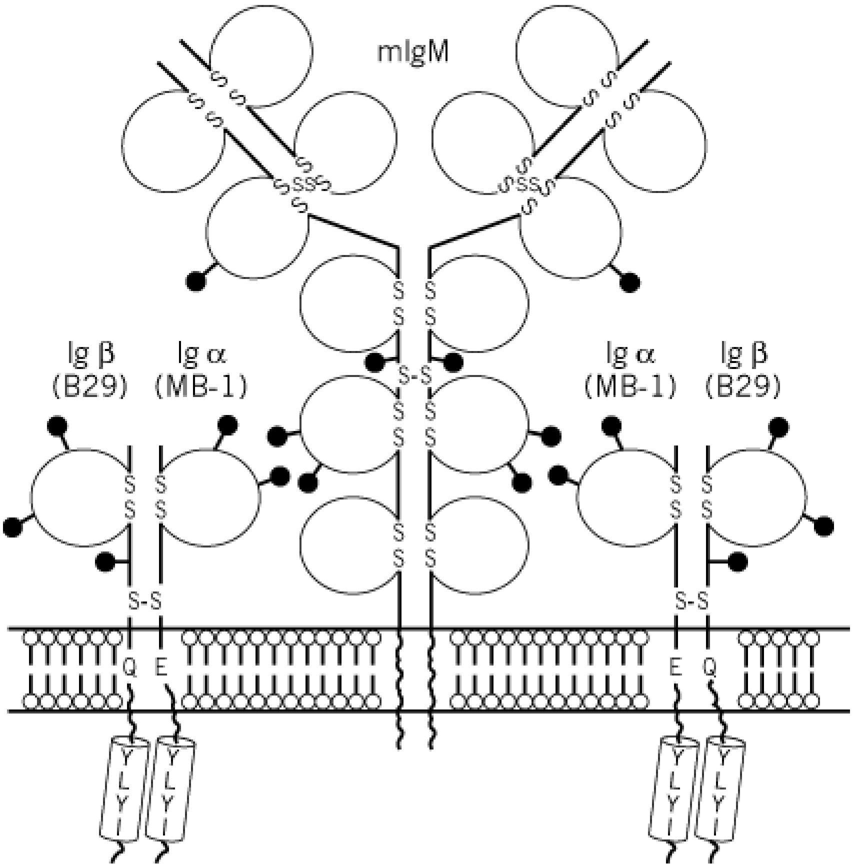
B-Cell Receptor (BCR)

Immunoglobulins can exist as membrane proteins, expressed at the surface of B cells. When B cells differentiate in the bone marrow from the initial hematopoietic stem cells, they reach a stage, called *immature B lymphocytes*, that is characterized by the presence of IgM at the cell surface (Fig. 1). This IgM, which is a basic m2k2 or m2l2 monomer, is anchored into the membrane bilayer by an extra portion at the COOH-terminus of the heavy chains that is not present in the soluble form. Differences in length result simply from the alternative splicing of membrane exons (see Introns, Exons) present in the germline. The **transmembrane** region is terminated by only three amino acid residues located in the cytoplasm of the B cell.

Figure 1. Schematic representation of the B-cell receptor (BCR). The BCR is composed of one antigen binding module, the surface IgM, connected to the signaling module, a heterodimer containing the Iga and Igb, encoded by the MB-1 and B-29 genes, respectively. Note the Ig domain organization of the ectodomains of the Iga and Igb chains that contain in their cytoplasmic part the ITAM (immunoreceptor tyrosine-based activation motif) motifs that play a central role in signaling by contacting intracellular protein tyrosine kinases.



Because the surface Ig clearly acts as a B-cell receptor (BCR) upon triggering by the antigen, the necessity of a signaling module, similar to CD3 in T cells, is apparent. This was indeed the case. The BCR-activating module is a heterodimer composed of one Iga and one Igb chain (also designated as CD79 a and b), each of which has an external Ig-like domain, a transmembrane portion, and an cytoplasmic region that contains several signaling motifs, called *immunoreceptor tyrosine-based activation motif* (ITAM). ITAM were first described on polypeptide chains of CD3 and consist of two Tyr—X—X—Leu/Ile sequences separated by a stretch of seven amino acid residues. They are found in a number of signal transduction modules associated with most crucial receptors of the immune system, such as the T-cell receptor (TCR), BCR, and FcR. Upon stimulation of BCR with cross-linking antigens, ITAM interact with protein **tyrosine kinases** of the **src** family ($p59^{fyn}$, $p53^{lyn}$, $p56^{lyn}$, $p55^{lck}$), leading to the translocation of $p72^{syk}$ to the membrane and activation of the **ras** pathway and **phospholipase C**g2. As a consequence, the BCR is internalized, which is the first step of processing of antigens by B cells. Full activation of B cells require other signals, involving molecules other than the BCR.

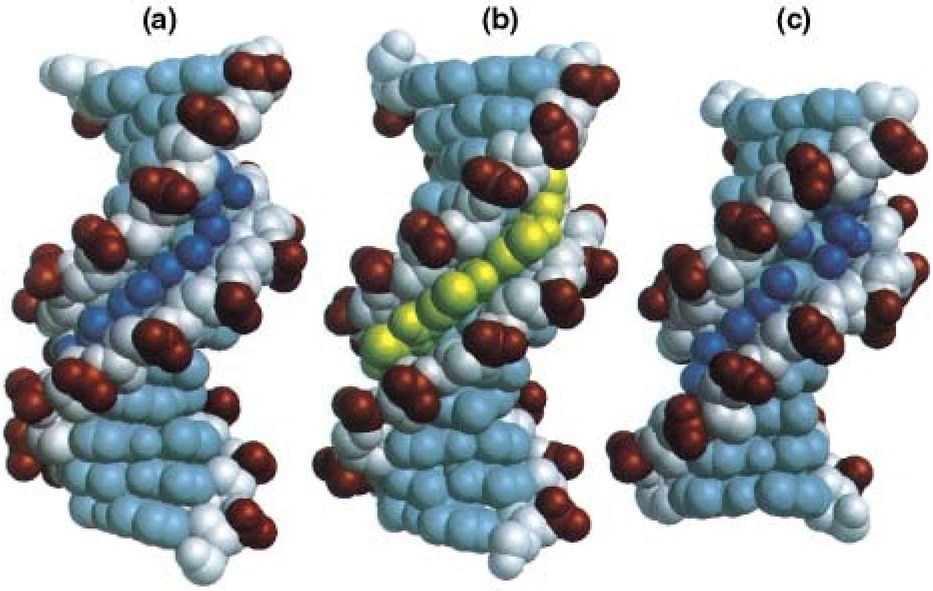
B-DNA

B-DNA is the predominant type of DNA structure under physiological conditions. The B-DNA double helix is right-handed, with its base pairs perpendicular to the helix axis that passes through the center of the base pairs. The major groove and minor groove are roughly equivalent in depth, 8.5 and 7.5 Å, respectively, whereas the width of the major groove is ~12 Å and that of the minor groove is ~6 Å.

The first X-ray crystallography structure of B-DNA (Fig. 1A) was that of a dodecamer sequence d $(CGCGAATTCGCG)_2$ that contains the EcoRI **restriction** sequence GAATTC (1). There are a number of interesting structural features associated with this B-DNA structure. A distinctive feature is that the minor groove is narrower at the AATT region of the double helix than the CGCG ends. The narrow minor groove at the AATT region is filled by a spine of water molecules that form hydrogen bonds to both the O2 of thymines and the N3 of adenines, although this spine of waters has been reinterpreted recently using a higher resolution structural analysis as a spine of waters on sodium ions (2). Additionally the base pairs in the central AATT region of the helix have high propeller twist angles. The propeller twisting enhances the stacking of the bases along each strand of the double helix, and the AT base pairs are in general less restrictive to propeller twisting because of fewer hydrogen bonds than the GC base pairs (3). Lastly, the sugar pucker of the deoxyribose ring favors the C2′-*endo* conformation, although a range of conformations from C1′-exo to O4′-*endo* is also present. This may reflect the greater flexibility associated with B-DNA structures.

Figure 1. Examples of the structure of B-form DNA. (**a**) Crystal structure of the double-stranded dodecamer d (CGCGAATTCGCG) (Protein Data Base BDL084), with the water molecules in the minor groove shown as spheres. (**b**) Crystal structure of the double-stranded d(CGCAAATTTGCG)-distamycin A complex (Protein Database GDL003). The drug displaces the waters in the minor groove. (**c**) Crystal structure of the double-stranded decamer d (CCAGGCCTGG) (Protein Database BDJS30), with the waters bound to the minor groove shown as spheres. See color insert.



The narrow minor groove region associated with the A-T sequences in B-DNA affords an excellent binding site for the minor groove-binding drugs, such as distamycin A, netropsin, Hoechst 33258, Hoechst 33342, and DAPI. The crystal structure and solution structures of the complexes of several DNA oligonucleotides with those minor groove-binding drugs, most of them in 1–1 drug-to-duplex complexes (Fig. 1B), have been determined (4, 5). Those structures revealed that the drug replaces the spine of hydration in the narrow minor groove and stabilizes the DNA structure, without perturbing the overall conformation significantly. The narrow minor groove associated with the central AATT base pairs is essential for the 1–1 binding mode of drugs. The binding energy derives in part from the gain in **entropy** associated with the displacement of the water molecules. The sequence preference for A-T regions by minor groove-binding drugs is due to the greater negative electrostatic potential at the bottom of the minor groove at A-T regions. Finally the presence of N2 amino groups of guanines provides both a charge and a steric hindrance to drug binding.

NMR study of the binding of distamycin A (a pyrrole-containing anti-tumor antibiotic) to DNA containing A-T sequences revealed a more complex pattern. Distamycin A can bind DNA not only in a 1–1 drug/duplex complex but also in a 2–1 mode, with two distamycins bound to the minor groove in an antiparallel, side-by-side manner (6). The latter binding mode requires that the minor groove width at the binding site be expanded so as to accommodate two drug molecules, reflecting the flexibility of B-DNA. This new finding has stimulated an active study in the design of new minor groove-binding compounds that can bind to all four base pairs, (A-T, T-A, C-G, and G-C), with high specificity. It was found that compounds with imidazole-containing units do not have a great discriminating power regarding the recognition toward G/C versus A/T base pairs. However, compounds that combine the imidazole units with the pyrrole units can be designed to possess excellent sequence-specific binding properties. Rules for such designs have been proposed recently (7).

Additional work on the high-resolution crystal structures of several DNA decamer oligonucleotides with “mixed” sequences, including d(CCAGGCCTGG) (Fig. 1C), showed that the minor groove width of those structures in general is wider, but with some variations. Those DNA decamers have a slightly narrow or wide minor groove, depending on the sequence. In general, the A-T regions have a narrower minor groove than the G-C regions. The hydration structure in the groove is dependent on the groove width. It was noted that a single spine of water molecules along the floor of the minor groove is associated with a narrow minor groove, whereas a ribbon of double water molecules, bridging the base edge N or O atom to the O4′ atoms of the sugar ring, is associated with the wide minor groove.

Backbone

Backbone, or main chain, is the general term used to describe the connecting chain in polymers. Different kinds of polymers have different chemical backbones. For example, in proteins the backbone is a polypeptide chain, but **nucleic acids** have a sugar phosphate backbone. The backbone of a polymer, which may adopt a regular structural conformation, is the constant or repeating part of the polymer, as opposed to the attached side chains, which can be variable.

Bacteriocins

Broadly defined, bacteriocins are substances produced by one **bacterium** that adversely affect another. Most of them are **peptide antibiotics** that are synthesized on ribosomes, as in normal **protein biosynthesis**. Others, such as bacitracin and **gramicidin**, are synthesized in bacteria by multienzyme complexes or sequential enzyme reactions (1). In a strict sense, bacteriocin is an abbreviation of bacterial toxin (with antibacterial activity). Many bacterial toxins act against **eukaryotic** cells and are not called bacteriocins. Some of them, however, like **diphtheria**, tetanus or **cholera** toxins, resemble bacteriocins, such as colicins or pyocins, in having domain structures that convey the binding and toxic activities specific to each molecule (2, 3). The current basis for allocating a name to the agent responsible for bacteriocinlike activity produced by **Gram-positive** or -negative bacteria is to adopt some derivation of either the genus or species name of the producer strain, together with an alphabetical and/or numerical code designation specifying that strain. To avoid confusion, bacteriocins that have the same amino acid sequence, irrespective of the species of origin, should have the same name, that first published. There is a wide variety of locations of the genetic determinants of bacteriocins. They can be encoded by conjugative or nonconjugative **plasmids**, by conjugative transposons, or be encoded on the chromosome (4).

Because of the different cell-wall structures of gram-positive or -negative bacteria, their bacteriocins have evolved differently in size and specificity. In gram-negative bacteria, the outer membrane necessitates receptor-mediated antagonistic activities, and very specific proteins are produced with domains for receptor binding, translocation, and activity (see Colicins). In contrast, gram-positive bacteria possess a multilayered peptidoglycan wall without an outer membrane. This favors peptides of small size that penetrate the murein network without receptor binding and specific translocation. Consequently, bacteriocins produced by gram-positive bacteria have a broad host range and are sometimes active on taxonomically unrelated genera. Thus, many of the bacteriocinlike agents produced by gram-positive bacteria kill species other than those likely to have the same ecological niche. Production of antibiotic peptides is the rule in gram-positive bacteria. Proteins the size of colicins are hardly ever encountered. In general the structures of these peptides must be stabilized by posttranslational modifications.

Presently there is a burgeoning interest in bacteriocins because of the possible applications in the food industry (particularly lactic acid bacteria) and as a strategy for preventing certain infectious diseases. This review gives the general features of the main classes of bacteriocins and emphasizes the common features that are beginning to emerge.

An organism that produces a peptide antibiotic must be able to (1) synthesize the antibiotic, (2) export the antibiotic into the extracellular medium, (3) protect itself from the action of the antibiotic, and (4) interact with the sensitive cell and interfere with its growth or survival. This interaction may or may not require entry of the antibiotic into the cell. Such entry is characteristic of some of the better-characterized ribosomally synthesized low molecular weight bacteriocins. For a detailed description of these bacteriocins, the reader is referred to the Suggestions for further reading.

1. Classes of Bacteriocins

A list of representative examples of lantibiotic and non-lantibiotic bacteriocins, together with their organisms of origin and mode of action is presented in Table 1. Four distinct classes of bacteriocins from lactic acid bacteria have been defined (5).

Table 1. Representative Examples of Lanthionine-Containing Bacteriocins

Bacteriocin	Type	Mass	Organism of Origin	Mode of Action (References)

Class I The lantibiotics (lanthionine-containing peptides) are small antibiotic peptides that are distingu content of dehydro and thioether amino acids (lanthionine and 3-methyl-lanthionine) (6). Two their distinctive ring structure. Type A comprises screw-shaped, amphipathic molecules that ha two to seven net positive charges. Type B consists of more globular molecules that have molec charge or a net negative charge. The lantibiotics include a growing list of modified peptides tha bacilli, lactococci, lactobacilli, staphylococci, streptococci, and streptomyces (Fig. 1). The func twofold. First, these small peptide molecules are less likely to achieve stable conformations by they are generally extremely heat stable. Unusual cross-links like the thioether bridge from lan retain their proper folded structure despite their small size (7). Secondly, unusual sidechains, su repertoire of chemical reactivity that is be important for the biological activity of these peptide

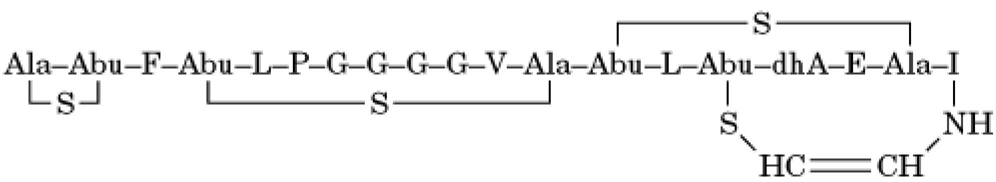
Mersacidin



Class II These bacteriocins are small (<10 kDa), relatively heat stable, non-lanthionine-containing pept been subdivided into Class IIa, *Listeria*-active peptides with the N-terminal consensus sequenc IIb, poration complexes requiring two different peptides for activity; Class IIc, thiol-activated j for activity. Unmodified peptide antibiotics (not containing lanthionine) share several characte prepeptide that has an N-terminal extension (**leader peptide**). Leader peptides are amphiphilic hydrophobic region of the **sec**-dependent exported proteins (see **protein targeting**). The leade particularly at the proteolytic processing site, where two glycine residues are found at position (4, 9). The processed, active bacteriocins contain a substantial amount of **hydrophobic** amino Accordingly, the plasma membrane is the target of most of these bacteriocins. Flanking region **gene** of non-lantibiotic peptides contain additional **open reading frames** for which a function demonstrated or postulated on the basis of sequence homologies. Such genes code for immunit proteins consisting of a histidine kinase and the respective regulator, and for proteins with sign family. Some of these genes have an operon-like organization.

Class III	These bacteriocins are large (>30 kDa) heat-labile proteins that include many bacteriolytic ext muramidases) that mimic the physiological action of bacteriocins.
Class IV	These are complex bacteriocins that contain essential lipid or carbohydrate moieties in additio purified antibacterial components is still necessary to confirm that the presence of the addition biological activity of these molecules, thereby justifying the establishment of this class IV.

1.1. Microcins

An additional class of bacteriocins comprises a family of antibiotic substances called "microcins" produced by diverse members of the *Enterobacteriacae* (10). They are distinguished from the majority of colicins by much lower molecular weight (<10 kDa) and because their synthesis is not induced by conditions that lead to induction of the **SOS repair** pathway. Instead, they are synthesized during the stationary phase, similar to that observed with most conventional antibiotics (11). The microcins were operationally defined as substances produced by gram-negative bacteria that pass through a cellophane membrane and inhibit the growth of an indicator *Escherichia coli* strain (12). Several substances known to be ribosomally synthesized fall within this group. The best known of these antibiotics peptides are microcin C7, microcin B17, and colicin V. Microcin C7 is a heptapeptide containing modifications at both the N- and C-termini that block protein synthesis *in vivo* and *in vitro* (13). Microcin B17 (Mcc B17) is a 43-residue peptide containing posttranslational modifications at the peptide backbone including serine, cysteine, and glycine residues, that result in thiazole and oxazole rings (14). Mcc B17 has much in common with lantibiotics because it is derived from a precursor peptide that is posttranslationally modified; 26 out of the 43 residues are glycine. Mcc B17 inhibits DNA replication and induces the SOS response (15). The target of this antibiotic is a DNA gyrase (16) (see DNA Topology). Colicin V (ColV) was first described in 1925 in the first report of an antibiotic substance produced by *E. coli* (17). It has a molecular weight of only 6000. The structure of mature colicin V is not totally known, even regarding side-chain modifications or N-terminal processing. Colicin V kills sensitive cells by disrupting their membrane potential (18).

2. Biosynthesis and Posttranslational Modifications

Generally the low molecular weight bacteriocins of gram-positive bacteria are first formed in an inactive precursor form that has a leader peptide. Following a variety of posttranslational modification reactions, the C-terminal propeptide domain is cleaved from the N-terminal leader sequence to yield the mature antimicrobial molecule. These prepeptides range from 18 to 30 amino acid residues and are not highly homologous except near the cleavage site. The prepeptides of all non-lanthionine-containing bacteriocins characterized thus far have two Gly residues at positions –2 and –1 relative to the processing site and b-turn promoting residues near the cleavage site. Possible functions of the prepeptide include (1) stabilizing the propeptide during translation; (2) keeping the bacteriocin inactive, particularly after completion of modifications and thus helping to protect the producing strain; (3) allowing recognition of the ABC transporter system; (4) directing the precursor through a specific recognition motif toward biosynthetic enzymes (modification enzymes); (5) interacting with the propeptide region to stabilize a conformation that is essential for correct modification and thioether formation. There is evidence that the modifications of lantibiotics are made at the prepeptide stage. Cross-similarities between leaders of the modified and unmodified bacteriocins indicate that the overall features of leader peptides are important during regulation, synthesis, and generation of the immunity of peptide bacteriocins, regardless of whether or not they are modified.

Table 2. Non-Lanthionine-Containing Bacteriocins

	Mode of Action

Bacteriocin	Type	Mass	Organism of Origin	(References)
Pediocin PA-1	NLC	4600	*Pedicoccus acido lantici* PAC 1.0	Pore formation (58)
Mesentericin Y-105	NLC	3666	*Leuconostoc mesenterides* Y105	Pore formation (59)
Carnobacteriocin A	NLC	5100	Carnobacterium piscicola LV17A	? (60)
Sakacin A	NLC	4308	*Lactobacillus sake* LB706	? (61)
Lactacin F	NLC	5600	*Lactobacillus* sp.	Pore formation (62)
Lactococcin A	NLC	5800	*Lactococcus lactis* (cremoris)	Pore formation (63)

The primary amino acid sequences of the propeptide components of many of the low molecular weight bacteriocins produced by gram-positive bacteria are known now. One important feature of the bacteriocins of gram-positive bacteria is their cysteine content. Those in which one or more cysteine residues are linked to dehydrated serine and threonine residues to form the thioether-linked amino acids lanthionine and methyl-lanthionine are called lantibiotics as previously mentioned (Fig. 1). Alternatively, bacteriocins in which pairs of cysteine residues undergo modification to form disulfide bonds are called cystibiotics (cysteine-containing antibiotics). A third subgroup of the bacteriocins, of which lactococin B is an example, are designated thiolbiotics, because they contain only a single cysteine residue that must be present in the reduced **thiol** form to be active (19). At neutral pH, many of the low molecular weight bacteriocins are cationic. This is a unifying feature of lantibiotic and non-lanthionine containing bacteriocins and may have some significance for their activity.

Little is known about the posttranslational modification reactions and the biosynthetic enzymes involved in the maturation of lantibiotics. The lantibiotic B and C genes (designated *Lan*B and *Lan*C, as stipulated by the 1st and 2nd International Workshops on Lantibiotics) are probably involved in the maturation pathways, because mutation studies indicate that the gene products are essential for producing functional lantibiotics. The products of these genes, designated LanB and LanC, but also known as NisB and NisC, respectively, may be involved in the dehydration and thioether bond formation. Limited similarity was reported between LanB and *E. coli* IlvA, a threonine dehydratase, thus suggesting a similar function (20). This leads to the hypothesis that LanC and other similar proteins are involved in the enzyme-catalyzed formation of thioether bonds from the dehydrated residues and cysteine. Another modification enzyme that has been identified is EpiD, which is encoded by the epidermin gene cluster located on the 54-kb plasmid pTu32 (21). EpiD has no homologue in other lantibiotic gene clusters, and it catalyzes the biosynthesis of the C-terminal aminovinylcysteine residue of epidermin (22).

3. Extracellular and Maturational Release

After biosynthesis, class I and II bacteriocins are released to the extracellular medium. For each bacteriocin there is a relatively specific membrane protein system whose function is to translocate a precursor form of the antibiotic across the cytoplasmic membrane to the outside of the cell. The secretion of several peptide bacteriocins is mediated by dedicated transmembrane translocators belonging to the ATP-binding cassette (ABC) transporter superfamily (23-26). The transporters are encoded in the same operons as the bacteriocin structural gene or on a neighboring operon. The C-terminal ATP-binding domain and the N-terminal hydrophobic integral membrane domain are expressed as a single polypeptide or as separate polypeptides. Recently, strong evidence has been reported that, very likely, all precursor peptides of the lantibiotic and non-lantibiotic bacteriocins that have leader peptides of the double glycine type (see above) are processed by their dedicated ABC-transporters, concomitant with export (27). It has also been proposed that the N-terminal domains of bacteriocin transporters are essential for initial recognition and subsequent proteolytic processing. These new proteolytic enzymes are thiol proteinases. In fact, genes for potential ABC transporters have been found in all the known lantibiotic gene clusters. The lantibiotic transporters range in size from 535 to 714 amino acid residues and generally have the ATP-binding **domain** and the membrane-spanning domain in the same single protein. Sometimes a second ABC transporter system has been identified, which is not essential for production but participates in producer self-protection, thus providing some type of additional immunity (28). Although the leader sequence of the double-glycine type may be cleaved concomitant with export by the ABC-transporter itself, this is not the general case.

The ABC transporters have thiol proteinase activity, and putative proteinase genes (designated P) have been described for the leader peptides of other lantibiotics. These gene products share similarities with **subtilisin**-like serine proteinases. For example, the *Nis*P gene encodes an extracellular serine proteinase with a C-terminal extension anchoring it on the outer side of the cytoplasmic membrane (29). With nisin, it has been shown that cleavage of the leader peptide is not a prerequisite for export by the ABC-transporter, and this conclusion may be extended to other peptides with antimicrobial activity (30).

A detailed maturational pathway has been proposed for nisin (31). First the inducing signal (which could be nisin itself) activates the transcription at the *nis*A promoter (which has features also found in other positively regulated **promoter** sequences) via a two-component response-regulator system (32). This results in the production of pre-nisin containing free cysteines and no dehydrated residues. The pre-nisin is directed, presumably by virtue of the leader peptide, to a membrane-located complex containing the modifying enzymes LanB (probably involved in dehydration) and LanC (probably involved in thioether bonds, as previously mentioned). At this stage, the leader helps to maintain the peptide in an inactive form. Subsequently, the precursor nisin is translocated via the ABC exporter NisT at the expense of ATP hydrolysis. Finally, precursor nisin is activated by proteolytic cleavage by the extracellular protease NisP attached to the outside of the cell envelope. The role of the leader is still not fully understood, apart from its function in producing an inactive conformation. In particular, it is not known how it functions in targeting the pre-lantibiotic to the maturation and export proteins, what its fate is after cleavage, and how it contributes to processes, such as self protection, after it has been cleaved off.

This proposed sequence of events may also apply to other lantibiotics. However, additional intracellular conversions are required in specific modification reactions, such as those involving the N- and C-termini of epidermin (33), lantibiotic Pep5, epilamin K7 (34, 35), and lactocin S (36). In these cases it is likely that the leader peptide cleavage occurs intracellularly.

4. Modes of Action

The various structural properties of the subgroups of bacteriocins are reflected in their three different modes of action. The primary activity of Class I type A lantibiotics is based on forming voltage-dependent, short-lived pores in the cytoplasmic membrane (37, 38). The peptides rapidly induce leakage of ions and small metabolites from bacterial cells and a collapse of the electrochemical proton gradient, leading to cessation of biosynthetic processes and eventually to cell death. Type A lantibiotics require a membrane potential of between 50 and 100 mV for pore formation, depending on the individual peptide. It is assumed that pores are formed by a transiently associated peptide oligomer in a transmembrane orientation (barrel stave model), as suggested for alamethicin. The susceptibility toward a particular peptide of different bacterial species, or even of strains within one species, varies much more than one would expect on the basis of the pore-formation model. *In vivo* pore formation or pore stability may be positively or negatively influenced by such factors as phospholipid composition of the membrane, interactions of the peptides with integral membrane components, or the presence of surface layers. The models may need to be refined, and pore formation may depend on local perturbation of the bilayer (39). In addition, the peptides could exert secondary effects that contribute to bactericidal activity, such as autolysis of cells by activating cell-wall hydrolyzing enzymes (40).

The antibacterial effects of class I type B lantibiotics are rather weak. They bind to the head groups of phospholipids, preferentially to phosphoethanolamine, which may cause membrane permeabilization and allow the release of cations and other small solutes. Duramycin also induces the formation of complex pores (41). Mersacidin and actagardine are distinguished from other type B lantibiotics by their mode of action. Both interfere with cell-wall biosynthesis in gram-positive bacteria, which may eventually offer new possibilities in antimicrobial therapy (42).

Generally, the bactericidal action of class II bacteriocin against sensitive cells is produced principally by destabilizing membrane function, such as energy transduction, rather than disrupting the structural integrity of the membrane. This effect results from the energy-independent dissipation of the proton motive force and loss of the permeability barrier of the cytoplasmic membrane. It contrasts with the energy-dependent bactericidal action of the lantibiotics. In addition, before pores are formed, all of the non-lanthionine containing bacteriocins interact with membrane-associated receptor proteins, in contrast to class I lantibiotic bacteriocins.

5. Immunity of Bacteriocin-Producing cells

One of the definitive features of bacteriocin-producing cells is their ability to resist the action of their own inhibitory substances through a specific immunity mechanism. Such a mechanism is based on dedicated peptides or proteins called immunity proteins, which specifically antagonize the bacteriocin. For nisin and subtilisin, their antagonist proteins of 245 and 165 amino acid residues, respectively, display the features of bacterial lipoproteins and are similar in amino acid sequence. Despite the high degree of similarity of these lantibiotics, there is no cross-immunity between producing cells. In other cases, as with pepS, the immunity is much more closely related to the immunity systems of unmodified bacteriocins, which are short, have only 69 residues, and have a hydrophobic N-terminal segment and a strongly hydrophilic C-terminal part.

Currently, there are no clues to the mechanism of the immunity phenomenon. The proposed location of the peptides outside the cell and the observation that the cytoplasmic membrane of immune clones is not depolarized by externally added bacteriocin suggest that the bacteriocins are directly antagonized by the immunity peptide, like colicin A, for example (43).

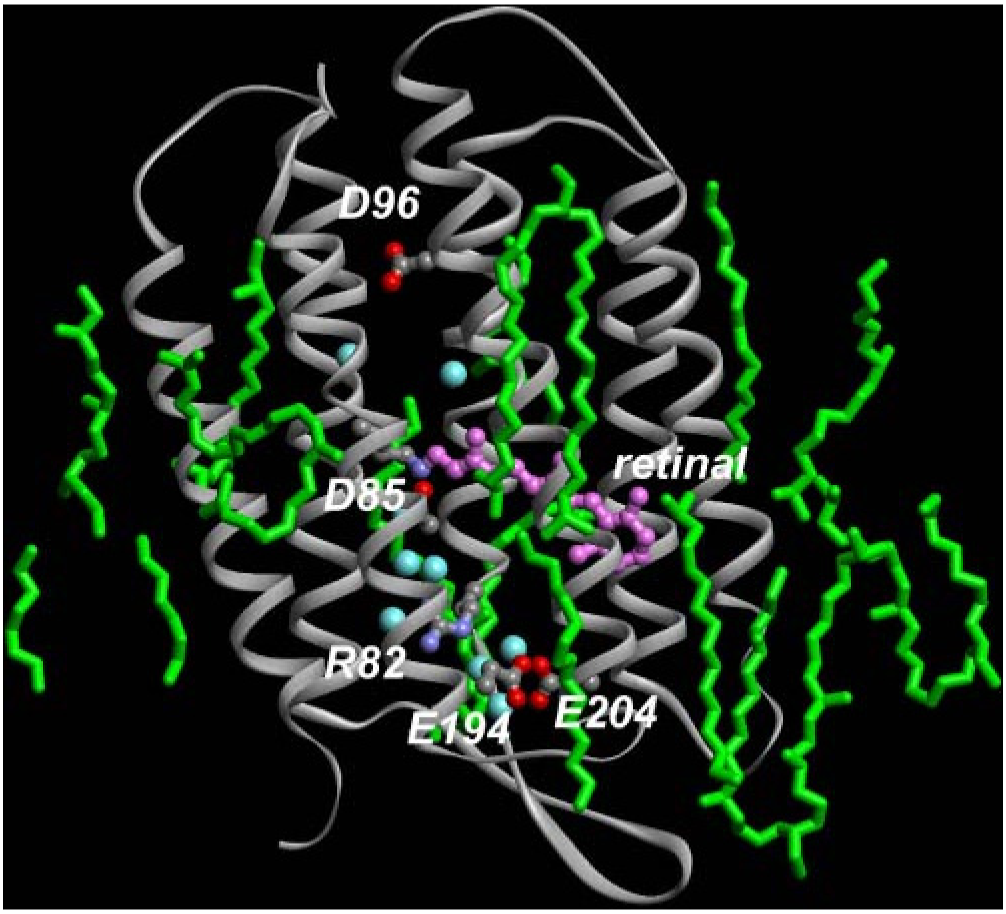
Bacteriorhodopsin

Bacteriorhodopsin is a small (26 kDa) integral membrane protein, the prototype of seven-helical **G-protein**–linked **receptors**, that upon illumination transports protons across the membrane. It forms extended two-dimensional hexagonal arrays in the cytoplasmic membrane of **halobacteria**. Its transmembrane a-helices surround the **prosthetic group** retinal, which is linked via a Schiff Base to Lys216 near the middle of helix G and lies at a small angle to the membrane plane. Photoisomerization of the retinal from all-*trans* to 13-*cis* sets off a sequence of thermal reactions (the "photocycle") in which the interaction of the retinal and the protein causes proton transfers between various donor and acceptor groups. Together, these transfers result in the complete translocation of a proton from the cytoplasmic to the extracellular surface, thus generating a transmembrane electrochemical gradient for protons. The proton gradient is utilized in the way usual in **bacteria** for the synthesis of ATP, the uptake of nutrients (amino acids) and K^+, and the transport of Na^+ out of the cells (see Proton Motive Force).

Bacteriorhodopsin forms trimers that assemble in the two-dimensional hexagonal array that constitutes the patches termed "**purple membrane**." The purple membrane contains only bacteriorhodopsin and lipids, and the regular crystalline lattice made it possible to determine its structure by cryo-**electron crystallography** at 7 Å (1) and then 3 Å (2) resolution. The protein was also crystallized from a lipid cubic phase, and its structure has now been determined by X-ray crystallography at 2.5 Å resolution (3). The protein consists of seven transmembranous a-helices, with short interhelical loops and short N and C termini. Three of the helices, B, C, and D, are normal to the plane of the membrane and the other four, A, E, F, and G, are inclined at various small angles to the perpendicular (Fig. 1). The retinal is bound to the ε**-amino group** of Lys216, forming a protonated Schiff base near the middle of helix G, and its polyene chain lies at about 23° from the membrane plane. Thus the Schiff base divides the protein into extracellular and cytoplasmic halves.

Figure 1. Structure of bacteriorhodopsin (1), and the pathway of proton transport. The seven transmembranous a-helices are shown, along with only the all-*trans* retinal and the most important residues. The curved arrows identify the proton transfers that occur at different times in the photocycle (see text) and add up to the complete transport of a proton from the cytoplasmic (upper) to the extracellular surface of the membrane.

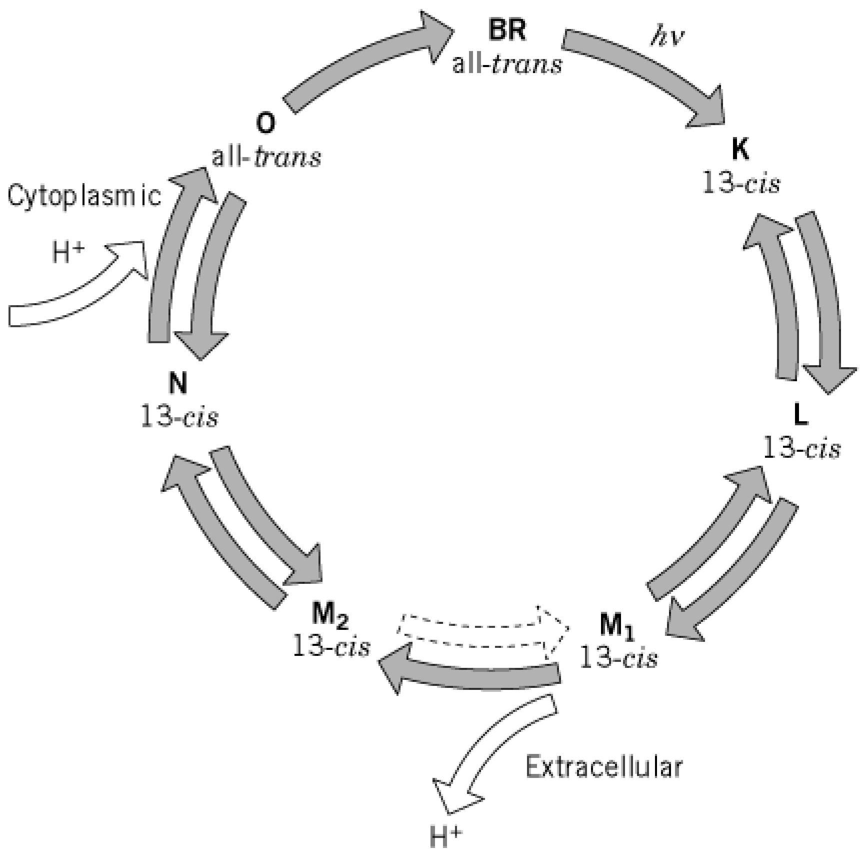


The trajectory of the transported proton from one surface to the other is through proton-conductive "half-channels" through each of the two halves of the molecule. Identification of the residues that participate in the two half-channels has been the objective of much research in the past few years. The extracellular half-channel is quite complex and contains polar and hydrogen-bonding residues. Many of them play roles in the release of protons to the extracellular surface. Asp85 and Asp212 are anionic residues located near the Schiff base. A possible pathway for protons leads from Asp85, via Arg82, Glu204, and Glu194, to the extracellular surface and is consistent with functional studies. Another plausible pathway is through Glu9 or Glu74, but the results of mutagenesis indicate that these two residues are dispensable. The cytoplasmic half-channel is simpler. It contains mostly **hydrophobic** residues between the retinal and Asp96, which is the proton donor in the reprotonation of the Schiff base. Thr46 is close enough to interact with Asp96, and mutagenesis confirms its significant role in the proton donor and acceptor function of Asp96. Acidic residues at the cytoplasmic aqueous interface include residues 36, 38, 102, and 104. It has been suggested that they form a "funnel" at the surface that directs protons into the cytoplasmic half-channel (2). Although immobilization of the protein in the purple membrane is responsible for the well-known, extraordinary thermal and photostability of bacteriorhodopsin, neither the trimeric arrangement of the monomers nor the rigid lattice structure have functional roles in the transport activity (4). Thus, availability of the structure of bacteriorhodopsin, even at the current limited resolution, has generated considerable insights into the proton transport mechanism and has provided the framework for mechanistically interpreting a wealth of spectroscopic information.

The chromophore with all-*trans*, 15-*anti* retinal has a broad **absorption** band with a maximum at 568 nm. This is considerably red-shifted from that of retinal in isolation (380 nm) or a retinal analog with a protonated Schiff base (440 nm). This red-shift results primarily from the diffuse counterion to the charged Schiff base, which comprises principally Asp85 with a contribution from Asp212, which is several angstroms removed and providing only partial compensation of the charge (5). The all-*trans* chromophore exists in thermal equilibrium with the 13-*cis*, 15-*syn* configuration, which absorbs at 555 nm. Sustained illumination converts the retinal to 100% all-*trans*, 15-*anti*, known as "light-adaptation" (6). The photoreaction of this isomer is normally active in transport.

The photocycle of the all-*trans* chromophore is described by the intermediate states J, K, L, M, N, and O, their substates, and the sequence of their interconversions (Fig. 2). Each intermediate is characterized by a distinct absorption maximum in the visible wavelength region, numerous vibrational bands of the retinal in the infrared and Raman region and of the protein in the infrared region (see Vibrational Spectroscopy). The kinetics of the photocycle describe the sequence and the energetics of the chemical reactions that translocate protons across the membrane. In the K intermediate, which arises on the nanosecond timescale after decay of the excited state, the retinal assumes a twisted 13-*cis*, 15-*anti* configuration, as indicated by high-amplitude hydrogen-out-of-plane vibrations. Its absorption maximum is red-shifted by 30 to 40 nm from the initial state. It is converted in about one microsecond into the L state, which absorbs at 540 to 550 nm. In L, the polyene of the retinal is more relaxed, but other changes begin to appear in the protein in both the extracellular and cytoplasmic regions (7). The Schiff base forms stronger hydrogen bonds that are correlated with structural changes of bound water detected in the infrared wavelength region. One of these water molecules is bound to the Schiff base, Asp85, and Asp212 and may play a role in the pK_a shifts that result in proton transfer from the Schiff base to Asp85. The hydrogen bonding of two other water molecules near Asp96 are also affected in L, suggesting that the structural changes near the Schiff base are transmitted all the way across the protein to the cytoplasmic region.

Figure 2. The photocycle of bacteriorhodopsin. The intermediate states are shown, and the isomeric configuration of the retinal is indicated. The Schiff base is protonated in all but the M states.



The M state is formed by transfer of a proton from the retinal Schiff base to Asp85 (8). It has a strongly blue-shifted absorption maximum at 410 nm. The kinetics of this conversion, measured at visible and infrared wavelengths, suggest that L is in equilibrium with an early M state, M_1, and that the mixture of L and M_1 decay together to form the late M state, M_2 (9-11). At pH > 6 this occurs in a unidirectional reaction, and thus L disappears as M_2 is formed. At pH < 6, however, the $M_1 \rightarrow M_2$ reaction is not unidirectional, and both L and M_1 remain present and coexist with M_2 because at the higher pH a proton dissociates from a site in the extracellular region that interacts with Asp85. This site is either Glu204 or depends on the carboxyl group of Glu204. Its proton is passed to Glu194 and is released from there to the extracellular surface. The anomalous titration properties of Asp85 indicate that the nature of the interaction between the proton affinities of this aspartate residue and the proton release site is such that either may be protonated but not both (12, 13). When Asp85 becomes protonated by the Schiff base, the pK_a of the proton release group is lowered, and the proton dissociates. When this proton is released to the bulk solution at a pH greater than the pK_a for the release, the pK_a of Asp85, in turn, is driven higher, and deprotonation of the Schiff base becomes complete. This prevents reprotonation of the Schiff base from the extracellular direction.

Reprotonation of the Schiff base is from the cytoplasmic direction by Asp96 (8, 14), which produces the N intermediate that absorbs near 560 nm but with a lower extinction than the initial state. Large-scale protein conformational changes in N are evident from a pair of negative and positive difference features in the infrared spectrum that originate from a shift of the amide I band (15). Electron and X-ray diffraction studies of the M and the N states, measured either at various times after flash illumination and freezing or in a photostationary state at ambient temperature, indicate considerable changes of conformation at the cytoplasmic surface. The most conspicuous of these is an outward tilt of the cytoplasmic end of helix F (16). Its occurrence in the M intermediate may be transitory during the M → N conversion of the unperturbed wild-type photocycle, but this feature is clearly observable when M is stabilized in the wild-type or in mutant forms of the protein. The movement of helix F as a rigid body is confirmed by distance measurements using pairs of spin labels (17). The effects of osmotic agents, humidity, and in-plane cooperativity in the purple membrane lattice on the M → N reaction and on the protein conformation change suggest that the rationale of the helical tilt is to increase the hydration of the cytoplasmic region and thereby to decrease the pK_a of Asp96. Thus, Asp96 becomes a proton donor to the Schiff base. The tilt of helix F is recovered during decay of the N state, presumably recovering the initial high pK_a of Asp96 and causing its reprotonation from the cytoplasmic surface.

Reisomerization of the retinal to all-*trans* occurs in the N → O transition (18). This is made possible by the lowered barrier-to-bond rotation in the polyene chain upon protonation of the Schiff base. Residues that contact the chain near the 9-methyl and 13-methyl groups, such as Trp182 (19) and Leu93 (20), facilitate the reisomerization, probably through steric interactions that transmit residue displacements in the protein to the retinal and vice versa. The O state has a strongly red-shifted maximum at visible wavelengths, at least partly because Asp85 is still protonated. Consequently, the main component of the counterion to the protonated Schiff base is lacking. Large-amplitude hydrogen-out-of-plane vibrations indicate that, as in the K state, the retinal chain is twisted. These features disappear in the final O → BR reaction, which appears to be limited by the rate of proton transfer from Asp85 to the still unprotonated proton release site (21). As expected from the recovery of the low initial pK_a of Asp85, this reaction is unidirectional under all conditions, and it ensures the full repopulation of the initial state and also the functioning of the **proton pump** against large transmembranous proton gradients.

Bacteriorhodopsin is one of three types of similar retinal proteins in halobacterial membranes. Their functions are all based on the photoisomerization of all-*trans* retinal to 13-*cis*, 15-*anti* and the protein reactions that accompany the thermal reisomerization. Halorhodopsin is an inwardly-directed, light-driven chloride ion pump. It lacks Asp85 and Asp96, and the retinal Schiff base does not deprotonate during the photocycle (22). Sensory rhodopsins I and II are receptors for phototactic behavior (23). A profound similarity in the mechanisms of these proteins with different functions is indicated by the fact that their activities are interconvertible with minimal perturbations. Thus, the Asp85Thr mutant of bacteriorhodopsin binds chloride, exhibits a photocycle similar to that of halorhodopsin, and transports chloride from the extracellular to the cytoplasmic direction (24). Halorhodopsin, in turn, transports protons when the weak acid, azide, is added, by binding near the Schiff base and functioning as a proton acceptor (25). Sensory rhodopsin I transports protons like bacteriorhodopsin when the transducing protein that is normally tightly bound to it is genetically deleted (26, 27).

BAL 31 Nuclease

The enzymes commonly referred to as BAL 31 nuclease have been widely used for manipulation of nucleic acids, most frequently through their ability to shorten both strands of double-stranded DNA from the ends in a controllable manner. Other activities include endonucleolytic attack on double-stranded DNA in response to the presence of a variety of covalent and noncovalent alterations in DNA structure (eg, DNA-carcinogen adducts and junctions between right- and left-handed helical regions) and highly processive unidirectional exonucleolytic degradation of single-stranded DNA.

1. Source and Some Physical Properties

BAL 31 is the strain designation given the original isolates of the marine bacterium that produces the nucleases, which was originally determined to be a species of *Pseudomonas* (1) but was reclassified as *Alteromonas espejiana* (2). The **nuclease** activity was discovered adventitiously as a contaminant in preparations of the *Alteromonas* bacteriophage PM2, but these enzymes proved to be bacterial products secreted into the culture medium (3, 4). The common name also appears as BAL31 and BAL-31; all should be used when searching electronic databases.

The bulk of the nuclease activity in culture supernatants is owing to two molecularly and kinetically distinct forms, both of which are active as single polypeptide chains (5). The smaller of these, designated the "slow" (S) form, is produced by **proteolysis** of the larger, "fast" (F) form, which in turn derives from an even larger precursor that has not been characterized (6). *Alteromonas espejiana* copiously produces extracellular proteinase activity (6), which accounts for the progressive conversion of larger to smaller species in the culture fluid as growth proceeds. At least the S species is not a fully homogenous protein, because its N-terminal amino acid is not unique; either the presumed endoproteolytic event that generates this species from the F form does not occur at a unique site or there is exoproteolytic activity as well. Conversion of the F form to a species indistinguishable in molecular size and catalytic properties from the S form can be done by proteolysis *in vitro* (6).

The American Type Culture Collection strain of this organism (ATCC 29659) is suitable for production of the nucleases. No overproducing strains, either of *Alteromonas* itself or of heterologous hosts containing **cloned** nuclease **genes**, have been reported. Purification procedures that effect separation of the S and F forms have been described (5) and modified (6). BAL 31 nuclease is available commercially from several sources, but these products are mixtures of the S and F species. A partial amino acid sequence of an internal fragment produced by cleavage with cyanogen bromide has been obtained (7). This new sequence did not have significant homology with any reported sequences. Some physical properties of the S and F forms are presented in Table 1 (5).

Table 1. Some Physical Properties of F and S Forms of BAL 31 Nuclease

Molecular Weight (kDa)	Isoelectric pH	Molar Absorption Coefficient(10^5 liter/mol-cm)	Weight Absorption Coefficient(dl/g-cm)
F 109.0	4.2	1.10 ± 0.09	10.2 ± 0.8
S 85.0	4.2	1.00 ± 0.03	11.7 ± 0.3

2. Reactions Catalyzed

Five activities appear to account for the degradation—ultimately to mononucleotides—of DNA: (1) a 5′ → 3′ exonuclease activity that acts on single-stranded DNA in a highly processive manner (ie, many nucleotides are removed in a single productive enzyme-substrate encounter) (8); (2) a 3′ → 5′ directed exonuclease activity that acts only on duplex structures, leaving a 5′-terminated single-stranded "tail" (9); (3) an endonuclease activity against single-stranded DNA, (much slower than the exonuclease activity on single-stranded DNA [8]), that is also elicited by a variety of covalent or noncovalent distortions or lesions in duplex DNA (3-5, 10-14); (4) an exonuclease activity that can excise a small number of nucleotides starting from the site of a strand break (nick) in duplex DNA (15), which is inferred to be 5′ → 3′-directed; and (5) an activity that can remove short 3′-terminated tails from otherwise duplex DNA. The F and S forms differ greatly in the rates of removal of nucleotides, at given molar concentrations of DNA ends and enzyme, via the 3′ → 5′ exonuclease action on double-stranded DNA, which led to their "fast" and "slow" designations (5). The two forms have comparable kinetic behavior toward single-stranded DNA (5, 8).

The BAL 31 nucleases also catalyze the terminally directed hydrolysis of double-stranded RNA and degrade RNA that contains nonduplex structure (16). Whether an analog of the endonuclease activity on altered duplex DNA exists has not been determined, except that cleavage probably occurs in response to a strand break in duplex RNA.

The 5′ → 3′ exonuclease activity on single-stranded DNA is highly processive, as the nucleases are able to degrade DNA polymers of nearly 500 nucleotides in length completely without dissociation of enzyme from substrate (8). The much larger (5,400-nucleotide) f**X174** DNA did not appear to be degraded processively, however, so there may be limits to the number of nucleotides removed in a single productive enzyme-substrate encounter (5). The values of V_{max} and the turnover number (k_{cat}), on the basis of the rates of internucleotide bond hydrolysis, are similar for the 500-nucleotide polymer described above and the minimal DNA substrate, a dinucleotide diphosphate (8). The kinetic data appear to require a **facilitated diffusion** mechanism for the activity on macromolecular substrates, in which nuclease molecules bind randomly and diffuse along the contour of the chain until a 5′ end is located, at which time catalysis can begin (8). This apparently was the first example of a requirement for facilitated diffusion in an enzymatic reaction.

The 3′ → 5′ exonuclease activity on duplex DNA and the 5′ → 3′ exonuclease activity on single-stranded DNA can account for the progressive reduction in the length of duplex DNA. Above certain nuclease concentrations, short 5′-terminated single-stranded tails from the 3′ → 5′ exonuclease activity are evident in partial digests (9). If 3′-terminated tails are present, they cannot be more than a few nucleotides in length. The 5′ tails have a limiting length, at the higher enzyme concentrations examined, of about 7 nucleotide residues when about 100 nucleotides are removed by the 3′ → 5′ exonuclease activity. Up to 50% of the ends could be joined in DNA Ligase reactions under conditions favoring the joining of fully base-paired ends. This indicates that the 5′ → 3′ exonuclease activity on single-stranded DNA can terminate at the junction between single- and double-stranded regions, to leave fully based-paired ends on a significant fraction of molecules in a partially digested population. **DNA polymerase**-mediated repair, to render ends with 5′-terminated tails fully base-paired, markedly increased the fraction of ends joinable by DNA ligase, as expected (9).

As the nuclease concentrations were decreased below those mentioned above, the average length of the single-stranded tails per 100 nucleotides removed increased dramatically, and the ligase-mediated joining of ends in the absence of polymerase-mediated repair became undetectable. This apparent dependence on the concentration of the enzyme of the relative velocities of two exonuclease reactions that it catalyzes has not been explained. The velocity of the overall reaction to shorten DNA, as measured by the hyperchromicity associated with the hydrolysis of internucleotide bonds, is proportional to enzyme concentration, as expected (17). Repair of ends generated at the low nuclease concentrations noted above with DNA polymerase rendered a high percentage of the molecules ligatable (9).

There must be an activity that can remove short 3′-terminated protruding single-stranded tails from duplex DNA, because the nuclease readily degrades such starting substrates (9). No evidence exists, however, for 3′ terminally directed hydrolysis of single-stranded DNAs (8).

The value of the Km(Michaelis constant), in terms of the molar concentration of DNA ends, for the overall exonucleolytic shortening of duplex DNA by the S form is so large that it is not practical for the substrate concentration to approach it in actual reactions. Consequently, the enzyme velocity is directly proportional to substrate concentration over the accessible range (18). A value for this K_m was reported in earlier work (5), but it appears to have been determined under conditions for which the substrate concentration did not exceed that of the enzyme, violating a premise of Michaelis-Menton-based kinetics. Kinetic parameters (V_{max} per unit concentration of nuclease and K_m) for the length reduction of duplex DNA by the F form can be measured accurately, because the K_m value is much lower than for the S form and lies in the range of experimentally accessible concentrations of DNA ends. More recent values (18) are in reasonable agreement with the earlier data (5).

These kinetic parameters for the F nuclease depend on the length of the DNA substrate (7) (not determinable for the S form as noted). This has been shown (7) to be consistent with a model in which nonspecific binding of the nuclease away from the ends is followed by a “search” process to form a productive enzyme-substrate complex, with the enzyme bound to a terminus, as for the degradation of single-stranded DNA. However, such a mechanism is not required by the kinetics as in the case of single-stranded DNA (noted in the text above).

The kinetics of length reduction of duplex DNA are also dependent on its guanine + cytosine(G + C) content (7, 18). This is significant in the case of the S form of the nuclease, for which the rate of nucleotide removal from DNA ends decreases over fourfold over the range of 37–66 mole% G + C residues. This dependence is somewhat less for the F enzyme. Data are available to predict these effects of DNA base composition on the kinetics (18).

In contrast to the high processivity for the 5′ → 3′ exonuclease action on single-stranded DNA noted earlier, the 3′ → 5′ exonuclease is quasi-processive, removing only about 18 and 28 nucleotide residues per productive binding event for the S and F enzymes, respectively (9).

The length reduction of duplex RNA (16) presumably proceeds by a similar mechanism but has not been characterized. The BAL 31 nucleases are the most efficacious enzymes known for the controlled length reduction of duplex DNA, and they are apparently the only enzymes that can catalyze this reaction for duplex RNA.

Duplex DNA is not attacked endonucleolytically (away from an end) at a significant rate unless there is some alteration of the duplex structure. Hence, nonsupercoiled, closed circular duplex DNA (form I° DNA) is extremely resistant to attack by the BAL 31 nucleases (11, 13, 14). The very limited attack on form I° DNA at high enzyme concentrations and long incubations (14), plus the kinetic parameters for exonucleolytic degradation of linear duplex DNA, lead to estimates of the relative rates of introduction of endonucleolytic breaks to exonucleolytic scissions of 8×10^{-11} and 7×10^{-12} for the S and F enzymes, respectively.

Negative supercoiling in closed circular DNA can elicit the endonuclease activity (12). In the majority of molecules of such supercoiled DNA, an endonucleolytic event (cleavage in one strand) is followed by the removal, in a processive manner, of several nucleotides (6.5 and 2.8 nucleotides for the F and S forms, respectively) from the initially nicked strand, to yield a gapped circular DNA intermediate (15). A fraction contain only a strand break, and no nucleotides are excised. The percentage of molecules with no nucleotides removed is significantly lower for the F nuclease than for the S species. The nicks and gaps are bounded by 5′-phosphoryl and 3′-hydroxyl termini. It is assumed that other alterations that result in endonucleolytic attack give rise to such gapped circular intermediates.

The removal of a small number of nucleotides could be accomplished exonucleolytically, starting from the site of the initial nick. Or, there could be a second endonucleolytic cut a few nucleotides away from the first one; the short oligonucleotide between endonucleolytic breaks would dissociate at room temperature to leave a gap. Available evidence supports the exonucleolytic mechanism. It was reasoned that the presumed exonucleolytic activity producing the gaps should be 3′ → 5′–directed, as the exonucleolytic activity attacking base-paired ends has this characteristic. However, this proved to be inconsistent with the results of further experiments carried out assuming the 3′ → 5′ mode of attack; the 5′ → 3′ attack is thus inferred. Because this activity operates on nominally duplex DNA, it might be expected that it could remove nucleotides in a 5′ → 3′ direction from fully based-paired ends, to leave 3′-terminated single-stranded ends. It was noted that, if these are present, they could not be more than a few nucleotides in length, but this does not rule out very limited activity comparable to that producing the gaps.

The nicked and gapped circular DNA intermediates are then converted to linear duplex DNA by a second endonucleolytic event in the other strand, which requires a second encounter with a nuclease molecule (15). The resulting linear duplex DNA is further degraded by the mechanism noted in the text above. As expected, circular duplex DNA containing a nick introduced by means other than BAL 31 nuclease action is converted to linear duplex DNA, with the occurrence of gaps of the average sizes noted above in most of the circular molecules before their linearization (15).

3. Effects of Solvent Variables and Denaturing Agents

Both Ca^{2+} and Mg^{2+} at concentrations above 10–12 mM are required for maximum activity on both single- and double-stranded substrates (9). All activities are optimal near neutral pH (4, 9). The nucleases are remarkably resistant to inactivation at elevated salt concentrations (4, 10). The reaction buffer in which most of the work described above was done contained 0.6 M NaCl). This salt tolerance is not surprising, considering that sea water is the natural milieu of these extracellular enzymes.

High concentrations of agents that normally **denature** proteins fail to eliminate the nuclease activities. Single-stranded DNA is degraded at 40% of the maximum rate in 6.5 M urea (4), and substantial activity on this substrate was found in the presence of 6 M **guanidinium** chloride. Crude preparations maintained activity against both single- and double-stranded substrates in the presence of 5% (w/v) SDS (3). At least a portion of the structure of the S nuclease does not become disrupted under the stringent denaturation conditions used for denaturing SDS-PAGE (6).

The nucleases are not remarkably resistant to thermal inactivation, as the half-life for disappearance of the activity on single-stranded DNA is only 3–5 minutes at 50°C (7). However, tests on preparations stored at 4°C imply that most of the activity should be retained for years in a buffer containing 5 mM Mg^{2+} and Ca^{2+} (4). Commercial preparations are often supplied in 50% (v/v) glycerol for storage at –20°C , under which conditions they should retain full activity indefinitely.

4. Applications

By far the most extensive use of the BAL 31 nucleases, represented by hundreds of literature citations, has been the controlled length reduction of linear duplex DNA. The bulk of these reports describe the production of deletion mutants and/or the elucidation of sequences required for a particular biological activity of a (usually) cloned DNA segment. Cloned sequences can be deleted unidirectionally by cleavage of the vector containing the cloned insert at a unique restriction site on one side of the insert (see Restriction Enzymes), carrying out a partial BAL 31 degradation, releasing the shortened insert from the shortened vector by use of a restriction site on the other side of the insert, and ligation to an intact linearized vector DNA (19).

Numerous reports have appeared of BAL 31 nuclease-mediated identification of **telomeric** sequences, which occur at the ends of linear eukaryotic chromosomes and hence are degraded first by the exonuclease in intact DNA; Yao and Yao (20) and De Lange and Borst (21) apparently represent the earliest work. Where these DNAs are too large to isolate as intact molecules in solution, in situ lysis in agarose has been used (22) so that the initial substrate DNA is largely intact.

The progressive removal of sequences from duplex ends allows the determination of the restriction map of a DNA, either naturally linear or linearized at a unique site, by noting the order in which fragments from subsequent digestion with the restriction enzyme in question disappear from gel electrophoresis patterns of progressively shortened aliquots (19, 23). This technique is greatly enhanced if unidirectional deletions can be done, as noted above (19), as ambiguity arising from loss of sequences from both ends of the fragment is eliminated. The sites of bound proteins, including nucleosomes, and interstrand crosslinks that block the exonuclease can be elucidated because intact duplex sequences between such sites will not be attacked (24, 25).

The endonuclease activity that cleaves in response to alterations in duplex structure has been used in several laboratories to detect such alterations. This attack will be followed by cleavage of the other strand and exonucleolytic attack from the ends thus generated, as noted in the text above. Where chemical modification is done, form I° DNA is used (this requires that the modification does not introduce nicks), and the rate of its loss on incubation with nuclease is monitored. Some of the chemical lesions that give rise to endonucleolytic attack are pyrimidine dimers and possibly other photoproducts of ultraviolet irradiation, adducts with carcinogens such as *N*-acetoxy-*N*-2-acetylaminofluorene and *N*-methyl-*N*-nitrosourea, interstrand cross-links produced by reaction with nitrous acid, apurinic sites, and adducts with Hg^{2+} and Ag^{+} ions (11, 13, 14). Strand breaks were noted in the text above as eliciting cleavage of the opposite strand. Noncovalent alterations eliciting endonucleolytic attack include moderate degrees of negative supercoiling and very high degrees of positive supercoiling (12), junctions between right-handed B-DNA and left-handed Z-DNA regions (10), the presence of unpaired nucleotides in one strand of an otherwise duplex DNA (26), and cruciform structures resulting from the extrusion of inverted repeated sequences under supercoiling stress (27, 28). **Matrix attachment sites** for **nucleolar** DNA are apparently sensitive to the nuclease (29). Finally, the lack of sensitivity of form I° DNAs has been used to help identify such species in DNA populations (30).

Balbiani Ring

The polytene chromosomes of insects have extraordinary utility in the investigation of **chromosomal** structure and function. Polytene chromosomes display the phenomenon of puffing in which the chromatin associated with chromosomal bands is decondensed. In the larval salivary glands of the midge *Chironomus*, several puffs become very large and are described as *Balbiani rings* . Balbiani is the cytologist who discovered polytene chromosomes in 1881. The visible aspect of a puff is essentially the complex of **RNA** and protein that accumulates as a result of vigorous **transcriptional** activity. Among the gene products encoded by the Balbiani rings are the glue proteins required to attach the midge pupa to its substrate. All of the Balbiani ring genes are expressed coordinately and maximally during the second larval instar. Then they show differential expression in prepupae (1). The most detailed ultrastructural analysis has been performed on Balbiani ring 2 in chromosome IV of *Chironomus tentans*. Although the polytene chromosome band itself contains more than 470 kbp of DNA, the major gene is 37 kbp long and contains two very well-defined transcription units that are differentially expressed at the prepupal stage. Electron microscopy detects the first engaged **RNA polymerase** molecule at the approximate start site of transcription and the last RNA polymerase at the site of termination (2, 3). Within each puff, the Balbiani ring gene forms a loop of transcriptionally active chromatin with attached ribonucleoprotein complexes. As synthesis proceeds, the nascent transcripts fold up into compact ribonucleoprotein complexes that head toward the **nuclear pores** when they are exported to the cytoplasm. Each 37-kb pre-mRNA transcript is processed in the nucleus by staged association with specific proteins (4).

Contour measurements of chromosomal structure in the puff indicate that the chromatin is fully extended into an array of nucleosomes 10 nm in diameter at the site of transcription, whereas once transcription is completed, chromatin coils back up into a 30-nm diameter fiber, which is then finally packaged into a supercoiled loop. Upstream of the start site of transcription is a region free of nucleosomes, presumably corresponding to the **promoter**, and compacted chromatin fibers are further upstream and downstream of the gene. Immunologic analysis allows defining the structural components of chromatin on active and inactive segments of the Balbiani ring. Surprisingly, proteins, such as histone H1 and the core histones, remain on chromatin even while it is actively transcribed (5). Thus keen observation allows a rather complete ultrastructural picture of the transcription process.

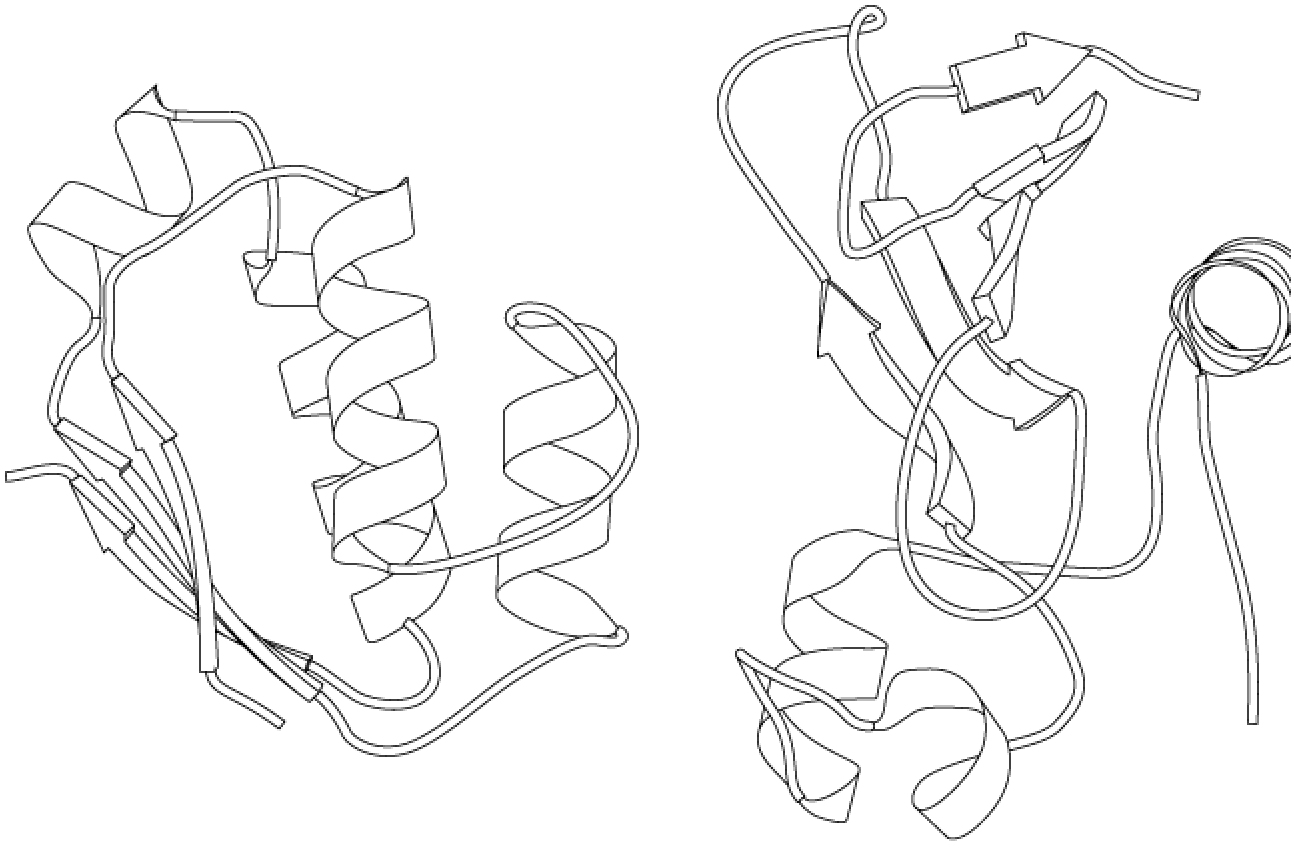
Barnase and Barstar

Barnase is a **ribonuclease** secreted by the bacterium ***Bacillus*** *amyloliquefaciens*. It is a small protein of 110 amino acid residues with no disulfide bonds or nonpeptide components (see Protein Structure). As such, it was recognized in the early 1960s to be an ideal subject for the then-emerging study of **protein folding**. Its specific inhibitor, barstar, is produced intracellularly by the same organism and is an equally simple and even smaller protein of only 89 residues. Together they form a two-subunit complex in which the active site of barnase is buried, providing a model system for the study of protein–protein interactions. The system has contributed substantially to our understanding of how proteins fold and interact and has potential for further uses.

The three-dimensional structures of both proteins and their complex have been determined (Fig. 1) (1). The genes for both proteins have been **cloned** into **plasmid vectors** in ***Escherichia*** *coli* and the expressed products obtained in high yield. Expression of barnase alone is lethal, so simultaneous expression of barstar is necessary for production of barnase.

Figure 1. Molscript (1) representation of the structures (**a**) barstar and (**b**) barnase in their complex.



(a) (b)

The catalytic mechanism of barnase and its relatives is essentially the same as that of the pancreatic ribonuclease family (see **Ribonuclease A**), with a histidine and a glutamic acid residue acting respectively as proton donor and acceptor, in place of the two histidines of the latter. The barnase active site lies in a broad groove on the side of the b-sheet opposite the major **a-helix** (see Fig. 1). In the complex, which has a **dissociation constant** on the order of 10^{-14} M, barstar completely blocks the active site, with most of its contacts involving its second helix and an adjacent loop. An aspartic acid carbonyl group of barstar occupies the position of the attacked phosphate group of substrate RNA. The rate at which barnase and barstar associate is controlled largely by charged groups, positive on barnase, negative on barstar. Mutation to alanine of any of these charged residues reduces binding but increases the stability of each protein, indicating the evolutionary balance between function and stability.

Both barnase and barstar may be unfolded reversibly by heat or by **denaturants** such as urea or **guanidinium chloride** (see **Protein unfolding**). Both fold and unfold in a highly **cooperative** two-state manner; that is, only the native and unfolded states are significantly occupied at **equilibrium** under most conditions. During the kinetics of folding, however, barnase passes through an observable intermediate state. In this it exemplifies the behavior of most larger proteins or protein **domains** (see **Protein folding**). Barstar, on the other hand, appears to collapse more directly to the folded state, as do most other smaller proteins. Studies of barnase folding, using kinetic and equilibrium techniques and site-directed mutagenesis, have traced the order in which its parts come together to form the native fold and have estimated the free energies of various interactions in several states that occur during folding.

Barnase is a member of a large family of microbial ribonucleases that share the same basic tertiary structure but have quite divergent sequences; this provides a wider system for approaching the central problem of how the fold is determined by the sequence (see Protein Structure Prediction).

The homologous ribonucleases of the *Streptomyces* share less than 25% sequence identity with barnase, but the structure of the active-site region is so well conserved that these enzymes are also inhibited by barstar, with dissociation constants as low as 2×10^{-12} *M*; consequently, coexpression of barstar permits the high level expression of the cloned genes for these enzymes as well. As the *Streptomyces* also produce barstar homologues, it seems clear that the extreme structural conservatism of the active site of the ribonucleases is based on the strict requirement of strong binding to the inhibitor.

Separate from the continuing application of barnase and barstar as small model proteins to general problems of protein structure and chemistry are more recent uses of their genes that take advantage of the toxic effect of barnase expression in tissues of heterologous organisms. Under control of a specific **promoter**, expression of the barnase gene can ablate cells under conditions or in tissues where the promoter is turned on. This property is being applied, for example, in studies of development, strategies against **viruses**, design of a conditionally lethal selective **cloning vector**, and, most spectacularly, in the development of male-sterile **plants**. In the last instance, male sterility can be reversed by inclusion of the barstar gene.

There have been several efforts at **computer simulation** of aspects of barnase folding and unfolding, and more can be expected. The continued application of directed mutagenesis, physical chemistry, and computer modeling to the folding mechanisms of barnase and barstar and their homologues will provide insight into the manner in which the sequences of these two interdependent families of proteins determine their native folds. *In vivo* use of the barnase gene, with its lethal effect limited to specific conditions or tissues, will be useful to developmental biologists and should have many practical applications in agriculture and possibly in medicine as well.

Barr Body

In eutherian (placental) mammals, **dosage compensation** mechanisms operate in female cells to silence one of the two **X-chromosomes**, so that female cells have as many X-chromosome-derived transcripts as male cells containing a single X-chromosome. This **X-chromosome inactivation** process was first proposed by Mary Lyon (1961) and is known as the **Lyon hypothesis** (1). Female mammalian embryos begin development with two active X-chromosomes, but very early in embryogenesis almost all of the genes on one of the two X-chromosomes become inactivated Random X-Inactivation). Although the initial choice between inactivation of the maternal or paternal X-chromosome is random, once established in a repressed state the same X-chromosome are inactivated after every cell division. The inactivation process occurs over the entire chromosome, and practically all of the genes on the chromosome are silenced. This transcriptional inactivation is concomitant with the chromosome taking on the appearance of **heterochromatin** and also becoming late replicating during **S phase** (see Facultative Heterochromatin). Only a small fraction of the inactive X-chromosome, including the genes located in the pseudoautosomal region at Xp22.3, escapes the global silencing process (2). The inactive chromosome remains in the nucleus and can be detected cytologically as a *Barr body* in somatic cells (3). The Barr body is found only in cells containing more than one X-chromosome, if cells are trisomic for the X-chromosome, two Barr bodies will be detected. The staining procedures used to detect Barr bodies argue for a global difference in chromatin condensation (4). Differences in staining of heterochromatin compared to transcriptionally competent **euchromatin** may be caused by differences in compaction or differences in the association of many more accessory proteins in heterochromatin (5).

The use of advanced microscopy and molecular **cytogenetics**, in which fluorescent ***in situ* hybridization** is used to "paint" chromosomal territories, has recently allowed detailed dissection of chromosomal organization (see Denaturation Mapping. Light microscopic optical serial sectioning of the active and inactive X-chromosome territories reveal that they occupy similar volumes. However, reconstructed active X-chromosomes have a flatter shape and a more extended, folded surface area than the inactive X-chromosome (6). The conclusion is that the differential staining properties of the Barr body are caused mainly by the association of a distinct group of accessory proteins and RNA with this inactive chromosome (see X-Chromosome Inactivation).

Even on the active X-chromosome, most of the chromatin is not transcriptionally active. Thus, on both the inactive and the active X-chromosomes, the great majority of the chromatin is maintained in a folded state typical of a transcriptionally repressed state. There are, however, global differences in chromatin organization between active and inactive X-chromosomes. The inactive X chromosome has high overall nucleosomal density—i.e., it carries a higher "concentration" of all histones, including the unusual variant macroH2A, than all autosomes or the active X (7). This likely contributes to the optical density of the Barr Body as visualized microscopically. The Barr body contains methylated DNA, hypoacetylated histones, a specialized structural RNA (Xist), and is late replicating during the S phase. Association with Xist RNA is an important causal factor in X-inactivation, and somehow leads to the selective hypermethylation of the inactive X, which results in deacetylation of chromatin assembled over it and transcriptional quiescence. The three-dimensional distribution in the nucleus of Xist RNA coincides with the chromosomal territory occupied by the inactive X-chromosome (8). Even after removing bulk chromatin in the preparation of a nuclear matrix (which is responsible for the overall morphology of the nucleus), the Xist RNA remains in the matrix. This is consistent with the hypothesis that Xist RNA has a structural role in establishing the inactive X-chromosome territory. The Barr body still has a great deal to teach scientists about the molecular mechanisms that establish and maintain nuclear compartments.

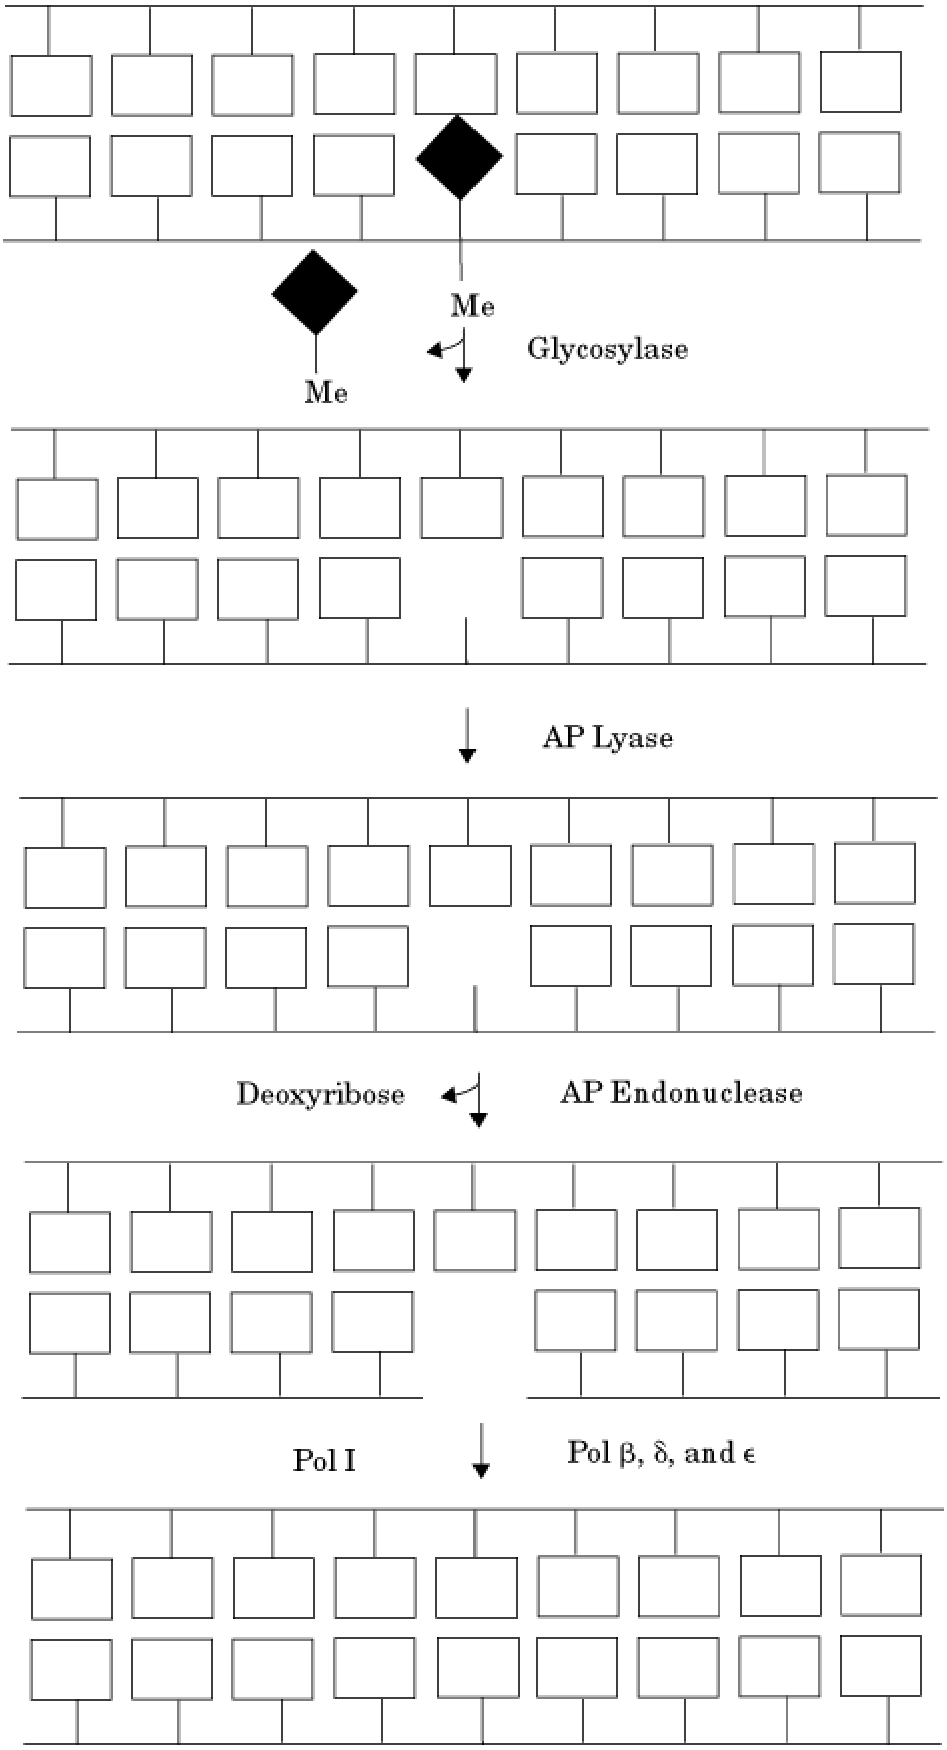
Base Excision Repair

Base excision repair is the DNA repair system for abnormal bases in DNA, such as uracil, hydroxymethyluracil, and hypoxanthine, and for nonbulky base modifications, such as thymine glycol and hydrates, 8-hydroxyguanine, O^4-methylthymine, and 3-methyladenine (Fig. 1). The abnormal bases and simple base lesions are removed from DNA by the combined actions of DNA glycosylases (1-3) and AP (apurinic/apyrimidinic) endonucleases. The basic reaction carried out by glycosylases is the cleavage of the glycosylic bond joining the base to deoxyribose. Some of the glycosylases cleave both the glycosylic bond and the phosphodiester bond 3′ to the resulting AP site in a more or less concerted reaction. Hence, DNA glycosylases have been classified either as "pure" glycosylases or as glycosylase/AP lyases. AP endonucleases are also classified as either 3′- or 5′-AP endonucleases. All 3′-AP endonucleases are lyases that cleave the phosphodiester bond by b-elimination. The 5′-AP endonucleases carry out true hydrolysis.

Figure 1. Repair of 3-methyl adenine by base excision repair. Methyladenine DNA glycosylase cleaves the glycosylic bond of the alkylated base; this releases the alkylated base and leaves an AP site. An AP lyase and an AP endonuclease cleave 3′ and 5′, respectively, of the AP site, releasing the abasic sugar. The resulting gap is filled in by Pol I in *E. coli* and by Pol b or Po ld and e in humans, to produce repair patches of 1 to 10 nucleotides.



The combined actions of glycosylase, AP lyase, and AP endonuclease/exonuclease creates a one- to two-nucleotide gap in the damaged strand. This gap is filled in by **DNA polymerase** I in *Escherichia* *coli*, and mostly by DNA polymerase b (4) and to a lesser degree by DNA polymerases d and ε in yeast and humans (5). The resulting nick is ligated by DNA Ligase in *E. coli*, and in eukaryotes by the ligase I– (6) or ligase III–XRCC1 complex (7). Depending on the polymerase/ligase combination involved in filling in and sealing the gap, a repair patch of 1 to 10 nucleotides may be produced.

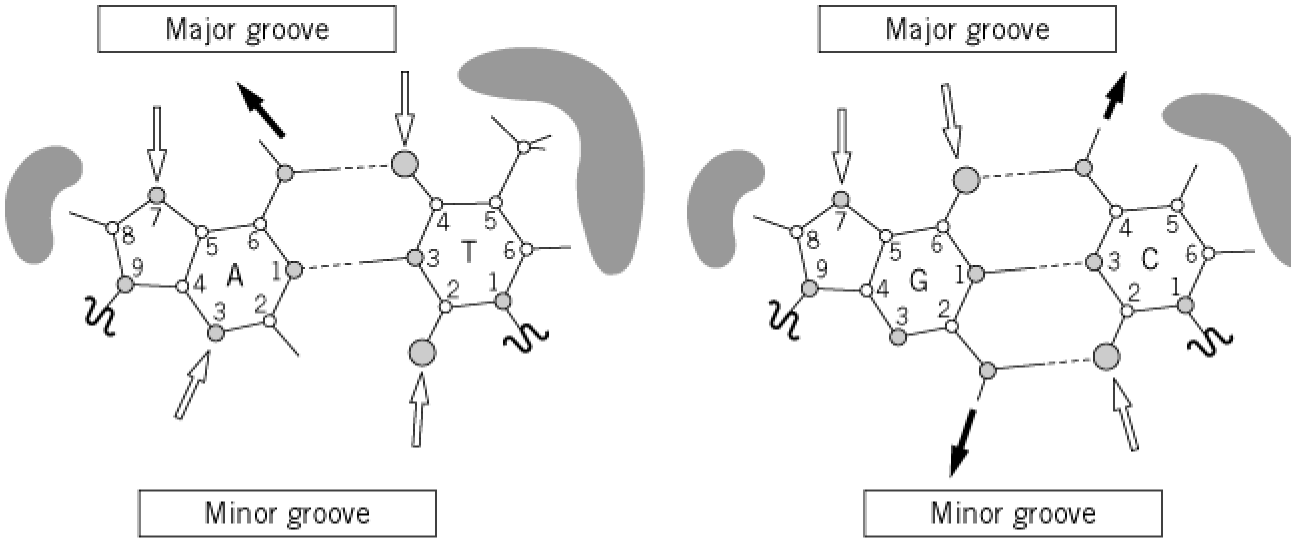
Base Pairs

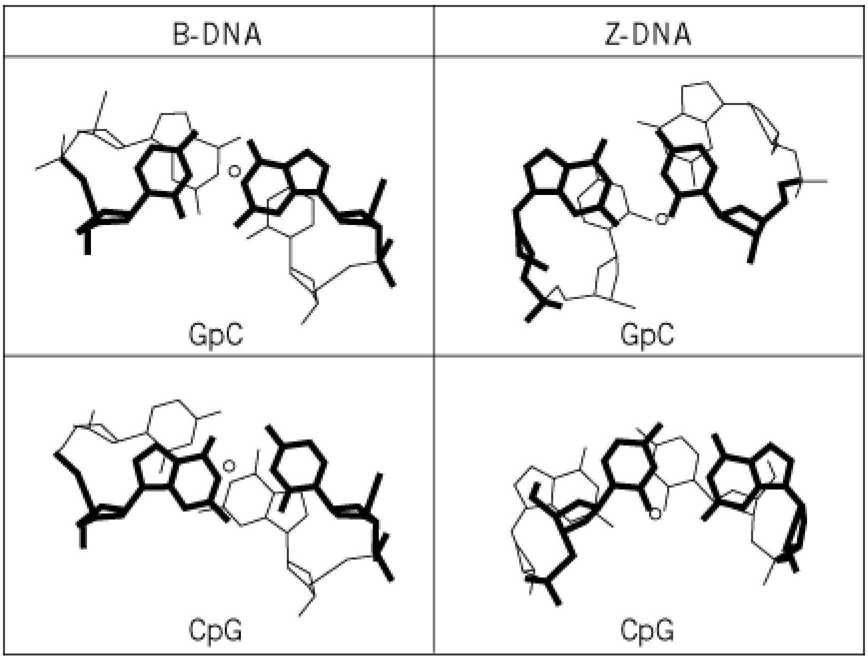
DNA exists predominantly as an antiparallel double-stranded helix. The two strands are helically coiled, which maximizes the exposure of the negatively charged sugar–phosphate backbone to water and shields the **hydrophobic** aromatic bases in the middle from water. Figure 1 shows the Watson–Crick base pairs in which the specificity of base pairing is provided by hydrogen bonds. The complementary arrangements of hydrogen bond donors and acceptors allow the Watson–Crick base pairing of guanine with cytosine (G:C) and adenine with thymine (A:T). The two C1′ atoms within a G:C base pair and an A:T base pair are equidistant (~10.5 Å). It should be noted that other types of base pairs are also known to exist, and they often are involved in unusual DNA structures.

Figure 1. Schematic illustration of the A:T and G:C Watson–Crick base pairs. Hydrogen bonds are shown as dashed line Hydrogen bond donors (gray arrow) and acceptors (white arrow) of the bases are shown. Note that the bases can pair in more than one way. Hydrophobic edges of the base pairs are emphasized by gray shade. The major and minor groove edges of the base pair are shown.



Bases in a DNA double helix are stacked on top of each other. The stacking interaction is stabilized by the electronic p━p interaction of the aromatic rings, and it also minimizes the exposure of the bases to the solvent. The base stacking has preferred interactions, depending on the characteristic dipole–dipole interactions between adjacent base pairs. Thus, the stacking patterns vary with the helix type and the particular base–base step. In B DNA, the 5′-purine-*p*-pyrimidine-3′ (Pu-Py) base-pair step has a good stacking overlap, and is thus more stable, whereas the 5′-pyrimidine-*p*-purine-3′ (Py-Pu) base-pair step has a poor stacking overlap, and is thus less stable (Figure 2). Such differences in stacking energy have strong implications in the bendability of DNA associated with protein binding. It has been noted that DNA sequences with Py-Pu steps in B-DNA are deformed more easily; therefore steps such as CpG, TpA, or TpG (=CpA) are often associated with kinked DNA structures.

Figure 2. Stacking interactions in B-DNA (left) and Z-DNA (right) showing Pu-Py step stacking (top) and Py-Pu step stacking (bottom). The circle shows the position of the helix axis. Note that the Py-Pu steps (including CpG, TpA, and CpA (=TpG)) in B-DNA have very small stacking interactions, causing those steps to be easily deformed.



Through the high resolution X-ray structures of DNA oligonucleotides, it has been found that base pairs within a DNA duplex (or other structures) have significant departures from a strict coplanar geometry. The conformational parameters associated with the DNA base pairs are defined in Figure 3. For a more complete definition, the reader is referred to the Cambridge Convention (1).

Figure 3. Definitions of various base pair conformations. (upper two rows) or two successive base pairs (bottom row). In the top row the motions of the bases are coordinated, while in the middle row their motions are opposed. The left, center, and right columns describe rotations about the *z*, *y*, and *x* axes, respectively. The standard coordinate frame is defined at the upper left.

Base-Pair Substitution

These mutations of DNA affect only one base pair at a time, possibly producing either amino acid substitutions or chain termination codons in a gene (see Genetic Code). Amber (UAG), ochre (UAA), and UGA codons will all terminate polypeptide synthesis (see Stop Codons). Amino acid substitutions often produce leaky and/or **temperature-sensitive** mutations, whereas chain-terminating mutants are usually nonleaky. It has been suggested that there is an important difference between the consequences of frameshift and base-pair substitution mutations in diploid organisms. Frameshifts are often **recessive**, whereas base-pair substitution mutations may exert partial **dominance** (1).

Freese (2) divided base-pair substitutions into two classes, *transitions* and *transversions*. Transitions are mutations in which the purine–pyrimidine orientation is conserved; that is, a purine is replaced by another purine, a pyrimidine by another pyrimidine. The eight possible transversion mutations in double-stranded DNA are: A.T ↔ T.A; T.A ↔ G.C; G.C ↔ C.G; C.G ↔ A.T. Transition mutations have the purine–pyrimidine orientation conserved, as in A.T ↔ G.C or C.G ↔ T.A.

Transitional mutations have been traditionally considered to be due to **tautomerism** of nucleotides. All of the four common DNA bases can exist in tautomeric forms, of which the biologically most interesting involve keto–enol pairs for thymine and guanine and amino–imino pairs for cytosine and adenine. The tautomer, although obeying the usual purine–pyrimidine pairing rules, is capable of hydrogen bonding with a base that is normally noncomplementary. If this occurs and is not repaired, it will lead directly to base-pair substitution mutagenesis in subsequent cell generations. Some base analogues are highly mutagenic, presumably through direct incorporation into DNA through mispairing with a normal base in a tautomeric form (see 2-Aminopurine (AP), 5-Bromouracil). Some DNA alkylating chemicals may be mutagenic through adding an alkyl group onto a normal nucleotide base, thereby affecting its base-pairing properties in subsequent rounds of replication (see Dimethyl Sulfate (DMS)). Such premutagenic events will be fixed at a low level during subsequent rounds of replication, typically leading to transition mutations of various types.

Bence-Jones Proteins

By the middle of the nineteenth century, a British physician made a curious observation on the urine of a patient suffering from a bone disease (in fact, a multiple myeloma). Perhaps because his name was Dr. Watson, this practitioner was curious. So, once back home he heated the urine and observed the formation of a precipitate at 60°C, which redissolved upon boiling. Because he was also clever, he realized that this was not normal, but could not provide any explanation. He thus sent a sample to a member of the faculty in London, Dr. Henry Bence-Jones, who not only confirmed the fact but also gave the answer. The mysterious substance was tagged as "hydrated albumin deutoxide." Dr. Watson was certainly pleased with the answer, but was forgotten. Dr. Bence-Jones became immortal, although the nature of the Bence-Jones protein (BJP) remained a puzzle until it was solved by Edelman and Gally (1), who showed, more than a century later, that BJP were the free form of the monoclonal immunoglobulin light chain that is associated with a heavy chain in the corresponding myeloma protein.

BJPs have been of great interest for quite a while because they are present in large amounts in urine of most patients with multiple myeloma, thus providing a simple source of monoclonal materials, perfectly suitable for structural analysis of light chains, including amino acid sequencing. The first two sequences were obtained by Hilschmann and Craig in (2) in 1965 for two BJPs of the k isotype, giving the first evidence that immunoglobulin chains contained **variable** and **constant** regions. In normal physiological situations, the synthesis rates of the heavy and light chains are similar, whereas they are most often imbalanced in malignant conditions. In most cases of multiple myeloma, an excess of light chain is produced and secreted, quite often as **disulfide-bonded** dimers, causing an associated kidney disease. The presence of BJP is still a valid sign for the diagnosis and prognosis of multiple myeloma.

In the mouse, an equivalent disease may be induced, at a frequency dependent upon the strain, with a high response in BALB/c, as shown by Potter (3). In the mouse too, BJPs are present in the urine of animals that develop a plasmacytoma. Because the tumor may be transplanted for generations and produce unchanged myeloma proteins and BJP, this provided most of the materials that allowed the immunologists to solve the basic features of immunoglobulin structure and to open the way to monoclonal antibodies, as well as the key to Ig genes and thus to the elucidation of the genetic basis for antibody diversity.

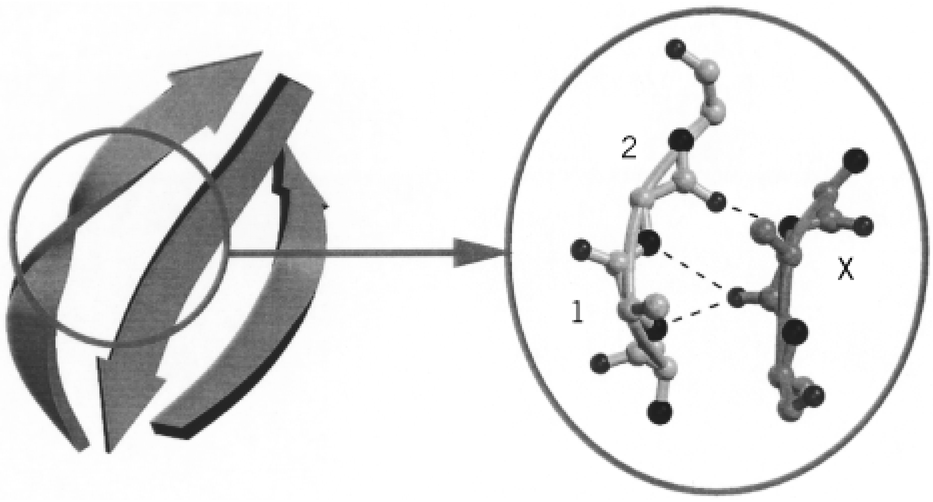
Beta-Bulge

The b-bulge is a term used to define a specific **secondary structure** feature of protein structures, where the regular hydrogen bond interactions and backbone conformation of the b-sheet are disrupted by the presence of an extra residue. The additional residue is usually located on a b-strand at one edge of the b-sheet, where the bulge is more easily accommodated within the structure of the protein (Fig. 1). b-Bulges occur frequently, and often there are two or more per protein (1). In some cases, b-bulges have been found to be conserved in the structures of related proteins, where they may play a functional role. The more general role of the b-bulge is to alter the direction of the b-strand, so that it may be considered a type of turn. However, the change in direction of the polypeptide chain is not as pronounced as that caused by other types of turns.

Figure 1. Example of a classic b-bulge in an antiparallel b-sheet. Three b-strands of the antiparallel b-sheet are shown. The normal twist of the b-sheet is clearly accentuated by the b-bulge, caused by an additional residue in the middle b-strand at the edge of the b-sheet. The close-up view of the b-bulge **(right)** shows residue X from the b-strand forming backbone hydrogen bonds (shown as dashed lines) with two residues (1 and 2) from the outer b-strand. For clarity, side-chain atoms have been removed, backbone nitrogen atoms and backbone oxygen atoms are shown as dark spheres. This figure was generated using Molscript (3) and Raster3D (4, 5).



A b-bulge is that region between two consecutive b-type hydrogen bonds that includes two residues (called positions 1 and 2) on one b-strand opposite a single residue (position X) on the other b-strand (2). There are several different classes of b-bulge, most (90%) occurring between antiparallel b-strands. The two most common are the classic and the G1, accounting for about 80% of b-bulges. In the classic b-bulge, the residue at position 1 has backbone dihedral angles (f = –100, y = –25) (see Ramachandran Plot), closer to those of an a-helical than to a b-strand conformation, but residue 2 has angles closer to the b-strand conformation (f = –180 and y = 160). In the G1 b-bulge, the residue at position 1 has a positive f value (f = 85 and y = 0) and is therefore almost always glycine (thus the name G1). The residue at position 2 of the G1 class has dihedral angles corresponding to b-strand (y = –90 and y = 150). The G1 b-bulge often occurs in combination with a type II b-turn (which requires a glycine at position 3). Compared to the usual b-sheet structure, a b-bulge disrupts the alternating side chain placement on one of the b-strands and increases the right-handed twist of the b-strand from the usual 10° to 35° to 45°.

Beta-Galactosidase of *Escherichia Coli*

Exploration of the lactose (*lac*) system of *Escherichia coli* was started in the late 40s at the Pasteur Institute in Paris by Jacques Monod and his collaborators. As a result, most of the major concepts of **gene expression** and regulation were established with this system (see Lac Operon). The major gene product of the *lac* operon is b-galactosidase, the enzyme that splits lactose into glucose and galactose and the product of the *lac*Z gene. In addition to its importance for studies of enzyme induction, this protein has become very useful as a reporter gene in very many studies of **gene expression**.

1. Characterization

Because of its importance in genetic studies of *lac* operon, *E. coli* b-galactosidase was purified and characterized by several groups in the early 50s (9, 10). It could be easily measured quantitatively because of a chromogenic substrate, *o*-nitrophenyl-b-D-galactoside (ONPG). The enzyme is a hydrolytic transglucosidase and accounts for up to 5% of the total protein in haploid, fully induced or constitutive strains of *E. coli*. The purified enzyme was crystallized, although its three-dimensional structure had to wait 40 years to be solved (see later). Several procedures for producing large amounts of enzyme have been described (reviewed in Ref. 6). b-galactosidase is a particularly stable enzyme. It can be stored in 40% ammonium sulfate for several years at 4 °C without significant loss of activity. In buffered solution, the enzyme is stable at 37 °C for several weeks. At 57 °C the half-life of heat inactivation is 10 min (11). Active enzyme is recovered with 100% yield after **denaturation** with 8 M urea, and fairly good recovery is possible after treatment by 6 M **guanidinium chloride** (12).

b-Galactosidase is specific for the b-D-galactopiranoside configuration and cleaves the bond between the anomeric carbon (C1) and the glycosyl oxygen (10). The enzyme acts as a hydrolase, but also as a transferase. The galactosyl moiety can be transferred to monosaccharides, oligosaccharides, alkyl alcohols, and phenols and also to **mercaptoethanol**. b-Galactosidase also transfers the galactosyl moiety from the C4 position to the C6 position of glucose to form *allolactose*, which is the natural **inducer** of the *lac* operon (13). b-Galactosidase requires Mg^{2+} and Na^{+} ions for maximal activity (9), but the reason for needing these cations is still unclear.

That b-galactosidase is a tetramer of four identical subunits, possessing one active site per subunit, is well documented, and the tetramer is the only active form of the enzyme. Because of its high turnover number (about 6000 moles of ONPG hydrolyzed/sec/mole of enzyme, one molecule of b-galactosidase per bacterial cell can be accurately measured. Several residues (Glu 461, Met 502, Tyr 503, Glu 537) have been identified as important for catalytic function or to be near the active site (14, 15). These residues are found in the three-dimensional structure in close proximity to one another and form a pocket likely to be the substrate-binding site (16).

The amino acid sequence of b-galactosidase, determined before DNA **sequencing** techniques had been developed, was the longest protein sequence ever determined (17). According to this sequence, the protein contains 1021 amino acid residues and a subunit molecular weight of 116,248. Subsequently, the nucleotide sequence of the *lacZ* gene was also determined (18), from which it was predicted that b-galactosidase consists of 1023 residues, with a molecular weight of 116,353 per subunit. It is quite remarkable that the amino acid sequence deduced from the DNA sequence differs only in ten amino acid residues from that obtained by amino acid sequencing of such a large protein.

There is also a **homologue** of b-galactosidase, evolved b-galactosidase (EBG). Normally *E. coli* does not grow on lactose when the *lacZ* gene is deleted. However, cells with *lacZ* deletions were selected that grow on lactose and produce a new b-galactosidase, called EBG (19). The *ebgA* gene maps at 66 min on the *E. coli* chromosome, whereas that for *lacZ* maps at 8 min. The active EBG protein is a hexamer containing 964 residues per monomer. The sequence identity between the *ebgA* and *lacZ* genes at the DNA nucleotide level (50%) exceeds that at the amino acid level (30%). This led to the conclusion that the two genes descended by **divergence** from a common ancestral gene. b-galactosidase and EBG do not cross-react with antisera prepared against each type of protein.

2. b-Galactosidase Complementation

The term complementation has been generally used in genetics for the phenomenon by which a biological function lost or altered by a mutation is restored through mutual compensation by two differently altered mutant genes. In the case of *intracistronic complementation*, where the two mutations occur within different copies of the same **cistron**, it is generally accepted that the repair of function occurs at the level of the protein product of the gene and involves the interaction of differently altered polypeptide chains (see Interallelic Complementation). Such complementation involves noncovalent interaction of polypeptide chains and may occur by reassociation of differently altered subunits of an oligomeric protein or by interaction between fragments of a single polypeptide chain. Studies of b-galactosidase complementation contributed to elucidating the structure of the enzyme and to understanding the mechanism of the specific recognition, reassociation, and folding of proteins (for reviews, see Refs. 20, 21).

2.1. Complementation Between Point Mutants

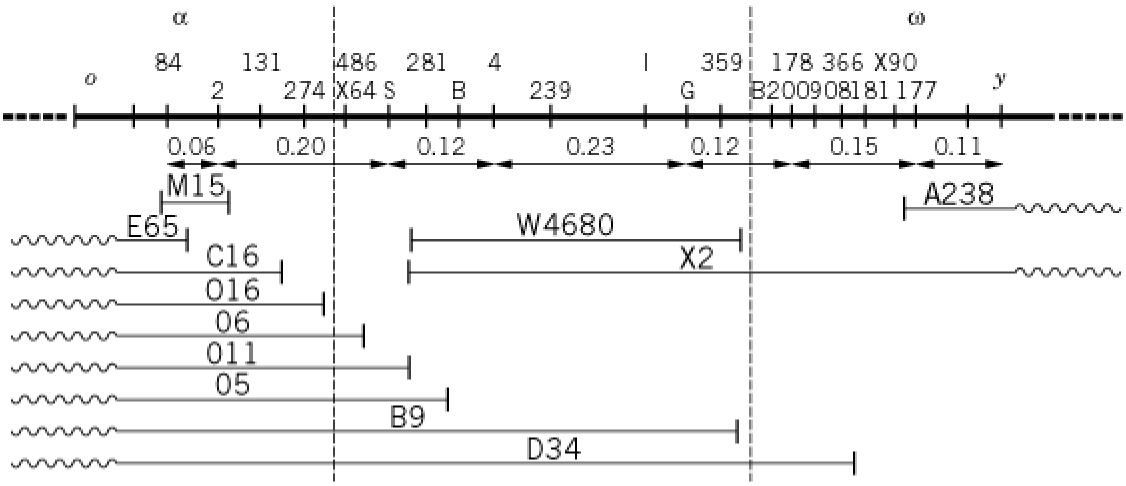
Jacob and Monod (8) showed that heterogenotes carrying different *lacZ*$^{-}$ point mutants may become *lacZ*$^{+}$ by complementation. *In vitro* studies carried out by Perrin (22) showed that many of the inactive proteins containing these point mutations exhibit monomeric structures, but cross-react immunologically with b-galactosidase. In contrast, the active, complemented, b-galactosidase had a sedimentation coefficient like tetrameric wild-type 16 S, although it was more heat-labile. The restoration of enzyme activity in this type of complementation can be accounted for by a mechanism suggested by Crick and Orgel (23), repair of lesions by reassociation of differently altered subunits.

Some inactive b-galactosidase proteins with point mutations exist as dimers. A specific class of these mutants can be activated up to 1000 times by specific antibodies raised against wild-type b-galactosidase (24, 25). The activating antibody directs the formation of active tetramers. In a strict sense this is not a complementation reaction, but the kinetics of activation are similar to those of complementation between point mutant proteins *in vitro*: In both cases, the appearance of b-galactosidase activity is a relatively slow process, requiring about 300 min at 37 °C.

2.2. Complementation Between Deletion Mutants

The isolation of deletion mutants of the *lacZ* gene involving quite large genetic segments (26) led to the discovery of a new type of intracistronic complementation (for a review, see Ref. 27). Inactive *lacZ* deletion mutants, lacking part of the gene corresponding to either the amino- or the carboxy-terminal region of the b-galactosidase polypeptide chain, would complement another inactive deletion mutant containing the region missing in the first. The N- and C-terminal regions involved in the two distinct classes of complementation are known as the a and w regions, respectively (Fig. 1). Both a- and w-complementation represent noncovalent reassociation of complementary fragments of the b-galactosidase subunit polypeptide chain, which then can reassemble into an enzymatically active tetrameric structure. a- and w-complementation takes place *in vivo* in partial diploids and *in vitro*, with extracts of relevant mutant strains.

Figure 1. Diagrammatic representation of the *lacZ* gene. The figures and letters above the solid line indicate the position of point mutations in the *lacZ* gene: *o*, operator; *y*, structural gene of Lac permease. The figures below the line represent recombination frequencies, as determined by crosses between two point mutants. The lines below indicate the extent of various deletions: M 15 isolated by Beckwith (28); A 238 and W 4680, isolated by Cook and Lederberg (29); all others by Jacob, Ullmann and Monod (26). Reprinted from (20) by permission of Cold Spring Harbor Laboratory.



2.3. a-Complementation

All mutants that have their promoter-proximal segment (a-segment) intact are a-donors. All genes that contain partial deletions of the N-terminus not extending beyond a barrier (which is located by the dashed line in Figure 1 between mutants 274 and X64) are a-acceptors when the proteins they produce are mixed with that of an a-donor (30). The time course of *in vitro* a-complementation is relatively slow and reaches a plateau in about 3 h. The a-complemented enzyme, like wild-type b-galactosidase, is a tetramer but is less stable to heat or urea treatment. The equilibrium constant for the complementation reaction was estimated to be approximately 1 to 2 × $10^9 M^{-1}$ (21). Given the slow association rate constant, one can predict a very low dissociation rate, indicating that the complementation process is virtually irreversible under physiological conditions.

The most unusual property of the a-peptide is its high temperature resistance in 6 M guanidinium chloride. Bacterial extracts of *lacZ* strains containing a-donors liberate soluble a-peptides after boiling in this denaturant (30) or after autoclaving in its absence (31). The smallest a-peptide still capable of complementation has a size of about 7400 Da. Upon cleavage of b-galactosidase with **cyanogen bromide**, Langley et al. (32) isolated and sequenced a peptide that has a-donor activity corresponding to residues 3 to 92 of the polypeptide chain.

The best studied a-acceptor is the M15 protein, produced by the *lacZ* mutant DM15 isolated by Beckwith (28) and shown genetically to be a small deletion in the early part of the gene (Fig. 1). The M15 protein lacks residues 11 through 41 of b-galactosidase and is a dimer (33). It has a trace level of enzyme activity and can be significantly activated by addition of anti-b-galactosidase antibodies (34), up to 15% of that obtained by a-complementation.

The nature of the a-complementation process and its probable pathway have been studied extensively (21). It is believed that the a-peptide modifies the quaternary structure of the a-acceptor by causing its tetramerization and consequently the recovery of enzymatic activity. The three-dimensional structure of b-galactosidase (16) fully confirms this prediction by showing that the a-peptide segment of the polypeptide chain participates in forming specific subunit contacts (see later).

2.4. w-Complementation

All mutants that have their promoter-distal region (w-region) intact are w-donors. They complement w-acceptors that are products of deletion or point mutants in the w-region (27) (Fig. 1), which represents about one-third of the total genetic length of *lacZ*. The purified w-peptide has a molecular weight of 40,000 Da (35). The kinetics of w-complementation are faster than those of a-complementation and reach a maximum extent in about 1 h. Although w-peptide is reversibly **renatured** from 8 M urea or 6 M guanidinium chloride, it is highly heat-labile.

w-Acceptor proteins active in complementation have not been obtained in pure form. In crude bacterial extracts (36, 37), w-acceptor exists in different forms of aggregation, depending on the ionic strength. At low ionic strength it is probably a tetramer that dissociates at high ionic strength, most probably into monomers. Both forms are active in complementation. The w-complemented enzyme is a tetramer, like the wild type, and exhibits very similar catalytic properties. The main difference appears after denaturation in 8 M urea. Recovery of its enzyme activity after renaturation does not exceed 5%, whereas it is practically 100% with wild-type enzyme. Moreover, the w-peptide is recovered quantitatively from the complemented enzyme after urea treatment (11).

One of the most remarkable features of w-complementation is the high affinity and specificity that the peptide fragments exhibit. They reassociate even at high dilution and in the presence of a large excess of foreign proteins. The yield of complementation is considerably increased in the presence of a b-galactosidase substrate analog or in the presence of anti-b-galactosidase antibodies (36, 37). Comparing wild-type and w-complemented b-galactosidase, Goldberg (38) proposed a model for the tertiary structure of the two monomers. After having shown that the active, complemented enzyme involves reassociation into a tetrameric structure of four w-acceptor polypeptides with four w-peptides, he showed that both w and acceptor are folded to form compact globular structures, close to those of the corresponding segments of the complete polypeptide within the native enzyme. This “globule model” involves the notion that large polypeptide chains contain several distinct **domains** that assemble specifically to give the polypeptide chain its final tertiary structure. The well-defined compact w-domain is apparent within the native monomer in the three-dimensional structure of b-galactosidase (16), which also shows an unstructured 10-residue exposed segment that joins the w-domain to the rest of the chain. This explains, *a posteriori*, why mild proteolytic treatment of the wild-type b-galactosidase liberates significant amounts of w-peptide (11).

3. Three-Dimensional Structure

The structure of tetrameric b-galactosidase was solved by X-ray crystallography at 2.5 Å resolution by B.W. Matthews et al. (16). It is the longest polypeptide chain for which an atomic structure has been determined. The crystal structure shows that b-galactosidase is a tetramer with dimensions of roughly 175 × 135 × 90 Å along the respective twofold axes. The constituent monomers interact through two different monomer–monomer contacts. The b-galactosidase monomer consists of five compact domains and a relatively extended 50-residue N-terminal segment, corresponding to the a-peptide, which contributes to the activating interface (Fig. 2). The monomer is relatively flat and elongated and has approximate dimensions of 50 × 100 × 40 Å. The first domain consists of residues 52 to 217, the second of residues 220 to 334, the third of residues 334 to 627, the fourth of residues 627 to 736, and the final fifth domain, corresponding to the w peptide, of residues 737 to 1023. Topologically, the second domain is identical to the fourth domain. The modular structure of the monomer corroborates earlier findings (37, 38), which suggested that the folding of this rather long polypeptide chain is facilitated by each domain acting as an independent unit.

Figure 2. Three-dimensional structure of b-galactosidase. (**a**) Ribbon representation of the b-galactosidase tetramer showing the largest face of the molecule. Contacts between red/green and blue/yellow dimers form the long interface. Contacts between the red/yellow and blue/green dimers form the activating interface. Formation of the tetrameric particle results in two deep clefts that run across opposite faces of the molecule. Each contains two active sites. (**b**) Ribbon diagram of the blue/green dimer viewed down the molecular two-fold axis, showing the composition of the activating interface. Residues 1 to 50 from each chain, which form the a-complementation region (see text), are shown

in red. The interface includes contacts between the respective complementation peptides, between two a-helices from the respective monomers that pack together to form a four-helix bundle and between an extended loop (residues 272 to 288) from each monomer that reaches across the interface and extends into the active-site region of the neighboring monomer, stabilizing the active site structure. (**c**) Stereo ribbon diagram of the b-galactosidase monomer showing the domain organization of the chain. Residues corresponding to successive domains are colored in successive spectral colors. See color insert.

At present, no structure of a complex of b-galactosidase with a substrate or analog is available, so the specific interaction sites between enzyme and substrate are not known. Nevertheless, earlier biochemical studies (14, 15) concluded that residues important for catalytic function or near the active site (Glu461, Met502, Tyr503, Glu537) are found close to one another and located around a deep pit within the third domain, which is postulated to be the substrate-binding site. Residues from distant regions of the sequence (Trp568, Trp999) also contribute to the active site.

The X-ray structure of b-galactosidase provides a structural rationale for both a- and w-complementation. The N-terminal segment, representing the a peptide, participates in forming a subunit interface, which in turn allows formation of the active site, made up of elements from two different subunits. The w-fragment, corresponding to the fifth domain of the subunit, exhibits a specific topology. Rotation of this domain by more than 90° positions Trp 999 at the active site in the vicinity of the third domain.

4. b-Galactosidase as a Tool

The b-galactosidase of *E. coli* is one of the most commonly used enzymes in molecular biology for several reasons: (*1*) numerous genetic and biochemical aspects of the *lac* system are known; (*2*) several indicator media are available for detecting lactose metabolism and monitoring Lac^+ and Lac^- bacteria; (*3*) the assay procedure based on o-nitrophenyl-b-D-galactoside (ONPG) hydrolysis is exquisitely sensitive; (*4*) the protein is highly stable and easy to purify; and (*5*) the availability of substituted galactoside derivatives permits selecting and screening *lac* mutants exhibiting a variety of phenotypes. For example, the chromogenic noninducing and colorless substrate, 5-bromo-4-chloro-3-indolyl-b-D-galactoside (X-Gal), forms an insoluble blue dye upon hydrolysis, thus providing a sensitive test for b-galactosidase in solid media. X-Gal also discriminates between strains that produce high and low levels of b-galactosidase, allowing detection of plaque-forming **bacteriophages** that carry the *lacZ* gene.

5. b-Galactosidase Fusions

The observation that the N-terminal 23 residues of b-galactosidase can be replaced with other amino acids without affecting enzymatic activity enabled Müller-Hill and Kania (39) to obtain fusions between *lacI* and *lacZ* genes that produce a hybrid protein that has both Lac repressor and b-galactosidase activities. Several genetic methods have been developed to construct *lac* fusions that produce hybrid genes which specify hybrid proteins. Subsequently, *in vitro* construction of hybrid genes facilitated obtaining a variety of fusions (40). A number of commercially available vectors exist for constructing *lacZ* fusions *in vitro*. They contain a *lacZ* gene truncated at the 5′-end and preceded by a synthetic oligonucleotide containing multiple restriction enzyme cleavage sites, a *polycloning* site. Thus, if a 5′-coding sequence is cloned into one of these sites so that transcription and translation are restored across *lacZ*, a hybrid protein with b-galactosidase activity is produced. The sensitive detection of this activity with X-Gal has made b-galactosidase one of the most commonly used *in vivo* **reporter enzymes**. Using the *lacZ* gene as a reporter provides a sensitive method to detect genes subject to specific regulatory signals or to study the mechanism localizing a protein to a given cellular compartment. The regulation, identification, and localization of many proteins of various origins have been uncovered by using the b-galactosidase activity of fusion proteins as a marker.

During the last few years, a number of new eukaryotic expression vectors that produce b-galactosidase fusion proteins have been designed. They are currently being used to analyze developmentally regulated genes, transgenic expression, tissue-specific expression, and a number of other aspects involved in embryogenesis or developmental biology. This approach has been facilitated by using replication-defective retroviral vectors that encode the *lacZ* gene (41), which has become a widely used cell lineage marking system. The labeled cells are easily identified by histochemical staining, using X-Gal or **immunofluorescence** with antibodies raised against b-galactosidase.

b-galactosidase fusions provide a unique and versatile experimental tool. The hybrid proteins are easy to purify (42) and can be used as antigen to raise antibodies against the target gene product. In addition, because there is no restriction on the size of the target gene DNA fused to *lacZ* and because many hybrid proteins retain all or a portion of the activity of the target gene product, these fusions provide a means to identify functional domains within the target gene product.

5.1. a-Complementation

Perhaps the most widely exploited property of b-galactosidase is a-complementation, described previously. Whereas the region of the foreign protein that can replace the N-terminus of b-galactosidase is more or less random in hybrid fusion proteins, replacements in the a-peptide for a-complementation are more restrictive. That insertion of a few amino acid residues does not always interfere with complementation capacity (43) was widely used during the late 70s to develop new cloning vectors, now commercially available. Indeed, a-complementation has become one of the most commonly used methods for identifying bacterial colonies containing recombinant DNA.

The first vector based on a-complementation was developed by Messing et al. (44). Within the major intergenic region of the filamentous bacteriophage M13, they inserted the *lac* regulatory region and the DNA sequence that codes for the first 146 amino acids of b-galactosidase that have a-complementation capacity. When infected with these phages, bacteria that produce the M15 a-acceptor protein produce active b-galactosidase by complementation and form blue plaques in the presence of the chromogenic substrate X-Gal. Insertion of foreign DNA into the a region of M13 interferes with a-complementation and gives rise to recombinants that form pale blue or colorless plaques. This simple test has made cloning in filamentous bacteriophages a routine procedure. The insertion of a series of synthetic restriction enzyme sites into the a-region provides a variety of targets for cloning foreign DNA fragments. Insertion of these polycloning sites, representing up to 18 extra amino acid residues, into the a-region has practically no effect on a-complementation capacity. Insertion of additional DNA into a cloning site, however, generally abolishes a-complementation and creates recombinant bacteriophages that produce colorless plaques when grown on X-Gal plates (*blue/white screen*). The great advantage of using vectors generated from single-stranded DNA phage, like M13, is that one obtains both the double-stranded replicative form from the infected bacteria and the single-stranded DNA, from the progeny phage. The latter is frequently used as a template for sequencing with the dideoxy-mediated chain-terminating **Sanger method** (45) and also for *in vitro* mutagenesis. Many other vectors that permit identification of recombinant clones based on a-complementation have been designed subsequently. The most commonly used are the pUC vectors (46).

Recently, Mohler and Blau (47) adapted intracistronic complementation of the *lacZ* gene for use in eukaryotic cells. By constructing replication-defective **retroviral** vectors that express a-donors and a-acceptors and w-donors and w-acceptors, complementation of the relevant *lacZ* mutants in mammalian cells permits analyzing cell fusion and detecting colocalized interacting proteins within single intact cells. a- and w-complementation can be exploited for a wide range of studies, including **transgenic** animals that express complementing *lacZ* mutants from two **promoters** of interest, which then could reveal cell lineages in which the products of both genes coincide spatially and temporally. In line with these results, Rossi et al. (48) applied b-galactosidase complementation to monitor protein–protein interactions in intact eukaryotic cells.

Given the wide range of applications for b-galactosidase during the last decades, one can anticipate that further development of the b-galactosidase fusion and complementation systems will contribute to our understanding of many features of cellular regulation and organization.

Beta-Glucuronidase

b-Glucuronidase (E.C. 3.2.1.31; GUS) is the most widely used reporter gene in plant molecular biology (1). The *gusA* gene cloned from *Escherichia coli* encodes a 68-kDa b-glucuronidase that forms a stable homotetramer and catalyzes the hydrolysis of a large number of glucuronides, in which D-glucuronic acid is conjugated through a b-*O*-glycosidic linkage to any aglycone. b-Glucuronidase has emerged as the reporter gene of choice to be used in plants, because there is very little or no endogenous glucuronidase activity across the phyla. This minimizes the detection of background activity and allows very small quantities of GUS to be detected. GUS activity may be followed in cell lysates or *in situ*. The major use of GUS has been to study gene expression patterns in transgenic plants by expressing GUS under the control of regulatory sequences of interest. A second use has been to monitor the intracellular fate of chimeric proteins by generating GUS fusion genes. For example, GUS has been fused to gene leader sequences that target the fusion gene to different organelles and allow intracellular trafficking of proteins to be studied (2).

GUS activity may be detected using a variety of substrates. As in the case of **beta-galactosidase** and X-gal, GUS expression is most commonly detected using histochemical substrates, such as X-GlcU (5-bromo-4-chloro-3-indolyl b-D-glucuronide), which gives a dark blue precipitate upon hydrolysis. Alternative substrates include 5-bromo-6-chloro-3-indolyl b-D-glucuronide, 6-chloro-3-indolyl b-D-glucuronide, and indoxyl b-D-glucuronide that give magenta, pink, and blue precipitates, respectively (3). The variety of substrates also makes GUS a valuable component of dual (or multiple) reporter gene systems; for example, GUS and *lacZ* expression could be detected in the same tissues by using substrates that give different colored histochemical precipitates. In addition to histochemical substrates, a number of fluorescent and chemiluminescent substrates have been developed that are analogous to the substrates for b-galactosidase, such as CFDG-GlcU (Molecular Probes Inc.) and 4-methylumbelliferyl b-D-glucuronide (MUGlcU) (4).

In the case of *lacZ*, problems may be encountered in loading substrates into cells; to load FDG, for example, cells must undergo a moderate osmotic shock that can affect cell viability. In the case of GUS, however, a second gene, *gusB*, may be expressed that encodes a **permease** that actively takes up and transports glucuronide substrates into the cell. In addition to substrates that allow reporter gene visualization, a number of other bioactive molecules can be conjugated to glucuronides, which could then be released by hydrolysis in GUS-expressing cells. Thus, combined use of gusA and gusB increases the use of the reporter gene, from merely indicating gene expression to controlling a specific cell manipulation (1).

Beta-Helix

A b-helix is a type of protein motif or **domain** found in a very few protein structures. It is characterized by an unusual parallel b-sheet topology formed from three parallel b-sheets wound together into a right-handed helical structure (Fig. 1). The b-strands in each b-sheet are short, having only 2 to 5 residues. Each coil of the b-helix has the same three-dimensional arrangement of a group of **secondary structure** elements and is thus similar to other coiled repeating structures, such as the b-roll, composed of two parallel b-sheets forming a b-helix, and the leucine-rich repeat of **ribonuclease inhibitor** that is composed of repeating a-helices and b-strands forming a horseshoe-shaped structure. In the b-helix, the side chains of repeating residues are packed into the center of the helix and interact with one another to form, for example, "asparagine ladders," "serine stacks," and/or "aromatic stacks."

Figure 1. Orthogonal views of the b-helix of pectate lyase E (1), showing the three parallel b-sheets. For clarity, only the b-strand secondary structure (as purple arrows) and loops connecting the strands (yellow) are shown. Short helical regions and the *N*- and *C*-terminal loops have been removed. This figure was generated using Molscript (2) and Raster3D (3, 4). See color insert.

Beta-Lactamases

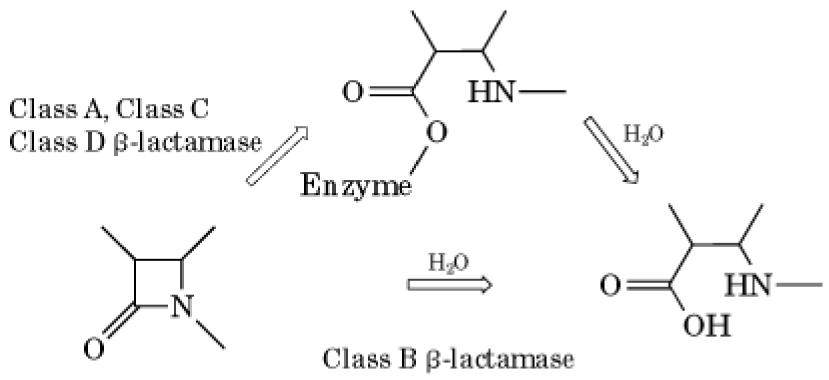
b-Lactamases constitute one of the oldest known mechanisms of bacterial antibiotic resistance and one of the most widely distributed. The enzymes hydrolyze b-**lactam** antibiotics, such as penicillin, rendering them inactive (Fig. 1).Most of these enzymes also react with other cyclic structures, such as g-lactams and isatoic anhydride derivatives (1), and some have low reactivity with simple esters, peptides, and depsipeptides. Richmond and Sykes (2) and Bush (3) classified b-lactamases according to their catalytic activity and apparent substrate specificity, which remains the most useful classification for the clinical microbiologist. Today, the ready availability of b-lactamase amino acid sequences obtained from their **genes** provides the basis for a structural classification first proposed by Ambler (4). There are two types of b-lactamase:

1. those with a serine residue at their active site that is transiently acylated by the b-lactam substrate during hydrolysis (Richmond and Sykes groups I and II; Ambler class A, plus the more recently distinguished classes C and D); for an example, see Serine Proteinase.
2. those with metal ion cofactors, which are Zn(II) in the physiological state, and with apparently no acyl-enzyme intermediate (Richmond and Sykes group III; Ambler class B) (see

Metalloproteinases).

The serine b-lactamases include enzymes that have both narrow and broad substrate specificities and are sensitive, to varying degrees, to b-lactam **enzyme-activated inhibitors**. This group is the more abundant and currently poses the greater clinical problem. The metallo-b-lactamases are active on a broad spectrum of b-lactam substrates and are much less sensitive to the mechanism-based inhibitors, although they can be inhibited by metal-ion chelating agents. This group has been relatively scarce in nature, but its prevalence is rising because of the increased use of b-lactam antibiotics that resist hydrolysis by serine b-lactamases.

Figure 1. The reaction catalyzed by b-lactamases.



1. Serine b-lactamases

Sequence comparisons of the active serine enzymes indicate six major groups:

1. The class A b-lactamases: Richmond and Sykes Group II enzymes; Bush groups 2a (penicillinases), 2b (broad spectrum b-lactamases), 2b′ (extended broad spectrum b-lactamases), 2c (carbenicillinases), 2e (cephalasporinases). This group also includes a few proteins identified as D-Ala-D-Ala carboxypeptidases (DAC).
2. The class C b-lactamases: Richmond and Sykes and Bush Group 1, together with three proteins from *Streptomyces*, *Nocardia*, and *Bacillus subtilis*, identified as carboxypeptidase/transpeptidases.
3. The Class D b-lactamases from gram-negative bacteria (Bush Group 2d oxacillinases), together with b-lactam receptor proteins from gram-positive bacteria.
4. The bifunctional transglycosylase/transpeptidase, class A penicillin-binding proteins (PBP).
5. The monofunctional transpeptidase, class B PBP.
6. D-Ala-D-Ala carboxypeptidases (DAC).

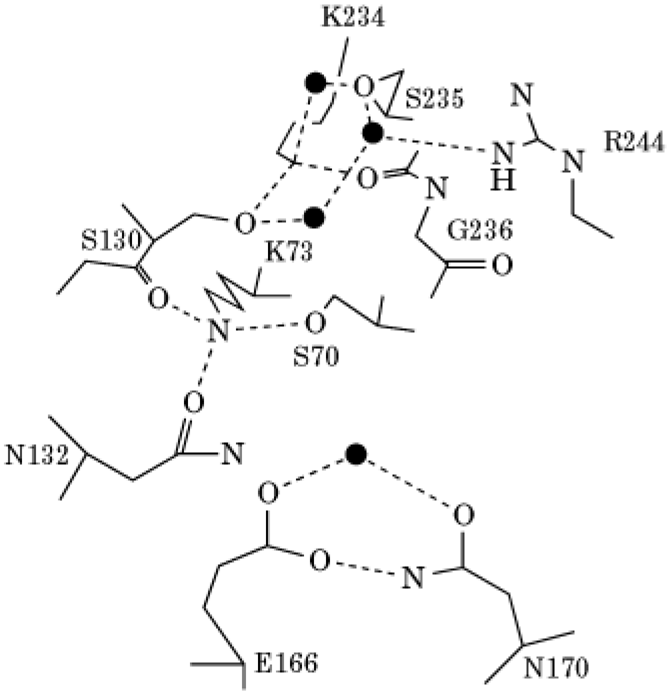
The last three groups are biosynthetic enzymes of the bacterial cell wall that react with D-Ala-D-Ala.

All six groups have three sets of conserved residues in common, which comprise the active site of the enzyme (see later). The first comprises the sequence Ser-X-X-Lys, where X is any residue and the serine residue is the one that is transiently acylated by substrates and the only residue that is absolutely conserved in all of the proteins. The second has either a serine (class A) or a tyrosine residue (in class C and class D b-lactamase groups), followed after one residue by an asparagine (except in one class D b-lactamase). The third conserved segment is usually Lys-Thr-Gly, but only the glycine residue is absolutely conserved. Sequence analyses have suggested that b-lactamase activity may have arisen several times by a process of evolutionary **convergence**.

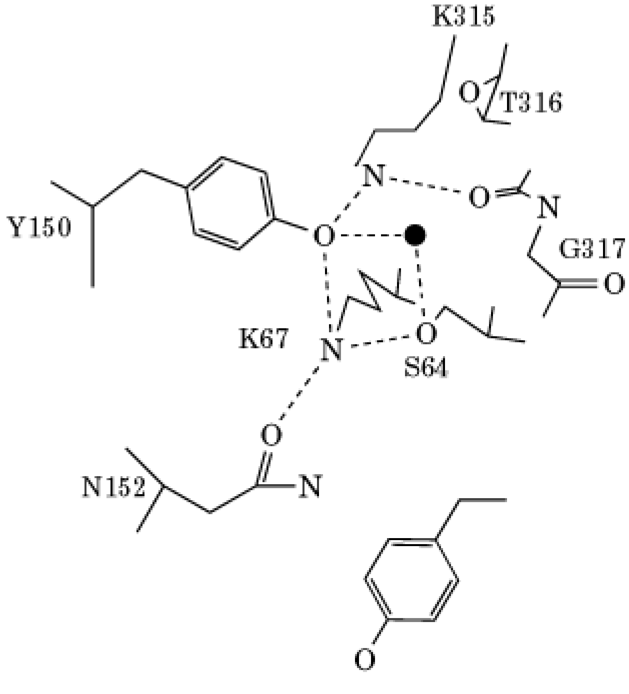
Three-dimensional structures of class A enzymes from *Staphylococcal aureus* (5), *Bacillus cereus*

(6), *B. licheniformis* (7), *Streptomyces albus* (8), and *Escherichia coli* TEM-1 (9, 10) have been published, which include only two of the five activity groups of class A enzymes. Structures of the class C b-lactamases from *Citrobacter freundii* (11) and *Enterobacter cloacae* (12) have been published, and this group is extended by the homologous structure of the transpeptidase domain of the *Streptomyces* carboxypeptidase/transpeptidase (13). The overall structures of all of these enzymes and a DAC are similar. The core of each molecule is a five-stranded, antiparallel b-sheet flanked on one side by three a-helices and on the other by a larger, more diverse a/b domain (see Protein Structure). The active site lies between the two domains and is bound by one edge of the b-sheet. As shown in Figure 2, the conserved residues listed previously make up the active site regions and occupy very similar positions in all of the structures (Figure 2). Even the alternative serine and tyrosine residues in the second conserved segment of class A (DAC) and class C (DAC), respectively, have their hydroxyl groups in the same positions; see Ser 130 and Tyr150 in Fig. 2 a and b, respectively. Major differences between the two classes of enzymes that are believed to have functional consequences occur in the area that serves as a recognition pocket for the side chain of the substrate. The class A enzymes have a loop (the W loop) that forms the base of the acyl amino side-chain binding pocket. This loop includes residues Glu166 and Asn170, which localize and activate a water molecule for attack on the ester bond of the substrate (14, 15). The projection of this loop into the active site also limits the scope for binding bulky acyl side chains, which was exploited in developing b-lactamase-resistant antibiotics, such as methicillin.

Figure 2. Comparison of the similar active-site regions of b-lactamases of class A (a) and class C (b). The residues are identified with the one-letter code. The lack spheres are water molecules observed crystallographically that are probably hydrogen-bonded (dashed lines) to various groups of the protein. The active-site serine residue that is acylated in the catalytic reaction is S70 in (a) and S64 in (b).



(a)



(b)

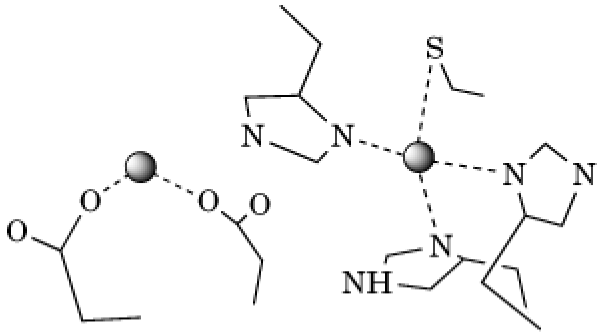
Evolutionary accumulation of peripheral mutations that modify the conformation of the W loop and of neighboring surface loops that define the edges of the side-chain recognition pocket has led to the appearance of enzymes that belong to groups 2b′, 2c, and 2e that have extended substrate recognition profiles (16). In the class C enzymes, the water molecule that attacks the ester of the acyl intermediate is located on the opposite side of the plane of the ester and is activated by direct interaction with components of a hydrogen-bonded relay formed by the conserved residues. Identification of the individual residues involved in activating of the water has not yet been achieved, although Tyr150 has been implicated (11). The class C enzymes have a deeper, more **hydrophobic** side-chain binding pocket, lined by Tyr122, that enables them to bind substrates with large 7-acyl amino side chains.

Conformational changes during the b-lactamase reaction have been proposed for the class A, C, and D b-lactamases on a variety of grounds. With simple substrates, NMR and circular dichroism spectroscopy have suggested changes in the structure accompanying acyl-enzyme formation (17, 18). A number of substrates show nonstoichiometric bursts of hydrolysis (19), and a conformation change leading to a substrate-induced inactivation has been invoked (1, 20). These observations in solution contrast with the finding of very few differences in the structures of the free enzyme and the acyl-enzyme complex determined by X-ray crystallography (9, 11). An unambiguous description of the reaction mechanism must wait until these observations can be reconciled.

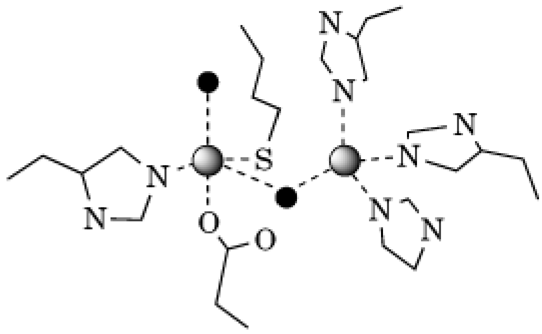
2. Metallo-b-lactamases

Sequence comparisons suggest that there are four groups of this type of b-lactamase that are not closely related, but share similarities with a protein from the actinorhodin biosynthetic gene cluster of *Streptomyces*. A few residues involved in binding the metal ion cofactors are absolutely conserved within this diverse group. Three structures are available, that representing two of the major subgroups of metallo-b-lactamases (Fig. 3). All three structures are similar overall to each other, but not to the serine b-lactamases, and the core of each molecule is formed from two antiparallel b-sheets, each with additional parallel strands and flanked by a-helices. The structure of *Bacillus cereus* b-lactamase II was solved with Cd(II) in place of the natural Zn(II) metal ion (21). One Cd(II) ion is bound tightly, with a dissociation constant of about 1 µM, by the side chains of three histidine and one cysteine residue (22-24). In the homologous enzyme from *Bacteroides fragilis*, one Zn(II) ion is similarly coordinated by three histidine side chains, as in the *B. cereus* enzyme, but the fourth ligand is a water molecule that is shared with a second Zn(II) ion (25). The second zinc ion is further coordinated by three other side chains, those of His, Cys, and Asp residues. Two more Cd(II) ions are located in the *B. cereus* structure, but the coordination of one of them is much weaker (23), so it may not be physiological. Early stoichiometries determined for the binding of Zn(II) and Cd(II) suggested that two ions per molecule are bound (22). The second Cd(II) ion is bound by two Asp residues and lies only 10 Å from the tightly bound ion (Fig. 3), where it might modulate the catalytic activity. It is believed that the water molecule complexed with the two Zn(II) ions in the *B. fragilis* enzyme is activated to form hydroxide for attack on the b-lactam ring, and a corresponding water molecule is probably activated by the tightly bound ion in the *B. cereus* enzyme.

Figure 3. Comparison of the similar active-site regions of metallo-b-lactamases from *Bacillus cereus* (a) and *Bacteriodes fragilis* (b). The shaded spheres are the two metal ions, cadmium (II) in (a) and zinc (II) in (b), and the smaller solid spheres are water molecules observed crystallographically.



(a)



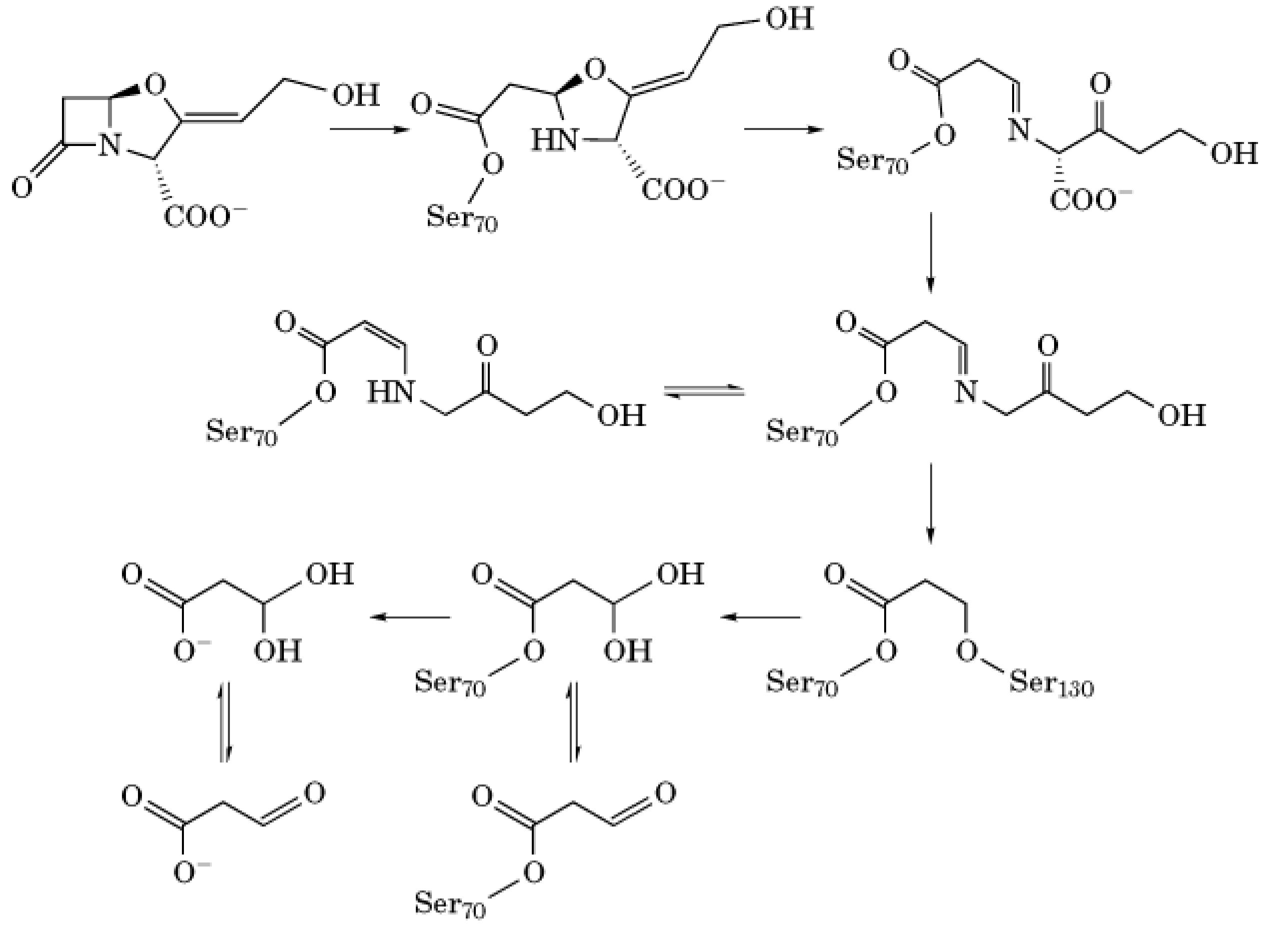
(b)

3. Inhibition

The important role of b-lactamases in antibiotic resistance has led to the development of specific b-lactamase inhibitors that can be used to protect b-lactamase-sensitive antibiotics. For the serine b-lactamases, several classes of mechanism-based inhibitors have been discovered, and several inhibitor proteins are known (26). In many cases, the mechanism of action of the small-molecule inhibitors is not clear, and only two classes have been used in combination with antibiotics.

Clavulanic acid has been widely used clinical application. It is selective for the class A and class D b-lactamases. Opening of the b-lactam ring of clavulanic acid by the initial attack of the b-lactamase triggers a series of chemical rearrangements in the inhibitor moiety (Fig. 4) that results in an acyl-enzyme that is resistant to attack by water and may even be cross-linked by the inhibitor moiety (27).

Figure 4. Suggested mechanism for the reaction of TEM-2 class A b-lactamases with clavulanic acid (27).



The penam sulfone acids *sulbactam* and *tazobactam* are also used clinically as b-lactamase inhibitors. As with clavulanic acid, a series of chemical rearrangements are provoked by the reaction with b-lactamase. Although sulbactam and tazobactam are relatively selective for class A and class D b-lactamases, analogs that have increased activity against class C b-lactamases have been reported (28).

4. Regulation of Biosynthesis

Expression of chromosomal b-lactamase in *Bacillus* and of **plasmid**-encoded b-lactamases in staphylococci is under the control of a typical repressor protein (Blal and Mecl, respectively) and a second regulatory protein (BlaR and MecR, respectively). The BlaR and MecR regulatory proteins are similar. Both are integral membrane proteins that have a b-lactam-binding **domain** homologous to the class D serine b-lactamases (29). The predicted topology of the polypeptide in the membrane is three to five membrane-spanning **a-helices**, and the N-terminus in the cytoplasm and the b-lactam-binding domain is on the outer surface of the membrane, where it could act as a **receptor** for b-lactams.

Expression of chromosomal class C b-lactamases in Enterobacteriaceae from the *amp*C gene is under the control of the *amp*D, *amp*E, *amp*G, and *amp*R gene products. AmpR protein is a typical transcription activator that is lost in organisms, such as *E. coli*, that have constitutive AmpC production. AmpR responds to the binding of 1,6-anhydro-*N*-acetylmuramyl-[L]-alanyl-[D]-glutamyl-*meso*-diaminopimelic acid (MurNAc tripeptide) produced by breakdown of the peptidoglycan of the cell wall (30). The three other proteins are involved in transmembrane signaling for induction of the b-lactamase. Inactivation of AmpD results in massive overproduction of b-lactamase, whereas loss of either AmpE or AmpG activity results in a total block of induction.

AmpD is an amidase that cleaves the tripeptide from the MurNAc tripeptide, thus inactivating it as an inducer. It is thought that AmpG is an integral membrane protein that acts as a transporter for the MurNAc tripeptide, whereas it has been suggested that AmpE, also an integral membrane protein, provides energy for its uptake (31).

Beta-Lactoglobulin

b-Lactoglobulin is the major whey protein in the milk of ruminants, and it has also been reported in milk from many other species, although not human, lagomorph, or rodent. Where found, genetic variants have also been reported in most cases. Isolation of whey protein from bovine milk is straightforward (1), and its concentration is 2 to 3 g/L. Consequently, the protein has been used since its first isolation in 1934 as a convenient, small, soluble protein with which to develop and calibrate new techniques. For example, it is used as a component of standard mixtures for isoelectric focusing and SDS-PAGE and a calibration sequence for automatic sequenators (see Protein Sequencing). The extensive literature on b-lactoglobulin, largely that from the domestic cow, can be broadly divided into studies related to the molecule as a protein and those related to its importance to the dairy industry. Reviews of both abound (2-6).

The polypeptide chain of the protein contains about 160 residues. That of ruminant species is dimeric, and in other species it is monomeric. Figure 1 shows some of the known sequences from the SWISSPROT database (7). Disulfide bonds link cysteines 66 to 160 and 106 to 119. The asterisks show structurally conserved regions that were recognized following the structural determination first of the homologous plasma *retinol-binding protein* and then of bovine b-lactoglobulin (8, 9). These motifs define a widely distributed family called the *lipocalins* (10, 11), whose structure is an eight-stranded antiparallel b-barrel with $(+1)_8$ topology (see Beta-Sheet) and with an **a-helix** on the outer surface. The structure of b-lactoglobulin is shown in Fig. 2 (12). The family relationship has also been observed in the gene sequences, which show similar arrangements of **introns** and **exons** (13). The 400 bp upstream of the **open reading frame** controls the high level of expression and its restriction to the mammary gland (14). This has led to successful use of the b-lactoglobulin operon in transgenic technology (15).

Figure 1. Sequences of mature b-lactoglobulins with the totally conserved residues in bold. The sites of possible genetic shown in the bovine sequence in italics, and changes in the bovine B variant are shown above. The N-terminal sequence (34). The asterisks show the structurally conserved regions indicative of the lipocalin family.

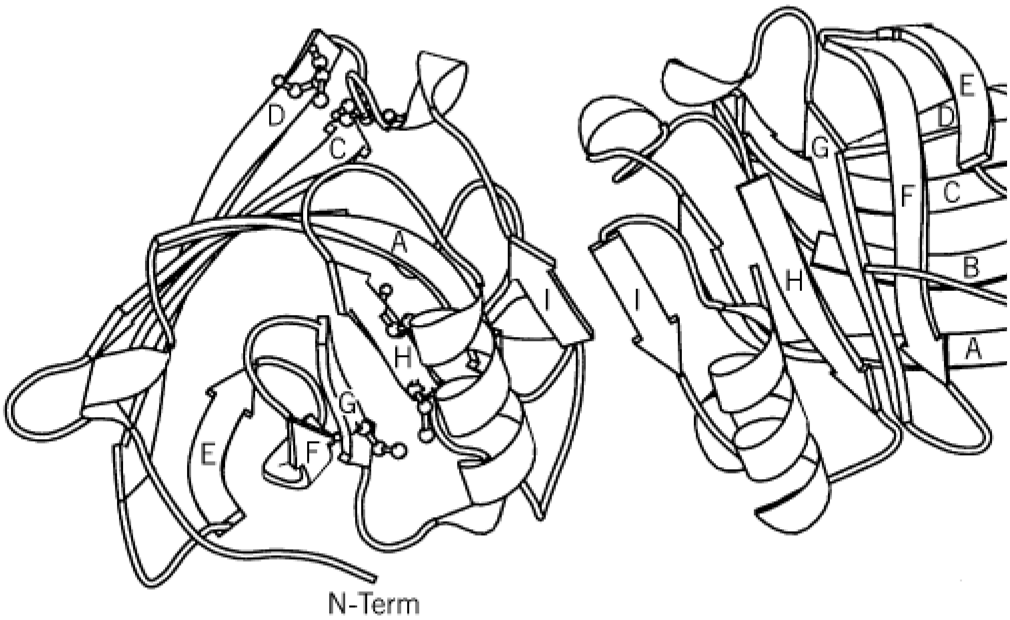
Figure 2. A MOLSCRIPT (35) diagram of the dimer of b-lactoglobulin showing the fold of the main chain.



No definite function has yet been ascribed to b-lactoglobulin, but its presence in a family containing mostly small, secreted proteins that transport **hydrophobic** molecules perhaps implies that its function, other than the obvious nutritional one, is associated with the transport or uptake of fatty acids or retinol, both of which it binds (16, 17). Indeed, over 20 different **ligands** have been reported that have **association constants** varying between 5×10^7 and 4×10^2M (3). By analogy with other lipocalins, the binding site should be in the central pocket formed by the b-strands, but there is no definitive evidence that this is the case. Recently it has been shown that palmitate and retinol can bind independently and simultaneously (18).

Some physical parameters of the protein are summarized in Table 1. The bovine protein is stable down to pH 2, and conformational studies have shown that there are several pH-dependent changes between pH 2 and pH 9 (19, 20). At the extremes of pH, the dimer dissociates, and it aggregates above pH 8.5 to 9.0. The conformational change between pH 6 and 8 leads to increased reactivity of the free cysteine residue, perhaps triggered by the titration of a carboxyl group with a pK_a of 7.3. An association of four dimers forms an octamer at 5°C and pH 4.5 mainly in the A variant. This probably results from a carboxyl–carboxylate interaction involving the Gly64Asp change between the most common B and A genetic variants of b-lactoglobulin (21).

Table 1. Selected Fundamental Parameters of Bovine b-Lactoglobulin

Number of amino acids	162
A variant	Asp64, Val118
B variant	Gly64, Ala118
Relative molecular mass	18,400
Sedimentation coefficient ($S°_{20w}$)	2.83×10^{13} s^{-1}
Diffusion coefficient	7.70×10^{-7} cm^2s^{-1}
Stokes' radius	2.68 nm
Radius of gyration	2.17 nm

Axial ratio	2:1
Dipole moment	730 Debye
Absorbance at 280 nm	0.96 (1.0 g/l solution, 1 cm cell)

The complex behavior during refolding from urea between 2° and 25°C is ascribed to **disulfide interchange**. Cys106 pairs with either Cys119 or Cys121, and the former is the native (22, 23). It is not yet clear whether this also explains the partially folded form observed at pH 2, where the protein is predominantly a monomer (24). Refolding from **guanidinium chloride** at low pH shows a transient increase in helical content (25), an effect that is stabilized in ethanolic solution (26).

b-Lactoglobulin has been cloned and expressed both in *Escherichia coli* and in **yeast**, allowing creation of **site-directed mutations** (27) for probing the solution properties (28) or modifying the thermal denaturing behavior (29). Thermal denaturation is of particular interest to the dairy industry because heating milk is the basis of much processing and also the genetic variants exhibit different behavior (30). In addition, protein concentration, pH, temperature, ionic strength, dielectric constant, and buffer type all contribute to the denaturing behavior. Differential scanning **calorimetry** and thermal aggregation studies show that the A variant is less stable than the B variant (31), but studies at lower protein concentration show that the reverse is true (32). Thermal aggregation also involves intermolecular disulfide interchange, presumably initiated by the free thiol group (33).

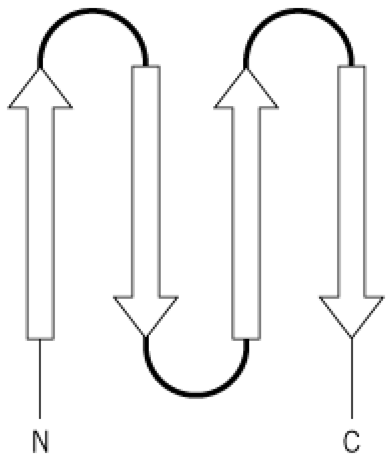
Beta-Meander

The b-meander is a protein motif frequently observed in protein structures. It has a particular type of antiparallel b-sheet structure, with a very simple topology in which two or more b-strands that are consecutive in sequence are also adjacent to one another in the three-dimensional structure (Fig. 1). b-Meanders are equivalent to multiply linked **hairpins**.

Figure 1. Schematic representation of a b-meander consisting of four b-strands (shown as arrows).



[See also Beta-Sheet.]

Beta-Pleated Sheet

b-Pleated sheet is an alternative name for b-sheet, a type of **secondary structure** occurring in protein structures. The name arises from the pleated nature of the sheet and the individual b-strands when viewed from the side.

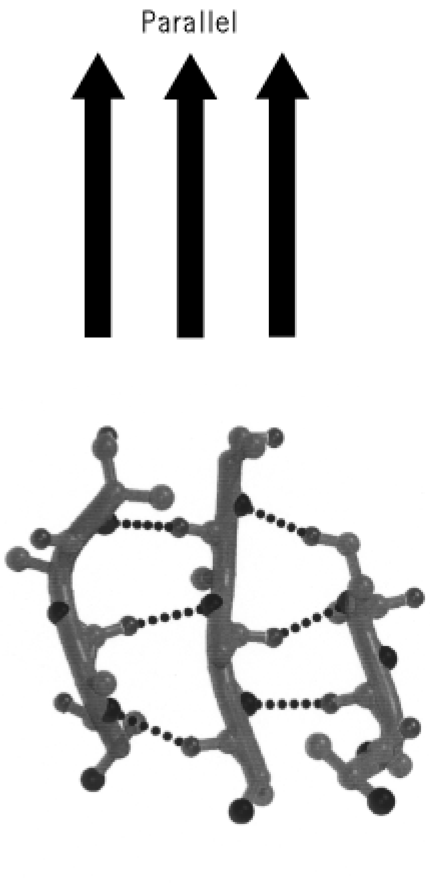
[See also Beta-Sheet.]

Beta-Sheet

The b-sheet is a **secondary structure** component of protein structure, comprising two or more adjacent b-strands linked by hydrogen bonds. In contrast to the coiled backbone of the **a-helix**, the structure of a b-strand is characterized by an extended backbone conformation, corresponding to the favorable upper left region of the Ramachandran Plot. b-Sheets are formed by a side-by-side arrangement of b-strands, with backbone hydrogen bonds between adjacent strands linking the sheet together. The side chains of consecutive residues on a b-strand do not interact with each other, but lie alternately above and below the sheet, giving a pleated appearance to the b-sheet backbone (the b-sheet is sometimes referred to as a b-pleated sheet).

b-Strands are often depicted as arrows in protein structure diagrams, with the direction of the arrow running from the N-terminal end to the C-terminal end of the b-strand. When packed together in a b-sheet, the b-strands may all be oriented in the same direction (parallel b-sheet) or in alternating directions (antiparallel b-sheet). In some cases, the b-strands will be a mixture of parallel and antiparallel (mixed b-sheet). The backbone hydrogen bonding patterns of parallel and antiparallel b-sheet structures differ (Fig. 1). In the parallel b-sheet, hydrogen bonds are evenly spaced along the b-strand and point at an angle to the other strand. The antiparallel b-sheet has alternately wide and narrow spacings between adjacent hydrogen bonds. The average backbone angles for parallel and antiparallel b-sheets also vary, with f of –119° and Y of 113° for parallel structures and f of –139° and Y of 135° for antiparallel structures (see Ramachandran Plot). Most b-sheets have a right-handed twist of about 10°. The regular hydrogen bonding pattern and backbone angles of b-sheets are sometimes disrupted at the edges by the formation of a b-bulge, accentuating the twist to 35° to 45°.

Figure 1. b-Sheet structure in proteins. Schematic representation of parallel and antiparallel b-sheets, with each strand of the sheet depicted as an arrow having direction from the *N*-terminal to the *C*-terminal end. In the lower half of the figure, the atomic detail of the b-sheet structure is shown, with hydrogen bonds between backbone carbonyl oxygen atoms and amide nitrogen atoms indicated by dotted lines. Note the approximately equal spacing of hydrogen bonds in the parallel b-sheet compared with the alternating wide and narrow spacing in the antiparallel b-sheet. For clarity, only Cb atoms of side chains are shown. Nitrogen atoms and oxygen atoms are shown as dark spheres. This figure was generated using Molscript (1) and Raster3D (2, 3).



Because a b-sheet can be formed from sections of polypeptide chain that are distant from each other in the primary structure, many different types of b-sheet have been identified in protein structures. The b-meander is a simple antiparallel b-sheet topology where b-strands that are consecutive in sequence are also located adjacent to one another in the three-dimensional structure. The adjacent b-strands in a b-meander are often connected by **hairpin** turns. Other types of antiparallel b-sheet structure include the jelly roll motif, the Greek key motif, and the b-barrel. The b-helix is formed from parallel b-sheets.

Beta-Strand

A b-strand is one of the two regular types of **secondary structure** (the other being the a-helix) that is commonly observed in protein structures. The b-strand is characterized by an extended backbone conformation. The b-strand is not stable as a discrete structural unit by itself, but is stable only when it associates through hydrogen bond interactions with adjacent b-strands to form a b-sheet.

[See also Beta-Sheet and Secondary Structure, Protein.]

Beta-Turns

A b-turn is a type of nonregular **secondary structure** in proteins that causes a change in direction of the polypeptide chain. In the b-turn, a hydrogen bond is formed between the backbone carbonyl oxygen of one residue (i) and the backbone amide NH of the residue three positions further along the chain ($i + 3$) (Fig. 1) (1). This (i) to ($i + 3$) interaction distinguishes b-turns from g-turns, which have an (i) to ($i + 2$) hydrogen bond. There are several different types of b-turns, classified according to the backbone dihedral angles of the two intervening residues, ($i + 1$) and ($i + 2$). The type I and II turns are the most common, together accounting for about two-thirds of all b-turns, but they have very different amino acid preferences (2). Type I turns prefer Asn, Asp, or Ser in the (i) position; Asp, Ser, Thr or Pro in ($i + 1$); Asp, Ser, Asn, or Arg in ($i + 2$); and Gly, Trp, or Met in ($i + 3$). In contrast, type II turns have a preference for Pro at position ($i + 1$), Asn or Gly at position ($i + 2$) and Gln or Arg at ($i + 3$) (2). Other b-turn types include type I′ (related to type I by inversion of the sign of the f and y angles of the Ramachandran Plot), II′ (related to type II in the same way), IV, VIa, VIb, and VIII. Types I′ and II′ are almost exclusively found in **hairpins**; that is, they usually connect two adjacent antiparallel b-strands. The type IV b-turn is a miscellaneous type that includes any (i) to ($i + 3$) hydrogen-bonded turn in a protein structure where the f and y angles are different (by >40°) from the values that define the other b-turn types (Table 1). Types VIa and VIb have a proline *cis*-peptide bond at the ($i + 2$) position; in type VIa the proline adopts a backbone conformation close to that of a-**helical** residues, whereas in type VIb the proline has a conformation similar to that of residues in a b-strand.

Figure 1. Schematic representations of a b-turn in a protein structure. (**Left**) The b-turn is shown connecting two b-strands in a hairpin motif. (**Right**) The detailed atomic structure of the b-turn is shown. Residues are numbered 1 to 4 for (*i*) to (*i* + 3). The hydrogen bond between the backbone carbonyl oxygen of residue 1 and the backbone amide nitrogen of residue 4 is shown as a dotted line. This example is a type I b-turn, because the backbone angles for the (*i* + 1) residue are f = –63° and y = –33°; and for the (*i* + 2) residue, f is –86° and y = –3°. Oxygen atoms and nitrogen atoms are shown as dark spheres. This figure was generated by Molscript (3) and Raster3D (4, 5).

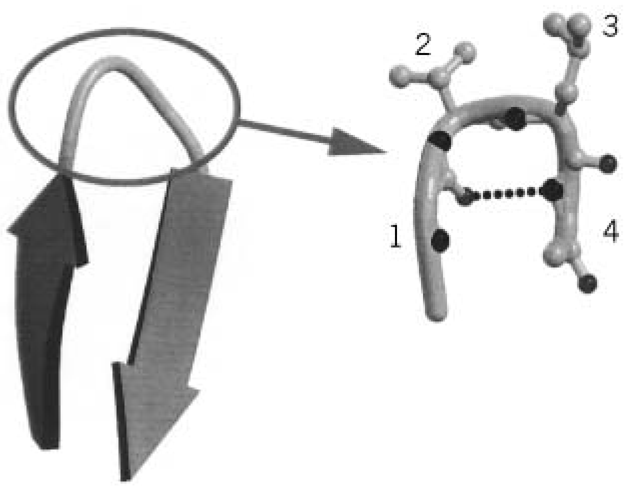

Table 1. Classification of Beta-Turn Types

	Backbone Dihedral Angles of Central Residues			
Beta-Turn Type	**f*i* + 1**	**y*i* + 1**	**f*i* + 2**	**y*i* + 2**
I	–60°	–30°	–90°	0°
I′	60°	30°	90°	0°
II	–60°	120°	80°	0°
II′	60°	–120°	–80°	0°
IV	Any (*i*) to (*i* + 3) hydrogen-bonded turn having angles that differ by more than 40° from those of other b-turn types			
VIa	–60°	120°	–90°	0°
VIb	–120°	120°	–60°	0°
VIII	–60°	–30°	–120°	120°

Bicoid

Mutational analysis in the fruitfly *Drosophila melanogaster* has demonstrated that many aspects of anteroposterior patterning are already programmed in the oocyte by maternal gene activity (1, 2). During embryonic development, cells within an embryonic field receive positional information and are instructed by the concentration gradient of morphogens (3). Historically, the graded distribution of the Bicoid protein (Bcd) has provided the first evidence for the existence of such a morphogenetic gradient. Maternally derived *bcd* messenger RNA is localized to the anterior pole of the oocyte, where it serves as the source for the Bcd concentration gradient. Then, Bcd acts as a concentration-dependent activator of transcription and as a **translational repressor**. However, Bcd is only part of a wider regulatory network of maternal determinants, and its presence might actually be restricted to dipteran flies.

0.1. Anterior Localization of the Maternal Determinant *Bicoid*

Evidence for an anterior organizing center has been obtained by experimental embryology, for example, the removal and transplantation of polar cytoplasm (4) (see Organizer). The nature of the patterning agents has been identified as RNA-containing particles (5). Genetic experiments have shown that the anterior morphogenetic function requires the activity of the *bicoid* maternal gene (*bcd*). Mothers homozygous mutant for *bcd* are normal, but all of their progeny lack head, thorax, and some abdominal structures. Instead posterior terminal structures are duplicated at the anterior (Fig. 1; (6)). Cloning of the *bcd* **gene** revealed that *bcd* is expressed during oogenesis and that its mRNA is localized to the anterior tip of the oocyte and early embryo (Fig. 2) (7). This localization depends on the presence of the *bcd* 3′-UTR, which contains a specific structure recognized by factors that carry it to the anterior pole along the polarized microtubule array of the oocyte (8).

Figure 1. Phenotype of *bcd* embryos. Mothers homozygous mutant for *bcd* lay embryos that develop cuticles lacking all head structures (hs), thorax (T1, T2, T3), and two abdominal segments (A2, A4). Furthermore, the posterior structures like the spiracles (sp) are duplicated at the anterior.

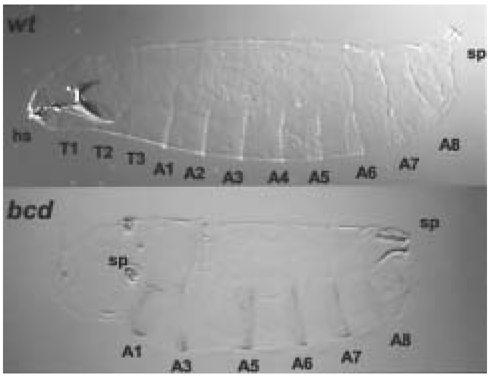

Figure 2. mRNA and protein expression of bcd and cad. The *bcd* mRNA is localized at the most anterior tip of the embryo. Its translation and diffusion of its protein product lead to the formation of the Bcd morphogenetic gradient. Maternal *cad* mRNA is distributed throughout the embryo, but its translation is blocked by the Bcd protein. This leads to the formation of a posterior to anterior gradient of the Cad protein.

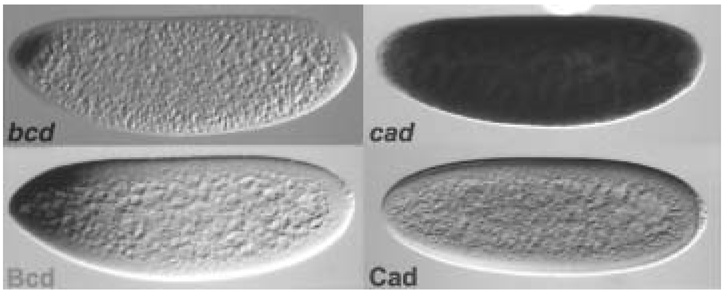
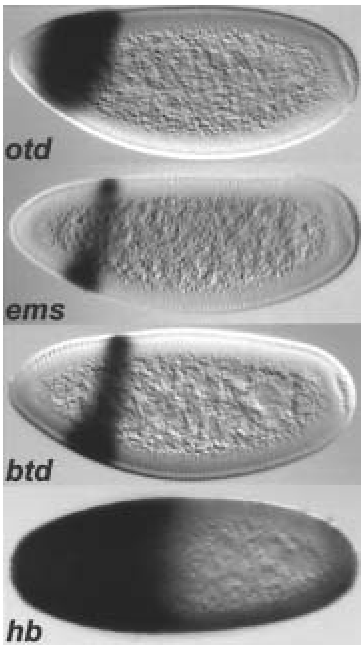


0.2. The Morphogenetic Gradient of the Bicoid Transcription Factor
After egg deposition, the anteriorly localized *bcd* mRNA starts to be **translated**, producing a source of the Bcd protein. Then, Bcd **diffuses** passively in the syncytial environment of the blastoderm embryo and generates an anteroposterior concentration gradient whose high point is at the anterior pole of the embryo and whose low point is near the posterior pole (Fig. 2; (9, 10)). Decreasing or increasing the copy number of the *bcd* gene changes the slope of the Bcd gradient and, consequently, changes the fate map of the early embryo. This suggests that anterior positional values are specified by Bcd in a concentration-dependent manner (9, 10).

The Bcd protein contains a homeodomain (7) that does not belong to any specific class (see Homeobox Genes). It is characterized by a **lysine** residue at residue 50 (Lys50) of the homeodomain that determines its **DNA-binding** specificity (14). Bcd functions as a transcriptional activator in cell culture and in yeast (11-13). The morphogenetic gradient of Bcd differentially activates the first zygotically active segmentation genes, the gap genes. At high concentrations of Bcd, the head gap genes *orthodenticle* (*otd*), *empty spiracles* (*ems*), and *buttonhead* (*btd*) are activated (15-18), whereas lower levels of Bcd are required to activate *hunchback* (hb), which is expressed in a broad anterior domain (Fig. 3; (13)). A detailed study of the proximal *hb* **promoter** suggested that the affinity of Bcd binding sites in the promoters of the different target genes determines at which threshold level, and therefore at which position along the anterior-posterior axis, these genes are activated (19, 20). The ability of Bcd to activate target genes differentially provided the first molecular explanation of how a morphogen might act.

Figure 3. Expression pattern of *bcd* target genes. *bcd* is a maternal gene that controls the expression of the zygotic gap

target genes. The morphogenetic gradient of Bcd protein differentially activates head (*otd, ems*, and *btd*) or thoracic (*hb*) gap genes.



Although Bcd is a DNA-binding protein, it also controls translation of the *caudal* gene (*cad*). *cad* is a gene required for posterior development, and its function is evolutionarily conserved in diverse organisms, including vertebrates (21). Maternal *cad* mRNA is ubiquitously distributed (22-24). Its translation is blocked at the anterior of the embryo by *bcd*, leading to a posterior-to-anterior gradient of the Cad protein (Fig. 3). *cad* is expressed ectopically in *bcd* mutant embryos throughout the embryo. Bcd binds to a sequence in the 3′-untranslated region of the *cad* mRNA (25-27). Like DNA binding, Bcd's RNA binding is conferred by the homeodomain and depends on the presence of Lys50 in the homeodomain. The Bcd homeodomain is the only one that binds RNA (25, 27).

0.4. Bicoid is Integrated into a Network of Maternal Determinants

Bcd is not the only maternal morphogen involved in anteroposterior patterning. A morphogenetic gradient of the Hunchback protein (Hb) creates the correct polarity in the embryo in the absence of *bcd*. The anteroposterior Hb gradient is established by translational repression of ubiquitous maternal mRNA by the *nanos* posterior determinant (28-30). Bcd and Hb are redundant for abdominal segmentation because high levels of maternal Hb rescue the abdominal phenotype of *bcd* mutant embryos (28, 29) and the activation of the central gap gene *Krüppel*. At the anterior of the embryo, Bcd and Hb synergize to activate the anterior gap genes (31). Because each morphogen has instructive functions on its own, both must be removed from the embryo to disrupt the polarity of the embryo completely. In more posterior regions, Bcd is also redundant with *cad* for activating the gap gene *knirps* (32). This shows that *bcd* function is partially redundant with other maternal functions. It should be noted that maternal *hb* and *cad* functions are not essential for viability in the presence of *bcd*. It is likely that they represent remains of ancestral systems that patterned the embryo before the appearance of *bcd*.

At the anterior pole of the embryo, Bcd function is influenced by the activity of the terminal system, which involves locally activating the Torso (Tor) **receptor tyrosine kinase** (33). Tor activity leads to two opposite effects on Bcd function. Tor activity increases the activator function of Bcd by lowering the threshold level of Bcd where target genes are activated (18, 34, 35). At the anterior pole, however, Bcd function is blocked in a Tor-dependent manner, and most *bcd* target genes retract from the anterior pole where Bcd concentration is the highest (36). The effect of *tor* activity on Bcd function might be mediated by *tor*-dependent phosphorylation of Bcd (36), or it may be indirect and may involve other factors (34).

0.5. Evolutionary Considerations on Bicoid

There are several reasons to believe that the critical functions of *bcd* in patterning the anteroposterior axis of the *Drosophila* embryo (Fig. 4) may not be conserved throughout evolution. *bcd* is unlikely to represent an ancestral morphogen. No *bcd* homologous genes have been identified outside higher dipterans (38), despite its homeobox and its specific location in the Hox cluster (7). Moreover, *bcd* shows an unusually high rate of **divergence** for a homeobox gene (39), and its function is not even conserved within higher dipterans (38, 40). Therefore, it is reasonable to assume that *bcd* is the result of recent gene duplication in the Hox cluster of dipterans and that it evolves relatively freely. Therefore, although the role of Bcd in *Drosophila* represents a striking example of a powerful morphogenetic **transcriptional factor**, it is likely that this function is not conserved in other insects and may exist only to allow the *Drosophila* embryo to develop quickly.

Figure 4. Morphogenetic functions of the Bcd gradient. The Bcd gradient differentially activates zygotic target genes (dark boxes) in head and thorax anlagen. The Bcd gradient also leads to the formation of the Cad protein gradient by blocking translation of its mRNA.

Bifunctional Crosslinking Reagents

1. Terminology

If a bifunctional chemical crosslinking agent is designed so that its two reactive groups are identical, it is referred to as a *homobifunctional* reagent; if its two reactive groups are different, it is a *heterobifunctional* reagent. If one or both reactive groups of the crosslinker become so only as the result of a photochemical reaction caused by exposing the reagent to light of an appropriate wavelength, then the crosslinking reagent is photoactivatable, photoreactive, photosensitive, or **light-activated (caged)**. The portion of the crosslinking reagent other than, and usually between, its two reactive groups is referred to as the *spacer arm*, or *crossbridge*. If the spacer arm contains a covalent bond that can be easily broken (by an oxidant, reductant, base, etc), then the crosslinker is termed *cleavable*; otherwise, it is classified as *noncleavable*. With most chemical crosslinkers, a portion of the reagent is incorporated into the final crosslinked complex; however, there is a special class of reagents that facilitate crosslinking without being incorporated into the final covalent complex. These reagents are referred to as *zero-length* crosslinkers, because the groups they crosslink are not separated by a spacer arm.

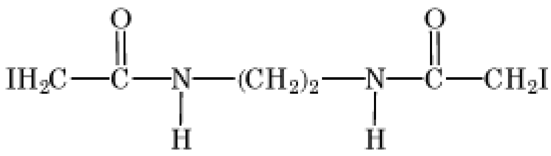
2. Variables in the Design of Crosslinking Reagents

By varying the chemical and physical properties of the reactive groups and spacer arm of a crosslinking agent, one can obtain crosslinkers with different properties and uses. A heterobifunctional reagent, with its two different types of reactive groups, allows for different selectivities in the functional groups that become crosslinked, compared to a homobifunctional reagent containing a pair of the same reactive groups. The selectivity shown by the reactive groups of crosslinkers for the side chains of particular amino acids mirrors the selectivity of those reactive groups when used as monofunctional reagents in the chemical modification of proteins, from which crosslinking is an outgrowth.

A number of variables pertain to spacer arms: (*1*) the length of the crossbridge, as in the case of bisimidoesters (Table 1) with different numbers of methylene groups in the spacer arm; (*2*) its geometry, which in the case of the phenylenebismaleimides (Table 1) also causes an increase in length, progressing from *ortho* to *para*; (*3*) its chemical nature, especially the number of charged or polar groups on the spacer arm, which influences the crosslinker's solubility properties and uses. For example, membrane proteins would more likely be crosslinked by bifunctional reagents that are **hydrophobic**, rather than hydrophilic. Reporter groups (chromophores, radioactive tracers, etc) can also be incorporated into spacer arms to facilitate quantification of the extent of protein modification, studies on the crosslinked complex, or identification of the crosslinked components. Incorporation into the spacer arm of cleavable bonds, such as disulfide bonds, is also useful in the identification of crosslinked components, especially by diagonal methods (1).

Table 1. Examples of Bifunctional Crosslinkers

Compound	Structure	Class
Homobifunctional		
1. *N,N′-p*-Phenylenebismalemide		Bismalemide
2. *N,N′*-Ethylene-bis (iodoacetamide)		Bishaloacetylamide

3. Dimethylsubermidate		Bisimidoester
4. *N*-Hydroxysuccinimidylsuberate		*N*-Hydroxysuccinimi
5. Glutaraldehyde		Dialdehyde
Heterobifunctional		
6. *N*-Succinimidyl-3-maleimidopropionate		*N*-Hydroxysuccinimide
7. *N*-5-Azido-2-nitrobenzoyloxysuccinimide		Arylazide/N-hydroxy ester

3. Examples of Bifunctional Crosslinkers

The compounds listed in Table 1 are representative of some of the most frequently used chemical classes of crosslinking reagents, but they represent only a small fraction of the literally hundreds of bifunctional crosslinking reagents that have been described in the scientific literature. The widely used *N*-substituted bismaleimides are selective for thiol groups, especially at pH values near neutrality, where amino groups are predominantly protonated. This class of crosslinkers is available with many different spacer arms, having large variations in length and solubility, or having chromophores or cleavable bonds incorporated. The alkylating bishaloacetyl crosslinkers are also selective at neutral pH for sulfhydryl groups, but they will also react with imidazole side chains of some **histidine** residues under this condition. It should be remembered that few reagents used to modify proteins chemically are absolutely specific for any given amino acid side chain; on the other hand, high selectivity can often be achieved empirically through varying the pH, reaction time, and concentrations of reactants.

The bisimidoesters were among the earliest used crosslinkers and are also available with a variety of spacer arms. These compounds preferentially react at alkaline pH with amino groups, with which they form amidine bonds, retaining the positive charge of the original amine. A more frequently used class of amine-selective reagents is the N-hydroxysuccinimide esters, which produce an amide-crosslinked product that is relatively stable in aqueous solution. The *N*-hydroxysuccinimide ester group is frequently combined with maleimide, such as in compound 6 of Table 1, to produce heterobifunctional crosslinkers with selectivity toward crosslinking amino and sulfhydryl groups. Another common class of heterobifunctional crosslinkers contains at one end a photoactivatable group, which is generally assumed to be nonselective for the functional groups it modifies. For this class of reagents, the two-step reaction protocol is particularly useful, with the chemical reaction being carried out first in the absence of activating radiation, followed by irradiation of the photosensitive group to bring about crosslinking. The arylazide shown in Table 1 (compound 7) is an example of a photosensitive crosslinker that is widely used. The bis-homobifunctional aldehyde glutaraldehyde (Table 1, compound 5) is perhaps the most frequently used chemical crosslinker.

Binding

Total binding B_L is the number of ligand molecules that at any moment are in contact with (occupy sites on) the accessible surface of a protein molecule. It is related to preferential binding (as measured by equilibrium dialysis) by

$$B_L = \left(\frac{\partial m_L}{\partial m_{pr}}\right)_{T,\mu_w,\mu L} + \frac{m_L}{m_w} B_w \tag{1}$$

where B_L and B_w are the numbers of ligand and water molecules, respectively, that are in contact with the protein surface.

When the interactions are weak, the ligand must be used at high concentration (eg, 1 *M* sucrose, 3 *M* glycerol, 8 *M* urea). As a consequence, the total binding is *not* given by equilibrium dialysis, as the last term of Eq. (1) (binding of water) becomes significant. Total binding can be measured by nonthermodynamic techniques that respond to contacts between ligand molecules and protein [(1)]. Such techniques include **calorimetric** titration, which detects the heat of protein–ligand contact, or spectroscopic techniques (eg, **fluorescence** or **uv absorbance**) that detect spectral perturbations each time a ligand–protein contact is made. If the total hydration is known from other techniques, then total binding can be derived from dialysis equilibrium results by the application of Eq. (1).

Bioinformatics

Bioinformatics is a new branch of molecular biology, also kown as computational biology. Computational physics and computational chemistry have emerged as third branches in their respective disciplines, after the experimental and theoretical branches, due largely to the advance of computational capabilities in modern computers. In contrast, bioinformatics has emerged in molecular biology as the result of advances in experimental technology, especially in the high-throughput DNA sequencing, which is generating a vast amount of **gene** and protein sequence data. Since initiation of the Human Genome Project in the late 1980s, bioinformatics has become an integral part of the coordinated efforts to sequence the entire genomes of a number of organisms from **bacteria** to human. Consequently, bioinformatics is a data-driven discipline requiring large-scale databases and associated technologies for data management and interpretation. This contrasts with the model-driven, theory-based approaches in computational physics and computational chemistry.

Bioinformatics covers a diverse range of topics, which broadly have two roles. First, bioinformatics is widely used in experimental projects, such as in determining the optimal **genetic mapping** strategy and how best to assemble raw sequence data, and in the storing and handling information and materials. Secondly and more important, the major task of bioinformatics is to develop new databases and new computational technologies that will help to understand the biological meaning encoded in the sequence data. Interpretation of sequence data cannot be achieved by numerical calculations based on first-principle equations, which are virtually nonexistent in biology, but it requires using and processing empirical knowledge acquired from experimental data. This is what human experts would do if the amount of data and knowledge were manageable in size. Thus, bioinformatics was born from the marriage of molecular biology, in the age of massive data production, with artificial intelligence, which is a mature branch of computer science, to automate knowledge processing.

Table 1 summarizes topics in bioinformatics for interpretating of sequence data. The methods of computer science have been used traditionally in artificial intelligence applications, such as speech recognition and natural language processing, but they are also quite effective in solving problems in molecular biology. There is a rough distinction between how data are organized and consequently what kinds of computational methods are used in the three categories of Table 1. In the first category of similarity searches, the database is a collection of all the known primary data, such as the sequence database and the structure database, which are the repositories of all reported sequences and three-dimensional structures, respectively, of **nucleic acids** and proteins. A basic operation in this category is comparing of individual sequences or structures to detect any similarity. For example, to understand the functional implications of a newly determined gene or protein sequence, it is customary to perform a sequence similarity, or homology, search, comparing the query sequence with each of the sequences in the database. If any similar sequence is found in the database, the query sequence is assumed to have a similar or related function. This reasoning is based on the empirical observation that homologous sequences generally share similar functions and similar 3-D structures, because they arose from a common evolutionary ancestor and because of functional constraints.

Table 1. Bioinformatics for Interpretation of Sequence Data

Problems in BiologicalScience		Methods in Computer Science
Similarity search	Pairwise sequence alignment	Dynamic programming
	Sequence similarity search	Simulated annealing
	Multiple sequence alignment	Genetic algorithms
	RNA secondary structure prediction	Other optimization algorithms
	3-D protein structure alignment	
Structure/function prediction	Motif extraction	Discriminant analysis
	Functional site prediction	Neural network
	Cellular localization prediction	Hidden Markov model
	Coding region prediction	Formal grammar
	Transmembrane segment prediction	Other pattern recognition and learning algorithms
	Protein secondary structure prediction	
	3-D protein structure prediction	
	3-D RNA structure prediction	
Molecular classification	Superfamily classification	Clustering algorithms
	Fold classification	
	Ortholog/paralog grouping of genes	

The procedure of comparing two sequences is a problem of sequence alignment, which is a major topic in sequence analysis. Given a similarity measure of amino acids or nucleotides, the problem of obtaining the best sequence alignment is equivalent to optimizing a given score function that represents the overall similarity. There are variations in how the optimal alignment is made, either globally for the entire sequences or locally to detect localized regions, how many sequences are aligned at a time, and which similarity measure is to be used. By allowing insertions and deletions (indels), the number of possible alignments grows exponentially as the number and length of the sequences to be compared increases. Thus, the sequence alignment problem is a typical combinatorial optimization problem in computer science. Although the alignment of two or three sequences can be solved rigorously by using dynamic programming algorithms (1), which effectively evaluate all possibilities, multiple alignment of many sequences requires heuristic algorithms to obtain approximate solutions. Furthermore, to search large databases effectively for similar sequences, heuristic algorithms such as FASTA (2) and BLAST (3) have been developed for rapidly identifying regions of two sequences that are similar locally. Other extensions of the sequence alignment algorithms include analysis of a single RNA sequence to predict any **secondary structure** (see RNA Structure Prediction) and compare two 3-D protein structures.

When humans try to interpret a sentence written in a foreign language, they use dictionaries and a knowledge of grammar. However, the process of using a homology search to interpret a sentence written in the DNA language is like comparing it with all the sentences written in the past and checking precedents as to how they were interpreted. Sequence interpretation would become more efficient if our knowledge of sequence-functional relationships were more advanced. The second and third categories in Table 1 involve such reorganizations of the primary data. In the second category of structure/function prediction, the primary data are classified into a group based on a given criterion, such as functional identity, and higher level knowledge is abstracted from this group. This is based on our empirical observation that the function of a protein molecule is usually exerted at a functional site in its three-dimensional structure, which is usually a **ligand-binding** site for other molecules, and that the site is formed by one or more linear polypeptide segments that have conserved sequence patterns. These conserved patterns are called sequence motifs, and they can be extracted, for example, by multiple alignment of a set of sequences that have the same function. A motif search against a library of known motifs is widely used as an alternative method for interpreting sequence data, when no similar sequences have been found by a homology search. However, the bioinformatics problem here is not how to search the known motifs, but how best to extract and define new motifs effectively. Thus, the problem is related to machine learning in computer science, where a higher level concept or a generalized pattern is abstracted from a set of given examples.

Although the second category in Table 1 is targeted at a specific function and a specific group of sequences, the third category of molecular classification represents a more global analysis, where the grouping is attempted with all the available data, and the relationship among groups, which is often hierarchical, is examined. For example, all known protein sequences can be hierarchically classified into families and superfamilies according to their level of sequence similarity. Because complete genome sequences are available, it has become possible to establish similarity relationships of all **genes** within species (paralogous genes) and across species (orthologous genes). These analyses are carried out by clustering algorithms, and the similarity score is used as a measure of the closeness of two sequences. In practice, however, there are biological difficulties, notably due to the abundance of multi**domain**, multifunctional proteins, which make automatic clustering a complicated task.

Molecular biology has been dominated by a reductionist approach where, starting from a selected functional aspect of life, such as metabolism, signal transduction, or development, molecular components and their interactions are identified experimentally. In contrast, sequencing an entire genome identifies a complete set of genes and proteins in an organism, but it does not tell how they should be interrelated to form a functioning, living system. This is where a synthetic approach based on bioinformatics will play an increasingly more dominant role in the basic research into understanding life and in the applied research into biomedical relevance. Table 2 summarizes the role of bioinformatics relative to the level of abstraction in nature. At the molecular level, an amino acid residue is represented by a symbol, for example, C for cysteine, which is a compound consisting of carbon, hydrogen, nitrogen, oxygen, and sulfur atoms. When comparing two amino acid sequences, only the one-dimensional connection of symbols is considered biologically relevant, neglecting any atomic details. At a higher level of abstraction, which may be called a network level, a gene or a protein is represented by a symbol, for example, Ras for an **oncogene** product. A primary concern here is the Ras signal transduction pathway, which is generated by a network of interacting molecules. Bioinformatics is relatively well established at the molecular level, such as in the sequence and structure databases and in the computational methods to analyze them. To step up to a higher level, however, it is necessary to develop new databases and new computational technologies, such as a network database containing all the wiring-diagram information about genes and molecules, plus the algorithms to analyze them. This direction would eventually lead to *in silico* reconstruction of a biological organism.

Table 2. Level of Abstraction

Level	Constituents	Entity	Informatics
Subatomic level	Elementary particles	Atom	Computational physics
Atomic level	Atoms	Amino acid, etc.	Computational chemistry
Molecular level	Amino acids, nucleotides, etc.	Protein, gene, etc.	Bioinformatics
Network level	Proteins, genes, etc.	Molecular pathway, molecular assembly

Biopolymer

Biopolymers, sometimes referred to as biological macromolecules, are polymers of biological importance such as proteins, **nucleic acids**, and carbohydrates. Like all polymers, biopolymers are formed by joining together many copies of repeating units to form long chains that have a repeating or constant backbone and variable side chains. The repeating units of proteins are the 20 naturally occurring amino acids that form a polypeptide chain. Nucleic acids are formed from **nucleotides** and have a sugar-phosphate backbone with **purine** or **pyrimidine** side chains.

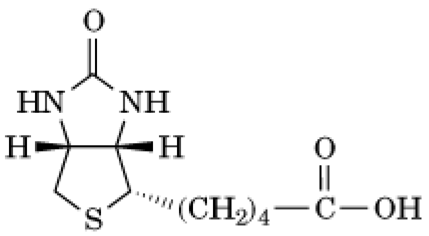
Biotin

Biotin is a vitamin (vitamin H) and a growth factor, first isolated by Kögl in 1935 (1). Its structure (Fig. 1) was established by du Vigneaud in 1942 (2, 3).

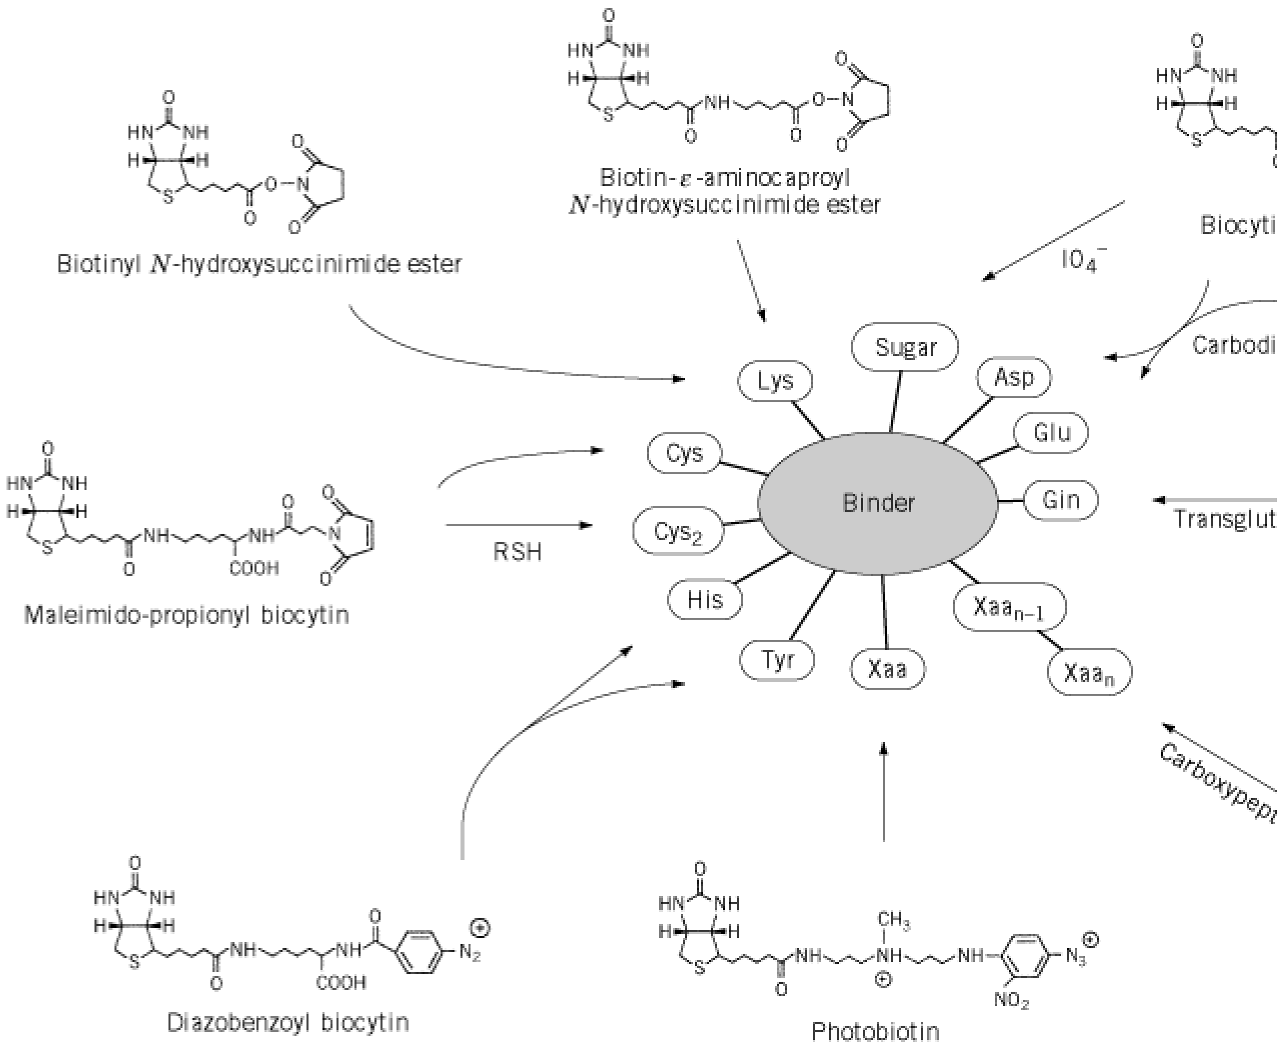
Figure 1. The structure of biotin.



Biotin is a prosthetic group for a family of "biotin-requiring" enzymes (carboxylases, decarboxylases and transcarboxylases) (4). These multisubunit enzymes contain two types of active sites, one wherein a molecule containing a carboxylic acid group serves as a donor of the carboxyl group and the second wherein another molecule acts as an acceptor. The biotin moiety is attached through a lysine residue in a particular sequence (Ala-Met-Lys-Met) that is exposed on the surface of a special type of biotin-binding subunit. The biotin group participates as a transient carrier to which the carboxyl group is bound covalently in the process of being transferred from the donor to the acceptor molecule. The biotin moiety of the enzyme is readily available for binding to avidin, which inactivates the enzyme. After serving their respective function, the biotin-requiring enzymes undergo degradation, whereby e-N-biotinyl lysine (termed biocytin) is released into the circulation. There the enzyme biotinidase hydrolyzes biocytin to regenerate biotin and lysine. A rare mutation in the gene in humans causes a deficiency in the level of this enzyme in the blood stream, which, in turn, causes a disease due to a deficiency of biotin (5).

Biotin attained true fame when it was recognized that the high-affinity interaction between avidin and biotin can be applied for a variety of biotechnological and biomedical purposes (as described in Avidin-biotin system)(6, 7). The varied application of this system is usually achieved upon coupling biotin covalently to different biologically active binder molecules, antibodies, hormones, **DNA**, etc. The binding of biotin to either avidin or streptavidin greatly enhances the stability of these proteins, such that the avidin–biotin or streptavidin–biotin complex is essentially irreversible. Because both proteins primarily recognize the ureido ring of the biotin molecule, the carboxylic acid side-chain can be modified almost at will, and the resultant derivatives can be used to incorporate biotin covalently into virtually any other molecule (Fig. 2).

Figure 2. Selected approaches using different biotin-containing reagents for biotinylating functional groups on proteins.



Both polyclonal and monoclonal antibodies have been produced against biotin. Comparing the sequence of the V_H region of a monoclonal anti-biotin preparation (8) with the sequences of avidin and streptavidin revealed an astonishing similarity in their binding sites, indicating that such functional elements are conserved in nature for a given purpose, irrespective of the protein type.

Biotin Repressor

All genes for the biosynthesis of biotin of *Escherichia coli* are grouped in a single operon located at 17 min on the chromosome, except for except for *bioH*, which is located at 75 min. The genes of the operon *bioA*,*BFCD* are transcribed divergently from a single regulatory region located between the *bioA* and the *bioB* genes. Transcription in both directions is corepressed by biotinyl-5′-adenylate and the biotin repressor. The following table shows the respective function of these genes:

bioC and bioH	Unidentified steps in pimeloyl CoA biosynthesis
bioF	7-Keto-8-aminopelargonic acid synthetase
bioA	7,8-Diaminopelargonic acid synthetase
bioD	Dethiobiotin synthetase
bioB	Biotin synthase (introduction of the S atom)

No precise information is available on the function of the *bioC* and *bioH* genes, other than that a mutation in either gene results in no excretion of a known intermediate in the pathway. Therefore the products of these genes have been assigned to some early steps before 7-keto-8-aminopelargonic acid synthesis. All biotin genes are coordinately repressed when biotin is added to the growth medium in excess of 1 ng/Ml.

The biotin repressor is a very interesting bifunctional protein of 321 amino acid residues, which acts at two different levels. In addition to its repressor function, it is endowed with acetyl CoA carboxylase biotin holoenzyme synthetase activity, which activates biotin to biotinyl-5′-adenylate and transfers the biotin to acceptor proteins. As soon as these proteins are totally biotinylated, biotinyl-5′-adenylate accumulates and serves as the corepressor of the biotin operon. This is a case of an enzyme synthesizing its own repressor, a unique property thus far among DNA-binding proteins. Mutations in the corresponding gene (*birA*) inactivate the repressor function partially or totally and also alter the enzymatic function. This repressor binds to a 40-bp symmetrical biotin **operator** site to prevent transcription of the biotin biosynthetic genes. The structure of the repressor is highly asymmetrical and consists of three **domains**. The N-terminal domain is mostly **alpha-helical**, contains a helix–turn–helix motif and is loosely connected to the remainder of the molecule. The central domain consists of a seven-stranded mixed beta-sheet, with a-helices covering one face. The other side of the sheet is largely exposed to the solvent and contains the enzyme's active site. The C-terminal domain comprises a six-stranded antiparallel b-sheet sandwich. The location of biotin is consistent with mutations affecting enzymatic activity.

Two molecules of the monomeric repressor bind cooperatively to one molecule of operator in the nanomolar concentration range. The data suggest that one molecule of repressor monomer binds to each of the two operator half sites and that they form a dimer only after they bind. Because the complex between repressor and DNA has not yet been crystallized, details of its structure remain an open question.

BiP (Hsp70)

The acronym BiP stands for binding protein, and it is the only member of the hsc,hsp70 family known to occur in the lumen of the endoplasmic reticulum (ER) of mammalian cells. It was identified originally as an ER protein that increases in amount when cells are starved of glucose (1) and subsequently as a protein that binds noncovalently to the heavy (H) chains of immunoglobulins as they enter the ER lumen (2). The alternative term of "Grp78" stands for **glucose-regulated protein** with an apparent subunit mass of about 78 kDa. BiP is now regarded as having a general **molecular chaperone** role for transport in the ER lumen and for protein folding in vivo. BiP proteins are highly conserved in mammals, and there is 67% identity between mouse BiP and a homologue in the ER lumen of *Saccharomyces cerevisiae* called "Kar2p" (3). Like all hsc,hsp70 proteins, BiP exhibits a weak ATPase activity.

1. Structure

BiP is encoded in a nuclear gene located on human chromosome 9q34, and cDNA from mammalian species indicate a primary translation product of 635 amino acid residues, including an 18-residue *N*-terminal signal sequence for ER targeting and the *C*-terminal tetrapeptide **KDEL sequence** for ER retention (GenBank accession numbers M19645 and M17169). The *N* and *C* termini contain clusters of acidic residues thought to be involved in Ca^{2+} binding (4). No crystal structure is available for mammalian BiP, but a structure is known for the *N*-terminal 45-kDa fragment of bovine hsc70, which retains the ATPase activity (5), and for the *C*-terminal polypeptide-binding domain of the *Escherichia coli* hsp70 homologue called **DnaK** (6). Purification protocols for BiP utilize affinity chromatography on ATP columns (7). Recombinant hamster BiP has been purified from *E. coli* cells (8) and is marketed by StressGen Biotechnologies Corporation, as are polyclonal antibodies to rodent BiP. *In vivo* BiP exists in interconvertible oligomeric and monomeric forms and is subject to **phosphorylation** on serine and threonine residues, as well as to **ADP-ribosylation**. However, only monomeric, unmodified species of BiP are found in complexes with unfolded or unassembled polypeptides (9).

2. Function

BiP binds transiently to a range of newly synthesized secretory proteins, as they traverse the ER membrane and enter the ER lumen, and more permanently to misfolded, underglycosylated, or unassembled proteins whose transport from the ER is blocked (10); it does not bind to native, folded proteins. The binding is reversed by the addition of ATP and is believed to exert a molecular chaperone function by preventing premature folding and/or aggregation; this function is achieved by the shielding of potentially interactive **hydrophobic** surfaces during the time when BiP is bound. There is also evidence that the BiP homologue in yeast functions as a molecular motor protein to promote the transport of proteins across the ER membrane (11). This transport function requires the binding of the BiP homologue to the *J* domain of the yeast ER membrane protein Sec63p (12) (see also text later in this article). Studies of the binding of synthetic peptides and bacteriophage peptide libraries show that the optimum peptide length for binding is seven to eight residues, with extensive sequence diversity but a marked preference for hydrophobic residues (13, 14). These observations support the idea that BiP binds to a wide range of sequences that normally occur inside fully folded proteins. A computer program is available that scores potential BiP binding sites in protein sequences (14); it has been used to map such sequences in immunoglobulin heavy chains to the regions that interact with light chains (15).

3. Interaction with Other Chaperones

Cytosolic hsc,hsp70 proteins in the bacterial and eukaryotic cytosol interact with other chaperones of the DnaJ (or hsp40) family that contain *J* domains (see DnaK/DnaJ Proteins). The yeast BiP homologue, Kar2p, interacts with two other ER proteins that contain *J* domains: Sec63p, a membrane protein involved in protein translocation across the ER membrane (16); and Scj1p, a lumenal protein (17). BiP also binds either sequentially or simultaneously with chaperones such as **calnexin** and Grp94 during the folding in the ER of proteins such as immunoglobulin light (L) chains (18), thyroglobulin (19), vesicular stomatitis virus G protein (20), and major histocompatibility complex class II chains (21). BiP is thus one component in a complex set of interactions in the ER lumen between different chaperones and polypeptide chains that are folding.

4. Induction of BiP

BiP is an abundant protein under normal growth conditions, constituting about 5% of the ER lumenal proteins, but its amount increases greatly under conditions that result in the accumulation of proteins within the ER lumen that are unable to fold correctly. These conditions include the biosynthesis of mutant chains, glucose starvation, and treatment with amino acid analogs, drugs that inhibit glycosylation, and calcium **ionophores** (22). The **promoters** of BiP genes in mammals contain several cis-acting regulatory elements required for high basal-level expression and for inducibility (22, 23).

Bisubstrate Analogue

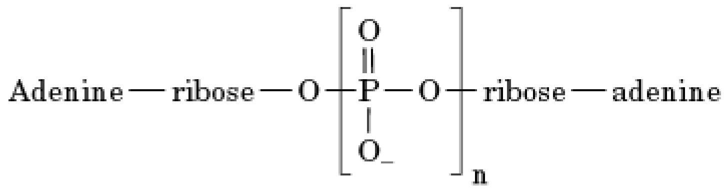
Bisubstrate analogues were developed originally for mechanistic studies on enzymes that catalyze reactions with two substrates or products. However, they have also proved to be of value in studies on enzymes by X-ray crystallography. Bisubstrate analogues are characterized by the fact that they embody in a single molecule the structural features of each of the two substrates (or products). Hence, it was expected that they would bind simultaneously at the binding sites for the two substrates, and therefore more tightly than the individual substrate molecules, and act as potent enzyme inhibitors. They have also been referred to as transition state analogues, but such a classification seems inappropriate.

Two early, and now classical, examples of bisubstrate enzyme inhibitors are P^1, P^5-di-(adenosine-5′) pentaphosphate (AP_5A) and *N*-phosphonoacetyl-L-aspartate (PALA), whose structures are given in Figure 1. AP_5A was developed as an inhibitor of adenylate kinase, which is a monomeric enzyme that catalyzes the reaction:

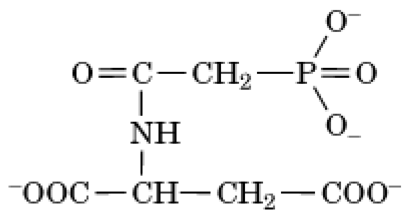
$$MgATP^{2-} + AMP^{2-} \rightleftharpoons MgADP^{-} + ADP^{3-}$$

The reaction conforms to a rapid equilibrium, random **kinetic mechanism**, which implies that the enzyme possesses two distinct nucleotide-binding sites within its active site. One is for either $MgATP^{2-}$ or $MgADP^{-}$ and the other is for ADP^{3-} or AMP^{2-}. Irrespective of whether they are substrates or products, the moieties bound by the enzyme include two adenosine moieties and four phosphate moieties, whereas AP_5A differs only in having five phosphate groups linked covalently. AP_5A is a potent inhibitor of the adenylate kinase reaction, with the apparent inhibition constant K_i value being in the nanomolar region; the inhibition is competitive with respect to both MgATP and AMP, as would be expected (1, 2). Binding studies indicate that the stoichiometry of binding is 1:1 and the **dissociation constant** is 15 nM (3). The binding affinity is reduced seven-fold in the absence of Mg^{2+}. It is of interest that the binding to adenylate kinase of AP_4A, which is the equivalent of covalently linking ATP to AMP, or ADP to ADP, is almost 3,000-fold weaker. An increase in the number of phosphoryl groups to six also reduces the binding affinity by 400-fold. The crystal structures of three adenylate kinases and enzyme–AP_5A complexes were solved well ahead of the spatial assignment of the substrate binding sites. A review of the problems associated with the determination of the structural relationship between the two nucleotide binding sites of adenylate kinase has been presented (4).

Figure 1. Examples of bisubstrate analogues. (**a**), P^1, P^n-di(adenosine-5′) *n*-phosphate, where $n = 4$ (AP_4A), 5 (AP_5A), or 6 (AP_6A). (**b**), *N*-phosphonoacetyl-L-aspartate (PALA).



(a)



(b)

AP_5A also acts as a strong inhibitor of ATP:NMP phosphotransferase from *Dictyostelium discoideum*, which utilizes either UMP or CMP as the acceptor of a phosphoryl group from ATP (5). Binding studies indicate that the dissociation constant of the enzyme-AP_5A complex is 160 µM. However, the corresponding bisubstrate analogue with uridine replacing one adenine nucleotide (UP_5A) is a more potent inhibitor and binds with a dissociation constant of 3 nM. The enzyme has been co-crystallized with UP_5A.

PALA has been used extensively for kinetic and structural studies on aspartate transcarbamoylase **(ATCase)**, which catalyzes the reaction:

$$\text{Carbamoyl phosphate} + \text{aspartate} \rightleftharpoons \text{carbamoylaspartate} + P_i$$

PALA is considered an analogue of the two substrates linked covalently. The intact ATCase enzyme consists of both catalytic and regulatory units, does not show Michaelis–Menten kinetics, and is subject to **allosteric** control by nucleoside triphosphates. However, it is possible to prepare an active trimer of just the catalytic subunits that shows Michaelis–Menten kinetics and is not subject to allosteric control. This form of enzyme has been very useful for elucidating fundamental information about the catalytic sites and mechanism of action of ATCase. Investigations with the catalytic trimer have shown that one molecule of PALA binds to each subunit of the trimer (6) and the inhibition is linear competitive with respect to carbamoyl phosphate and linear noncompetitive relative to aspartate (7). Additional kinetic data have indicated that the kinetic mechanism for the aspartate transcarbamoylase reaction is essentially ordered, with carbamoyl phosphate being the first substrate to add; this explains the inhibition pattern. The pH-independent K_i value for the enzyme-PALA complex is 7.2 nM, which is three orders of magnitude lower than the dissociation constant for the corresponding enzyme-carbamoyl phosphate complex (7).

PALA has also played an important role in the demonstration that the co-operativity observed with intact ATCase can be explained in terms of a two-state allosteric **concerted model** (8). Thus, the binding of up to three molecules of PALA to the intact enzyme, which has six active sites, leads to activation, even though PALA is occupying active sites, as a result of displacing the equilibrium between the T (inactive) and R (active) forms of the enzyme toward R. Only with greater occupancy is PALA inhibitory. Structural studies support the idea that PALA is a true bisubstrate analogue of the substrates for the enzyme (9).

Bithorax Complex

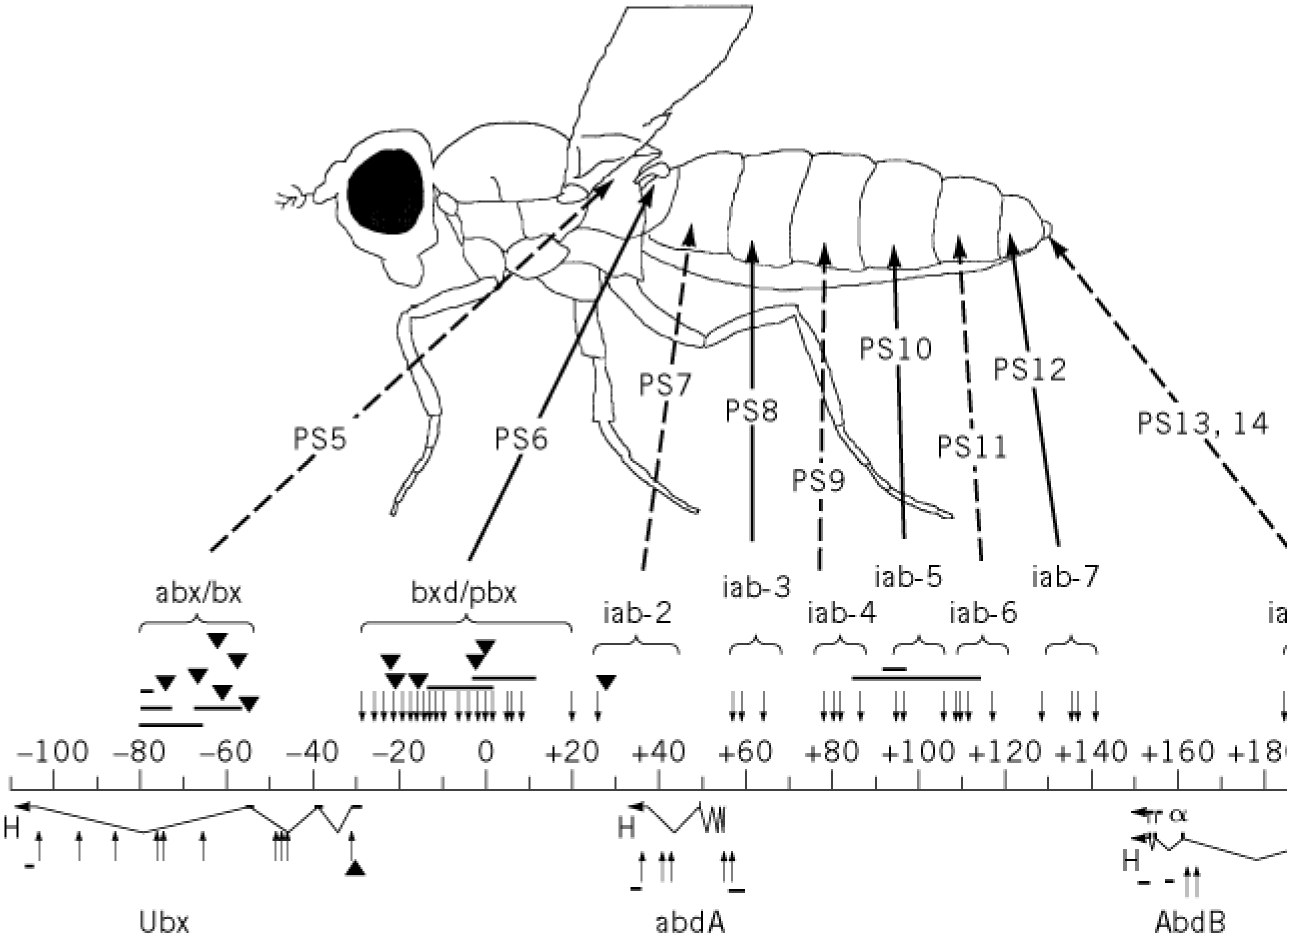
The homeotic genes of the bithorax complex (BX-C) have been the subject of many landmark discoveries in the field of **developmental** biology. Homeotic genes were first identified in *Drosophila* by mutations that affect their expression. These mutations lead to spectacular effects on the morphology of the fly; they cause the development of a specific body structure (ie, segment, antenna, leg, wing) at the place where another structure normally develops. The first homeotic mutations, *bithorax* (*bx*) and *bithoraxoid* (*bxd*), were described in 1923 by Bridges and Morgan (1). For example, in flies homozygous for *bxd* mutations, their first abdominal segment (A1) develops like a copy of the segment immediately adjacent anteriorly—namely, the third thoracic segment (T3). Thus, the role of the bxd^+ function is to assign the identity of A1. In the late 1940s, Ed Lewis pioneered the field of developmental genetics by discovering the existence of additional homeotic mutations near *bx* and *bxd*. Although these mutations seem to affect different body segments of the thorax and abdomen, their complementation patterns turned out to be rather complex. Because they all mapped at the same genetic and cytological position, Lewis decided to name the locus the bithorax complex (BX-C). The work of Lewis was compiled in a milestone article in 1978 (2) in which he describes a series of homeotic mutations of BX-C that affect the identities of the third thoracic segment and all of the abdominal segments. Mutations in any of them transform the considered segment into a copy of the segment immediately anterior. Remarkably, genetic mapping revealed that these mutations are arranged on the chromosome in the same order along the anteroposterior axis as the segments they affect. By combining three mutations, Lewis produced flies with four wings instead of two (transformation of T3 into T2). Because such animals look like more ancestor forms of insect, Lewis proposed that homeotic genes played an instrumental role in evolution. The correspondence between the order of the genes on the chromosome and the order of the segments on the body of the fly has now attained almost mystical status and has turned out to be true also of the vertebrate homologues of BX-C. The Nobel Prize Committee has recognized this pioneering works by awarding its 1995 Nobel Prize of Medicine to Ed Lewis and two other *Drosophila* geneticists (Y. Nusslein-Volhard and E. Wieschaus).

In 1978, BX-C was the first *Drosophila* gene **cloned** from the chromosome without any prior knowledge of the products. To clone what turned out to be a large complex, Bender, Spierer, and Hogness developed the method of **chromosome walking** (3). Finally, in 1983, the molecular characterization of the BX-C led to the discovery of the homeobox in the laboratories of W. Gehring and of M. Scott (4, 5).

1. Molecular Genetics of BX-C

Figure 1 summarizes the molecular genetics of the BX-C. The complex covers 300 kbp of DNA, which are represented by the thin horizontal line marked off in kb (6, 7). Above the DNA line are represented the sites of the homeotic mutations that affect the identities of each of the segments under the control of the BX-C. The vertical arrows represent the sites of chromosomal rearrangement breaks, the triangles the sites of insertion of transposons, and the horizontal lines the extent of deletions. Expression studies and analysis of the homeotic **phenotypes** in embryos have revealed that the unit transformed in each of these nine classes of mutations does not correspond to body segments; instead, it is composed of the posterior part of one segment and the anterior compartment of the next segment. These units are named parasegments (PSs) (8). For example, *bxd* mutations cause the transformation of the posterior part of T3 (pT3) and the anterior part of A1 (aA1) into p (T2) and aT3. This corresponds to the transformation of parasegment 6 (PS6) into PS5. The mutations affecting parasegment identity form nine discrete entities that, as predicted by Lewis, are aligned on the chromosome in the same order as the parasegments in which they act on the body of the fly (*abx/bx*, *bxd/pbx*, *iab-2* through *iab-8*). These mutations define nine PS-specific functions, and the arrows point toward the parasegments of the adult fly that are most affected in each class of mutations (Fig. 1). For reasons that will become clear later, it is worthwhile noting that all the mutations affecting the PS-specific functions are due to chromosomal rearrangements (more than 100 have been mapped). Thus, it seems impossible to affect these functions by point mutations, and it is unlikely that they correspond to individual **genes** coding for distinct proteins.

Figure 1. Genetic map of the bithorax complex (BX-C). The 300 kilobases of DNA that compise the complex are indica bottom line, which is marked off in 10^4 base pairs. Above the DNA line are represented the sites of the homeotic mutatic affect the identities of each of the segements under control of BX-C. The vertical arrows represent the sites of chromosoı rearrangement breaks, the triangles the sites of insertion of transposons, and the horizontal lines the extent of deletions. T parasegments (PS5 to PS13, 14) that each part of the complex controls are indicated above, in the adult fly. The three tra units (*Ubx*, *abdA*, and *AbdB*) are indicated below the DNA; in each case, transcription occurs from right to left. The exor indicated by the thick horizontal lines, the introns by the thin V's connecting them. H indicates the homeobox domain. Tl alternative promoters a and g are indicated for *AbdB*. Mutations that affect the transcription units are indicated below the



Northern blots and the isolation and sequencing of complementary DNA revealed the existence of only three transcription units *Ubx*, *abd-A*, and *Abd-B*. These three transcriptions units are all transcribed from right to left (of Fig. 1) and contain a **homeobox** sequence at their 3′ end. The *Ubx* transcription unit covers 7O kb of DNA and can generate 12 different transcripts by alternative splicing and polyadenylation. Translation of these messenger RNAs yields a family of six proteins characterized by constant amino- and carboxy-proximal regions of 247 and 99 amino acid residues, respectively. The latter homeobox sequence is encoded by the 3′-terminal common exon. The members of this family are distinguishable by a short variable region that links the constant regions and consists of different combinations of three optional elements of 9, 17, and 17 residues (9-11). The spectrum of RNA products changes with time and tissue. It has been demonstrated that the *Ubx* protein containing the portion coded by the second microexon is not expressed in the nervous system (12). However, the different **isoforms** of the *Ubx* product are not all essential, since a mutation that eliminates the second microexon (and thus four isoforms) has no effect on fly viability and development (13).

The *abd-A* transcription unit is spread over a 20-kb region of DNA, and the mature *abd-A* transcript is composed of at least eight exons (14). As in *Ubx*, the *abd-A* transcription unit contains a microexon, but no alternative splicing generating multiple forms of the *abd-A* product has been detected thus far. The homeobox homology is found near the middle of the 330-residue protein. Analysis of the sequence of the whole BX-C (15) indicates that the open reading frame extends further upstream from the published ATG initiation codon, raising the possibility that *abd-A* may be slightly larger than originally thought. In as much as this upstream open reading frame is conserved in *Tribolium*, it is likely that *abd-A* consists of 590 residues (16).

Finally, the *Abd-B* transcription unit consists of three classes of transcripts that are generated by the use of three alternate **promoters** and differential spicing (Fig. 1). While the alpha class of transcripts produces a protein of 55 kDa, the beta and gamma forms produce a product of 30 kDa that is truncated at the *N*-terminus (17, 18).

Mutations that affect the *Ubx*, *abd-A*, and *Abd-B* transcription units (shown below the DNA line in Fig. 1) are all lethal at the embryo stage of development, and cuticle analysis of the dead embryos detects homeotic transformations. In *Ubx* mutants, PS5 and PS6 are transformed into PS4. If such an embryo could survive, it would give rise to a fly with T3 and A1 transformed into T2 (ie, a fly with three pairs of wings). Homozygous *abd-A* embryos have PS7, 8, and 9 transformed into PS6 (in the adult this would correspond to a transformation of A2, A3, and A4 into A1). Finally, *Abd-B* mutations have PS10, 11, 12, and 13 transformed into PS9 [A5–A8 transformed into A4 (2, 7, 19, 20)].

2. Expression

The genetic and molecular data that have been described thus far appear to conflict. On the one hand, genetic analysis reveals the existence of nine parasegment-specific functions that are responsible for the identity of PS5 to 13, which will form the posterior thorax and the abdominal segments of an adult fly. On the other hand, molecular studies indicate that BX-C encodes only three protein products. This apparent discrepancy was solved when antibodies directed against the *Ubx*, *abd-A*, and *Abd-B* products became available, allowing determination of which part of the embryo these genes are expressed. A first observation derived from these studies is that each of the *Ubx*, *abd-A*, and *Abd-B* genes are expressed in domains composed of several parasegments. *Ubx* is expressed from PS5 to 13 (9, 21), *abd-A* from PS7 to 12 (14, 22), and *Abd-b* from PS10 to 14 (23, 24). Second, the expression patterns are complex, intricate, and dynamic. Comparisons of the expression patterns between wild-type embryos and those carrying mutations in the PS-specific functions revealed that the latter correspond to large *cis*-regulatory regions that are responsible for construction of the complex expression patterns of *Ubx*, *abd-A*, and *Abd-B*. The *abx/bx* and *bxd/pbx cis*-regulatory regions are responsible for UBX expression in PS5 and 6, respectively (21, 25, 26). The *iab-2*, *iab-4*, and *iab-4 cis*-regulatory regions control expression of *Abd-A* in PS7, 8, and 9, respectively, while *iab-5*, *iab-6*, *iab-7*, and *iab-8* are responsible for the pattern of ABD-B expression (initiated from the a promoter) in PS10 to 13 (14, 24, 27). PS14 expresses a truncated form of ABD-B, resulting from transcription initiated from the b and g promoters.

3. BX-C Regulation

BX-C gene regulation can be divided into two phases, initiation and maintenance. During the early phases of embryogenesis, when parasegment identity is initially selected, the PS-specific *cis*-regulatory regions are the targets of the **gap gene** and pair-rule gene products (28-31). These gap and pair-rule proteins activate the *cis*-regulatory regions in successively more posterior parasegments.

The gap and pair-rule gene products are present only transiently during early development. The fact that homeotic genes are expressed throughout development implies the existence of a mechanism that maintains the activity state of each of the *cis*-regulatory regions. This maintenance system requires the **Polycomb** *group* (*Pc-G*) and the **trithorax** *group* (*trx-G*) genes (32-34). While the products of the *Pc-G* function as negative regulators, the products of the *trx-G* act as positive regulators. The products of the *Pc-G* exert their regulatory effects by interacting with specific elements in each of the *cis*-regulatory domains called *polycomb*-**response elements** (35-39). There may be equivalent or overlapping *trx* response elements for the *trx-G* proteins (36, 40). Though their precise mode of action is unknown, the products of the *Pc-g* and *trx-g* are thought to stabilize the expression patterns in each parasegment by imprinting an inactive or active chromatin conformation of the PS-specific *cis*-regulatory subregions (33, 41, 42).

4. Regulatory Elements of BX-C

Molecular studies using reporter gene constructs have revealed the existence of elements within the PS-*cis*-regulatory units that seem to be responsible for the initiation and maintenance phases of BX-C regulation. Some DNA fragments are able to initiate expression of a *Ubx-lacZ* reporter gene in the proper parasegments during early embryonic development (28, 30, 43, 44). In most cases, however, these patterns are not maintained, and expression expands into more anterior parasegments around the time when BX-C regulation would switch to the maintenance mode. Other BX-C DNA fragments are capable of retaining the appropriate parasegmental restrictions in lacZ expression after the gap and pair-rule gene products disappear. These fragments contain "maintenance elements," also known as *Pc-g* response elements because their activity depends on *Pc-g* gene products (35-39, 43, 44). Finally, a third type of regulatory elements that has been identified in experiments with *Ubx-lacZ* reporter constructs are tissue- or cell-type-specific enhancers. They induce *lacZ* expression in specific tissue or cell types, with no restriction along the anteroposterior axis.

Many observations suggest that the PS-specific *cis*-regulatory units are organized into functionally independent domains. This is best illustrated by the expression patterns of "enhancer trap" transposons integrated in different domains of the complex (45, 46). These enhancer traps are subject to regulatory elements located within the same domain, but they are insensitive to regulatory elements in adjacent domains. The autonomy of each domain is ensured by elements that are believed to function as boundaries. Two such regulatory elements, *Mcp* and *Fab-7*, have been identified. *Mcp* is located between the *iab-4* and *iab-5 cis*-regulatory units or domains, while *Fab-7* is located between *iab-6* and *iab-7* (46-50).

5. Concluding Remarks

Molecular analysis of the BX-C has confirmed most of the predictions that Lewis had foreseen in his 1978 model. He had initially envisioned activation of a new gene product in each parasegment. It is now clearly established that there are only three major groups of related protein products encoded by BX-C (UBX, ABD-A, and ABD-B). Discrete genetic units exist, however, that are sequentially activated in each parasegment. These units function as transcription regulatory regions (PS-specific *cis*-regulatory regions). The complex *cis*-regulation that they mediate results in a very intricate pattern of expression, both between and within parasegments. Each parasegment is a mosaic of cells expressing different homeotic products. Under the direction of these proteins, different cells adopt different fates, yielding the complex array of pattern elements that characterizes a given parasegment (or segment). The PS-specific *cis*-regulatory regions are large (*bxd* is spread over more than 30 kb; see Fig. 1) and can act from remote distances on their target promoters (*iab-5* is localized 50 kb away from its target *Abd-B* promoter). These properties suggest that the structure of the chromatin plays an important role to allow such long-distance interactions. Chromatin structure is also evoked by the properties of the *Pc-G* gene. The products of these *Pc-G* genes function as cellular memory to maintain the repressed state of the homeotic genes in body regions where they have not been activated during early development. There are analogies between the *Pc-G* repression and **mating-type** silencing in yeast or heterochromatic position-effect variegation in *Drosophila*. Though little is known at the molecular level, these analogies suggest that *Pc-G* repression involves the formation of a complex of Pc-G proteins leading to a chromatin structure that is refractory to transcription. The finding of boundary elements insulating adjacent PS-specific *cis*-regulatory regions has led to a model in which the sequential activation the *cis*-regulatory regions would be due to the stepwise opening of chromosomal domains (45, 46, 49, 51). Although no molecular clues exist to support such a model, it provides a rationale for the remarkable correspondence between the genomic organization of the BX-C and the anteroposterior axis of the fly. A similar model has been discussed recently in the case of the clusters of homeotic genes in mice, the Hox clusters (52).

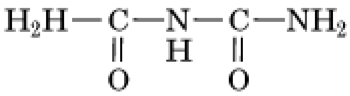
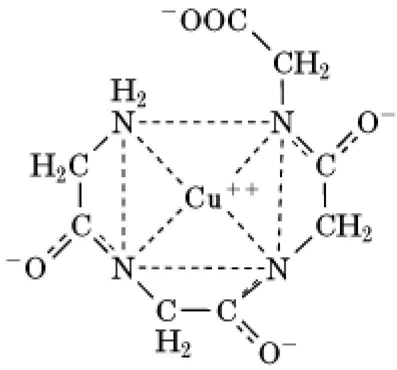
Biuret Reaction

Proteins form biuret-like compounds (structure **I**) in alkaline solution by losing a proton from the nitrogen atoms of the peptide bonds. In strong alkaline solution and Cu^{2+}, this compound forms a blue colored complex (structure **II**). This color reaction is called the biuret reaction. The sensitivity of the reaction is not very great, but the color yield is similar from protein to protein. Thus, this reaction has been employed to quantify proteins in widely varying samples.



[I] Biuret; carbamylurea



[II] A kind of biuret compound; copper glycine peptide complex under alkaline conditions

According to the method of Gornall et al. (1), 1 to 10 mg of protein is determined by **absorbance** at 540 nm after incubation with biuret reagent ($CuSO_4$, potassium sodium tartrate, NaOH) for 30 min at 20° to 25°C. An improved biuret method by Westley and Lambeth (2), which removes the free Cu^{2+} ion with an ion-exchange resin and adds Na-diethyldithiocarbonate as a coloring reagent, detects 0.05 to 1 mg of protein. A simple and sensitive micro-biuret method was developed by Itzhaki and Gill (3), where UV absorbance at 310 nm is employed to quantify protein.

Blastoderm

The blastoderm is an embryo at the stage that consists of a single cell layer. This cell layer is formed by the cleavage divisions of the fertilized zygote, largely under the control of maternally deposited gene products.

Blastomere

After fertilization, the zygote begins the cleavage divisions. During the cleavage divisions, the cells of the embryo are called *blastomeres*.

Blastopore

The blastopore is a line of invagination on amphibian embryos for gastrulation (1). After fertilization, the amphibian zygote divides to form a mass of cells called blastomeres. The upper surface is called the *animal pole*, and the lower surface is called the *vegetal pole*. During gastrulation, the cells at the vegetal pole move inside the embryo, and the cells of the animal pole are left to form the outer surface of the embryo. The animal cells left at the surface will form the ectoderm, including the nervous system. The cells that move inside during gastrulation form the mesoderm and endoderm.

The process of gastrulation begins with the formation of a small indentation between the animal and vegetal poles on one side of the embryo. This small indentation is the beginning of formation of the blastopore. As gastrulation proceeds, the blastopore expands laterally to form a crescent, and eventually it encircles the entire embryo as gastrulation proceeds. The vegetal cells and the marginal cells between the vegetal and animal cells invaginate through the blastopore and form a second layer inside the embryo. As gastrulation continues, the blastopore shrinks to cover the remaining vegetal cells, called the *yolk plug*. When the blastopore almost completely covers the yolk plug, organogenesis begins. Interactions between various groups of cells during gastrulation cause cells to become determined to form various organs and structures. The determination of cells caused by interactions with their neighboring cells is called *developmental induction*. One of the most well-known examples is the organizer region of the amphibian embryo that specifies the determination of the nervous system. This is the dorsal lip of the blastopore and is often called the *Spemann organizer*, because it was first characterized by Hans Spemann (2).

Bleomycin

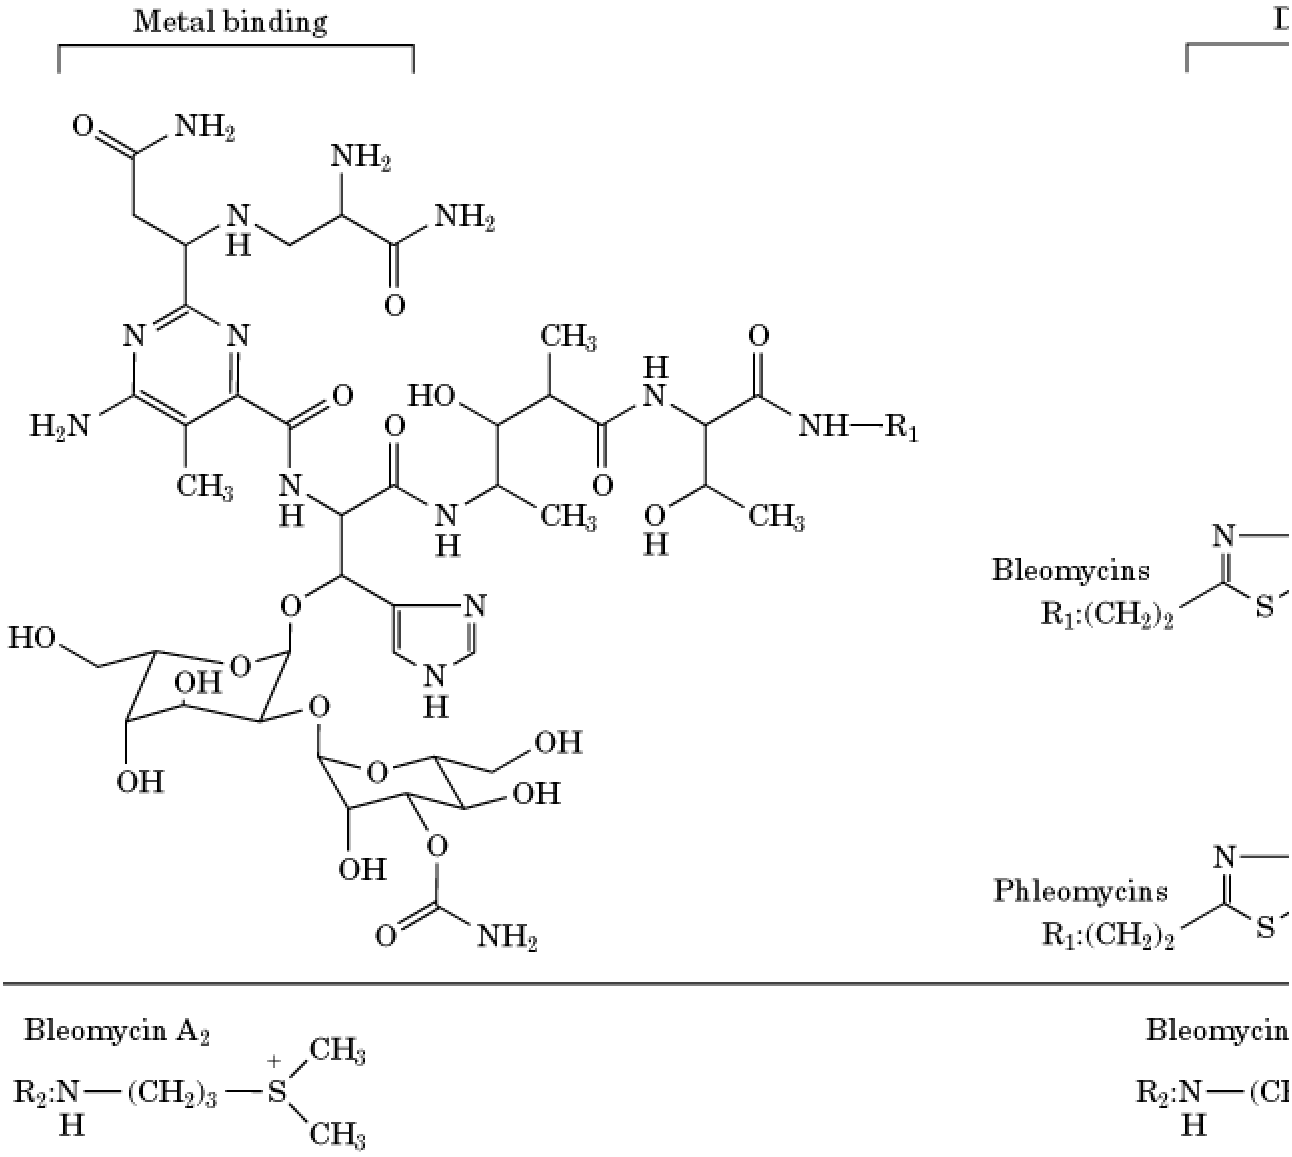
Bleomycin (BLM), discovered in 1962, is a family of low-molecular-weight metalloglycopeptides

(M_r approximately 1500) produced by *Streptomyces verticillus* and isolated from the culture media of *S. verticillus* as copper complexes (1-3). It is widely used as an anticancer antibiotic in patients. BLM acts as a limited endonuclease and produces a variety of lesions in DNAs by a mechanism involving free radical attack on deoxyribose in both DNA strands. BLM damages DNAs in ways that mimic ionizing radiation. The detailed knowledge of the complicated chemistry of BLM and its interactions with DNA *in vivo* and *in vitro* drives much of its use in applications to molecular biology. BLM and structurally related analogues are considered radiomimetic and oxidative DNA-cleaving reagents, and as such they are utilized as chemical tools to study and understand the activities of this class of agents. Tools of molecular biology are also employed to understand the chemical, biological, and clinical aspects of the mechanism of action of BLMs. In addition, broadly used cloning strategies in several organisms use a gene conferring resistance to BLM and structurally related analogues as a selectable marker. Phleomycin (PLM) is used as the selective agent and is available in commercial formulations. BLM causes multiple changes to cells and is cytocidal, and its cytotoxicity is high where there is no or only a limited barrier to BLM reaching cellular targets. BLM effectively kills all types of cells tested. Cellular resistance is conferred in several ways, including protection by nucleosomes in chromatin, DNA repair, metabolic inactivation of BLM, BLM-resistance proteins, and restricted entry of BLM. An overview of resistance mechanisms was recently published (4).

1. Structure and Activated Complex

The structurally complex BLMs contain a metal-binding domain and a **DNA-binding** domain (Fig. 1). BLMs require metals and oxygen species for their activity (5-9). The metal-binding domain is also the site of oxygen activation and is attached to a disaccharide group; it binds redox-active transition metals, such as Fe(II), Co(II), Cu(II), Ni(II), and Zn(II). The most stable BLM–O_2–metal complex is formed with cobalt (8). When a BLM-Fe(II)-O_2 complex binds to DNA and the Fe(II) oxidizes to Fe(III), the complex attacks the C4′ position of DNA deoxyribose (10-13). The complex thereby behaves as a limited endonuclease.

Figure 1. Structures of bleomycins and phleomycins (16, 117-119).



The coplanar bithiazole moiety partially intercalates into the minor groove between bases of DNA. The cationic *C*-terminal amines are also involved in interactions with nucleic acids. The terminal amines in BLM A_2 and BLM B_2 are dimethylsulfonium propylamine and agmatine, respectively, and are similar in length and bear one positive charge (Fig. 1). BLM B_2 produces considerably more DNA breaks and killing than BLM A_2 over a wide range of chemical concentrations (14). Without the terminal amine, the BLM molecule no longer cleaves DNA or possesses antitumor activity.

BLM and structurally related PLM (15) differ in the oxidation state of their sulfur heterocycles (Fig. 1). One of the two conjugated thiazole rings of the BLM bithiazole is modified by hydrogenation to 4,5-dihydrothiazole (thiazoline) in PLM (16, 17). In addition, the *C*-terminal amines in clinical preparations of BLMs differ chemically and quantitatively from prepared mixtures of PLMs. Tallysomycin is closely related to BLM (18, 19).

2. Anticancer Use

BLM is an important therapeutic agent that is useful as a single agent in treating several human cancers and is widely used in combination chemotherapy and radiotherapy. The water-soluble product used in cancer treatment, Blenoxane, is a family of 11 metal-free congeners differing in their terminal amines. The clinical mixture (20) is comprised mainly of BLM A_2 [approximately 55% to 70% (usually 68% to 69%)] and BLM B_2 (approximately 25% to 32%). The effectiveness of BLM as an anticancer agent is associated with its ability to produce lesions in DNA (21, 22).

BLM is principally used in patients with lymphoma or a variety of solid tumors. It has been included in regimens for treating malignant and peripheral T-cell lymphomas, as well as in combination BEP chemotherapy (BLM, etoposide, cisplatin) for metastatic testicular teratoma and Hodgkins and non-Hodgkins lymphoma. BLM is also used in the chemotherapy and management of Kaposi's sarcoma (eg, pulmonary, gastrointestinal, epidemic, disseminated), as well as with vincristine in combination chemotherapy for epidemic Kaposi's sarcoma. BLM does not cause bone-marrow, hepatic, or renal toxicities, nor does it cause cardiosuppression. Pulmonary fibrosis is a side effect of BLM treatment that limits its use. The molecular mechanism of lung fibrosis is being investigated, but is not fully known. Patients with genetic susceptibility are particularly susceptible to lung fibrosis (23, 24). In animal models, taurine (25) or taurine and niacin (26) counter BLM-induced lung fibrosis. The newer BLM derivatives, peplomycin and liblomycin, were developed because of their lower pulmonary toxicity and broader antitumor spectrum in animal studies (27).

3. Mechanism of Action on Nucleic Acids

3.1. Chemical Action on DNA: DNA Damage

The unique chemical action of BLMs in the presence of oxygen and Fe(II) catalytically cleaves double-stranded DNA *in vivo* and *in vitro*. Single- and double-stranded breaks are produced, leaving 5′-phosphate- and 3′-phosphoglycolate-termini (11, 28-32). The most genotoxic and lethal lesions for cells are double-stranded breaks. BLM recognizes 5′-phosphoguanylyl(3′,5′)thymidine or 5′-phosphoguanylyl(3′,5′)cytosine sequences most frequently, releasing the pyrimidines when they are located to the 3′ side of guanosine (28-30, 33-36) and leaving DNA alkali-labile (32, 37). While cleavage at the first site is G-Py-specific, the second nucleophilic attack by a BLM–Fe(II)–O_2 complex on the opposite DNA strand is not a sequence-specific cleavage and instead is probably targeted by the structural perturbation of the DNA at the first cleavage site (38, 39). Deoxyribose degradation also produces 3-(pyrimidin-1′-yl)-2-propenal and 3-(purin-9′-yl)-2-propenal (11, 31, 40) and oligonucleotide 3′-(phosphoro-2-*O*-glycolic acid) derivatives (11, 31, 41). DNA strand breaks are stoichiometric with the production of base propenals (42).

3.2. Preferential Cleavage between Nucleosomes

BLM preferentially cleaves **linker regions** of chromatin between nucleosomes (43-47). The enhanced resistance of DNA bound to nucleosomes seems to be related to the necessity of a conformational change for BLM binding and intercalation. In yeast, internucleosomal cleavage and DNA degradation (46) and killing (48) are less pronounced in logarithmic phase cells than in cells that are in stationary phase. The cellular and molecular basis for this may relate to the highly effective use of BLM on particular solid tumors.

3.3. Bleomycin and Phleomycin

PLM was discovered before bleomycin, but was too toxic in patients to be used as an anticancer drug. PLM is also substantially more effective than BLM on a per mole basis in yeast in producing cell killing (48), DNA breaks in intracellular DNAs (49), release of nucleosomes from chromatin (45), and genetic changes (50). Thus, the DNA lesions produced by the BLM and PLM could differ in their nature or frequency, or they could be processed differently by the cells. The mechanisms of BLM and PLM interaction with DNA *in vitro* also appear to differ (51-54). PLM exhibits a higher requirement than BLM for ferrous ions (49). Bithiazole intercalation in DNA is thought to be necessary for producing double-stranded, but not single-stranded, breaks *in vitro* (52). Accordingly, BLM produces more double-strand breaks than PLM in PM2 phage DNA (52, 54). Cu(II)BLM, but not Cu(II) PLM, intercalates (51). BLM, but not PLM, degrades relaxed DNA to a greater extent than either positively or negatively **superhelical** DNA (54). On the other hand, BLM and PLM cleave DNA *in vitro* at similar preferred sites at similar frequencies (55, 56) and produce comparable numbers of DNA breaks under some conditions (57, 58).

3.4. RNA

BLM cleaves a variety of RNAs. The most studied have been transfer RNA and tRNA precursors. In contrast to DNA cleavage, BLM-induced RNA cleavage is usually wholly or predominately at a single site, often at a junction between single- and double-stranded RNA regions (59-62).

4. DNA Repair

4.1. Biochemical and Genetic Evidence for Radiomimetic Properties

The cellular processes that repair BLM-induced DNA lesions are not entirely known. The most important mechanisms for the repair of BLM-induced DNA damage are recombinational repair, base-excision repair, and post-replication repair. BLM and ionizing radiation produce similar lesions in DNA, although BLM produces a narrower spectrum of products than ionizing radiation. DNA breaks are introduced approximately linearly with increasing concentrations of BLM (14) and ionizing radiation (63). Some of the chromosomal lesions produced after either BLM treatments or ionizing irradiation can be ligated immediately and lead to a quick component of DNA rejoining, but other lesions require more time for processing before the termini of the DNA molecules become substrates for ligation (14, 63-65). For example, the unusual phosphoglycolate must be removed by the DNA 3′-repair diesterase activity of apurinic and apyrimidinic endonuclease (66, 67). After extension of the remaining DNA strand by one nucleotide, DNA ligase resynthesizes intact DNA molecules by forming a phosphodiester bond between adjacent 3′-hydroxyl and 5′-phosphoryl termini (14). Rapid and slower components of DNA rejoining have been identified in several laboratories. An ultrarapid phase of cellular recovery accompanies rapid repair in human cells (64, 68), suggesting that some of the cytotoxic treatment effects of BLM could be counteracted in the clinic and reduce chemotherapeutic effectiveness.

The importance of DNA repair is shown by the many studies in various organisms of mutants hypersusceptible to killing by BLM and defective in repair of DNA lesions. All *rad* mutations of *Saccharomyces cerevisiae* (69-72) that confer hypersensitivity to killing by BLM analogues also confer cross-sensitivity to ionizing radiation (73-78), so pathways are shared for the repair of chromosomal damage by bleomycins and ionizing radiation. Moreover, mutant strains with altered resistance to lethal effects of BLM have been isolated and characterized in several laboratories, and direct selection for mutations conferring hypersensitivities to lethal effects of BLM resulted in mutants exhibiting cross-hypersensitivities to ionizing radiation.

4.2. Genetic Recombination and Mutation

Mechanisms of recombination are important for DNA repair and rejoining recombinant DNA. BLM is recombinogenic and mutagenic (38, 50, 79-85). The amount of recombination or mutation caused by BLM depends upon the assay system and treatment conditions. BLM was found to be weakly mutagenic to mitochondrial DNA (86).

5. Additional Cellular Targets

5.1. Membrane

The plasma membrane restricts BLM internalization in some mammalian cells (87, 88). This could be due to the polar and charged groups on the BLM molecule. Membrane damage by BLM (68, 89) or cell electropermealization (88) circumvents this restriction.

5.2. Cell Wall

BLM molecules are readily taken up into yeast cells, but are not equally distributed from cell to cell (89). BLM initially localizes to cell walls, causes cell wall and membrane damage, and aids the enzymatic conversion of cells to spheroplasts (75, 89-91). BLM alters the anchorage of several mannoproteins in the cell wall matrix of intact cells or isolated cell walls, and it disrupts essential cell wall polymers. These activities facilitate the entry of BLM into yeast cells.

5.3. BLM Hydrolase

BLM hydrolase hydrolyzes and inactivates BLM. The enzyme is a thiol proteinase that has DNA-binding and peptide-cleavage domains. It binds DNA and RNA. BLM hydrolase activity protects cells from BLM toxicity, but limits the use of BLM in cancer chemotherapy. Although its normal cellular function is unknown, the enzyme is present in diverse organisms, including humans (92-96) and yeast (97-100). Expression of the yeast BLM hydrolase in mammalian cells results in resistance to BLM (101). A member of a galactose regulatory system (102, 103), yeast BLM hydrolase binds to nicked double-stranded DNA, single-stranded DNA, and RNA, without sequence specificity (104). This enzyme associates with plasma membranes and is in the cytosol (105). Human BLM hydrolase was recently shown to exhibit endopeptidase activity (106). This enzyme is thought to play a role in the development of resistance to BLM during chemotherapy (95, 107-109).

5.4. BLM Resistance Proteins

Several proteins in microorganisms that produce BLM or structural analogues actually confer resistance to these products. Vectors bearing genes encoding these proteins confer high levels of resistance to BLM and related antibiotics and are used as cloning vehicles. The proteins bind and form stable complexes with BLM with high specificity, thereby preventing BLM from complexing with DNA. One of these proteins is encoded by the *Streptoalloteichus hindustanus* (*Sh*) *ble* gene (110-112) found on the Tn5 bacterial transposon, along with additional genes encoding resistance to other antibiotics. Expression of the *Sh ble* gene in transgenic mice reduced BLM toxicity in the mice and protected against lung fibrosis (113, 114). High levels of the protein were detected in lungs, kidney, and spleen.

5.5. Multiple Targets and Cytotoxicity

Multiple cellular targets of BLM are expected because of the chemical mechanism of action of the molecule and because some of the BLM-hypersensitive mutants isolated in different organisms do not exhibit hypersensitivity to lethal effects of radiation. Multiple cellular enzymes are important for surviving the toxicities of BLM, and deficiencies in their function could reduce chances of survival. The relationship and significance of each cellular target of BLM to cellular toxicity are not known. Why BLM causes apoptosis in some types of cells and not in others is also unknown. BLM is not considered apoptotic at low concentrations. Far less is known about targets of BLM in cells than about the chemical mechanism of action of BLM *in vitro* on defined substrates.

Additional factors modulate BLM activity. Generally, BLM preferentially affects mitotic cells in the G2-M phase of the cell cycle. BLM is unlikely to be a useful agent to study meiosis because of the abundant lesions the molecule produces in DNA. Intracellular metal ion concentrations and pH also modulate BLM activities (48, 115, 116). Studies elucidating the roles of the multiple targets of BLM and factors that modulate BLM activities will improve our understanding and efficacious uses of the widely studied BLM family of related compounds.

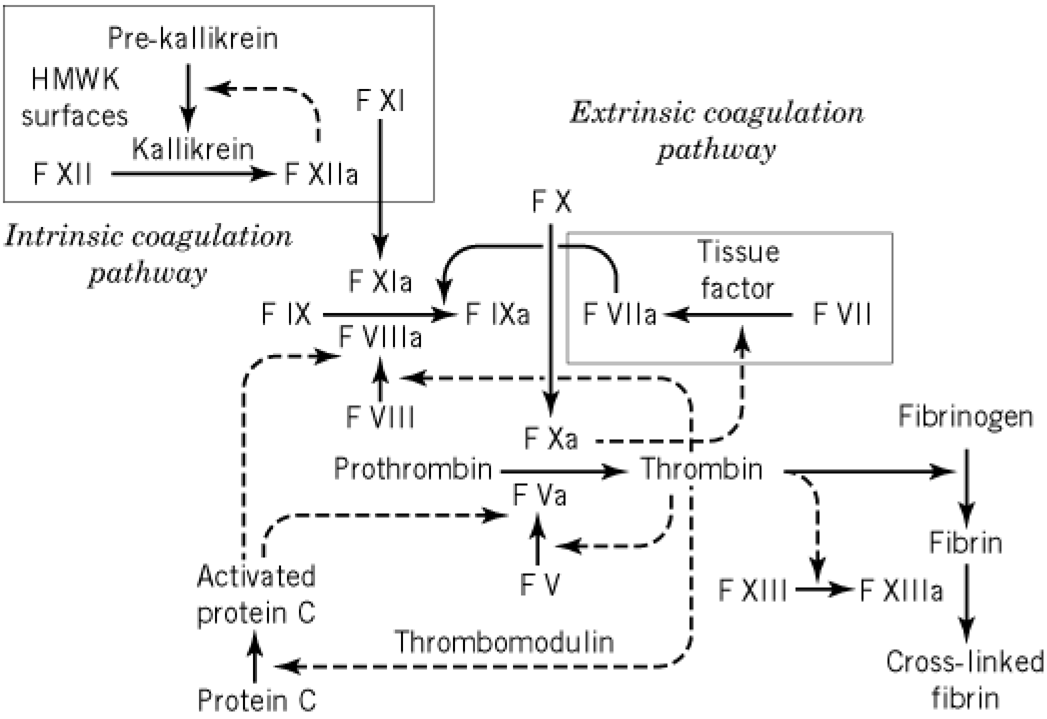
Blood Clotting

The clotting or coagulation of blood is necessary for the maintenance of vascular integrity, and is therefore essential to survival. Cessation of bleeding can be achieved within minutes, involving both cellular and soluble protein components present in blood. The overall function of the blood coagulation system is the rapid amplification of a small initial stimulus via a series of sequential reactions that activate various zymogens and pro-cofactors of serine proteinases, culminating in the generation of thrombin, which proteolytically converts fibrinogen to fibrin. Fibrin monomers subsequently polymerize to form the insoluble fibrin clot. The major enzymatic components of the coagulation pathways are a series of **homologous** serine proteinases whose function is determined primarily by differences in the organization of their *N* terminal, noncatalytic **domains**. Most of the reactions are catalyzed by complexes between these serine proteinases, nonenzymatic protein cofactors, and serine proteinase zymogens that are assembled on phospholipid surfaces in the presence of calcium ions. These complexes are able to catalyze activation of the proteinase zymogen by limited **proteolysis** at rates up to 10^6-fold greater than those in the absence of cofactor/phospholipid. The proteinase product of one reaction then participates in another analogous complex, thus providing the amplification, as well as the multiple levels at which both positive and negative regulation can be exerted.

Figure 1 shows the two classical pathways of blood coagulation, termed the *intrinsic* and *extrinsic* pathways. These were originally envisaged as elegant, essentially linear sequences of reactions, but **feedback inhibition** reactions and cross-reactions between the two pathways are now known to be important and to provide further amplification. The terminology used to describe the two pathways of blood coagulation is somewhat counterintuitive, tending to imply the opposite to what is now known to be the physiological clotting mechanism. Genetic deficiencies in the extrinsic pathway lead to severe bleeding tendencies, but initiation of this pathway *in vitro* requires components in the form of tissue extracts (containing tissue factor and phospholipid) that are not present in blood. By contrast, the physiological role of the “intrinsic” pathway is unclear, as genetic deficiencies in its components do not give rise to bleeding disorders, but all the components are present in blood, and it can be initiated by simply removing blood from the circulation. This is due to contact with a negatively charged surface, such as glass, giving the pathway its alternative name of “contact activation," and involves proteinases and cofactors quite distinct from those of the extrinsic pathway.

Figure 1. The proteolytic reactions of the blood clotting pathways. The zymogen/proteinase pairs are shown in black with the "forward" reactions as solid lines, the cofactors are shown in blue with the positive feedback reactions as dashed blue lines. The proteolytic negative feedback reactions are shown in red. The complexes initiating the two pathways of coagulation are boxed: the factor VII–tissue factor complex and the contact activation complex that assembles on high molecular-weight kininogen (HMWK). The Roman numeral system used for the coagulation proteinases and cofactors is based loosely on the order in which they were discovered, with the exceptions of the first four components fibrinogen, prothrombin, tissue factor–phospholipid complex, and Ca^{2+}. The proteolytically activated forms of these factors are denoted by a subscript "a," for example, factor X_a. Additional nonproteolytic inhibitory mechanisms exist, the principal of which are the serpin antithrombin (an inhibitor of most of the Gla-proteinases) and tissue factor pathway inhibitor (TFPI), a Kunitz-type proteinase inhibitor of factors VII_a and X_a.



A complete description of the coagulation system and the many proteolytic and inhibitory reactions that lead to its exquisite functional regulation is beyond the scope of this article. We will therefore focus on two key proteolytic steps that are representative of the two types of multicomponent complexes of the extrinsic pathway and that demonstrate the fundamental interactions and mechanisms underlying catalysis of the proteolytic reactions of blood coagulation; one requiring proteolytically activated soluble cofactors, the other requiring integral membrane protein cofactors that do not require proteolytic activation.

1. Regulation of Blood Clotting by Complexes Involving Soluble Protein Cofactors

The only proteolytic reaction common to both pathways is the activation of prothrombin, the final serine proteinase zymogen of the coagulation cascade. Factor X_a (i.e., activated factor X) is the proteinase component of the "prothrombinase complex" that catalyzes the generation of thrombin. Both zymogen and active proteinase have an *N*-terminal "Gla domain," which contains g-carboxyglutamic acid residues. The Gla domain is also present in prothrombin (as well as factors VII and IX, and protein C, the so-called vitamin K–dependent or Gla proteinases); it binds Ca^{2+} and participates in binding to negatively charged phospholipid surfaces, which *in vivo* are provided principally by activated platelets. Therefore, both enzyme and substrate bind to phospholipid surfaces, with **dissociation constants** of 0.1–1 μ*M* (1). The cofactor of the prothrombinase complex is factor V_a, which is generated by thrombin-catalyzed limited proteolysis of factor V, providing one of the major feedback activation reactions. Factor V_a also binds to negatively-charged phospholipid surfaces, but with a much lower dissociation constant of ~ 5 nM (2). It does not contain a Gla domain, and binds through a different mechanism involving partial insertion of the protein into the lipid bilayer; it is often viewed as a membrane binding site for factor X_a. The latter thus incorporates into the complex by both protein–phospholipid and protein–protein interactions. Kinetic experiments suggest that the two phospholipid-bound components associate by lateral diffusion, but the interactions involved are complex and to some extent **cooperative**. Although prothrombin also binds to phospholipid, it is not clear whether the relevant substrate is phospholipid-bound prothrombin or prothrombin in the solution phase but at a high local concentration in the vicinity of the membrane surface, which can be several orders of magnitude above that in bulk solution. The kinetic effect of prothrombin binding to phospholipid is a reduction in the apparent Km (Michaelis constant) for prothrombin activation ("apparent" as the K_m does not reflect the true concentration at the phospholipid–surface interface). This is of physiological significance, since the K_m falls from ~ 100 μM to < 1 μM (3), compared to a concentration of 1.4 μ*M* in blood plasma. In addition to this effect, the catalytic rate constant, k_{cat}, for prothrombin activation is greatly increased, primarily as a consequence of the X_a–V_a interaction (Table 1). This suggests that the active-site environment of the proteinase is significantly affected by complex formation, although the molecular basis of this effect is not known. The prothrombinase complex also helps to achieve maximum catalytic advantage by ordering the sequence of the two proteolytic cleavages required for prothrombin activation (see Thrombin).

Table 1. Effect of Various Components of Prothrombinase Complex on Kinetic Parameters for Prothrombin Activation[0]

Components	K_m, μ*M*	k_{cat}, s^{-1}	Relative Rates
X_a Ca^{2+} PL V_a	0.2	30	100
X_a Ca^{2+} PL	0.06	0.04	0.42
X_a Ca^{2+} V_a	34	6.2	0.12
X_a Ca^{2+}	84	0.01	0.00009
X_a	131	0.01	0.00005

The phospholipid-bound complex of factor IX_a (proteinase) and factor $VIII_a$ (cofactor) that activates factor X has molecular and functional characteristics very similar to those of the prothrombinase complex. Factor VIII shares homology with factor V and is also activated by thrombin; factor IX has the same domain structure as factor X and is also activated by factor VII_a. There is evidence that the phospholipid-binding properties of these proteinase–zymogen components enable the proteinase product of one complex to be transferred to the subsequent complex as its enzyme without dissociation from the membrane, thereby giving a further catalytic advantage (4).

2. Regulation of Blood Clotting by Complexes Involving Integral Membrane Proteins

Two integral membrane proteins with quite distinct and contrasting functions are involved in the regulation of blood coagulation: tissue factor and thrombomodulin, which are involved, respectively, in the initiation and termination of coagulation. Blood coagulation subsequent to injury of the vasculature is initiated by the exposure of tissue factor, a nonenzymatic cofactor widely expressed by cells of the subendothelium of blood vessels (although its expression can also be induced in endothelial cells and monocytes). Tissue factor binds factor VII_a, a Gla-proteinase, with high affinity (K_d = 1–5 n*M*) (5). The structure of this complex has been determined by X-ray crystallography (6); the extracellular part of tissue factor is composed of two homologous C2-type **immunoglobulin**-like modules, and the protein is most closely related to the IFNg receptor, a member of the class 2 **cytokine** receptors (see Interferons). Factor VII_a is engaged in multiple contacts with both of the tissue factor modules.

The classical substrate for factor VII_a in this complex is factor X, but it is now known that factor IX is also a physiologically relevant substrate (7) (see Hemophilia). Activation of these substrates, and the subsequent incorporation of their activated forms into their cognate complexes, thus propagates the initial stimulus proteolytically. In contrast to factors V and VIII, tissue factor is constitutively active as a cofactor and does not require proteolytic processing. However, factor VII does need proteolytic activation for the complex to be active, and what initially catalyzes this cleavage and thus constitutes the initial proteolytic event in the coagulation cascade has not been a trivial problem to address, because of the extraordinary sensitivity of the system to proteolytic activation, and it remains a topic of controversy. Proposals have included (*1*) that factor VII is not a true zymogen and possesses a significant degree of intrinsic proteolytic activity, (*2*) induction of activity in factor VII by tissue factor, (*3*) autoactivation of factor VII, (*4*) and activation of factor VII by trace amounts of activated proteinases. Although not demonstrated unambiguously, mechanism 4 appears to be favored, as factor VII can be activated by factors VII_a, IX_a, X_a, and thrombin *in vitro*. These may be generated by the contact activation system, alternative mechanisms, or "leakage" of the system, but in such low amounts that they are insignificant in the absence of tissue factor. The principal activator of factor VII once the system is initiated is considered to be factor X_a (8). Tissue factor has little or no effect on factor VII activation, but assembly of the tissue factor complex increases factors IX and X activation by up to 10^4-fold (9). Both the kinetic mechanisms and the molecular interactions responsible for this effect are analogous to those described for the prothrombinase complex, which involves the optimal presentation of the zymogen substrate to the catalytically efficient proteinase:cofactor complex for maximum catalytic advantage.

The other integral membrane protein of the coagulation system, thrombomodulin, is expressed by endothelial cells and acts as a cofactor for the proteolytic activation of the negative regulator of the coagulation system, protein C (10). Activated protein C (a Gla-proteinase) proteolytically inactivates the procoagulant cofactors factors V_a and $VIII_a$. In common with the principal feedback activation reactions, thrombin is again involved. But in this case, rather than proteolytically activating the cofactor, it is the enzymatic component of the thrombomodulin complex; thus thrombin can fully modulate its own generation. The interaction with thrombomodulin dramatically alters the substrate specificity of thrombin, such that protein C activation is increased 10^4-fold, while its activity toward factor V and fibrinogen is diminished (1). Although protein C can bind phospholipid through its Gla domain, this interaction plays only a minor part in these effects and, because thrombin lacks a Gla domain, protein–protein interactions are the major determinants in thrombomodulin complex anticoagulant function, in contrast to the procoagulant complexes described above.

Blot Overlays

Regardless of whether a blot contains immobilized **DNA**, **RNA** or protein (see Blotting), it is ultimately reacted with a specific probe that defines the type of **ligand-binding** interaction being studied (see Southern Blots (DNA Blots), RNA Blots (Northern Blots), and Protein Blots (Western Blots)). **Radiolabeled** probes are detected by autoradiography, and the radioactive complexes are quantified by computer-digitized imaging or simply by excising out the bands and “counting” the radioactivity. Often the primary probe itself is not easily detectable, so a secondary probe is used, such as an antibody against the first probe conjugated to an enzyme, or avidin or streptavidin when the primary probe is biotinylated (see Avidin-Biotin System). When using an enzyme-conjugated probe, one must ensure that the quencher or blocking reagent used on the blot has no interfering enzymatic activity. For example, hemoglobin should not be used when horseradish peroxidase is employed as the detection system.

1. DNA Probes

Traditionally, Southern and RNA blots of DNA and RNA, respectively, are probed with single-stranded DNA or double-strand DNA that has been **denatured**. The probes are usually radioactive, so that any duplex formed upon **hybridization** of the probe to a nucleic acid on the blot is detected by autoradiography. The rationale of such experiments is to identify the position of the immobilized nucleic acid in the electrophoretogram that is complementary to the sequence of the probe, so that they hybridize by **Watson-Crick base pairing**. The conditions for hybridization, the *stringency*, are regulated according to the degree of homology and complementarity between the probe and the target (1, 2). DNA is also used to probe protein blots, a procedure that has been named “Southwestern blotting.” As expected, this type of experiment is designed to reveal specific interactions between defined DNA sequences and the DNA-binding proteins that bind them, such as transcription factors (3). DNA probing of *colony* or *plaque* blots is a routine approach in recombinant DNA cloning (4).

2. Immunoblotting

The original application of protein blots was for identifying a particular antigen in a protein gel pattern by probing the blot with its corresponding antibody (5). Detecting the immunocomplex is often accomplished by using a secondary probe, for example, a goat antimouse IgG conjugated to an enzyme, such as horseradish peroxidase, when a murine monoclonal antibody is used for the primary probe. The sensitivity of these assays is increased by combining **immunoprecipitation** prior to gel electrophoresis. Thus, a crude sample of proteins is first immunoprecipitated with relevant antibodies, and the precipitated proteins are subsequently resolved by electrophoresis, blotted, and probed with a monoclonal antibody of interest. The use of antibodies to probe colony or plaque blots is very effective in screening expression libraries (6).

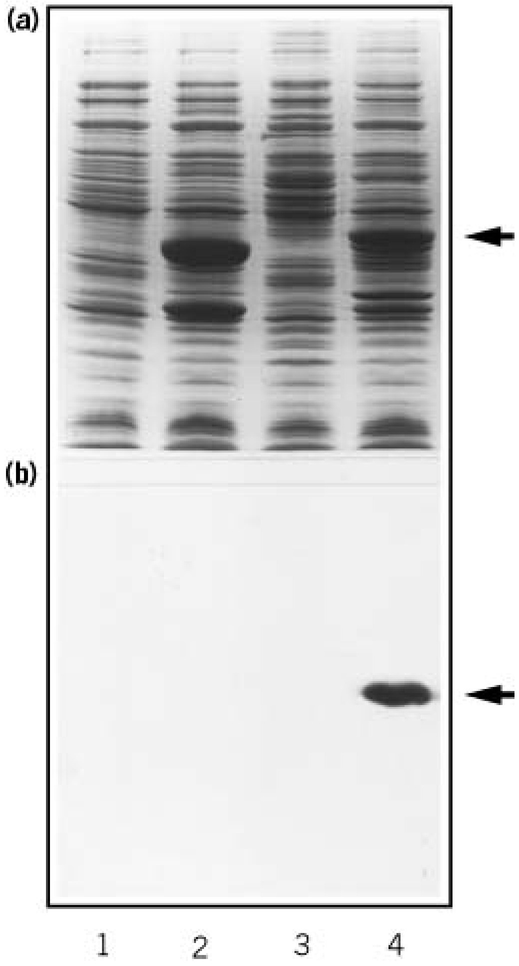
3. Lectin Blotting

To identify **glycoproteins**, lectins can be used to probe protein blots (7). A radioactive or enzyme-conjugated lectin is employed as the probe. A particular case of interest is the fact that the enzyme horseradish peroxidase is itself a glycoprotein. Thus, for example, a blot can be probed with the mannose-specific lectin concanavalin *A*, washed and further incubated with horseradish peroxidase directly (8). The multivalent concanavalin A binds to blotted glycoproteins containing mannose and subsequently also binds to the horseradish peroxidase without the need for chemical conjugation. When using lectins, ensure that the quencher used does not itself contain sugar.

4. Ligand Blotting

Blotting is usually considered for detecting antigens or nucleic acid hybrids, but it is also a very powerful way to identify all sorts of protein–protein interactions, even interactions involving nonpeptide ligands. Thus when studying any **receptor**, one should consider probing protein blots with any corresponding ligands that are detectable (9). In such experiments, it is usually advisable not to boil the protein sample or subject it to disulfide bond reduction before electrophoresis. Furthermore, the blot can be incubated in solutions that promote renaturation of the immobilized proteins. Omission of methanol from the transfer buffers used in electroblotting is also helpful for retaining functional conformations of the blotted protein. Ligand blotting has been used successfully to identify peptides that bind to hormones, **cytoskeletal** components, neurotoxins, nucleotides, calmodulin, and even ions such as Ca^{2+} (9-11) (Fig. 1).

Figure 1. Neurotoxin overlays of protein blots. *Escherichia coli* transformed with pATH2 expression **vectors** containing DNA inserts corresponding to the neurotoxin binding site (lanes 3 and 4) or not (lanes 1 and 2) were induced for gene expression (lanes 2 and 4) or not (lanes 1 and 3). Then samples of all four treatments were resolved by SDS-PAGE and stained with Coomassie brilliant blue (**a**) or blotted onto nitrocellulose membrane filters and probed using radioactive neurotoxin. Then the washed filters were autoradiographed (**b**). The arrows indicate the position of the fusion protein containing the toxin binding site.



5. Cell Blotting

Blots have even been probed with intact cells, which has proven useful for identifying interactions between proteins and cells (12). Furthermore, bacteria can be used to probe a blot, and the interaction with a protein is detected by subsequently allowing the bacteria to grow on the surface of the blot, so that colonies are observed at the site of the immobilized protein (13). **Viruses** have also been used to probe blots to detect their corresponding receptor proteins.

In summary, one should consider probing blots with selected ligands any time bimolecular interactions are to be analyzed. Surveying literature databases using specific conjugations, such as "ligand-blot", "calmodulin-blot" or "cell-blot," as key words usually produces results that provide the imaginative investigator with starting points from which to proceed.

Blotting

Blotting is a method in which a macromolecule is immobilized on a blotting matrix and subsequently probed with a detectable ligand to determine whether the macromolecule binds that specific **ligand**. The immobilized macromolecule can be **DNA**, **RNA** or protein, in which case one generates DNA blots (Southern blots), RNA blots (Northern blots) (1), or protein blots (Western blots) (2, 3). Blots of lipids have also been produced (4). The macromolecule can be applied to the blotting matrix directly (dot blot), or it can be derived and eluted from an electrophoretic gel (gel blot) or even from a **bacterial** colony or **bacteriophage** plaque (colony blot).

1. Typical Blot Analysis

The most common application of blotting involves a complex mixture of DNA, RNA, or protein to be resolved by using a standard gel electrophoresis procedure, such as agarose gel separation of DNA fragments or RNA or SDS-PAGE of protein samples. After electrophoresis, the gel is dismantled from its cassette or glass plates, etc., and a sheet of an appropriate blotting matrix (eg, a nitrocellulose membrane filter; see Blotting Matrices) is cut to size and applied to the surface of the gel. The transfer of the resolved polynucleotides or peptides is accomplished via a procedure called "blotting", and the blotted macromolecules adsorb to the surface of the matrix while retaining their relative positions, thus creating a faithful replica of the original electrophoretic pattern. The "blot" thus produced is subsequently incubated with a ligand probe, which might be **radioactive** for detection via autoradiography or conjugated to an enzyme whose activity is detectable (see Blot Overlays). Extensive washing of the blot removes the excess probe from that which is specifically associated with the immobilized macromolecule and remains bound. Subsequent detection of the retained ligand in the complex formed identifies the relevant bimolecular interaction.

2. Methods for Blotting

2.1. Dot Blotting
This is the simplest method of applying a sample to be tested (5, 6). The sample can be an unfractionated polynucleotide or protein mixture in solution. A small volume (typically 2 to 5 µl) is applied directly to the surface of a dry blotting matrix by micropipetting the sample onto the matrix or by using commercial vacuum manifolds that enable the application of larger sample volumes

(e.g., 100 µl to 1 ml) by filtration. Such manifolds often create focused and uniform dots or thin slots of sample, thus leading to the terms "dot blots" or "slot blots", respectively. Typically, an 8cm × 12 cm piece of blotting matrix contains as many as 96 different dots that correspond to the geometry of a standard 96-well **ELISA** plate. Once created, the dot blot is processed and probed as any other blot (see Southern Blots (DNA Blots), RNA Blots (Northern Blots), Protein Blots (Western Blots), and Blot Overlays). The advantages of the dot blot procedures are that they do not require any separation process and thus do not subject the sample to undue chemical modifications that could, for example, **denature** a protein sample (although some denaturation of protein occurs upon adsorption to the matrix). Moreover, dot blots are simple, cheap and quick. Where quantification is intended, direct dot blotting ensures maximal yields of sample recovery. Obviously, however, chromatography or electrophoresis is necessary to resolve a complex sample to ascribe the signal to a specific component.

2.2. Gel Blots

Gel electrophoresis is routinely employed to resolve macromolecules of DNA, RNA, or protein. Agarose gels and **polyacrylamide gels** can be blotted, and the common goal is to elute the "bands" efficiently from the gel to be immobilized on the surface of the blotting matrix, so as to generate a faithful replica of the electrophoretic pattern. This can be accomplished in a number of ways:

1. Diffusion blotting simply relies on the fact that the macromolecules in the gel spontaneously **diffuse** out of the gel (7). Consequently, blots are produced when a blotting matrix is simply applied to one or both sides of the gel. This approach is usually time-consuming (24 to 72 h) and of low efficiency, but it produces two equal copies simultaneously.
2. Convection blotting (also called capillary transfer) is the process of eluting the resolved macromolecules by mass flow of buffer through the gel. This is the original procedure introduced by Edwin Southern for transferring DNA restriction fragments from agarose gels onto nitrocellulose membrane filters (thus the term Southern blotting) (8). In this method, the gel is placed on top of a paper wick, which draws buffer from a reservoir. The gel is covered with a piece of blotting matrix that, in turn, is covered by a stack of paper towels or absorbent paper and a weight that ensures uniform pressure over the surface of the gel. The stack of paper towels draws a continuous flow of buffer vectorially through the gel, and with it the polynucleotides or peptides, which are eluted and deposited on the surface of the blotting matrix (9).
3. Vacuum blotting is an elaboration of blotting by convection in which the flow is accelerated by employing negative pressure (i.e., suction). Positive pressure has also been used to enhance blotting.
4. Electroblotting is achieved by applying an electric field so as to elute the proteins or polynucleotides from their corresponding gels by electrophoresis. This technique has been used primarily for proteins because binding DNA and RNA to nitrocellulose requires high salt conditions that are incompatible with electroblotting. Electroblotting of nucleic acids is possible, however, with alternative blotting matrices, such as nylon membranes. A variety of commercial apparatus equipment and home-made systems are available, including those that generate gradient electric fields and provide different elution efficiencies to compensate for differences in the molecular mass of the polymers to be eluted (10, 11). Electroblotting is performed by using tank systems, which require 2 to 4 liters of transfer buffer, or semidry blotting systems, which conserve buffer and are flexible because different buffers can be employed for the anode and cathode (12).
5. Direct blotting is an elaboration of electroblotting in which a conveyor belt passes the blotting matrix by the exposed bottom of the polyacrylamide gel during electrophoresis. As the proteins or DNA fragments reach the bottom of the gel, they are deposited directly onto the slowly moving blotting matrix and generate a blot. The resolution of the bands is modulated by regulating the conveyor belt speed (13).

2.3. Colony Blots

At times it is necessary to identify a specific bacterial colony or phage that contains DNA of interest or expresses a particular protein. Libraries of **recombinant DNA**-containing bacteria or lambda phage expression libraries are used to produce colony or plaque blots to be processed and screened like any other blot. The library of bacteria or phage is plated on agar after suitable incubation, and replicas are produced by simply placing a sheet of blotting matrix, such as nitrocellulose membrane or nylon membrane, onto the colony- or plaque-containing surface. The matrices pick up sufficient material from each colony or plaque at precisely the same relative position corresponding to that on the original agar plate. Then the colony blots are processed, for example, by standard DNA filter hybridization, immunoblotting, or ligand blotting (14, 15) (Fig. 1).

Figure 1. Bungarotoxin overlay of bacterial colonies. *Escherichia coli* were transformed with a pATH2 expression **vector** containing a DNA insert coding for a fragment of the a subunit of the nicotinic acetylcholine receptor. This fragment is responsible for the receptor's binding of the neurotoxin a-**bungarotoxin**. The bacteria were plated to a density of approximately 200 colonies per agar plate (**a**) and expression was induced. A replica of the plate was produced by using a nitrocellulose filter disc, which was processed for overlay with radio-**iodinated** a-bungarotoxin. The filter was subsequently washed and autoradiographed, illustrating those colonies that contain the relevant DNA fragment (**b**) (for details see Ref 15).

Blotting Matrices

Blotting is the process of transferring macromolecules from **electrophoretic** gels to immobilizing matrices, called blotting matrices. The variety of matrices available for blotting is quite diverse, and the characteristics of each directly affects the ultimate result and quality in different blot analyses [see Blotting, Southern Blots (DNA Blots), Protein Blots (Western Blots), RNA Blots (Northern Blots), and Blot Overlays]. Generally, two kinds of blot matrices are used: (1) chemically modified paper filters and (2) microporous membrane filters. Although filters are used, blotting depends on chemical adsorption of transferred molecules to the filter material itself, rather than filtration per se, where separation is achieved by size exclusion. Thus porosity is less important than the chemical composition, density, and thickness of the material. After binding of the desired ligand, normally the remaining binding sites on the matrix are blocked with a neutral compound, known as a quencher or blocking reagent.

1. Paper Filters

Initially, it was thought that transferred molecules would be best suited for blotting if they were covalently bound to the blotting matrix. This led to chemically modified paper filters that contained active moieties to bind DNA, RNA, and protein covalently. For example, **cyanogen bromide** (CNBr)-activated paper was produced (1), as was diazobenzyloxymethyl (DBM) paper, which was the most popular filter of this type (2). These filters covalently immobilize the blotted macromolecules, but they are cumbersome to handle, have the fibrous texture characteristic of blotting paper, and therefore are rarely used today.

2. Membrane Filters

Microporous membrane filters have become the matrices of choice for blotting. These materials are thin films of synthetic polymers with very fine, uniform surfaces. Filters with average porosities of 0.2 to 0.45 µm are extremely suitable for all types of blotting. A variety of materials exist, and each offers unique advantages.

2.1. Nitrocellulose
Nitrocellulose is by far the most commonly used blotting matrix. It binds DNA, RNA, and protein reasonably well, although the mechanism is not clear (3, 4). **Hydrophobic** interactions definitely play a role, and the salt conditions are critical, particularly for the adsorption of RNA. Nitrocellulose is often produced as a mixed ester with cellulose acetate, which reduces to some extent its binding capacity for proteins. The advantages of nitrocellulose are that it binds protein well and affords very good signal-to-background ratios in Western blotting assays. It allows staining of the immobilized protein patterns with such dyes as Ponceau S and Amido black. It becomes brittle, however, after baking at 80°C (typical for Southern and Northern blotting), which reduces the repeated use of these filters. Furthermore, nitrocellulose is less resistant to various organic solvents, such as methanol (5).

2.2. Nylon Membranes
Nylon membranes were introduced initially as an alternative to nitrocellulose for protein blotting (5), and subsequently they were applied in RNA and DNA transfers (4). These membranes are usually derivatives of nylon 66 and often are modified with positive charges. They have proven exceptional

binders of DNA, RNA, and protein, but at times this presents some difficulty by producing high backgrounds, particularly in protein blotting. These filters are mechanically stable and thus can be reprobed numerous times without lossing band definition or sensitivity.

2.3. Polyvinyl Difluoride

Polyvinyl difluoride (PVDF) membrane filters have a special application in blotting where subsequent chemical manipulation of the immobilized macromolecule is desired. A case in point is the use of these membranes in protein blots, where the individual bands are excised out of the blot and subjected to Edman Degradation for N-terminal amino acid sequencing of the resolved and blotted polypeptide chains (6, 7).

Blunt-End Ligation

Blunt-end ligation is covalently joining two or more double-stranded **DNA** fragments with flush ends by the enzyme DNA Ligase (1). Many restriction enzymes produce blunt ends, when they cleave both polynucleotide chains at the same site, and some **cohesive ends** are converted to blunt ends by the fill-in reaction. Blunt end ligation is a much less efficient reaction than ligation of DNA fragments with cohesive ends. One technique for overcoming the low efficiency of blunt-end ligation is ligating a short oligonucleotide **linker fragment** to the DNA ends that are to be joined (2). Because a large molar concentration of the linker can be added to the reaction, its ligation to the ends of the DNA occurs more readily than joining of the ends themselves. Linkers are designed to contain a unique restriction site so that the ligation mixture is digested with the corresponding enzyme to create cohesive ends, which can be joined by conventional ligation.

The efficiency of blunt-end ligation is greatly increased by carrying out the reaction in the presence of 15% polyethylene glycol, 6,000 MW (PEG), although only linear molecules are produced in this reaction. Circular **plasmids** are required for efficient transformation of *Escherichia coli*. An efficient way of producing circular molecules from the linear product of blunt-end ligation is including a bacteriophage P1 lox recombination site in one of the molecules being ligated (3). After ligation, the DNA is treated with Cre recombinase, which by recombination between the lox sites produces a circular molecule from a linear molecule that contains two lox sites. This type of molecule is created when the molecule without a lox site is ligated to two molecules with a lox site, one at each end.

It is possible to amplify the products of a low-efficiency ligation containing the desired insert by **PCR**, using primers that bind to vector DNA on each side of the cloning site. The PCR product of the expected size is purified and recloned. This results in transformants from ligations that give no positive colonies on direct transformation (4).

Bohr Effect

Bohr et al. (1) discovered that the oxygen dissociation curve of blood shifts to higher partial pressures of oxygen in the presence of increasing concentrations of carbon dioxide by lowering the oxygen affinity of hemoglobin. This effect, it was concluded, results from the concomitant decrease in pH, and the effect of pH on the oxygen affinity of hemoglobin has subsequently been known as the Bohr effect. It was subsequently discovered that CO_2 also lowers the oxygen affinity of hemoglobin (Hb) directly by binding to its a-amino groups, forming carbamino compounds (2, 3):

$$O_2 - Hb - NH_2 + CO_2 \leftrightarrow Hb - NHCOOH + O_2 \tag{1}$$

The original observations of Bohr et al. (1) are now known as the "classical Bohr effect," which is a composite of the specific effects of H^+ and CO_2.

The CO_2 content of blood is reduced upon oxygenation of hemoglobin at a constant CO_2 pressure (4). This phenomenon, known as the "classical Haldane effect," is a combination of the oxygen-linked dissociation of the carbamino groups (Eq. 1) and release of protons

$$Hb(H^+)_\delta + O_2 \leftrightarrow HbO_2 + \delta\ H^+ \tag{2}$$

followed by dehydration of bicarbonate:

$$H^+ + HCO_3^- \leftrightarrow H_2CO_3 \leftrightarrow CO_2 + H_2O \tag{3}$$

The release of protons upon oxygenation or their uptake upon deoxygenation of hemoglobin is known as the "Haldane effect."

The Bohr effect and the Haldane effect are thermodynamically equivalent (5) because they are linked functions (6). Whatever effect oxygen binding has on the affinity of hemoglobin for protons, changes in the pH must have the same effect on the affinity of hemoglobin for oxygen:

$$\left(\frac{\delta H^+}{\delta Y}\right)_{pH} = \left(\frac{\delta \log Po_2}{\delta pH}\right)_Y \quad (4)$$

where H^+ is the number of protons bound per heme group, Y is the fraction of hemoglobin binding sites occupied by O_2, and P_{O2} is the partial pressure of O_2. The left-hand side of Eq. 4 is known as the "Haldane coefficient," and the right-hand side is the "Bohr coefficient." They give the magnitude of the Haldane and Bohr effects, which must be the same.

These effects are physiologically important for efficient and regulated transport of O_2 and CO_2 in opposite directions (see Hemoglobin). When the shape of the oxygen dissociation curve expressed by Y versus log P_{O2} is independent of changes in pH, at least within the range $0.1 < Y < 0.9$, Eq. 4 is simplified to

$$\delta = \frac{\Delta \log P_{50}}{\Delta pH} \quad (5)$$

where P_{50} is the P_{O2} at Y = 0.5 and d is the Bohr coefficient, which is independent of the degree of O_2 binding. The Bohr coefficient expresses the number of protons (per heme group) bound to hemoglobin upon full oxygenation and is the same as d of Eq. 2.

d is negative above pH 6.3, and protons are released upon oxygenation of hemoglobin, whereas d is positive at lower pH values, and protons are taken up upon oxygenation. These two phenomena are known respectively as the "alkaline" and "acid" Bohr effects. At physiological pH 7.4, human adult hemoglobin A (HbA) has d = –0.6 in the presence of 0.1 *M* NaCl. This value is halved in the absence of Cl^-.

The Bohr effect arises from changes in the pK_a values of particular ionizable groups of hemoglobin as a result of changes in their environment upon binding oxygen. The group primarily responsible for the alkaline Bohr effect of human HbA is the imidazole side chain of the C-terminal His146 of the b chain. Its pK_a value changes from 8.0 to 7.1 upon oxygenation, contributing the greater part of the alkaline Bohr effect in the absence of Cl^-. In the presence of Cl^-, binding of these ions to several ionizable groups that line the central cavity of the hemoglobin molecule, including the a-amino groups of the a chains and the ε-amino groups of Lys82 of the b chains, affects the protonation of those groups. Consequently, the release of Cl^- ions upon binding of oxygen produces an additional, Cl^--dependent Bohr effect (7). It is thought that His143 of the b chains is one of the groups responsible for the acid Bohr effect (8), but the others are still unidentified.

The term "Bohr effect" is sometimes used for pH-dependent binding of other ligands, such as CO_2 and alkylisocyanides, to hemoglobin. It is also used for pH-dependent ligand binding to oxygen-binding proteins other than hemoglobin.

Bowman–Birk Inhibitors

Bowman–Birk proteinase inhibitor is a member of a widely studied family of serine proteinase inhibitors, protein. Most such inhibitors consists of a single polypeptide chain of 65–80 amino acid residues containing two homologous regions, each with a reactive site. In some Bowman–Birk inhibitors, both sites are specific for trypsin; in others, one is specific for trypsin and one for chymotrypsin; and, in still others, one is for trypsin and one for elastase. Ternary complexes of one inhibitor and two enzyme molecules are commonly found. The polypeptide chain is crosslinked by seven disulfide bridges, some within the homology regions, others between them, endowing the inhibitor with great stability.

BPTI (Bovine Pancreatic Trypsin Inhibitor)

Bovine pancreatic trypsin inhibitor, BPTI (Kunitz), is also called trypsin kallikrein inactivator, TKI, aprotinin, and Trasylol™. It is the first protein inhibitor of proteinases [see Proteinase Inhibitors, Protein] to be isolated and characterized by Moses Kunitz as an inhibitor of bovine trypsin. It was independently discovered as a kallikrein inactivator. BPTI was the first protein proteinase inhibitor to be sequenced. Shortly afterward, sequencing the kallikrein inactivator revealed the identity of the two inhibitors. They consist of 58 amino acid residues, crosslinked by three disulfides. Lys^{15} is at the P_1 position of the reactive site. The K_I for BPTI-bovine b trypsin interaction, 5×10^{-14} M, is often—probably incorrectly—referred to as the strongest of the proteinase–protein proteinase inhibitor interactions. BPTI is also extremely stable. Its T_m at neutral pH is 103°C. BPTI was the first protein proteinase inhibitor to have its three-dimensional structure determined both in free form and in complex with bovine b trypsin. It has been—and still is—widely used in Europe as a drug to avoid postsurgical complications. For this use, it is isolated from bovine lungs. BPTI has been the first superbly characterized small protein that was widely available. Therefore, it became the favorite substance of many protein researchers. It was the first protein to have its three-dimensional structure determined by nuclear magnetic resonance (NMR). It served as the object of numerous molecular dynamics and structure prediction calculations. It was the first protein for which the pattern of closure of disulfide bridges was studied in detail. BPTI (Kunitz) gave its name to a widely studied family of standard-mechanism canonical protein inhibitors of serine proteinases.

Bragg Angle

The Bragg angle is important for analyzing the diffraction from crystals in X-ray crystallography. W.L. Bragg noted that X-ray diffraction by a crystal can be understood without going into the details of diffraction theory (1). The process is similar to ordinary reflection of light from a mirror. In the crystal, the mirrors are the lattice planes. They are the planes constructed through the lattice points, which are the corners of the unit cells. Within a set, the planes are parallel and equidistant with perpendicular distance *d* (Fig. 1). q, the reflective angle, is called the Bragg angle. The beams reflected from the upper and the lower lattice plane are in phase and reinforce each other if the difference in path lengths of the two beams, which is given by the path A–B–C, is an integral number of the wavelength l. The path difference is also equal to 2*d* sin q. This results in Bragg's law: 2*d* sin q = n l, where *n* is an integer, 1, 2 3, etc.

Figure 1. Bragg's view on X-ray diffraction. The incident beam is reflected by lattice planes. *d* is their distance, and q is the reflective angle.

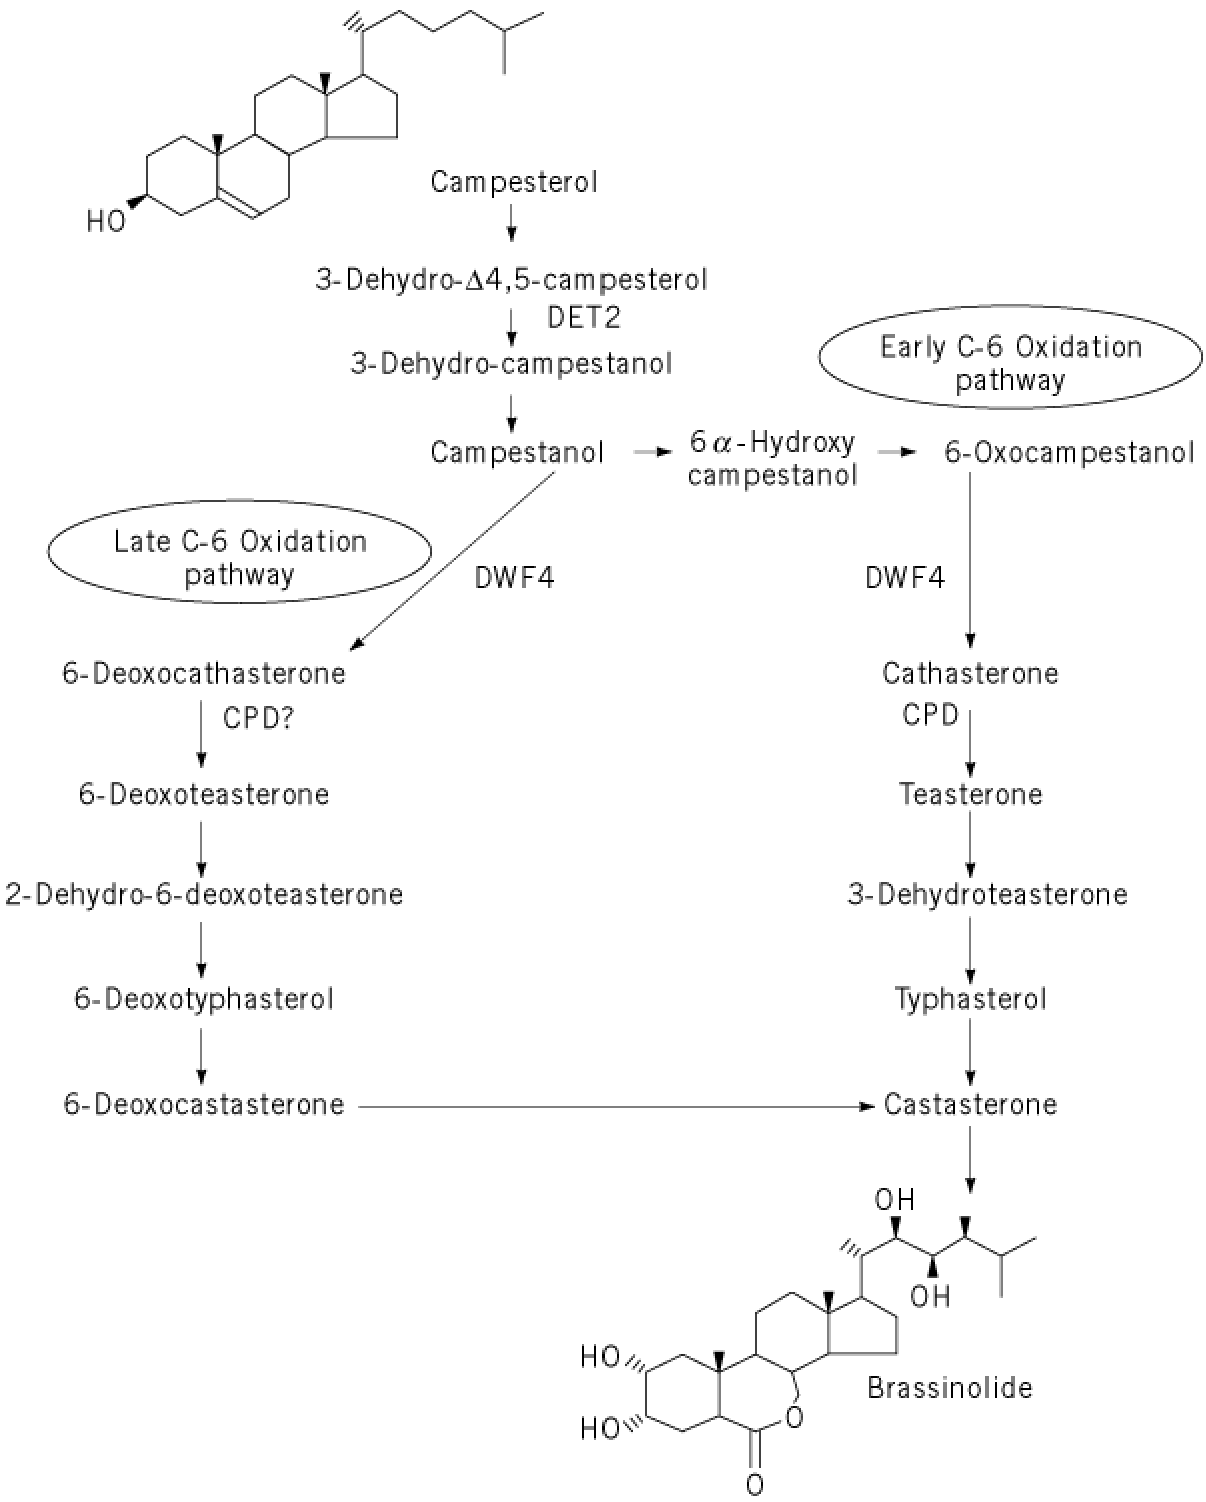
Brassinosteroids

1. History

Unlike the five other “classical” plant hormones, which were all discovered more than 35 years ago, brassinosteroids (BRs) have been identified only recently. In 1979, Grove et al. (1) reported on the first growth-promoting steroid from plants. The substance was isolated from *Brassica napus* (rapeseed) pollen and was called *brassinolide*. Brassinolide was found in minute quantities in pollen grains; about 250 kg of pollen were needed to obtain only 10 mg of the pure compound. BRs are widely present in angiosperm families, but are also found in gymnosperms, ferns, and green algae (2).

Recently, BRs have gained recognition as true plant hormones (3). Genetic experiments provided evidence that they are indispensable for normal plant growth. A second breakthrough in our knowledge of BRs owes to the recent elucidation of the entire biosynthetic pathway (2, 4) (Fig. 1).

Figure 1. Brassinosteroid biosynthesis in higher plants. Steps mediated by DET2, DWF4, and CPD in *Arabidopsis* are indicated. (Adapted from Ref. 7.)



2. Biosynthesis and Metabolism

Brassinosteroids are unique as plant hormones because they are structurally related to the insect molting hormone ecdysone and to mammalian steroid hormones. More than 40 BRs occur naturally, all of which share a common 5a-cholestane skeleton. The relative activities of the BRs increase according to their position in the biosynthetic pathway: brassinolide is most active, whereas early precursors up to 6-oxocampestanol are virtually inactive (5). Hydroxylation at position C22 is critical for biological activity.

Brassinolide is synthesized from campesterol via two pathways (2) (Fig. 1). These pathways were established by classical labeled-precursor feeding experiments. Campesterol is derived essentially from the mevalonate pathway. Initially, the double bond in the B ring of campesterol is reduced to campestanol (6) over 3-hydro-D4,5-campesterol and 3-dehydro-campestanol. From campestanol, two possible routes lead to brassinolide. In this branch, campestanol can be oxidized on C6 to yield 6-oxocampestanol, with 6a-hydroxycampestanol as an intermediate.

The first branch is called the early C6-oxidation pathway and seems ubiquitous in higher plants. 6-Oxocampestanol is subsequently hydroxylated at position 22 on the side chain (7), resulting in cathasterone, and further hydroxylated at position 23, to yield teasterone (4). This step is followed by epimerization of the hydroxyl function on C3, yielding typhasterol, with 3-dehydroteasterone as an intermediate (8, 9). Typhasterol is further hydroxylated on C2, resulting in castasterone that is finally converted to brassinolide by lactamization of the B ring (10). Two steps in the early C6-oxidation pathway appear to be rate-limiting: (a) the formation of cathasterone from 6-oxocampestanol and (b) the final conversion of castasterone to brassinolide (2).

A second possible route from campestanol to castasterone is the so-called late C6-oxidation path, with 6-deoxo brassinosteroids as intermediates. The latter compounds are the least active BRs and were therefore considered to be dead-end products. The second biosynthetic path has been discovered only recently; it was demonstrated in cultured cells and seedlings of *Catharanthus roseus*, as well as in seedlings of rice and tobacco (11, 12). Recent evidence indicates that 6-deoxoteasterone is formed from campestanol via 6-deoxocathasterone, by subsequent hydroxylations (7). This step is followed by an epimerization to yield 6-deoxotyphasterol, comparable to the conversion from teasterone to typhasterol in the early oxidation pathway. Finally, 6-deoxotyphasterol is hydroxylated at position 2, forming castasterone.

Compelling evidence for an essential role for BRs in plant growth and development came from recent genetic studies in Arabidopsis *thaliana* (3, 13). The *det2* (*de-etiolated 2*), *dwf4* (*dwarf4*), *cpd* (*constitutive photomorphogenesis and dwarfism*), and *dim* (*diminuto*) mutants identify different steps in BR biosynthesis (7, 14-17). All of these mutants display drastic **phenotypic** effects that can be reverted by application of brassinolide. In the light, the plants are smaller than wild type because of reduced cell size, the leaves are darker green, apical dominance is reduced, and the plants are less fertile. In the dark, a de-etiolation phenotype is observed, characterized by short and thick hypocotyls, open and expanded cotyledons, and formation of primary leaves. This phenotype is accompanied by derepression of light-regulated genes, with the exception of the *dim* mutant, where a normal repression of light-regulated genes is observed in the dark (18). Collectively, these observations support the existence of cross-talk between the light and BR signaling pathways. The four **genes** corresponding to the above-mentioned loci have been **cloned** recently. The *DET2* gene product shares similarity with mammalian steroid 5a-reductases. Definite proof for its function was given by two experiments that support functional conservation between mammalian and plant steroid 5a-reductases (19). When expressed in human embryonic kidney cells, DET2 catalyzed 5a-reduction of several animal steroid substrates. In addition, *det2* mutants could be rescued by expression of human steroid 5a-reductases. The *CPD* and *DWF4* genes were cloned by T-DNA tagging, and both encode cytochrome P450 monooxygenases that share homology with steroid hydroxylases (7, 15). Feeding studies indicated that DWF4 acts as a 22a-hydroxylase (7), whereas CPD functions as a 23a-hydroxylase (15). It is reasonable to assume that each enzyme would play a role in both branches of BR biosynthesis, although there is yet no evidence that CPD uses 6-deoxocathasterone as a substrate. Finally, the *DIM* gene encodes a protein with a putative FAD-binding domain and a nuclear localization motif (see Nuclear Import, Export) (18, 20). Feeding experiments indicate that *dim* mutations affect a step before typhasterol formation, so it might be involved in epimerization of teasterone (13).

As is the case for most other plant hormones, glucosylation plays a role in deactivation of BRs. Some of these conjugates may serve as a storage form, as for instance the C23-glucosylated brassinolide and esters at position C3 (21, 22). Permanent inactivation of BRs is achieved by C25 and C26 hydroxylation, as well as by cleavage of the side chain (13). It should be noted that transport of BR storage forms is facilitated after glucosylation, as a result of their increased hydrophilicity. Transport of labeled BRs has been shown to occur from root to shoot, probably via xylem (23). It is not yet clear, however, whether this also plays a role in determining the endogenous levels of BRs.

3. Signal Perception and Transduction

The conservation of steroid-like compounds as signaling molecules across several phyla including fungi, invertebrates, and vertebrates made it tempting to speculate on the existence of soluble nuclear BR receptors in plants (24, 25). Two BR-insensitive mutants, *bri1* (*brassinosteroid insensitive 1*) and *cbb2* (*cabbage 2*), have been isolated in *Arabidopsis* (16, 26). In both mutants, hormone insensitivity is specific to BRs, and neither one can be rescued by external BR application. Expression of BR-regulated genes was abolished in BR-insensitive mutants (16). *Bri1* and *cbb2* mutations result in dramatic effects on development, including an exacerbated dwarfism, bushy phenotype, dark green and thickened leaves, and male sterility. In addition, de-etiolation of dark-grown seedlings was observed (26). *Bri1* and *cbb2* are alleles of a single locus, and the corresponding gene has been cloned using a map-based approach (27). Surprisingly, BRI1 does not share similarity with **steroid receptors**, but belongs to the class of receptor-like transmembrane kinases (28). Members of this family have an *N*-terminal extracellular leucine-rich repeat (LRR); there are 25 such repeats in BRI1, with a unique stretch of 70 amino acid residues between the 21st and 22nd LRR. These are followed by a transmembrane domain and an internal **serine/threonine kinase** domain that relays the signal. Other LRR kinases include proteins that influence meristem size and organ formation, such as clavata1, erecta, and Xa21, which confers resistance against *Xanthomonas oryzae pv. Oryzae* in rice (29-31). The *BRI1* gene is ubiquitously expressed in plant tissues in light and dark, consistent with a presumed role as a BR receptor in different cell types (27). The BRI1 protein could bind BR either directly or indirectly, via a protein intermediary. Although none of the previously identified LRR kinases can bind nonproteinaceous ligands, the island of 70 unique amino acid residues in the LRR of BRI1 could serve the purpose of directly binding BR. Mutation of this region severely affects BRI1 activity. In animal systems, LRR kinases are known to form homo- or heterodimers upon ligand binding, thereby activating the intrinsic kinase activity (28). Heterodimerization of BRI1 and XA21, or other LRR domains of disease resistance proteins, could control cross-talk between BR and pathogenic signaling (27).

4. Downstream Targets

To date, genes involved in the primary response to BR have not been identified. Likewise, cis-acting sequences or trans-acting factors involved in the BR response remain to be characterized. In contrast, the expression of at least 50 genes was altered upon treatment of soybean hypocotyls and epicotyls with BR for 2 to 17 h (32, 33). One of these genes was cloned, and the predicted polypeptide chain shared similarity with xyloglucan endo-*trans*-glycosylases (XETs) (34). The gene was termed *BRU1* (*BR up-regulated*) and is not responsive to either auxin or gibberellin. Its recombinant product catalyzed endo-*trans*-glycosylation *in vitro* (35). The *in vivo* function of *BRU1* is thus to control expansion growth, either by cell-wall loosening or by integration of newly synthesized xyloglucans in the wall (36).

In *Arabidopsis*, the *TCH4* (*touch 4*) gene encodes an active XET, and its transcriptional activation is maximal within 2 h of BR treatment (37). XET is encoded by a multigene family in the *Arabidopsis* genome. Some family members, such as *TCH4*, are responsive to BR and auxin, but not to gibberellins, whereas others, such as *meri5* (*meristem 5*), are regulated by gibberellins, less generally by BR, and not by auxin (16). Certain *XET* genes do not respond to BR. The *XET* gene family thus appears to be differentially regulated by a combination of hormonal and environmental cues (such as light, heat, cold, and touch) (38). In Situ Hybridization of soybean epicotyl cross sections with a *BRU1* probe revealed highest gene expression in vascular tissues (phloem cells and xylem parenchyma), as well as in the cortical starch sheath layer (35). In contrast to the rather restricted action of auxin on cell elongation, BRs have been shown to have an effect both on epidermal and internal tissues (39). Nevertheless, the action is more profound on internal tissues, correlating well with the spatial expression pattern of *BRU1*. Comparative kinetic analysis of auxin and BR action indicates that auxin possibly initiates cell wall elongation at the epidermis, whereas BR continues to stimulate elongation of both outer and inner layers (39-41). BRs thus seem to have a prolonged effect on cell elongation. Brassinolide application results in a predominantly transverse orientation of cortical microtubules, allowing expansion in the longitudinal direction (42).

5. Effects

The final effects of BRs result from expression of an array of secondary response genes, mentioned above. A multitude of BR functions in plant development are known, including leaf bending and unrolling, stem elongation, root inhibition, xylogenesis, and pollen tube growth (5). It is clear that several of these activities may result from cross-talk with light and other hormonal signaling cascades.

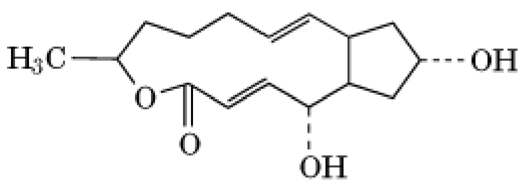
Brefeldin A

Brefeldin A (BFA) is a fungal metabolite that is a powerful tool for dissecting membrane traffic and organelle dynamics. It is named after *Penicilium brefeldianum*, which produces it. BFA is a macrolide antibiotic with a molecular weight of 280.36 Da and the structure



BFA is normally used on cells in culture at concentrations of 1 to 10 µM. As first discovered by Misumi et al. (1), BFA primarily inhibits secretion, without significantly affecting endocytosis. It does not affect protein biosynthesis significantly, does not deplete cellular ATP levels, and does not affect **cytoskeletal** elements. The unique feature of BFA, which distinguishes it from other inhibitors of protein traffic, is that it causes coalescence of organelles. Within minutes of BFA application, the Golgi apparatus fragments and fuses with the endoplasmic reticulum (ER), which does not fragment (2), leading to mixing of the two compartments.

The effects of BFA are completely reversible. Retrograde movement of Golgi proteins into the ER occurs via long, tubulovesicular processes extending out of the Golgi along microtubules. This retrograde traffic pathway can be separated into two distinct phases: movement of Golgi proteins into the intermediate compartment between the ER and Golgi complex, followed by cycling between the modified ER and the intermediate compartment (3). Remarkably, many Golgi enzymes are still active in this environment and can modify proteins in the ER (4).

One of the important uses of BFA-induced redistribution has been the functional demarcation of compartments along the secretory pathway (5). It is clear that BFA affects the early Golgi compartments, the *cis* and medial cisternae. Whether BFA also affects the *trans*-most cisternae of the Golgi stack and the *trans*-Golgi network seems to be dependent on tissue and cell type. Thus, in pancreatic acinar cells, exit from the Golgi complex and formation of **secretory granules** are not BFA-sensitive (6), while in other cells the formation of secretory granules is inhibited (7). Secretion of preformed secretory granules is not inhibited by BFA. Thus, the effects of BFA point to a common mechanism in the traffic of proteins that follow either the constitutive or the regulated pathways of exocytosis.

BFA's effects are not limited to the Golgi apparatus and are reiterated throughout the **endosome**/**lysosome** system. BFA treatment induces tubulation of these compartments (8). Similar to the mixing of the Golgi with the ER, the *trans*-Golgi network mixes with the recycling endosomal system. Remarkably, this mixed system remains partly functional, with normal cycling between plasma membrane and endosomes, but with impaired traffic between endosomes and lysosomes (8). This suggests that the vesicle-budding mechanisms (see below) in the endocytic pathway are similar to, yet distinct from, those in the exocytic pathway. Furthermore, these observations reinforce the plasticity of the endocytic pathway, which is largely functional even when some traffic steps are inhibited.

The major effects of BFA on protein traffic are explained by its ability to prevent binding of cytosolic coat proteins onto membranes (9). The target of BFA's action is a **nucleotide exchange factor** for **ADP-ribosylation** factor (ARF), a small GTP-binding protein. BFA inhibits the ability of Golgi membranes to catalyze the exchange of GTP onto ARF specifically, thereby preventing ARF from interacting with the membrane. As a result, the association of the coat protein b-COP with the Golgi membrane is inhibited (10, 11). b-COP is a subunit of a cytosolic protein complex, the coatomer, that reversibly associates with Golgi membranes and controls vesicular transport.

One possible mode of ARF action is via its ability to stimulate phospholipase D in Golgi membranes (12). Phospholipase D converts phospholipids into phosphatidic acid and thus can alter the lipid content of membranes. Stimulation of the Golgi-associated phospholipase D activity is BFA-sensitive, suggesting a possible link between transport events and the underlying architecture of the lipid bilayer.

The pathogenic bacterium *Staphylococus aureus* mimics the action of BFA and disassembles the Golgi apparatus (13, 14). This effect is mediated by the secretion of EDIN (epidermal-cell differentiation inhibitor), an extracellular enzyme that ADP-ribosylates Rho GTPase. As a result, all the manifestations of BFA treatment are reproduced. Thus, the regulatory circuit of coat-membrane assembly may involve more than one small GTP-binding protein. In addition to the effects of the small GTP-binding proteins, heterotrimeric G proteins of the Gi/Go subfamily also contribute to the regulation of the cycle of coatomer binding (15, 16). Activation of heterotrimeric G proteins promotes binding of b-COP to Golgi membranes and antagonizes the effect of BFA.

Several BFA-resistant cell lines exist, including the PtK1 rat kangaroo cell line, a derivative of monkey kidney Vero cells, and two derivatives of the human epidermoid carcinoma KB cell line (17). The BFA resistance is dominant and is due to a Golgi-associated factor that is **homologous** to the target of BFA in cells that are sensitive to the drug. In Golgi membranes from BFA-resistant PtK1 cells, the basal phospholipase D activity is high and insensitive to BFA (12), suggesting a mechanism for the drug resistance. Another mechanism may involve a member of the ATP-binding cassette superfamily of transport proteins, as suggested by BFA-resistant mutants in yeast (18).

The ability of BFA to affect budding of **clathrin**-coated vesicles from the *trans*-Golgi network (observed in many, but not all cells) is mediated through the rapid and reversible redistribution of g-adaptin (19). This component of the clathrin coat is specific to Golgi-derived coated vesicles and is absent from plasma membrane-derived coated vesicles. The kinetic and pharmacological similarities between BFA's effects on g- adaptin and b-COP underscore the biochemical similarities between membrane budding mechanisms that are mediated by various coat complexes.

The effects of BFA are readily reversible, and this reversibility is due partly to its detoxification. The mechanism of BFA detoxification was studied in CHO cells and is mediated by the **glutathione *S*-transferase** system via conversion of the antibiotic to its **glutathionyl** and **cysteinyl** derivatives, followed by secretion (20).

BFA affects cellular compartmentalization not only via protein traffic, but also through lipid metabolism (21). Its main effect on lipids is enhanced hydrolysis of sphingomyelin, a key regulator of cell proliferation and differentiation. Sphingomyelin is produced from ER-derived ceramide and is delivered to other membranes, presumably via the same trafficking system used for proteins. The effect of BFA on the level of sphingomyelin seems to be a result of the mixing of cellular membranes. BFA treatment also increases the rate of sphingomyelin biosynthesis from phosphatidylcholine, and this effect may be related to the above-mentioned action on phospholipase D. In this context, it is noteworthy that C6 ceramide, a cell-permeable ceramide analogue, partially restores BFA sensitivity in a BFA-resistant cells (22).

The various effects of BFA on a number of cellular membranous organelles indicate both the common and distinct mechanisms that operate to sort membrane components. BFA seems to inhibit a common key step in the mechanism of vesicle budding, namely, regulation of the nucleotide status of different small G proteins. The BFA-sensitive G proteins are each endowed with organelle specificity, coupled perhaps to tissue specificity, which explains the variable sensitivity of membranes to BFA. On the other hand, the use of BFA has also revealed a physiological connection between cellular signal transduction pathways and the traffic of membrane lipids and proteins through the cell.

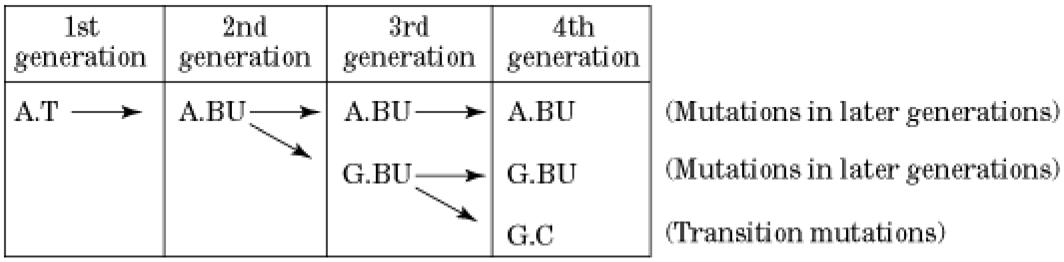
5-Bromouracil

Litman and Pardee (1) found that three **thymine** analogues (5-bromouracil, 5-chlorouracil and 5-iodouracil) were all incorporated fairly efficiently into the **DNA** of **bacteriophage** T4, and all were powerful mutagens in this organism. Further studies on 5-bromouracil (BU) mutagenesis by Freese (2, 3) were important in defining transition and transversion mutations and distinguishing these events from frameshift mutation. All the mutants induced by BU could be reverted by either BU or 2-aminopurine, although spontaneous and **acridine**-induced mutants could not. The BU-induced mutations were suggested to be transitions, because it was considered that the most likely effect of incorporating this base analogue into DNA would be to induce mispairing with guanine, by a mechanism that was unknown at that time (3). Mispairings with guanine do occur and can lead to BU mutagenesis (for example, as shown in Fig. 1).

Figure 1. Mechanism of generation of transition mutation by 5-bromouracil (BU) after DNA replication. The presence of BU in one DNA strand in place of the original thymine (T), causes guanine (G) to be inserted in the complementary position upon DNA replication, instead of the original adenine (A).



There is some evidence that ionization of bromouracil leads to a high probability of mispairing with guanine and that ionized structures are more likely to be involved in this type of mutagenesis than a neutral wobble-pairing structure containing the favored keto structures of BU (4). Goodman et al. (5) suggested that BU may exhibit substantially different base-pairing behavior depending upon whether it is present as a template base or as a deoxyribonucleoside triphosphate substrate. They interpreted differences in mutagenesis by this base analogue in different organisms and different systems as due partly to the relative size of and imbalance of the deoxynucleoside triphosphate pools. Classic interpretations of BU mutagenesis invoke direct base mispairing, and this is likely to be involved in the mutagenesis seen in bacterial and bacteriophage systems. However, studies in **yeast** (6) suggest that the majority of BU-induced mutants do not occur at the site where BU is incorporated. Szyszko et al. (7) have identified uracil as a major lesion after BU incorporation into DNA of *E. coli*, presumably because of dehalogenation of incorporated BU. They suggested that this would be followed by formation of apyrimidinic sites by the enzyme uracil-DNA glycosylase, followed by single-stranded nicks. Efficient BU mutagenesis is dependent upon various DNA repair gene functions, suggesting a major role for SOS response repair in many of the BU-induced mutations (8).

Buffers

1. Basic Principles

The term *buffer* solution usually refers to a solution that minimizes changes in pH when hydrogen ions (hydrons, H^+) are added to the solution or removed from it. (As discussed in reference1, IUPAC has approved *hydron* to designate a hydrogen cation when a term independent of hydrogen isotope is desired.) Such a solution is therefore said to buffer the pH. Solutions can also be designed to buffer other species, particularly metal ions, as will be described below.

Because the concentration of hydrogen ions in biological media is low, usually about 0.1 µM, it could be greatly changed by the production or consumption of very small quantities of hydrogen ions in chemical reactions. This is what makes buffering commonly necessary in experiments in molecular biology. The principle of a buffer is simple. Relative to the low concentration of free hydrogen ions, the buffer consists of much higher concentrations of both a base, A^-(ie, a substance that can combine reversibly with the hydrons), and its conjugate acid, HA, which is formed when the base combines with a hydron. Hence the equilibrium

$$HA \rightleftarrows H^+ + A^- \tag{1}$$

is established. Subsequently, any addition of H^+ causes a much smaller increase in its free concentration, $[H^+]$, because some of the hydrons are used up in making more HA to displace this equilibrium to the left. Likewise, any fall in $[H^+]$ is diminished because it leads to the dissociation of HA.

2. Simple Theory

Users of buffers need to be aware of many features of their action if they are not to make mistakes that can easily ruin their experiments. For this, a little theory of buffer solutions is required.

2.1. Dissociation of Water

Water spontaneously dissociates into one hydrogen ion and one hydroxide ion:

$$H_2O \rightleftarrows H^+ + OH^- \tag{2}$$

Because of the equilibrium, the product $[H^+][OH^-]$ is constant; its value, about 10^{-14} M^2, changes only slightly with temperature. Both the hydrons and the hydroxide ions will be largely hydrated, reversibly combined with one or more water molecules. In this article, the term *acid* is used in the sense of a Brønsted acid, a substance that can donate a hydron, and *base* is used to mean a Brønsted base, a substance that can combine with one. If no such acid or base is added to pure water, the values of $[H^+]$ and $[OH^-]$ are equal, namely, 10^{-7}M, ie, 0.1 µM. Given that the pH is defined as

$$pH = -\log_{10}[H^+] \tag{3}$$

the pH is 7. The pH scale is useful in water over about the range 0 to 14, over which $[H^+]$ varies from 1 M to 10^{-14} M, and $[OH^-]$ from 10^{-14} M to 1 M.

2.2. The pK_a and the pH

The acid HA will have a dissociation constant, K_a, the equilibrium constant for reaction (1), which is defined as

$$K_a = \frac{[H^+][A^-]}{[HA]} \tag{4}$$

Rearranging this to find $[H^+]$ gives

$$[H^+] = \frac{K_a[A^-]}{[HA]} \tag{5}$$

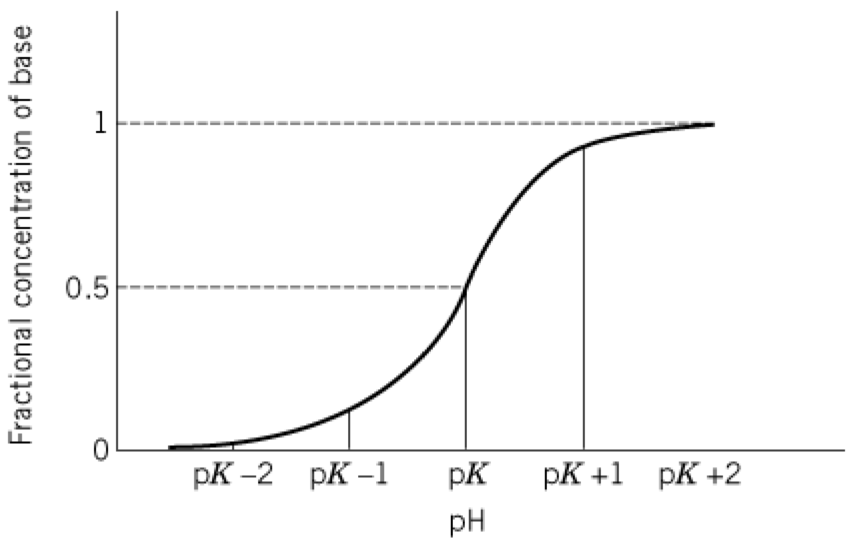
and taking the negative logarithm of each side to find the pH [eq. (3)] gives

$$pH = pK_a - \log\frac{[A^-]}{[HA]} \tag{6}$$

if we define pK_a as $-\log K_a$. This is known as the Henderson–Hasselbalch equation, and it is fundamental for understanding buffer action and how single groups titrate.

Figure 1 shows the fractional concentration of the base, ie, $[A^-]/([HA] + [A^-])$, as a function of pH. The first point to note is that, when the pH = pK_a,$\log([A^-]/[HA] = 0$, and so $[A^-]/[HA] = 1$, and $[A^-]$ is 0.5 of its maximal value. Hence, the pK_a is the pH at which the acid is half-dissociated. When the pH is one unit above the pK_a, $\log([A^-]/[HA]) = 1$, and so $[A^-]/[HA] = 0$, and hence $[A^-]$ is 10/11, ie, 0.91, of its maximal value as shown; when the pH is two units above the pK_a, $\log([A^-]/[HA]) = 2$, and so $[A^-]/[HA] = 100$ and, hence, $[A^-]$ is 100/101, ie, 0.99 of its maximal value. Similarly, when the pH is one unit below the pK_a, $\log([A^-]/[HA]) = -1$, and so $[A^-]/[HA] = 0.1$, and $[A^-]$ is 0.091 of its maximal value; when the pH is two units below the pK_a, $[A^-]$ is 0.01 of its maximal value. These figures illustrate that comparing the pH with the pK of a substance instantly indicates how much of the substance or group is in its hydronated and unhydronated forms. All simple acids follow the curve of Figure 1; they differ only in their pK_a values.

Figure 1. The dependence of the fractional concentration of the basic form of a monobasic acid on the pH. The vertical axis shows the concentration of A^- expressed as a fraction of the sum of the concentrations of A^- and HA. Vertical lines mark: (1) pH = $pK_a - 1$, when $[A^-] = 0.1[HA]$, so the fractional concentration of A^- is 1/11; (2) pH = pK_a, when $[A^-] = [HA]$, so the fractional concentration of A^- is 1/2; (3) pH = $pK_a + 1$, when $[A^-] = 10[HA]$, so the fractional concentration of A^- is 10/11.



2.3. Theory of Buffering

With properly buffered solutions, both [A^-] and [HA] will be much greater than [H^+] and [OH^-]. In this case, any H^+ produced in a reaction converts A^- into HA, and any H^+ taken up dissociates from HA to convert it into A^-. To see the consequences of this, it is convenient to modify the Henderson–Hasselbalch equation as follows:

$$\mathrm{pH} = \mathrm{p}K_\alpha - \log\frac{[\mathrm{A}^-]}{[\mathrm{HA}]} = \mathrm{p}K_\alpha - \log[\mathrm{A}^-] + \log[\mathrm{HA}] \tag{7}$$

For good buffering, it is necessary for *both* [A^-] and [HA^-] to be large enough so the logarithm of neither is changed enough to produce an unacceptable change in pH when some of one is converted into the other.

This means that there are two basic requirements for a buffer: (1) It must be sufficiently concentrated (in terms of the total of [A^-] + [HA^-]), and (2) the pH must not be too far from the pK_a of the buffer so that the concentrations of *both* A^- and HA will be large. It is the second of these that is most often forgotten. If the pH and pK_a differ by one unit, only 1/11 of the total buffer concentration will be in the minor form.

This point may be illustrated by the example of a worker who wondered why mercaptoethanol and **iodoacetate** inhibited his enzyme when neither one by itself did so. He was using more than 10 mM of each reagent in a 10-mM Tris buffer of pH 7. Hence, the 10-mM H^+ released when the mercaptoethanol and iodoacetate reacted exceeded by tenfold the concentration of free Tris, which was less than 1 mM in a solution far below its pK_a of 8.1.

To a first approximation, dilution does not affect the pH of a buffer solution because it does not affect the ratio [A^-]/[HA^-]. There are, however, two qualifications to this conclusion. First, it is assumed that the dissociation constant of the buffering acid is unaltered whereas, in fact, it is likely to change with ionic strength (see below). It is also assumed that dilution is not so extreme that either [A^-] or [HA^-] become comparable to [H^+] or [OH^-]. In any case, dilution decreases the concentrations of both A^- and HA; hence dilution makes the solution a worse buffer in that a given amount of conversion of one form into the other will produce a larger change in the ratio.

3. Practical Points

3.1. pH Measurement

Methods of measuring pH are outside the scope of this article but the process is important because reproducibility of buffer preparation often depends on it (see below). The most common method uses a glass electrode. This method depends on dipping the electrode into the solution to be tested in such a way that an electrical cell is created and that the potential given by this cell depends on the pH of the solution. Normally, a layer of thin glass separates the solution under test from one containing one of the electrodes of the cell. This glass is selectively permeable to hydrons, so that the potential across it depends on the pH of the solution. Provided that the other junction potential between this solution and the other electrode is negligible—a condition approached by a bridge containing concentrated KCl—the potential should reliably indicate the pH.

Such pH meters require calibration, and standard buffers are used for this. The makers normally give reliable instructions for calibrating the electrode, but some of these are easily overlooked. The first concerns the temperature. The pH standards have pH values that may themselves vary with temperature. Standardization is valid at only one particular temperature, and it cannot be assumed that an electrode standardized at one temperature gives a meaningful reading at a different one. The pH range specified by the makers of the apparatus should also be noted. Glass membranes may be slightly permeable to Na^+, so that when $[H^+]$ is low, as in alkaline solution, even a slight sensitivity to Na^+ may cause overestimation of $[H^+]$ and hence too low an estimate of a high pH.

3.2. Specifying a Buffer Solution

Buffer solutions are often specified in a conventional way, such as 0.2-M sodium acetate buffer, pH 4.8. The concentration given should refer to the sum of the two forms of the buffering species, designated here as $[AcO^-]$ and [HOAc] in the case of acetate buffer, but such a specification does not make fully clear how this solution has been obtained. It might have been prepared by (1) mixing the appropriate amounts of sodium acetate and acetic acid, as calculated from the p*K* and the Henderson–Hasselbalch equation, (2) adding 0.2-M sodium acetate to 0.2-M acetic acid until a pH of 4.9 was reached, or (3) adding strong NaOH to 0.2-M acetic acid to reach pH 4.9, on the assumption that the volume added diluted the acetic acid negligibly. It would not have been appropriate, however, to have added strong HCl to 0.2-M sodium acetate, as this would have produced NaCl in addition to the buffering species.

Measuring pH is not straightforward, especially in view of the effects of temperature on the measurements (see above); for reproducibility, especially between different laboratories, it is much safer to specify the concentration of *each* form of the buffering substance, given that weighing material out with an accuracy of 1% to 2% is easy. Even an error of 2% in each would change the pH by only log(1.04), ie, by 0.017 of a pH unit. Hence, it would be better to describe the buffer just mentioned as 0.12-M sodium acetate, 0.08-M acetic acid (pH 4.8), thus adding the pH for information rather than as part of the definition.

3.3. Effects of Temperature

Users should remember that the pH of a buffer may change with temperature. This is because the dissociation constant of the buffering acid, like any other equilibrium constant, depends on temperature if the dissociation has an appreciable **enthalpy** change, D*H*. Dissociations of carboxylic acids and phosphoric acid have low values of D*H*, and so this effect is small with buffers based on them, but the dissociation of ammonium to ammonia and a hydron is accompanied by a large heat intake (ie, D*H* is positive), and increasing temperature promotes dissociation, ie, lowers the pK_a. Hence, the pH of a buffer that uses an amino group decreases on heating. The effect is quite large, a fall of 0.028 per degree Celsius.

The importance of this needs to be considered in each experiment. If a user wished the glutamate residues of an enzyme to be hydronated to the same extent in an experiment at 0 °C as they would be in a buffer of pH 7 at 20 °C, it would be wrong to use an amino buffer with a pH of 7 at 20 °C and simply cool it. Cooling would raise the pH of the buffer, but not the pK_a of the residues, so these residues would dissociate more on cooling. But this would be a proper procedure if the experimenter was concerned with the state of the lysine residues because their pK_a would rise with that of the buffering amine so that their degree of hydronation would remain the same.

3.4. Effects of Concentration

The dissociation constants referred to above are those actually exhibited by the buffering species in the solution being used; ie, they are not idealized values extrapolated to standard conditions of ionic strength and temperature. They therefore change with ionic strength and the addition of other components to the solution, eg, organic solvents or deuterium oxide. Many experiments may require a solution with a particular ionic strength or particular concentrations of specified ions. Remember that these may affect the apparent value of the p*K* of the buffering species.

An acid and its conjugate base differ by one H^+ and therefore by one charge. Typically, they will have charges 0 and –1, or +1 and 0. If, however, one of the forms has more than unit charge, positive or negative, the p*K* will have a greater dependence on ionic strength. The most commonly used buffer to which this applies is phosphate buffer, where the acid is $H_2PO_4^-$ and its conjugate base is the doubly charged HPO_4^{2-}. This makes its pK_a particularly sensitive to ionic strength. For example, a solution of 0.2-M phosphate may increase its pH by over 0.2 of a unit on tenfold dilution.

Many chemical reactions are catalyzed by acids or bases, so that an increased buffer concentration can accelerate them even at a fixed pH. This should be borne in mind when altering buffer concentrations. It is not very common for enzyme-catalyzed reactions because natural selection often ensures that if such catalysis accelerates the reaction, a corresponding acidic or basic group will be present in the enzyme to provide it.

3.5. Volatile Buffers

Separation methods such as chromatography and electrophoresis often require a buffered solution. This solution needs appreciable ionic strength (in ion-exchange chromatography to give a constant competition for the sites of the exchanger, in electrophoresis to give a constant conductivity and therefore electric field) that is negligibly affected by the substances being separated. Because it is convenient to be able to remove the buffer at the end of the procedure, a volatile buffer that can be removed by evaporation is desirable. The two forms of the buffering substance must differ in charge, however, so that one at least will have a net charge and hence be nonvolatile. Nevertheless, volatile buffers can be prepared by mixing a volatile acid with a volatile base, provided that their pK_a values are not greatly separated. An example is a mixture of pyridine (pK_a 5.2) and acetic acid (pK_a 4.8). On mixing, some of the acetic acid dissociates to acetate and hydronates some of the pyridine to pyridinium. Hence, the pH will be given by

$$\mathrm{pH} = 5.2 + \log\frac{[\text{pyridine}]}{[\text{pyridinium}]} = 4.8 + \log\frac{[\text{acetate}]}{[\text{acetic acid}]} \tag{8}$$

The concentrations of pyridinium ($C_5H_5N^+$-H) and acetate (AcO^-) ions will be equal, because each acetic acid molecule that dissociates to acetate forms one pyridinium ion. As the solution is evaporated off, water, pyridine (C_5H_5N) and acetic acid (AcOH) evaporate, and so the equilibrium

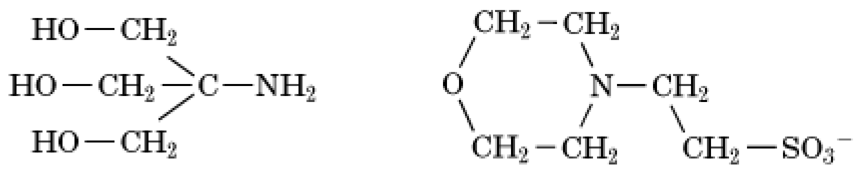
$$\mathrm{AcO^- + C_5H_5N^{-}\text{-}H \rightleftarrows AcOH + C_5H_5N} \tag{9}$$

is displaced to the right to replace the un-ionized forms as they are removed.

Ammonium bicarbonate forms a useful buffer of this type. Although it is highly volatile in solution, it is not volatile when dry, as it has a stable crystal lattice. Hence to allow ammonium and bicarbonate to react to form ammonia and carbon dioxide, it may be necessary after one drying to add a little water and then dry it again. Alternatively, triethylammonium bicarbonate, prepared from triethylamine and carbon dioxide, may be used, as it does not form nonvolatile crystals. Ammonium acetate and ammonium formate have been used in this way (2), but the procedures for drying them are complicated because their pK_a values are so far apart that there is very little of the un-ionized forms at equilibrium.

3.6. Appropriate pK_a Values

Biological material usually has a pH near 7, and it is not always easy to find a buffering species with the desired pK_a. Carboxylic acids possess values that are too low, whereas amines have values that are too high. A large number of the commonly used buffers are amines with electron-attracting substituents, which make the lone pair of electrons on the nitrogen atom less available and so lower the atom's pK_a. Examples include:



Tris 2-Morpholinoethanesulfonic acid

(**10**)

with pK_a values of 8.1 and 6.2, respectively (see Tris Buffer). Phosphate Buffers are commonly used because they have a convenient pK_a of about 7 between $H_2PO_4^-$ and HPO_4^{2-}. Their main disadvantages are their propensity to support fungal and algal growth and the sensitivity of their pK_a to ionic strength (see above).

3.7. The Need for Buffers
It should be remembered that it is pointless to add a buffer if the components of the reaction mixture are already highly buffering. Glycolytic intermediates, for example, are phosphate esters, and adjusting them to a pH near 7 creates a buffered solution.

3.8. Chemical Reactivity
It is often important to use buffering species that will not react chemically under the conditions of an experiment. Hence an experiment to acylate amino groups of proteins should use a buffer whose basic component has as low a nucleophilic reactivity as possible. Exclusion of primary amines, such as Tris, may be all that is needed. But extreme conditions may demand introduction of steric hindrance; eg, 2,6-dimethylpyridine has a pK_a close to that of pyridine but vastly less nucleophilic reactivity because the methyl groups have little steric effect on protonation of the nitrogen atom but greatly slow its reaction with larger molecules.

Another form of reactivity is the possibility of precipitating desired components in the solution, eg, cations such as Ca^{2+}, by phosphate. Occasionally, reactivity may even be of advantage. Urea is often used as a protein **denaturant** but, if kept for long in concentrated solution, especially at raised temperatures, its equilibration

$$NH_2—CO—NH_2 \rightleftarrows NH_4^+ + CNO^- \qquad (11)$$

can produce about 20-mM cyanate (CNO^-) from 8 M urea (3). The harm in this is the reverse reaction, because the cyanate can carbamoylate lysine residues in proteins, forming *uncharged* ureas and destabilizing the folded protein. This process is minimized if ammonium ions are present in the buffer as they compete with the protein for the cyanate.

3.9. “Good” Buffers
A number of buffers were recommended by Good and colleagues (4) for a variety of reasons. The most important was that both acidic and basic forms were charged and, therefore they could not rapidly permeate biological membranes. If **organelles** are suspended in a buffer without this feature, acetate, for example, molecules of acetic acid, but not acetate ions, may penetrate them and lower the internal pH below that of the external buffer. Many of the Good buffers have strongly acid groups, such as sulfonate, $—SO_3^-$. An example is 2-morpholinoethanesulfonate (eq. **10**); its sulfonate group renders it impermeant even when its nitrilo group is un-ionized. Other desirable characteristics of buffering species are also listed (4). For many purposes, transparency at UV wavelengths is necessary.

Under other circumstances, the possession of a further charge can be a disadvantage. Ideally, buffers for ion-exchange chromatography possess only one species with a charge opposite in sign to that of the exchanger so that the equilibration of the exchanger can be followed by pH changes; for example, a buffer cation cannot adsorb to, or desorb from, the exchanger except by exchange with H^+, which changes the pH.

4. Metal-Ion Buffers

The free concentration of many metal ions in biological media is very low, and it may be necessary to buffer it. The principles are exactly the same as those that apply to buffering $[H^+]$. Some compound that binds the metal ion is introduced in roughly equal concentrations of the free and metal-bound forms. A substance that buffers in the correct concentration range can be chosen from a tabulation of binding constants (5).

A complication is that many of the compounds that ligate metal ions with suitable affinity also bind hydrons, resulting in competition between the cations for the ligand. This means that the affinity of the ligand for the metal ion varies with pH. The complex of the buffering species with the metal ion is often a chelate, so that two or more ligating groups are involved. Hence, the competition is not a simple 1:1 replacement, and the pH dependence of the net affinity may be complex.

bZip Domain

The bZip DNA binding domain and the closely related **helix-loop-helix** (HLH) domain are found in many eukaryotic transcription factors. Both bind in the major groove of DNA and have the capability of forming homo- or heterodimers with proteins of the same class. The simplest of these domains is the bZip domain which, when bound to DNA, forms a continuous a-helix. The lower basic part of this helix (the b of bZip) forms sequence specific contacts with DNA whereas the upper part can dimerize with an appropriate partner through the formation of a leucine zipper. The dimer thus has the appearance of a pair of scissors binding to a palindromic DNA sequence in which each half-site is exposed on the opposite face of DNA. The helix-loop-helix domain binds to DNA in a similar manner with the difference that the a-helix involved in dimerization is separated from the DNA binding a-helix by a short loop.

Buoyant Density

The buoyant density of a macromolecule is its effective density in solution. It is defined relative to the fluid medium in which it resides and/or through which it is sedimented (see Centrifugation). The dimensions of buoyant density are in cm^3/g. If a macromolecule is sedimented through a fluid column in which the density of the column is adjusted so that it spans a gradient of density *both* less than *and* greater than the macromolecule, the macromolecule moves to a fixed position in the fluid column (see Density Gradient Centrifugation). At this position the density of the macromolecule is equal to that of the solvent. This is an equilibrium position that is independent of time. This process or technique is termed density gradient sedimentation-equilibrium, equilibrium banding or isopycnic gradient centrifugation. These techniques have uses that range from the analysis of macromolecule solvation to the separation of both living cells and subcellular **organelle** systems (1). Recently the evaluation of macromolecular values of buoyant density have been been employed in a variety of research situations including (1) the analysis of viral infectivity during therapy (2, 3); (2) the nature of circulating immune complexes of **viruses** (4); (3) as a preselection method for **PCR** methods (5).

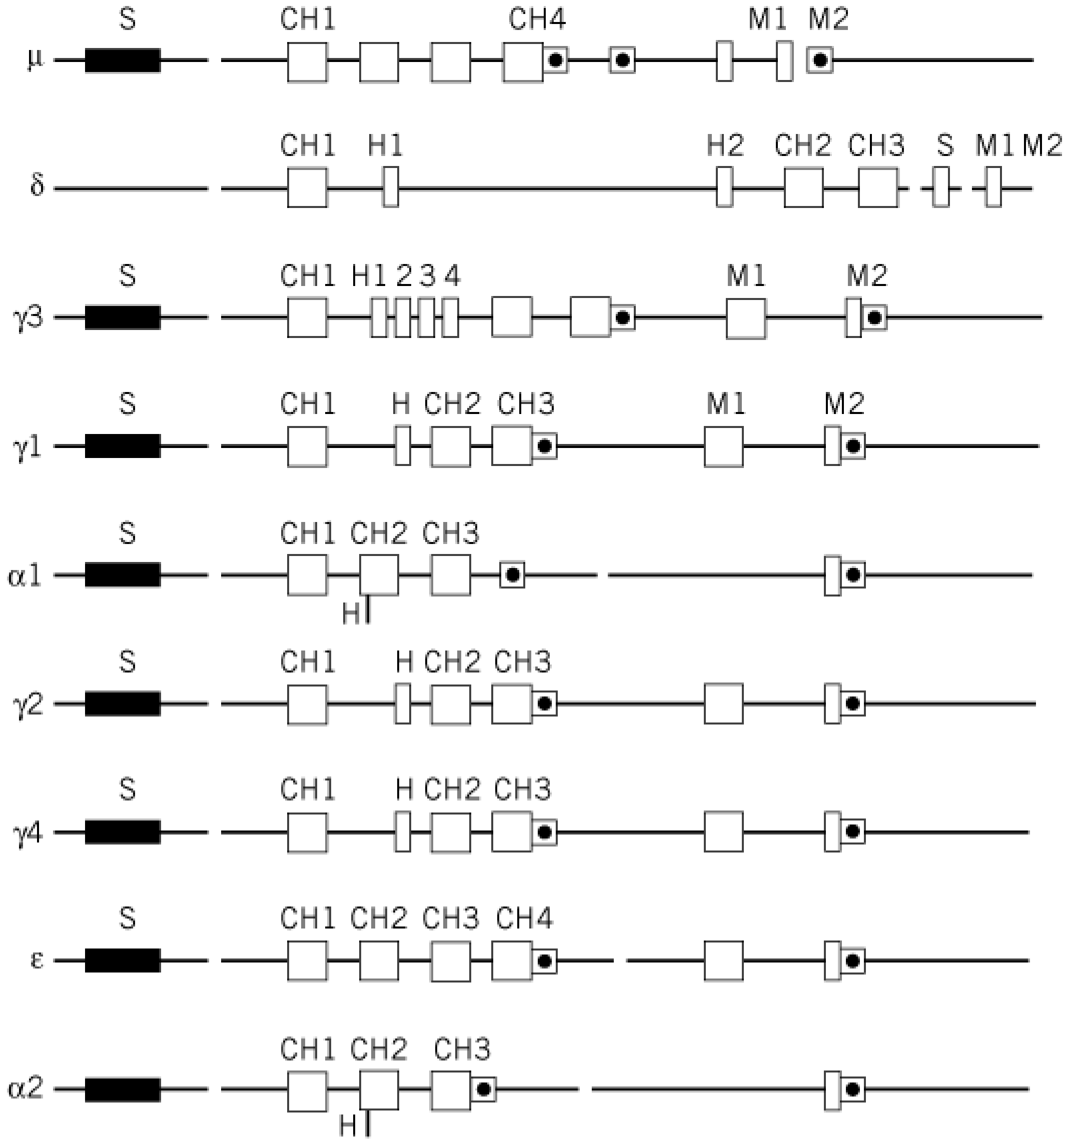
C Genes of Immunoglobulins

C genes encode for the constant (C) regions of immunoglobulin (Ig) heavy and light chains and therefore define the isotypes of H (g, m, a, d and l) and L (k, l) chains. The simplest structure is that of the Ck gene, which is unique in both the human and mouse species. It encodes for the entire constant region of the k chain. In humans, the Ck gene has three **allelic** variants based on single amino acid substitutions at two positions, which constitute the Km allotypes. The Ck gene is separated from the Jk region by a noncoding region of 1.2 kbp that contains a k enhancer. A second enhancer region is present in the 3′ flanking region. The organization of the Cl genes is somewhat more complicated, and there are some minor differences between humans and mouse. In both cases, they are present as tandem duplications of a JlCl unit, in which each J gene is separated from the C gene by a noncoding sequence of about 1 kbp. There are four discrete tandems in the mouse, Jl1Cl1 to Jl4Cl4, of which only three are functional. In humans, four functional tandem JC pairs are present, in addition to three pairs of pseudogenes. An enhancer region is present 3′ of the coding region in both species. In humans, the IgK and IgL loci are located at **chromosomal** positions 2p12 and 22q11, respectively.

The heavy-chain constant gene locus, located at 14q32 in humans, spans over 200 kbp. The detailed organization of the individual human CH genes is given in Figure 1. Some characteristic features may be identified. First, each isotype is encoded by a mosaic of exons (see Introns, Exons) that precisely reflects the **domain** structure of the Ig. The constant region of Cm is encoded by four exons, Cm1 to Cm4, corresponding to the four constant domains of the m chain, whereas in the case of the Cg isotypes one of the exons encodes the hinge region. Second, each isotype encoding C gene has additional membrane exons (one or two, depending on the isotype) that encode the transmembrane section and the short COOH-terminal cytoplasmic tail. Coding units that make secreted or membrane heavy chains result from alternative splicing and terminate at two distinct polyadenylation sites (see Fig. 1). The overall CH region also contains two pseudogenes. It will be noticed that a switch region is located at 5′ of each set of C genes, with the exception of the d locus, which accounts for the coexpression of IgM and IgD at the surface of mature B cells.

Figure 1. Organization of human heavy-chain constant region genes. Exons encoding discrete constant domains (CH), hinge regions (H), or transmembrane portion of surface heavy chains (M) are represented by open squares or rectangles. Polyadenylation sites are indicated by a dot. (From Ref. 1, with permission; adapted from Ref. 2.)



A final remark should be made regarding the general organization of the regulating elements that control IgH gene expression. **Promoter** regions are present at 5′ of each V gene and will be discussed elsewhere. Enhancers are split into two regions; one is located at 5′ of the Sm switch region, so that with each switching event it will control the newly adjacent isotype gene; the other is located at 3′ of the entire IgCH locus and may thus control whatever gene is to be turned on.

C-Banding

The procedure of C-banding is used to highlight regions of constitutive heterochromatin. In man, sites of C-banding include the centromeres of all of the chromosomes and large segments of heterochromatin in chromosomes 1, 3, 9, 16 and the Y-Chromosome. The DNA sequences in constitutive heterochromatin are highly **repetitive** and include many satellite DNA sequences that are thought to be genetically inert. The distribution of satellite DNA sequences in chromosomes varies considerably from species to species and can even provide information that is specific to a particular individual.

C-banding involves the depurination of DNA in the chromosomes by treatment with hydrochloric acid. The sugar-phosphate backbone of DNA remains intact. Treatment with hydrochloric acid (0.2 M) is halted before depurination is complete (a treatment of several minutes). Then the chromosomes are incubated for several minutes with either sodium hydroxide (0.07 M) or barium hydroxide (0.07 M). This **denatures** the DNA, which aids solubilization. Then the chromosomes are washed overnight with 2 × SSC (0.3 M NaCl plus 0.03 M trisodium citrate) at 66°C. This warm salt wash breaks the sugar-phosphate backbone and allows DNA fragments to dissolve. Then the chromosomes are stained with **Giemsa**. Staining relies on the retention of intact nucleoprotein complexes in the highly compacted heterochromatin.

C-banding of metaphase chromosomes is greatly enhanced in resolution by two methodological improvements: first, by using chromosomes isolated early in **metaphase**, when the contraction of chromatin is incomplete; second, by the use of a sophisticated microscopic technique known as epi-illumination, in which the chromosome is viewed from the same side as it is illuminated. This provides enhanced contrast between stained and unstained bands.

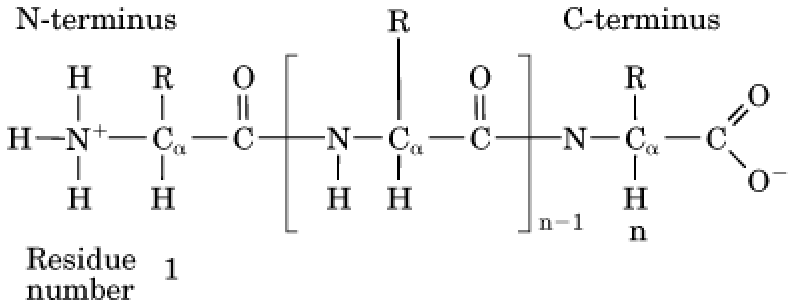
C-Terminus

The *C*-terminus is the term for one end of the polypeptide chain of a protein. Proteins are polymers formed by condensation of the amino groups and carboxyl groups of amino acids. That end of the polypeptide chain having an uncondensed or “free” carboxyl group is called the carboxyl terminus, or ***C*-terminus** (Fig. 1). By convention, the *C*-terminus is the last residue in the protein sequence or primary structure. Similarly, the other end of the polypeptide chain, having an uncondensed or free amino group, is termed the amino terminus, or ***N*-terminus**, and by convention it is the first residue in the protein sequence. The *C*-terminal carboxyl group is usually negatively charged at physiological pH.

Figure 1. Schematic representation of a protein, showing the *C*-terminus as the last residue in the polypeptide chain. The square brackets indicate the repeating part of the chain (the backbone), and the R group denotes the variable side chain of each amino acid residue. The *N*-terminus is the first residue in the chain.



The *C*-terminal carboxyl group can be changed by post-translational modification such as **amidation**. An amidated *C*-terminus is more common in smaller proteins, or peptides, including hormones and toxins, and may be important for biological function or stability. Another important covalent modification that occurs only at the *C*-terminal residue is the attachment of membrane anchors to secure an otherwise water-soluble protein to a hydrophobic membrane. Proteins can be degraded by carboxypeptidases that specifically hydrolyze the *C*-terminal peptide bond.

[See also N-Terminus and Polypeptide Chain.]

C-Value

The *C*-value is the long-used term for the mystery, or paradox, of the wide range of genome sizes present among **eukaryotes**. They range from 13 Mbp (megabase pairs, 1.3×10^7) for **yeast** to 1.7×10^{11} bp for *Amphiuma*, or the mudpuppy, a urodele amphibian. The units used above, the number of nucleotide pairs in one haploid set of DNA, should be used consistently. In much of the literature, the amount of DNA per cell is expressed in picograms (1 pg is 9.8×10^8 nucleotides), and the classic tables are often in error due to the limited accuracy of the methods used. The most accurate genome sizes are those for which complete nucleotide sequences are available; for example, the yeast genome has 13,105,020 bp (base pairs), give or take a small uncertainty because not all copies of repeated sequences (see Repetitive DNA) have been sequenced. The smallest bacterial genome accurately known from sequence is that of Mycoplasma *genitalium*, with 580,073 bp. Viruses have even smaller genomes, but they are not free-living and depend on their hosts for much of the required information. A part of the range in DNA content is apparently due to the different requirements of different species for genetic information, but that is not all there is to it, by any means.

The familiar fruit fly, **Drosophila**, is a complete animal, with all of the necessary structures, and it is not surprising that it has more DNA than yeast, which has an apparently simpler structure. The genome of *Drosophila melanogaster* is about 170 Mbp. It is easy to imagine that more genes and associated regulatory systems are needed to program the development and specify the complex structure of an animal. That is clearly true, but life is not so simple. The yeast genome has little space between its **genes** and almost no **introns**, and it is this compactness of organization that accounts for the relatively small size of its genome. The Drosophila genome, and plant and animal genomes in general, do not share this very compact organization, although some are more compact than others. They typically have large intergenic spaces, and most of the genome is not made up of genes and regulatory systems and has no known function. Most mammals, including humans, have about 3×10^9 bp, and it is not obvious why we require 20 times more DNA than does *Drosophila*. Some believe it is required for the brain, but humans have no more DNA than do mice. It is not reasonable that the mudpuppy requires almost 50 times more genetic information than we do, and its large genome must have some other explanation. One might expect that the very large urodele genomes are burdened with repeated sequences, and they do have a larger fraction of repeated sequences (90%) than *Drosophila* (30%). That is not the only source of the large genome size, however, since the so-called single-copy DNA is also very large in absolute quantity in the large urodele genomes. The genome sizes of single-celled protozoa range from about 1.0×10^9 to 1.0×10^{12}, but that information does nothing to reduce the mystery.

The "*C*-value paradox" remains as paradoxical as when it was first observed. It is known that a more compact genome is typically more compact in many features, such as smaller introns and smaller amounts of repeated sequences. Natural selection forces controlling genome size must exist, but remain unknown. How genomes have evolved is not well known, but it seems that there have been events of growth, some due to doubling of the entire set of chromosomes, others due to increases in the interspersed repeated sequences. Extraordinary reductions in DNA have also occurred in some species, while closely related species have retained their large genomes. There is a correlation between genome size and cell size, but it is not known how the two are connected, although cell size does affect metabolic rates. All that can be said is that genome size is not a parameter that is understood, although it is nevertheless intimately connected with gene structure and organization. That mammals have a quite uniform genome size is evidence for selective forces that control the *C*-value. Some geneticists consider the extra DNA in large genomes as a possible limitation in searching for genomic and regulatory function and have favored organisms with relatively small genomes, such as the puffer fish (*Fugu rubripes*) and a weed (Arabidopsis *thaliana*). Of course, the small genomes do reduce the amount of work required to determine the complete genome sequence.

CAAT Box

A CAAT box is a *cis*-acting regulatory element in transcription that contains the sequence 5′-CCAAT-3′ at its core and is bound by one or more different transcription factors. These include but are not limited to C/EBP and various members of the CTF/NF1 family of proteins. Because of the multiplicity of transcription factors that recognize a CAAT box, it is usually not possible to determine the identity of the particular factor that regulates expression of a gene by simple sequence inspection. CAAT boxes are found upstream of a number of genes transcribed by **RNA polymerase** II and increase the transcriptional rate of the gene above the level that could be achieved by the transcriptional core machinery in the absence of a CAAT box. These *cis*-acting sequence elements are generally found upstream of the TATA box, but their exact position relative to it is variable, and they may be found in either orientation relative to the direction of transcription from the downstream initiation site.

Cadherins

The cadherins are a family of **transmembrane** proteins that regulate cell–cell adhesion in a Ca^{2+}-dependent manner during **embryogenesis** and as the animal matures (1). Three general groups of cadherins exist within the superfamily: (i) the “classical” cadherins, (ii) the desmosomal cadherins, and (iii) the protocadherins (1). The classical cadherins, of which there are more than 40 examples, display much conservation in their structures. The sequences of their cytoplasmic domains may be as much as 90% identical for proteins within the same species and up to 60% between widely divergent species. In contrast, there is more variation in sequence within the extracellular domains, and 30% to 60% identity is common. These cadherins are located at the adherens junction and at other points of contact between cells that lack a highly organized structure. The desmosomal cadherins, on the other hand, are the Ca^{2+}-dependent cell adhesion molecules found in **desmosomes**. Within the desmosomal cadherins there are two subclasses: the desmogleins and the desmocollins. **Isoforms** of both have been characterized. The desmogleins and desmocollins are structurally distinct, implying different roles *in vivo*. The third group of cadherins, the protocadherins, are more variable in their structures, and their claim for inclusion in the cadherin family lies with the repeating structures in their extracellular domains that are similar to those displayed by the classical and desmosomal cadherins. The protocadherins also have cell adhesion properties, which again link them to the cadherin family.

Cadherins are classified as Type I integral **membrane glycoproteins** (ie, their *N*-termini lie on the extracellular side of the cell membrane) and, with one exception (glycosylphosphatidylinositol-anchored T-cadherin), each molecule contains a single a**-helica**l transmembrane-spanning region (M) separating the cytoplasmic from the extracellular domain (1). The extracellular domain generally contains four quasi-repeating motifs (E1, E2, E3, and E4), each about 112 residues long and with one or two potential Ca^{2+}-binding sites per repeat (Fig. 1). A (partial) fifth domain of quite variable length has been designated the *extracellular anchor* (EA). Some at least of the first four repeats participate in an antiparallel overlap with similar domains in cadherin molecules emanating from other cells, thus facilitating homotypic assembly under Ca^{2+} control. Other proteins are also believed to be involved in this interaction. Details of the conformation of a cadherin repeat have recently been obtained using nuclear magnetic resonance (NMR) and X-ray diffraction methods (2, 3). These repeats are also important in determining the specificity of adhesion between the different cadherins. The cytoplasmic domain, which is able to bind a variety of proteins, contains a substructure that shows considerable variations in size between different members of the cadherin family. Consider, for example, human desmoglein and human *N*-cadherin (4). Both display a proline-rich region (albeit of different lengths) termed the *intracellular anchor* (IA), followed by a highly charged region (C1). This represents the full extent of the human *N*-cadherin sequence, in contrast to human desmoglein, which contains a further 320 residues. The C1 domain, being highly conserved between *N*-cadherin and desmoglein, is likely to be involved in interactions with cytoskeletal microfilaments and other key proteins in the cytoplasm, such as plakoglobin. The remaining part of human desmoglein can be subdivided into a 59-residue proline-rich domain (C2), a region with novel 29-residue repeats (C3) that contain a high density of putative **phosphorylation** sites, and a *C*-terminal domain (C4) that is quite divergent in sequence between human and cow, for example. The first half of domain C4 (known as C4a) is very nonpolar and contains two partial repeats of length 28 residues that are rich in glycine residues. They are not related to the 29-residue repeat seen in domain C3. Subdomain C4b is clearly basic in character, in contrast to all of the other cytoplasmic domains, which are acidic. A model of the spatial arrangement of desmoglein in the desmosome has been proposed (4).

Figure 1. Comparison of the domain structures of human desmoglein 1 (HDSG1), desmoglein 3 (HDSG3), desmocollin 3 (HDSC3), and *N*-cadherin (NCAD). This illustrates the structural similarities between the classical cadherins and those in the desmosomes. The transmembrane a-helical segment (M) separates the extracellular domains E1 to E4 and the extracellular anchor EA from the intracellular anchor IA and the intracellular domains C1 to C4. Putative calcium-binding domains in the E domains are shown as shaded rectangles. The two desmocollin 3 forms result from alternative splicing. The black rectangle represents 11 amino acids at the *C*-terminal end that are unique to the shorter structure. (From Ref. 5, with permission.)

Caenorhabditis

Caenorhabditis is a genus of primarily free-living soil nematodes. The free-living species *Caenorhabditis elegans* has become well known after being chosen by Sydney Brenner in the 1960s for a concerted genetic, ultrastructural, and molecular analysis of animal development (1). A few other Caenorhabditis species have been characterized in less detail, largely for comparison, but the findings summarized in this article are for *C. elegans* unless otherwise indicated.

C. elegans was chosen for a variety of features, including its short life cycle and **hermaphroditic** mode of development (facilitating genetic analysis), its anatomical and cellular simplicity (<1000 somatic cells in the adult hermaphrodite), and its transparency and small size (facilitating light microscopy of developing animals and ultrastructural analysis, respectively). Its genome size has turned out to be relatively small as well (100 Mb), making molecular biology convenient. An entire field of *C. elegans* biology has grown out of Brenner's original investigations. As a result of this effort and the relative simplicity of “the worm,” as it is sometimes referred to, *C. elegans* is now the most completely understood metazoan in terms of genetics, ultrastructure, development, and physiology, and it has taken its place with the fruit fly ***Drosophila*** and the laboratory mouse as one of the most important model organisms for research biology (2, 3). Its entire cell lineage from zygote to adult has been determined; its ultrastructure including the complete connectivity of its nervous system has been described in detail; an extensive genetic map has been assembled; and DNA sequencing of its entire genome will be completed in 1998. It is beautifully suited for the genetic approach: identifying **genes** required for any biological process of interest by mutations that affect it, molecularly characterizing these genes after isolation by positional cloning, and eventually studying the biochemical functions of the corresponding gene products. As in all organisms, the genetic control of development and physiology is still only beginning to be understood in *C. elegans*. The rapidly accumulating detailed knowledge of the worm's biology, as well as the recent realization that many developmental and physiological mechanisms are remarkably conserved throughout the animal kingdom, make *C. elegans* a powerful experimental system for investigating a variety of the most important questions in current biological research.

1. General Description

C. elegans inhabits soil in most parts of the world and feeds on soil **bacteria**. The adults are about 1 mm in length, and the two sexes, hermaphrodites and males, are morphologically distinguishable (Fig. 1). The hermaphrodites produce both eggs and sperm and can self-fertilize. Males can mate with hermaphrodites to give cross progeny; hermaphrodites cannot fertilize each other. A hermaphrodite can produce about 300 self progeny, in addition to cross progeny if mated. Embryos begin development in the hermaphrodite uterus and are laid at the gastrulation stage. They hatch as first-stage juveniles (L1 larvae), which as in all nematodes grow through three subsequent larval stages punctuated by molts, before a final molt to the sexually mature adult. The adult reproductive period lasts for about 4 days, after which the animals live for an additional 2 weeks.

Figure 1. Anatomy of hermaphrodite and male *C. elegans* adults. Major structural features mentioned in the text are labe Hermaphrodite. (**b**) Male. (**c**) Hermaphrodite, bright-field photomicrograph. Scale bar 0.1 mm. P, pharynx; I, intestine; C vulva; DG, distal gonad. (**d**) Hermaphrodite, cross section through the anterior, viewed toward the anterior. *d*, *v*, *l*, *r*, dor muscle; h, hypodermis; I, intestine; g, gonad; pc, pseudocoelom; nc, nerve cord. (a)

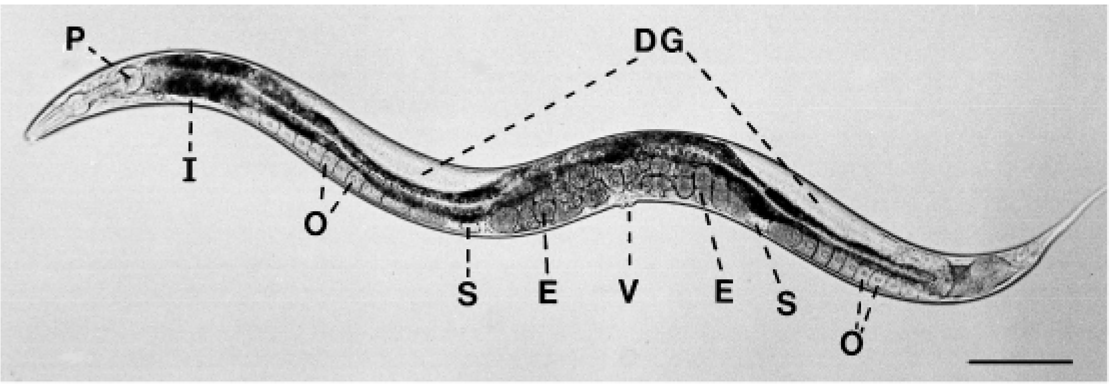
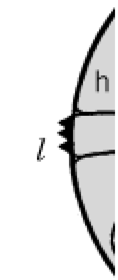
(b)





(c)

C. elegans is one of the simplest metazoans and has fixed numbers of **somatic cells**: 959 in the adult hermaphrodite and 1031 in the adult male. In the laboratory it can be cultured conveniently on agar plates spread with *Escherichia coli* bacteria, or in liquid culture when larger quantities are desired for biochemical work. Individual animals can be observed and transferred from plate to plate with a platinum wire “worm pick” under a dissecting microscope, which is sufficient for scoring many mutant phenotypes. Taking advantage of the animal's transparency throughout the life cycle, it is possible to follow individual cells during development at higher magnification using a compound microscope, preferably equipped with Nomarski differential interference-contrast optics (see Microscopy).

2. Genetics and the Genome

C. elegans is **diploid**, with five autosomes (I–V) and a sex chromosome (X). Hermaphrodites are XX and males XO; sex is determined by the X chromosome to autosome ratio. Males arise spontaneously in self-fertilizing hermaphrodite populations at a frequency of about 0.2%, as the result of X chromosome **nondisjunction**.

The haploid genome size of *C. elegans* is 100 Mb, about 10 times that of **yeast**, one-half that of *Drosophila*, and one-thirtieth that of mammals. Based on frequency of predicted coding units in the genomic DNA sequence, which is now nearly complete, the estimated total number of functional **genes** is about 13,000. Over 1000 genetic loci have been identified by mutation following chemical mutagenesis and mapped to the six linkage groups. Positional cloning of mutationally identified genes is facilitated by an extensive physical map of overlapping clones, which is anchored to the genetic map at many locations. The DNA sequence of the entire genome will soon be completely known.

3. Anatomy

C. elegans has the typical nematode body plan (see Nematodes): an outer tube of hypodermis with attached musculature and neurons, surrounding an interior space (the *pseudocoelom*), which contains the gut and, in adults, the gonad (see Fig. 1). The hypodermis secretes a three-layered, **collagenous** cuticle that is shed and replaced at each larval molt (see text below). Four bands of body-wall muscles run the length of the animal. The neuromuscular system bends the body only in the dorsal–ventral direction, so that the animal always lies on one side or the other on a solid surface. Specialized hypodermal cells on each side secrete “treads,” known as *alae*, on which the worm moves. The digestive system consists of a muscular pharynx in the head, which crushes bacteria and pumps them into the intestine, which empties at the anus near the tail. An excretory system controls the hydrostatic pressure on which the worm depends to maintain its body shape.

The entire nervous system of the hermaphrodite consists of only 302 neurons and 56 supporting and glial cells. The major ganglion is the nerve ring at the base of the pharynx, which sends processes down ventral and dorsal nerve cords to a secondary ganglion in the tail. Motor neurons from the cords enervate the body-wall muscles. Sensory neurons extend into the nerve ring from chemoreceptors and touch receptors in the head. Hermaphrodites have specialized neurons that control egg-laying (see text below); males lack these but have additional neurons that provide input from sensory structures in the tail and control male mating behavior.

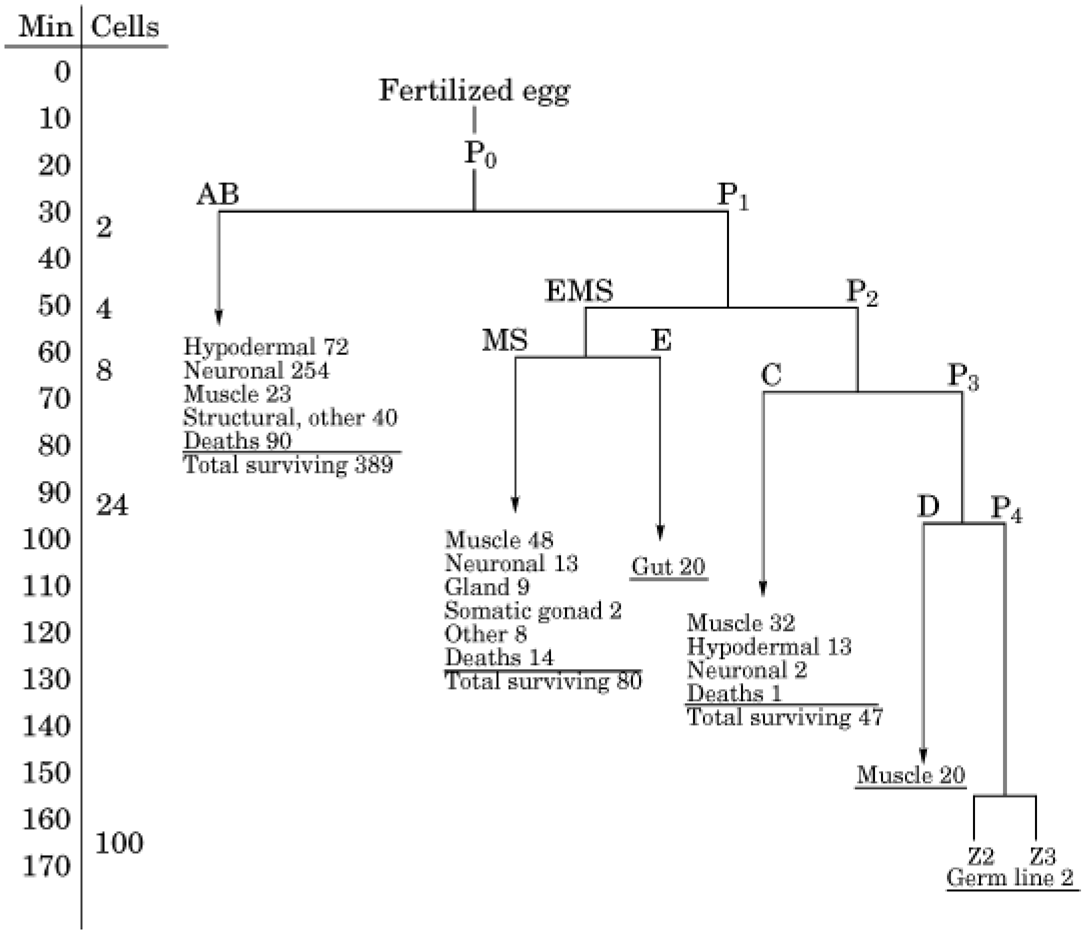
The hermaphrodite reproductive system is comprised of a bilobed gonad, with one lobe extending anteriorly and one posteriorly from the uterus near the middle of the animal. The gonad consists of a somatic sheath surrounding the germ cells and has several specialized regions. The distal arm of each lobe contains **mitotically** dividing germ-cell **nuclei** in a common **cytoplasm**. The nuclei enter **meiosis** as they move away from the distal tip. The earliest nuclei to mature differentiate into sperm during the fourth larval stage; at the molt to adulthood the germ line switches sex, and subsequent meiotic nuclei are recruited to form **oocytes** as they round the bend into the proximal arm, which contains the oviduct. At the proximal end of the oviduct is the spermatheca, containing stored sperm, through which the oocytes pass and become fertilized on their way to the uterus. A muscular vulva connects the uterus to the outside and serves as the egg-laying apparatus. In the male, the gonad is single lobed and produces only sperm, which are stored in the vas deferens and released through the cloaca in the tail. The fan-shaped male tail is specialized for mating, which is accomplished by deposition of sperm through the hermaphrodite vulva into the uterus, where they move to the spermatheca and compete for oocytes with the resident hermaphrodite sperm.

4. Fertilization and Embryonic Development

Following fertilization, a tough chitinous egg shell forms around the zygote, and embryonic cleavage begins. The spheroidal embryos, about 70 µm in length, are viable if dissected out of the hermaphrodite at this time, but normally they remain in the uterus for about 2 h until the onset of gastrulation, when they are laid through the vulva. Gastrulation is simple; only 53 cells move from the exterior to the interior, but the result is a triploblastic embryo with outer ectodermal precursor cells that will form the hypodermis and nervous system, inner endodermal precursors that will form the gut, and in between a layer of mesodermal precursors that will give rise to muscles and the somatic gonad. By 6 h after fertilization, midway through embryogenesis, the embryo consists of about 600 cells. At this point, cell proliferation essentially ceases and a process of morphogenesis begins which literally squeezes the spheroidal embryo into the shape of a worm as organogenesis proceeds internally and cuticle is formed externally. During this time about 40 cells undergo programmed cell death and are engulfed by neighboring cells. At the end of embryogenesis the worm, about 3.5 times the length of the original embryo, digests the shell from the inside and hatches out of the egg.

The process of **embryogenesis** is essentially invariant at the cellular level. It proceeds by a stereotyped series of **cell divisions** (Fig. 2), whose timing and relative spatial orientations are the same in every embryo. This feature and the transparency of the embryo made it possible for John Sulston and his colleagues to trace out the entire embryonic cell lineage from fertilization to hatching, so that the ancestry of each of the 558 cells in the L1 is known (4). Most cells are born close to their final locations; only about 12 cells undergo long-range migrations during embryogenesis.

Figure 2. Early divisions in the *C. elegans* embryonic cell lineage, showing cells and tissues derived from each of the major branches. The vertical axis shows time after fertilization and total number of cells in the embryo. Horizontal lines indicate times of cell divisions. P_0 through P_4 are germ line cells; the cells named AB, MS, E, C, and D are somatic founder cells for the various branches of the lineage. The number of cells of each different type produced in each branch is indicated. Note that many cells are programmed to die during embryonic development, especially in the AB and MS branches.



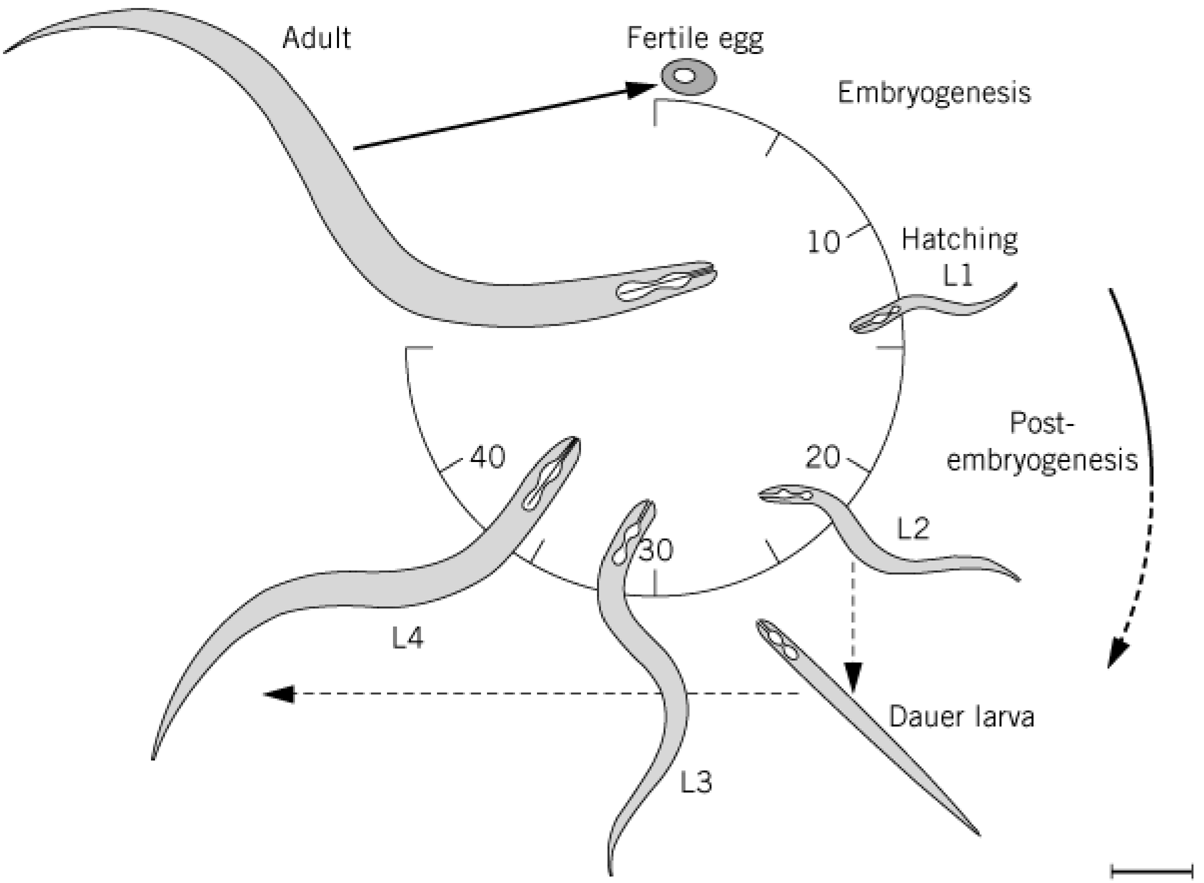
Genetic and molecular analysis of the cleavage stage has revealed that cell fates in the early embryo (Fig. 2) are determined by a combination of maternally derived factors, which segregate asymmetrically to specific cells during cleavage, and cell-signaling mechanisms by which certain cells induce new cell fates in their neighbors. This patterning process appears to proceed by evolutionarily conserved mechanisms that are common to all embryos; for example, the signaling pathways so far known to be employed include several that are also important for insect and vertebrate development, such as the *wingless* (Wnt), and ***Notch*** pathways (5).

5. Larval Development

5.1. Larval Stages

After hatching as an L1, the worm grows through three more larval stages, L2–L4 (Fig. 3), separated by molts at which a new cuticle is secreted by the underlying hypodermis and the old one shed. The newly hatched L1, 250 μm long with 558 cells in the hermaphrodite and 560 in the male, includes functional digestive, neuromuscular, and neurosensory systems and a gonad primordium consisting of two somatic and two germ-line cells. Most of the cells in the L1 divide no further during larval development. However, 55 are *blast* cells that undergo additional divisions during larval development to produce, primarily, the adult reproductive structures and the neurons that control them: the hermaphrodite and male gonads, the vulva and egg-laying muscles in the hermaphrodite, and the sex muscles and specialized tail mating structures in the male. Additional motor neurons are also produced in the nerve cords for finer control of the body-wall muscles. As in the embryo, the invariance of these processes, the transparency of all stages, and the small number of cells involved made it possible to map the larval cell lineages in both sexes from L1 to adulthood (6). Consequently, the entire cell ancestry of *C. elegans* is known, from fertilized egg to adult.

Figure 3. The *C. elegans* life cycle. Clock circle indicates hours of development after fertilization at 25°C. Eggs containing developing embryos are laid at about 2 h. The L1 larvae, hatching at about 14 h, undergo four more molts at the times indicated as they grow to adulthood. See text for further explanation.



5.2. Cell Interactions during Larval Development

Elaboration of larval structures involves cell interactions, again occurring by evolutionarily conserved signaling pathways such as those involving homologues of Notch, Wnt, epidermal growth factor (EGF), and transforming growth factor (TGF)-b-superfamily ligands as the signaling molecules. Application of the genetic approach to the process of vulval development, for example, has revealed details of a ***ras***-based pathway by which the developing gonad signals underlying hypodermal cells to differentiate using an EGF-like ligand. The molecular components are very similar to those of *ras* pathways found in mammalian cells, in which conversion of *ras* to an **oncogene** causes a variety of cancers, and the *C. elegans* pathway has become an important model system for cancer research.

Cell interactions during larval development also include guidance cues by which several cells, including the growing axonal processes of motorneurons and the distal tip cells of the enlarging hermaphrodite gonad, find their way along the basement membrane of the pseudocoelom en route to their final destinations. Again, application of the genetic approach in *C. elegans* has shown that this process is accomplished by a conserved mechanism: The so-called *netrin* ligands and their **receptors** that guide these cells in the worm are remarkably similar to the molecules that guide axonal growth from the neural floor plate to the spinal cord in developing avian and mammalian embryos, making *C. elegans* a potentially useful model system for study of nerve regeneration.

The cell divisions and molts in larval development occur in a precisely timed sequence. Again, application of the genetic approach has identified many of the genes in the timing mechanism and is providing new information on how developmental clocks function.

5.3. The Dauer Larva

Like most free-living nematodes, *C. elegans* can molt to an alternative form of the L3, called a *dauer larva* (German for "enduring larva") when conditions are unsuitable for reproduction. Dauer larvae, often simply called dauers, do not feed, are relatively resistant to drying, and can live for up to a year if desiccation is prevented. If conditions improve, they can molt to the L4 stage and resume the normal developmental pathway, with no change in subsequent lifespan. Dauer development is triggered by lack of food and overcrowding, signaled by a pheromone of unknown nature that stimulates chemosensory structures in the head. This process is of interest for at least two reasons. First, the signaling mechanism involves homologues of ligands, receptors, and downstream components of the evolutionarily conserved TGF-b pathway, which is of widespread importance but not fully understood in mammalian development. Second, entry into the pathway of dauer development appears to turn off genes that normally limit the *C. elegans* lifespan to less than 3 weeks, allowing the dauer to live much longer. This finding, and the experimentally convenient short normal lifespan, make *C. elegans* an exciting model system for studying genetic control of aging, which is under active investigation (7).

6. Behavior and the Nervous System

C. elegans can move forward or backward and change direction, by coordinated flexing of its body-wall muscles. It is touch-sensitive, moving forward in response to a touch on the tail and backward in response to a touch on the head. Chemosensors in the head, connected by sensory neurons to the ring ganglion, can detect a variety of ions as well as volatile odorants and elicit either an attractive or repulsive response (see Chemotaxis). For example, *C. elegans* is attracted to Na^+ , K^+ , Cl^- , and several alcohols and ketones; it is repelled by Cu^{2+} , acid pH, D-tryptophan, and benzaldehyde. Males are attracted by a pheromone of unknown nature that is produced by hermaphrodites. Although some of its relatives have photoreceptors, *C. elegans* does not appear to respond to light or use it as a sensory cue. It does, however, sense and respond to temperature and will move to a preferred point in a temperature gradient.

Is an animal with only 302 neurons capable of learning? Simple conditioning experiments suggest that *C. elegans* not only can habituate to several stimuli, but also is capable of associative learning, that is, learning to use a normally neutral stimulus to predict the arrival of a second more significant stimulus. For example, if presence of food is paired with one of two equally attractive ions and absence of food with the other during conditioning, the conditioned animals will preferentially move toward a source of the paired ion when tested subsequently in the absence of food, and this preference lasts up to 7 h after training. In addition, *C. elegans* not only can sense a temperature gradient, but also can "remember" the temperature at which it has previously fed and move to the same temperature when placed in a new gradient without food. The genetic approach should allow the genes involved in learning and memory in *C. elegans* to be identified and the mechanisms of the proteins they encode to be elucidated.

C. elegans does not show obvious circadian rhythms, but it exhibits much higher frequency (ultradian) rhythms, such as a regular defecation cycle that is repeated about once every 45 s when the animal is feeding, regardless of the temperature. As in other organisms, the mechanisms of the temperature-compensated molecular clocks that control such cycles (like the human heartbeat) are just beginning to be understood. Application of the genetic approach to cyclical behaviors in *C. elegans* is identifying the genes and proteins that control ultradian rhythms.

7. Current Investigation and Online Information about *C. elegans*

Knowledge about *C. elegans* genetics, development, and behavior is accumulating rapidly in several areas of currently exciting biological research, some of which are mentioned above. These include mechanisms of pattern formation in development, origins of left–right asymmetry in animal body plans, cell fate determination, programmed cell death, cell migration and guidance, developmental timing mechanisms, physiological sensory mechanisms, organization of animal genomes, and animal evolution.

As a supplement to the references listed below, much current knowledge of *C. elegans* is accessible electronically on the World Wide Web. A convenient access site can be found at `http://eatworms.swmed.edu`.

Caged ATP

The synthesis of caged ATP (caged ADP and caged phosphate) and many of the properties that make these reagents useful in a variety of biological applications were first published in 1978 (1). The driving force for the development of such a reagent was the desire to be able to introduce ATP rapidly (and synchronously) at sites of biological interest at a desired time. A pulse of ATP would be released by **light activation** and would then initiate the processes being studied (Fig. 1). In contrast to affinity labeling, here the ATP analogue should not bind to its site prior to activation and ATP is released freely in solution. The strategy employed was an approach that had previously been used in synthetic organic chemistry (ie, photodeprotection). In the chemical applications, a desired functionality in a molecule was modified and protected from a variety of reagents and conditions during a multistep synthesis, to be deprotected at a later step by a light-activated process. In biological applications, the caged substrates are "protected" from their receptor, enzyme, or binding site by the chromophoric moiety, and following the pulse of light they are released to their biological target.

Figure 1. Basis of photorelease of a caged substrate. The biological ligand (L) or substrate is rendered inactive by the attachment of a photocleavable chromophore (x). Following photoactivation the ligand is released accompanied by the modified chromophore, or photofragment.

$$\mathrm{L{-}X} \xrightarrow{h\nu} \mathrm{L + X'}$$

The properties of molecules appropriate for the study of biological systems are subject to more constraints than those used in synthetic organic chemistry. Much of the subsequent work on various caged ATP molecules and other caged compounds has been aimed at refining or improving their basic properties to expand the areas of application or overcome a particular limitation. The design requirements for a caged ATP are illustrative of the needs of any caged biological ligand or substrate (2).

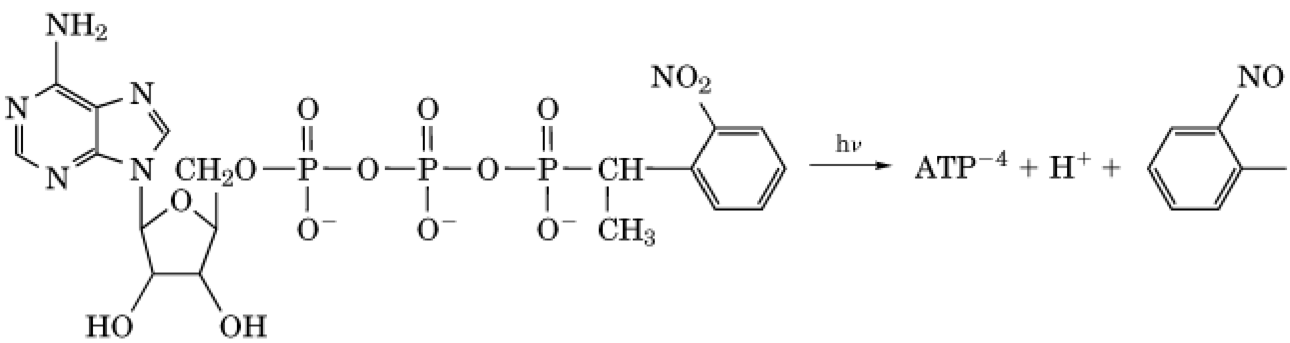
The basic requirements for a biologically useful caged ATP (and for most other caged compounds) are as follows: (i) The activating light must be at wavelengths long enough to avoid damage to biological material (usually greater than 300 nm). (ii) The photorelease process must be as efficient as possible; that is, the quantum yield (ratio of molecules of product obtained to molecules of caged compound excited) must be as high as possible. (iii) The photorelease process should be as rapid as possible, relative to the rate of the process of interest; this has been achieved in the tens of microseconds to millisecond range, at normal temperatures and pH values. (iv) The photoreleased fragment, which usually is the modified chromophore, should not be harmful to biological materials (see text below). (v) The **absorbance** of the caged compound should be reasonably high at the exciting wavelength or wavelength range. Initially it was thought that too high an absorbance might lead to nonuniform release of substrate across the depth of an illuminated sample. Interestingly, for the recent application of multiphoton excitation, very high absorbances are an advantage. (vi) Prior to photolysis, the caged substrate should neither bind to nor interact with the biological material of interest. In many respects, the first caged ATP reported and subsequently used (but the second synthesized) fulfilled many of these requirements. In a variety of systems, one or other of these properties has been less than ideal, and this has led to various variations on the original structure in attempts to provide an improved caged ATP.

1. Synthesis and Photochemical Properties of Caged ATP

The initial synthesis of caged ATP was based on a strategy of first preparing caged phosphate and then coupling this to ADP. This had the advantage that the photochemical lability, quantum yield, and so on, could be first characterized, using caged phosphate and the readily assayed free substrate, inorganic phosphate (1). This route suffered from the following disadvantages: (i) It was less direct than was desirable to achieve a gamma ^{32}P-labeled caged ATP for a variety of **phosphorylation** studies, and (ii) it was not generally applicable to a wide range of phosphate-bearing biological ligands that might be desirable to cage. It would be better to have a more universal caging moiety that could be readily attached to the nucleotide or other organophosphates. These disadvantages were overcome by the development of a synthesis by Trentham and co-workers, who were able to attach the protecting 2-nitrobenzyl-based chromophore directly to the terminal phosphate of ATP, using a diazoprecursor (3). This was based on an approach that had been used by others to prepare a photosensitive cyclic AMP phosphotriester analogue (4). This method was used to prepare a wide array of caged phosphorylated biological ligands, including GTP, ADP, inositol trisphosphate, and so on (3).

The quantum yield for the first successful caged ATP was 0.54 and has not been bettered by subsequent analogues. The first caged ATP that was synthesized, the primary 2-nitrobenzyl analogue, yielded on photolysis some ATP, but only very low levels, even though photolysis was complete. It was hypothesized that this was due to a reaction between ATP and the released photofragment (2-nitrosobenzaldehyde), so that a chemically modified ATP resulted (1). The 2-nitrophenylethyl analogue (from the secondary benzyl alcohol) then became the molecule of choice, because photolysis yielded the less reactive 2-nitrosoacetophenone and free ATP in high yield (Fig. 2). This is the caged ATP that has been used most frequently in biological studies. The absorbance properties of caged ATP are simply the sum of the spectra of the 2-nitrobenzyl moiety and of ATP. This results in a long tail of absorbance that extends to above 350 nm. This has enabled illumination above 300 nm to be employed (using lasers or flash-lamps) so that photodamage due to absorption by most biological samples is avoided.

Figure 2. Photolysis of caged ATP. Photolysis of caged ATP produces a proton, free ATP, and the photofragment, 2-nitrosoacetophenone.



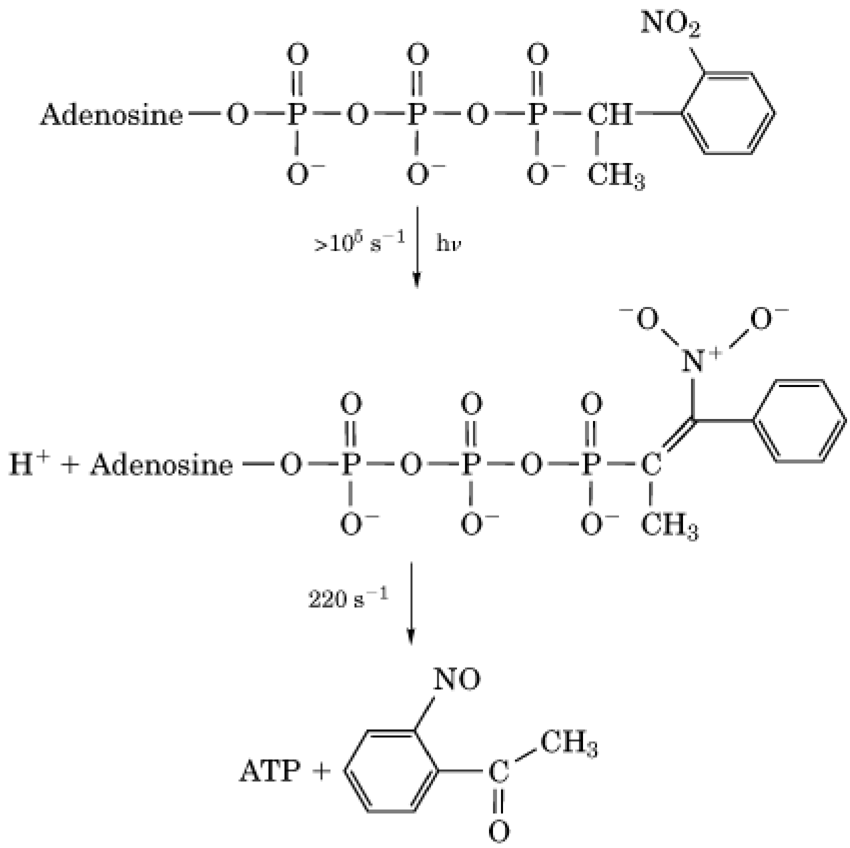
2. Mechanism and Kinetics of Photorelease

Although the earliest studies showed that ATP release could be achieved in a subsecond time frame, ideas about the kinetics of the release process and the likely mechanism were initiated by the report of McCray et al. in 1980 (5). From this work it was apparent that the rate of release of ATP from caged ATP was pH-dependent and in the millisecond time range.

Importantly, it was also pointed out in this work that there was a chromophoric intermediate on the reaction pathway, identified tentatively as an aci-nitro intermediate. The intermediacy of this type of chromophore has proven useful in later mechanistic studies of the photorelease of caged substrates, because it is central to almost all photorelease processes in which the protecting moiety is a 2-nitrobenzyl residue. Another tool that has been useful in mechanistic studies, and profitably used by Trentham and colleagues, is the reaction of the photoreleased nitrosoketone with thiol groups. This reaction had been initially employed by Kaplan et al. (1) to protect biological samples against any damaging effects of the photofragment, because it was known that nitrosoketones react readily with thiols. It was shown that the inhibition of the Na,K-ATPase enzyme due to the actions of the photofragment could be prevented by the simultaneous presence of **dithiothreitol** (DTT) or similar reagents. Furthermore, the protecting thiol had to be present in amounts at least stoichiometric with the released photofragment. In many subsequent applications, it has become routine to include reduced glutathione or DTT in the reaction media to mop up the released photofragment. Trentham and colleagues (6) used the rapid rate of this reaction to examine the release rates of the photofragment. This proved valuable because with caged ATP, as with many photoreleased biological substrates, it is often difficult to identify a biological process that is sufficiently fast to be used unambiguously as a bioassay to determine the photorelease rate of substrate. It should be emphasized, however, that for all new caged substrates it is essential to measure the release rate of the photoproduct of interest and not merely the rate of decay of an intermediate on the release pathway. There have been several reports of biphasic decay of putative aci-nitro intermediates when their breakdown was followed using transient ultraviolet spectroscopy (7, 8).

The most recent estimates (obtained from time-resolved infrared spectroscopy) of the formation of free ATP following the photolysis of caged ATP are about 220 s^{-1} at pH 7 and 22°C, a rate that is the same as the aci-nitro anion intermediate decay rate (9). An outline of the steps involved in the photolysis pathway are shown in Figure 3.

Figure 3. Scheme of breakdown of caged-ATP following excitation. The release rate of ATP is controlled by dark reactions that follow photoexcitation and relaxation to ground states. A detailed study of the products and intermediates has been made using time-resolved infrared spectroscopy and isotopomers of caged ATP (6).



3. Other Caged ATP Structures

The most familiar caged ATP is P^3-(1-(2-nitrophenyl)ethyl) adenosine 5′-triphosphate. Variations on the basic theme have been made in the hope of increasing the long wavelength absorbance of the molecule or of speeding the rate of release. Unfortunately, no molecule yet reported has achieved this aim while simultaneously maintaining the relatively high quantum yield. Most attempts have involved variations in the chromophore, while maintaining the same nitrobenzyl photochemical cleavage mechanism (10). Recently potentially useful alternative photochemistries have begun to be exploited, but as yet no generally useful molecule has emerged (11-13).

4. Biological Applications of Caged ATP

The two areas where caged ATP has been used most extensively are in studying the mechanism of **active transport** by **ion pumps** and in the mechanism of muscle contraction and its regulation. In single turnover studies of the Na,K-ATPase (see text below), Forbush showed that caged ATP did in fact bind with low affinity to the enzyme prior to photolysis (14). This leads to extra complications in kinetic modeling of events following photolysis. Subsequently, similar effects have been noted in muscle fibers (15). Such observations suggest that a caged ATP with a bulkier chromophore might reduce the pre-photolysis binding.

5. Studies on Ion Pumps

The ion pumps are P-type ATPases that couple the transport of ions against their electrochemical potential gradient to the hydrolysis of ATP. This family of membrane proteins includes the Na pump or Na,K-ATPase, the Ca pump [from intracellular membranes (SERCA) or plasma membranes (PMCA)], **proton pumps** from a variety of organisms such as yeast, bacteria, and so on, and a range of heavy metal pumps that transport Cu, Cd, Ni, and so on, across cellular membranes throughout the animal and plant kingdom (16). The studies on ion pumps that have used caged ATP illustrate well several of the different advantages of this experimental strategy. These proteins carry out a series of biochemical transformations that are thought to accompany the transport of cations across the membrane. These transformations arise from the intermediate involvement of a phosphoenzyme, which is formed by transferring the terminal phosphate of ATP to the protein at an early step in the cycle, and from the protein to water in a later step. These kinase and **phosphatase** activities are linked to ion binding, translocation, and ion release steps (17). In order to probe the cation activation of some of these processes, it was necessary in the case of the Na pump to be able to initiate the pump cycle in a sealed system. This was required because the activating and inhibitory cations have very asymmetric effects, depending on whether they act at the extracellular or intracellular surface. The strategy employed was to trap caged ATP within resealed human erythrocyte ghosts. The extracellular medium could then be altered at will, and the Na pump process could be initiated by illumination of the ghost suspension and release of intracellular ATP from caged ATP. This enabled characterization of the side effects of activating and inhibiting cations on the transphosphorylation reactions under genuine initial rate conditions (18, 19). The essential properties of the photorelease strategy here were the stability of caged ATP during experimental procedures, until ultraviolet irradiation, when ATP could be released in good yield synchronously inside the cells in suspension. The possibility of releasing ATP from caged ATP in a rapid synchronous fashion within an ordered structure was also exploited in structural studies of the Ca pump in oriented multilayers where diffraction before and after the release of ATP from caged ATP showed movements of the protein mass relative to the membrane structure during the reaction cycle (20). Such studies would not have been possible without the photorelease approach.

Ion pumps transfer charge during their reaction cycle across cell membranes; and electrophysiological measurements of such movements, along with their analysis, have been a central area of study. In recent years, Bamberg and co-workers (21) and Apell and co-workers (22) have initiated the use of caged ATP in a novel experimental system to analyze the mechanistic consequences of these phenomena in a variety of ion pumps. These workers have used black lipid membranes and have either attached or fused to them biomembrane fragments or vesicles containing ion pumps. Following the rapid, synchronous release of ATP from caged ATP in the medium bathing the membranes, the current-carrying and charge translocating steps can be analyzed with a conventional electrophysiological measuring system (23, 24). Such studies have probed the basis of the electrogenic nature of the Na pump and of the electrically neutral basis of the gastric proton pump, for example (25). Recent studies have dissected out the electrical properties of the bacterial active K transporter, the Kdp-ATPase of *Escherichia coli* (26).

5.1. Regulation and Control of Muscle Contraction

An adequate understanding of the mechanism of muscle contraction can only be achieved from experiments in a fairly intact and complex tissue. This is because the structure of the muscle fiber and its organization is an inherent feature of its function. The sliding filament model for the molecular basis of muscle contraction is the prevailing paradigm in this field, and its central feature is this relationship (27, 28). Thus it is necessary to be able to perform high-resolution kinetic studies in an ordered array of macromolecules. Recent efforts have been aimed at understanding the precise steps in the ATP hydrolysis cycle carried out by myosin that lead to the generation of force during contraction. Caged ATP has found application in detailed studies on the kinetics of ATP hydrolysis, structural changes in the fiber organization associated with contraction and relaxation (at the macroscopic and molecular levels), spectroscopic measurements on muscle fibers, and the process of relaxation associated with Ca pumping by the sarcoplasmic reticulum. Studies in all these areas have received considerable impetus by the introduction of the photorelease strategies. It has been shown that it is possible to photorelease ATP (or other substrates) in chemically skinned muscle fibers in the millisecond time range and to cause the synchronized initiation of biochemical processes that produce contraction (or relaxation) in the bundle of fibers (29, 30). Prior to this technology, such experiments were limited by the diffusional delays that were inherent in mechanically adding substrate and allowing it to diffuse into the fiber to its site of action. Initial studies that employed this approach to analyze the kinetics of the mechanical processes have now been greatly extended; by using covalently attached chromophoric reporters or paramagnetic reporters, the kinetics of conformational changes in the myosin protein can be monitored (31, 32). As well as such structural studies, it has also been possible to carry out time-resolved diffraction studies of fibers in a synchnotron beam prior to and following the release of caged ATP within the fiber (33, 34). These applications use the highly ordered skeletal muscle system to understand the basis of muscle contraction and relaxation. In smooth muscle, the contractile system has evolved to a highly complex level of cellular regulation, and many signal transducing systems and effectors play a role in regulating smooth muscle activity (35). In this area, the photorelease of caged ATP (and a variety of second messengers) continues to be a highly fruitful strategy. Recent studies by the Somlyos and their group provide a wide range of applications of this technology to the smooth muscle system (36, 37).

5.2. Other Systems

Since 1980 to the present time (early 1999) there have been more than 200 articles published using caged ATP, and many more using related substrates. These have extended from difference Fourier structural determinations of proteins with or without bound substrates (38, 39), to the cellular effects of occupancy of receptors (40). Structural biology of macromolecules, especially proteins, continues to provide enormous insights into molecular biological processes, and it is in this area that several interesting applications have great potential. The possibility of obtaining not merely a static picture of a protein at atomic resolution, but also one that contains dynamic information, is enticing. The accessibility of high-intensity radiation sources and a revival of interest in the Laue Diffraction method have made fast X-ray crystallography studies an attainable goal. The idea that such measurements could be made with protein crystals before and after laser-induced release of caged substrates within a crystal has received recent attention; and although many of the technical difficulties (uniformity of release, fate of photofragment, local heating effects) have not been overcome, this approach offers great promise for the future (41, 42). The number of physiological systems that have begun to be probed using caged ATP continues to increase; recent additions to this group include L-type Ca channel modulation (43), single kinesin molecules in optical traps (44), ATP-sensitive K channels in cholinergic interneurons (45), sea-urchin sperm **flagella** motility (46), and limulus photoreceptors (47).

6. Summary

The introduction of the photorelease strategy that followed the description of caged ATP has now been extended to a wide array of biological substrates, including nucleoside phosphates, cyclic AMP, cyclic GMP, protons, Ca^{2+}, Mg^{2+}, peptides, inositol phosphates, sugars, amino acids, neurotransmitters, toxins, and so on. In almost all cases, the photochemical process has the same basis as the original caged ATP strategy; along with a wide array of biological substrates, the approach can now be employed to probe systems that range in complexity from single protein crystals to brain slices.

Calcium Signaling

Calcium ion is an important second messenger involved in cell signaling and signal transduction. Most calcium in cells is sequestered in intracellular vesicles, the endoplasmic reticulum (ER) or mitochondria, where it is stored for release when needed. Small, localized increases in calcium result from its regulated release from the ER, which is produced by inositol trisphosphate, IP_3. IP_3 is produced by the **hormone**-dependent hydrolysis of phosphoinositides, to produce **inositol phosphates**, including IP_3. The IP_3 binds to a specific ER protein, a specialized **calcium channel** with four identical subunits, each with a single membrane-spanning segment and a single IP_3-binding site (1). The binding of IP_3 to this receptor results in a stereospecific release of calcium from the ER.

IP_3-sensitive calcium channels are expressed ubiquitously in tissues. However, the process of regulated calcium release is most tightly regulated in endocrine and neuronal cells, and it is often involved in coupling stimulus to secretion, which is usually a calcium-dependent process. Calcium release from the ER is oscillatory in nature. Increases in intracellular calcium are modulated not by increases in the amount of the ion released, but instead by the frequency of the oscillations. This may explain why the release of some hormones is pulsatile.

One of the critical targets in calcium signaling is CAM kinase, a multigene family of protein kinases that are sensitive to regulation by calcium/calmodulin. There are at least four members of this protein kinase family, with differences in distribution and substrate specificity. CAM kinases appear to be especially critical to modulation of signaling in the central nervous system (2).

Calcium-Binding Proteins

Calcium-binding proteins (CaBPs) are a key component linking the inorganic and organic systems that produce biological activities. Calcium is one of the most abundant inorganic elements in nature and is ubiquitous throughout biology, playing roles at the organismal, cellular, and molecular levels. Calcium is an essential component of shells and bones, where it is essentially deposited in crystals to create macroscopic support structures. At the cellular level, Ca^{2+} is one of the crucial currencies of most living organisms, acting as a second messenger in a wide range of key intracellular and extracellular systems. Calcium-binding proteins play important roles in mediating each of these effects. These proteins can be grouped into four primary categories: (*1*) intracellular proteins involved in Ca^{2+}-mediated signal transduction, (*2*) enzymes, (*3*) extracellular cell surface and extracellular matrix proteins, and (*4*) proteins containing g-carboxyglutamic acid (Gla) residues. Although a variety of structural motifs bind Ca^{2+} , all involve oxygen atoms of the protein backbone or side chains, reflecting the intrinsic affinity of Ca^{2+} for oxygen atoms.

1. Intracellular Calcium-Signaling Proteins

1.1. EF-Hand Calcium-Binding Proteins

This family is the most extensively studied class of CaBPs. These proteins are characterized by a highly conserved helix–loop–helix motif termed the EF-Hand Motif, which consists of a 12-residue Ca^{2+}-binding loop flanked by two alpha-helices. Almost all EF-hand CaBPs are composed of pairs of EF-hands. This pairing of Ca^{2+}-binding sites is presumed to stabilize the protein conformation, increase the Ca^{2+} affinity of each site over that of isolated sites, and provide a means for cooperativity in Ca^{2+} binding. The cooperativity between sites allows for an “all or nothing” response to Ca^{2+}-binding, which is crucial for the function of these CaBPs as intracellular Ca^{2+} sensors.

Calmodulin and troponin C are the best known members of this family of CaBPs. They each have two largely independent domains connected by a flexible linker. Each domain contains two EF-hands, so these proteins each bind four Ca^{2+} ions. In the resting cell, they exist in an inactive state, with either Mg^{2+} or no ion bound. When the intracellular Ca^{2+} concentration rises in response to a signal, the proteins bind Ca^{2+}. This induces a dramatic conformational change, exposing a large **hydrophobic** surface within each domain that can interact with target proteins. There are many other CaBPs thought to function in a similar manner including caltractin and the calmodulin-like domain of plant Ca^{2+}-dependent protein kinase.

Less is known about the S100 proteins, another large and important subfamily of EF-hand CaBPs. The proteins in this subfamily are composed of two EF-hands each, the first of which is a variant version with a 14-residue binding loop, termed a pseudo-EF-hand. The ligands in the pseudo EF-hand are mainly carbonyl oxygens of the peptide backbone, whereas the canonical 12-residue loop coordinates Ca^{2+} primarily with oxygen atoms of side chains. Many S100 proteins are found as hetero- or homodimers, and they exhibit tissue-specific expression patterns. While these proteins are thought to be involved in signal transduction, the molecular mechanism of this function is not known, nor have any target proteins been positively identified. However, the expression of S100 proteins is deregulated in some diseases, including cancer, rheumatoid arthritis, and Down's syndrome, and antibodies against these proteins are commonly used as markers for screening for these diseases.

Most EF-hand CaBPs are directly involved in intracellular calcium signal transduction. However, at least three fulfill other cellular requirements. Parvalbumin and calbindin D_{9k} (an S100 protein) are thought to play roles in Ca^{2+} buffering and in Ca^{2+} uptake and transport, respectively. These and other members of the EF-hand protein family are active in various aspects of intracellular Ca^{2+} homeostasis. The diversity of the roles of EF-hand CaBPs is further illustrated by the recent structure of BM-40, a glycoprotein found in the extracellular matrix (1), which was shown to contain two EF-hands. Prior to this discovery, the EF-hand motif was thought to be unique to intracellular CaBPs. This diversity in function of the EF-hand CaBPs provides evidence of very extensive evolutionary optimization of the fit between the EF-hand CaBP fold and the calcium ion.

1.2. Annexins

The annexin family is a second important class of intracellular CaBPs. The exact function of the proteins in this family is unknown, but they do exhibit an intriguing Ca^{2+}-dependent high-affinity binding to phospholipids (see Membranes). Annexins bind a large number of Ca^{2+} ions with high cooperativity. They assist transport of Ca^{2+} ions across membranes *in vitro*, although the physiological relevance has not yet been established. The mechanism of membrane binding is not known. The current model involves the Ca^{2+} ions acting as “glue” by simultaneously interacting with the protein and the membrane (2).

2. Ca^{2+}-Binding Enzymes

Two well-known enzymes exhibit Ca^{2+}-dependent translocation to the membrane fraction, presumably through a mechanism similar to that used by the annexins. Some **isoforms** of protein kinase C bind to phospholipids with high affinity in the presence of Ca^{2+} (2). The intracellular group IV phospholipase A_2 also requires Ca^{2+} for membrane association (3).

Many other enzymes require Ca^{2+} ions for stability. This includes many **serine proteases**: members of both the **trypsin** and the subtilisin families have been found to bind Ca^{2+}. These proteases each bind one to three Ca^{2+} ions, which are required for structural stability but do not directly participate in catalysis. In most cases, the Ca^{2+} ions are coordinated by ligands dispersed throughout the structure. Trypsin is an exception, however, and binds Ca^{2+} using a single 12-residue surface loop. The use of Ca^{2+} ions to stabilize the protein fold is not unique to the serine proteases. Another example of an enzyme that uses Ca^{2+} in this manner is thermolysin, a Zn^{2+}-dependent protease.

In other enzymes, the Ca^{2+} ions are directly involved in catalysis. This includes the secreted forms of phospholipase A_2, in which the required Ca^{2+} ion is thought to be involved in transition state stabilization (4). **Staphylococcal nuclease**, a secreted protein that catalyzes DNA and RNA hydrolysis, also relies on Ca^{2+} for catalysis. The structure of this protein shows Ca^{2+} bound in the active site, where it is thought to be used to polarize the phosphate at the scissile phosphoester bond (5, 6).

3. Extracellular Cell Surface and Extracellular Matrix Ca^{2+}-binding Proteins

3.1. Cadherins

These are tissue-specific cell adhesion molecules that are strongly Ca^{2+}-dependent (see Cadherins). At the levels of Ca^{2+} found in the extracellular milieu, cadherins bind several Ca^{2+} ions. A major conformational change is seen when Ca^{2+} is removed from these proteins. The resulting change to the apo state conformation is thought to prevent cadherins from interacting with each other.

3.2. C-Type Lectins

The C-type lectins are a Ca^{2+}-dependent class of lectins, which mediate many cell surface carbohydrate recognition events. Selectins, concanavalin A, and mammalian mannose-binding protein are examples of this type of CaBP. The structure of mannose-binding protein shows that Ca^{2+} is directly involved in binding the carbohydrate to this protein. In concanavalin A, on the other hand, the Ca^{2+}-binding site is $1.0–1.4 \times 10^{-9}$ m from the carbohydrate binding site; Ca^{2+} does not participate directly in binding the carbohydrate, but instead stabilizes the protein structure. It is not known whether selectins use Ca^{2+} directly in carbohydrate binding or to stabilize the fold required for carbohydrate recognition.

3.3. EGF Modules

A subset of EGF motifs present as **domains** in a number of proteins contain b-hydroxy–aspartic acid residues and have Ca^{2+}-binding activity. This type of EGF motif is found in some proteins involved in the blood clotting cascade and also in the extracellular matrix protein fibrillin. Fibrillin has 54 EGF modules, 43 of which are thought to bind Ca^{2+}. It is thought that Ca^{2+} is important in maintaining the structure of the fibrillin monomers and also in allowing the monomers to aggregate into microfibrils. A sheath of these microfibrils covers and stabilizes the elastin fibers that give tissues such as skin, blood vessels, and lungs their needed elasticity.

4. Gla-Containing Proteins

The Gla-containing proteins contain g-carboxyglutamic acid residues. This is a glutamic acid residue that has been carboxylated in a vitamin K–dependent process. These proteins are found in the bones and teeth, in the kidney, and in the blood. Osteocalcin (bone Gla-protein) and matrix Gla-protein are found in bone. They are believed to be involved in the mineralization of this tissue (7). Similar proteins are thought to be involved in the mineralization of teeth. In the kidney, the Gla-containing protein nephrocalcin inhibits the nucleation, aggregation, and growth of calcium oxalate crystals. An abnormal form of this protein is found in the urine of people suffering from kidney stones. However, it is not entirely clear whether this defect is responsible for the growth of kidney stones (8).

By far the best studied of the Gla-containing proteins are those found in blood. The majority of Gla-containing proteins are zymogen forms of serine proteases involved in the blood clotting (coagulation) cascade. These proteins are: pro**thrombin**, factor VII, factor IX, factor X, protein C, protein S, and protein Z. The protease domains of these proteins are very similar to the pancreatic digestive proteases **trypsin**, **chymotrypsin**, and elastase. The Gla-containing coagulants require Ca^{2+} binding in order to bind to phospholipids. This Ca^{2+}-dependent phospholipid binding is responsible for the membrane association properties required for the function of the proteins. Ca^{2+} binding also appears to be necessary for the formation of the native conformation of the Gla domain (9).

The Gla-containing coagulants have two classes of metal ion binding sites. There are approximately three higher affinity sites that are not metal ion–specific, and three to four lower affinity sites, which are specific for Ca^{2+}. Only Sr^{2+} can substitute for Ca^{2+} in both types of binding site.

The high resolution three-dimensional structure of the Gla domain of prothrombin, with seven Ca^{2+} ions bound (10), reveals the Gla domain to involve nine to 10 turns of alpha-helix, in three separate helices. Seven Ca^{2+} ions interact with 24 oxygen atoms from 16 of the 18 carboxylate groups of the nine Gla residues that are ordered in the structure. A 10th Gla residue is disordered and does not participate in Ca^{2+} binding. The coordination geometries of the Ca^{2+} ions do not correspond to any idealized polyhedra. Five of the Ca^{2+} ions are involved in a polymeric array with 18 of the liganding oxygen atoms. Four of these Ca^{2+} ions are completely buried in the protein. This complex structure is thought to nucleate the folding of the Gla domain, and is essentially electrically neutral. The complexity and irregularity of this structure explains the selectivity for Ca^{2+} ions. Ca^{2+} is able to adopt different and distorted coordination geometries. Mg^{2+}, on the other hand, is fairly rigid in its requirement for six ligands, and cannot accommodate the unusual network of ligands in the Gla domain. The remaining two metal ion sites in the Gla domain of prothrombin are solvent accessible, and carry a net charge of about +0.5 each. Because of the positive charge, these sites are thought to be involved in neutralizing the negatively-charged phospholipids, allowing the protein to associate with membranes.

Calmodulin

Calmodulin is the quintessential member of the **EF-hand** family of calcium-binding proteins and functions as a key mediator in numerous signal transduction pathways. It is an acidic protein (isoelectric point of 4.2) of molecular weight 16.8 kDa that is found in most eukaryotic cells, from yeast to humans. It is composed of two largely independent globular **domains** connected by a flexible central a-helix. The affinity of calmodulin for Ca^{2+} is fine-tuned to respond to intracellular calcium signals. Conformational changes within each of the domains induced by the binding of Ca^{2+} leads to the transduction of the Ca^{2+} signal.

1. Biological Function

Calmodulin is a signal transduction protein. It has been implicated in the control of a wide range of cellular functions, including cell proliferation, smooth muscle contraction, the regulation of **ion channels**, long-term potentiation and memory, and exocytosis. Furthermore, it has recently been found inside the nucleus, where it is thought to be involved in the regulation of DNA replication, **gene expression**, and DNA repair. In a resting cell with basal levels of Ca^{2+} , calmodulin exists in the inactive apo state. When a calcium signal is initiated and the intracellular levels of Ca^{2+} increase, calmodulin binds Ca^{2+} ions. This causes the protein to undergo a dramatic conformational change that exposes a large **hydrophobic** patch on the protein. This newly exposed hydrophobic surface then interacts with various cellular proteins, modulating their activity and thereby transducing the calcium signal.

Protein kinases and **phosphatases** are among the best studied of calmodulin's targets. These enzymes are activated by the release of an autoinhibitory **domain** that is bound to the active site in the resting state. Ca^{2+}-loaded calmodulin activates these proteins by binding to a site near to or overlapping with the autoinhibitory domain, causing the auto-inhibitory domain to dissociate from the active site. Myosin light chain kinase and calcium-calmodulin-dependent protein kinase II are two well-known examples of this class of calmodulin-regulated proteins. Calmodulin also regulates proteins involved in the generation of other second messengers, such as calmodulin-dependent cyclic nucleotide phosphodiesterase and nitric oxide synthase. The mechanism of regulation of these enzymes is thought to be very similar to that used to regulate the kinases and phosphatases. Calmodulin has also been shown to interact with proteins of the cytoskeleton and their regulatory proteins, such as spectrin and brush border myosin. However, the biological significance of these interactions is still unclear.

Recently, interactions between apocalmodulin and targets such as neuromodulin and unconventional myosins have been described. These interactions are thought to be mediated by an “IQ motif” (with the consensus sequence IQXXXRGXXXR, where X is any amino acid) in the target (see Protein Motif). This motif and its interaction with a Ca^{2+}-free EF-hand calcium-binding protein was first described in myosin (1, 2). The functional significance of the interaction of proteins containing the IQ motif with apocalmodulin is not clear. It has been suggested, however, that perhaps neuromodulin, which is associated with the plasma membrane, functions as a trap for calmodulin, sequestering it near the membrane in the absence of the activating calcium signal (3).

2. Ion-Binding Properties

Calmodulin binds four calcium ions, with a **dissociation constant** of about 10^{-6} *M*. Binding is selective for Ca^{2+}; calmodulin does not bind Mg^{2+} or monovalent ions with appreciable affinity. The binding of Ca^{2+} is also highly **cooperative**, which is very important for calmodulin's biological function as a calcium sensor, because it allows for a tightly controlled "all or nothing" response to the calcium signal: the four binding events all occur within a very narrow range of Ca^{2+} concentration. If these binding events were spread over a large range of Ca^{2+} concentrations, calmodulin would be at least partially activated over the entire range. The system would therefore lack the required sharp separation between the activate and inactive states.

3. Structure

Calmodulin is a largely helical protein composed of four EF-hand motifs organized into two independent globular domains, each of which contain two EF-hands. The two domains are connected by a long, flexible central a-helix, giving the protein a dumbbell-like appearance (Figure 1a). This quaternary structure is relatively similar in the apo- and Ca^{2+}-loaded states of the protein. However, significant conformational changes occur within the individual domains on Ca^{2+} binding (Fig. 1b). In the apo state, each domain occupies the "closed" conformation (4-6). In this conformation, the four helices in the domain are nearly antiparallel, with interhelical angles near 180°. In Ca^{2+}-loaded calmodulin, each domain occupies an "open" conformation in which the four a-helices are nearly perpendicular to each other (7, 8). Each domain exposes a hydrophobic surface of about 1.25×10^{-8} m^2 in this open conformation (5).

Figure 1. Ribbon representations of the three-dimensional conformations of $(Ca^{2+})_4$-calmodulin in the (**a**) absence and (**b**) presence of a target peptide. The peptide-free diagram was constructed using the coordinates of 1CLL (8). The two domains at the ends of the central a-helix consist of two EF-hand motifs. The diagram of $(Ca^{2+})_4$-calmodulin and the peptide analog of the myosin light chain kinase was constructed using the coordinates of 2BBM (10). The bound peptide is depicted darker than calmodulin.

(b)

4. Interactions with Target Peptides

The biophysical characterization of the interaction between calmodulin and its targets is often studied using small peptides (10–20 amino acid residues) derived from the calmodulin-binding domain of target enzymes. Calmodulin binds to these target peptides extremely tightly, with dissociation constants ranging from 10^{-7} to 10^{-11} M. The peptides adopt an amphiphilic helical conformation, and tend to have a bulky hydrophobic residue at either end, often (but not always) spaced 12 residues apart. However, the sequences of the target peptides are not highly similar. Calmodulin is able to bind so tightly to such a wide array of targets because of its own plasticity. The flexible central a-helix connecting its two domains can function as an "expansion joint," allowing calmodulin to bind to peptides with different numbers of residues between the two bulky hydrophobic anchors. Furthermore, **van der Waals** interactions, which can be rather nonspecific, tend to dominate as the critical components stabilizing the interaction between calmodulin and the peptides. Hydrogen bonds, which are more structurally specific, are not as important in these interactions. The adaptability of the peptide binding surface of calmodulin may be further aided by its high proportion of methionine residues. Methionine is an unusually flexible and polarizable amino acid, which may allow calmodulin to mold its peptide-binding surface to meet the requirements of many different peptide sequences (9, 10).

High resolution three-dimensional structures of three complexes of calmodulin and peptides derived from target enzymes have been reported (11-13). These structures show that the relative disposition of the two domains of calmodulin is altered by the binding of a target peptide, but there is little change within the Ca^{2+}-activated domains themselves. The calmodulin–peptide complex forms a well-packed ellipsoid, which contrasts sharply with the dumbbell shape of calmodulin observed in the absence of target (Fig. 1). The two domains of calmodulin essentially wrap around the target peptide, forming a hydrophobic tunnel in which the peptide binds. As of yet, there are no structures of calmodulin bound to an entire target protein. It is thought, however, that the mode of binding to the target sequence on the intact enzyme will be very similar to that seen in the calmodulin–peptide complexes.

Calnexin/Calreticulin

Calnexin (also known as *p88*, *IP90*, and *CATCHER*) is a membrane-bound **molecular chaperone** present in the endoplasmic reticulum (ER) that binds selectively to many monoglucosylated **glycoproteins** that fold in this compartment during synthesis by ribosomes bound to the cytosolic face of the ER membrane. Calreticulin is a soluble homologue of calnexin, with the same glycan specificity, but occurs in the ER lumen. Together with other proteins, calnexin and calreticulin provide a means for improving the efficiency of protein folding and assembly in the ER compartment and form part of the quality-control system that ensures that only correctly folded and assembled proteins are transported from the ER compartment along the pathway followed by secretory proteins (1). Unlike some other molecular chaperones, calnexin and calreticulin are not **stress response** proteins, do not exhibit ATPase activity, and appear to recognize glucose residues in core glycans rather than **hydrophobic** surfaces in partially folded polypeptides (1). In some cell types, calreticulin also occurs in the nucleus and cytosol, where it binds to steroid hormone receptors and integrin molecules, respectively; these interactions may indicate roles for calreticulin in **gene expression** and cell signaling.

1. Discovery

An 88-kDa protein termed *p88* was found in transient association with class I **major histocompatibility** molecules synthesized by several murine lymphoma cell lines (2). Newly synthesized-class I heavy chains bound rapidly to p88 before they associated with b_2-microglobulin chains. In mutant cells that lack microglobulin, the incompletely assembled class I molecules exhibited prolonged interaction with p88 and were correspondingly impaired in their transport to the **Golgi** stacks (3). Moreover, microglobulin and peptides derived from the cytosol need to be assembled with the heavy chain before the latter can be released from p88. These findings led to the proposal that p88 is a molecular chaperone that promotes assembly of class I molecules by retaining intermediates in the ER until complete complexes are formed.

Independent **pulse-chase** experiments on a human ER protein termed *IP90* showed that it transiently associates with many newly synthesized proteins, including the T-cell receptor (TCR), the B-cell antigen receptor, and class I molecules (4, 5). The binding of IP90 to TCR complexes lacking a chains was prolonged, consistent with a retention role for this protein in the ER for incompletely assembled complexes (6). Subsequently, p88 and IP90 were found to be identical with the Ca^{2+}-binding phosphoprotein calnexin (4-7), a protein originally identified as one of several proteins labeled by **phosphorylation** of canine pancreatic **microsomes** with [g-^{32}P]-GTP (8).

2. Structure

Calnexin is a type I nonglycosylated integral membrane protein of 573 amino acid residues, with a predicted molecular weight of 65,400 and with its substrate-binding domain in the lumen of the ER. It has a cytosolic tail of 89 residues that is phosphorylated and contains a *C*-terminal RKPRRE (━Arg━Lys━Pro━Arg━Arg━Glu) sequence that acts as an ER-retention signal (9). It also possesses four **domains** with high sequence similarity to calreticulin, the major calcium-binding protein of the ER lumen. Calreticulin contains 400 amino acid residues (46,000 molecular weight), which include both a KDEL ER-retrieval sequence and a strongly negatively charged region involved in Ca^{2+} binding at its *C* terminus (10). Both calnexin and calreticulin appear to function as monomers.

3. Function

Calnexin and calreticulin are both lectins that specifically recognize glycoproteins that contain monoglucosylated core glycans; they do not recognize glycans containing two, three or no glucose residues (11, 12). When nascent chains of glycoproteins enter the ER lumen, a core glycan containing three terminal glucose residues is added en bloc to specific asparagine sidechains (see N-Glycosylation). This addition of glycan may have evolved initially to make folding intermediates more soluble under the conditions of high protein concentration that characterize the ER lumen. These glucose residues are then rapidly removed one at a time by glucosidases I and II in the ER lumen. Another lumenal enzyme called UDP-Glc:glycoprotein glucosyltransferase then adds back one glucose residue. Thus glycans containing single terminal glucose residues can arise either as intermediates in the glucose-trimming process or after regeneration by the transferase. Such monoglucosylated glycans then bind to calnexin and calreticulin. In the case of pancreatic ribonuclease B, this binding occurs solely through the glycan and does not involve additional recognition of the protein moiety by the lectins (13, 14), but such additional recognition may occur in the case of other proteins (11, 15).

The function of the binding of calnexin and calreticulin to monoglucosylated glycoproteins appears to be to assist their correct folding by preventing aggregation of partially folded or misfolded chains and ensuring retention of the latter until they are degraded (see DNA Degradation In Vivo). Evidence for this conclusion comes from experiments in which proteins unable to fold correctly because of mutation remain bound to these chaperones for much longer than normal proteins and are eventually degraded (16-18). Additional possible roles include the suppression of formation of nonnative disulfide bonds (19) and the premature assembly of oligomers (18).

The distinction between correctly folded and partially folded chains is not made by these lectins but by the glucosyltransferase. This enzyme has the unusual property of distinguishing, by an unknown mechanism, between subtly different protein conformations; it adds glucose to the core glycan only if the protein attached to this glycan is not correctly folded (20, 21). Such reglucosylated glycoproteins will then bind back to calnexin and calreticulin. The removal and addition of the terminal glucose residue then continues until the protein has folded sufficiently to be no longer recognized by the transferase. The binding of calnexin to ribonuclease B *in vitro* is dynamic, indicating that the binding is readily reversible; glucosidase II cannot remove terminal glucose residues while calnexin is bound to the glycoprotein (14).

Calnexin and calreticulin associate with a wide range of proteins in the ER, including soluble secretory proteins, extracellular matrix molecules, **ion channels**, membrane **receptors**, and various glycoproteins of **viruses**. They also retain misfolded proteins that accumulate in some ER-storage diseases such as cystic fibrosis and a1-antitrypsin deficiency (22). Addition of glucosidase inhibitors to cells results in reduced rates of secretion of many glycoproteins, presumably due to the inhibition of their binding to the chaperones (23). All these observations support the view that the functions of calnexin and calreticulin are important for cell function. Nevertheless, viable mammalian cell lines are known that lack either glucosidase I or II or calnexin, while mutants of *Saccharomyces cerevisiae* that lack genes for any one of these three proteins show no growth defect. However, mutants of *Saccharomyces pombe* that lack calnexin are not viable. Both species of *Saccharomyces* appear to lack calreticulin. These discrepancies may indicate some redundancy and overlap of function amongst the chaperones in the ER compartment, which include BiP, hsp90, and protein disulfide isomerase, as well as calnexin and calreticulin (1).

5′ Cap

The 5′cap is characteristic of all **RNAs** transcribed by RNA polymerase II, and it is added to the nascent transcript soon after transcriptional initiation. Many lines of evidence suggest that the cap contributes to many aspects of RNA metabolism, including RNA stability (1), pre-mRNA **splicing** (2, 3), polyadenylation (4), U **small nuclear RNA** (snRNA) export (5), and translation of messenger RNA (6). The influence of the cap on RNA metabolism, in both the nucleus and the cytoplasm, is mediated by cap-binding proteins.

The cap consists of an inverted 7-methyl guanosine nucleotide linked by a 5′-5′-triphosphate linkage to the first template-encoded nucleotide of the RNA, to give the following structure: $m^7G(5')ppp(5')N$. The cap modification is one of the earliest covalent modifications detected on a nascent RNA transcript, and it occurs cotranscriptionally (7). The actual capping reaction requires the sequential action of several enzymatic activities and is well understood (see Fig. 1). The capping enzyme possesses an RNA 5′-triphosphatase activity, which converts the 5′ terminal triphosphate of the RNA to a diphosphate. RNA guanylyltransferase then catalyzes the transfer of GMP, derived from GTP, to the diphosphate, resulting in the formation of the G(5′)ppp(5′)N cap. This cap structure is the substrate for methylation by RNA (guanine-7)-methyltransferase, which converts it to the monomethylated cap structure. In the absence of cap methylation, the reaction is reversible. The genes encoding the capping enzyme and methylase are essential in the **yeasts** *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*, underlining the importance an intact cap for viability (8-10). The cause of death in these mutants is probably due to cumulative defects in the various processes in which the cap is involved, such as RNA stability and **splicing** (11).

Figure 1. The capping reaction at the 5′ nucleotide (N) of an RNA transcript: (*1*) the 5′-triphosphate of the nascent transcript is hydrolyzed by RNA 5′-triphosphatase to a diphosphate; (*2*) mRNA guanylyltransferase adds the cap from GMP (which is derived from GTP). The cap is then methylated on the N-7 (position 7 nitrogen) of guanosine by mRNA (guanine-7) methylase.

Cap-Binding Proteins

Most of the functions in the nucleus and cytoplasm of the cap of messenger RNA (mRNA) are mediated by cap-binding proteins (CBP), which show highly specific binding to the cap structure, $m^7G(5')ppp(5')N$. Two major cap-binding activities have been characterized in **eukaryotes**. The first is the nuclear cap-binding complex (CBC), which plays a role in pre-mRNA **splicing** (1-3), polyadenylation (4), and U **small nuclear RNA** (snRNA) export (5). The second, eIF4E (6), is part of a trimeric complex, eIF4F, which is required for cap-dependent translation of mRNA.

CBC was initially identified in nuclear extracts from HeLa cells as an activity that bound specifically to a normal 7-methyl guanosine-5′-capped RNA. Purification of the activity showed that it was a heterodimeric complex comprising two subunits; CBP80 and CBP20 (1). Neither protein alone can bind specifically to the 5′cap—only as a heterodimer. Current evidence has shown that CBC is required for efficient (*1*) pre-mRNA splicing, (*2*) polyadenylation, and (*3*) the export of RNA polymerase II–transcribed U snRNA (see below).

CBC is required for efficient splicing of the cap-proximal **intron**, where its major function is to facilitate the binding of U1 snRNP to the cap-proximal 5′ splice site (3) (see Gene Splicing). Experiments in the yeast *Saccharomyces cerevisiae* and in HeLa splicing extracts have demonstrated that this function of CBC is conserved in evolution (2, 7).

A role for CBC in polyadenylation has also been demonstrated *in vitro* (4): (see Polyadenylation). Depletion of CBC from HeLa cell polyadenylation extracts results in a reduction in the efficiency of polyadenylation. Further analysis of this defect demonstrated that CBC was required for efficient cleavage of the pre-mRNA, but not for the polyadenylation reaction itself.

Nucleocytoplasmic transport of some classes of RNA, specifically the 5′capped uracil-rich (U) snRNAs, is facilitated by CBC. Antibodies raised against one of the subunits, CBP20, can specifically inhibit the interaction of CBC with the cap and, as a consequence, inhibit the export of these U snRNAs from the nucleus to the cytoplasm (5).

The other CBP, eIF4E, is required for cap-dependent translation of mRNA in the cytoplasm, and it can bind directly to the cap as a monomer (6). In order to function in translation, eIF4E has to assemble with two other polypeptide chains in a heterotrimeric complex of eIF4A, eIF4G, and eIF4E, to form a complex known as eIF4F. This trimeric complex binds to the cap of mRNAs and complexes with a second translational initiation complex, eIF3, which has an RNA helicase activity. This helicase activity is thought to unwind **secondary structure** in the mRNA and to allow the cap-dependent association of the 40S **ribosomal** subunit with the mRNA. The 40S subunit then scans for the initiation codon complexes with the 60S ribosomal subunit to initiate translation.

Capillary Zone Electrophoresis

Capillary zone electrophoresis (CZE) is electrophoresis in very thin capillaries. It is an analytical separation method that is compatible with high field strength (200 to 800 V/cm) and small samples (micrograms to nanograms). The high field strength makes the separation rapid and gives high resolving power (1). The very small capillary diameter, less than 0.2 mm, counteracts dispersion of the zone, presumably through interaction of the analyte with the inner wall of the capillary. The sample is detected by its absorbance or fluorescence as it proceeds past a stationary detector at the end of the migration path.

The inner walls of the silicate capillary carry negatively charged groups, so electroendosmosis is significant; this can be used for the purpose of separation, but it is usually suppressed by coating the inner wall with a polymer such as polyacrylamide gel or dextran. Separations based predominantly on size and shape differences are achieved in CZE in the presence of soluble polymers to produce a **molecular sieve** effect. A variety of uncharged hydrophilic polymers in a wide range of molecular weights are available for that purpose (2-4). Although providing high resolving power (see Gel Electrophoresis), gels are less applicable to CZE because the gelation process may introduce air bubbles and inhomogeneities within the capillary; also, a gel-filled capillary can only be used once or a few times, while polymer solutions can be replaced easily. One drawback of CZE is that the analyte bands are enclosed within the tube and therefore are unavailable for detection by immunological, hybridization, and staining techniques. However, the eluate of CZE can be subjected to mass spectrometry to provide molecular weights of the species detected, in addition to their mobilities (5).

Capsids, Viral

The capsids of **viruses**—the protein part of the virus particle (virion) that surrounds and protects the nucleic acid genome—have been the subject of intense study by biochemists and structural biologists for over 50 years (see Virus Structure). Capsids are also noteworthy in that they provide one of the few examples in which the detailed properties of a biological system have been predicted successfully from "first principles." This entry describes the principles on which we understand capsid structure—that is, what we expect capsids to be like and why we expect that, and then describes the ways in which real viruses do or do not follow those expectations.

A **gene** of double-stranded DNA can encode a protein of only about 1/20 the mass of the gene itself. As a consequence, if a virus is to encode its own capsid (and in almost all cases, viruses do so), it will only be able to make enough protein to produce a useful sized capsid if it can use multiple copies of the protein(s) encoded in its genes. Crick and Watson (1), who made the first concrete proposal for how proteins might be arranged in virus capsids, assumed that the capsids would be made of multiple identical virus-encoded protein subunits. They also made another assumption, based on a prominent property of proteins, namely that proteins are very specific in the interactions they make with other molecules, presumably including other proteins in the structure of a virus capsid. They assumed that the identical protein subunits would be packed into the capsid structure in such a way that they all made the identical set of contacts with their neighbors—so-called **equivalent packing**. Mathematically, there are only two general ways to satisfy these assumptions when packing asymmetric objects like proteins; these are to arrange the protein subunits with helical symmetry or to arrange them with one of the cubic symmetries. Helical symmetry is easily visualized: The subunits are arranged in a helical array as if they were on successive steps of a spiral staircase. Formally, each subunit is related to the preceding one by a characteristic rotation and a translation in the direction of the helix axis. "Cubic" symmetry refers to a small group of symmetries characterized by having multiple axes of rotational symmetry. These correlate with the five classical Platonic solids, which have these symmetry axes. Besides the cube, from which the entire group of symmetries takes its name, the Platonic solids include the tetrahedron, the octahedron, the dodecahedron, and the icosahedron. Of these, the icosahedron allows (or more properly, arranging protein subunits according to the five-, three-, and twofold rotational symmetry axes of an icosahedron) allows the largest structure to be made with a given size of subunit for any of the group. More to the point, of this group of symmetries, it is icosahedral symmetry that is used by real viruses.

1. Helical Symmetry

Many viruses can be shown to have helical symmetry. The best studied of these is the well-known tobacco mosaic virus (TMV), which has a virion with only one type of protein subunit, present in something over 2000 copies and arranged in a simple helix with 16.33 subunits per turn. There is in principle no limit on how long a helical structure such as this can be, but in TMV it is limited during assembly by the length of the genomic RNA. In the mature virion, the single-stranded RNA genome follows the helix of the proteins and lies in the groove between successive layers of the helix on the inside of the helical tube, three nucleotides per protein subunit. A domain of each subunit closes over this groove after the RNA has entered it during assembly and effectively seals off the RNA from the solvent (2).

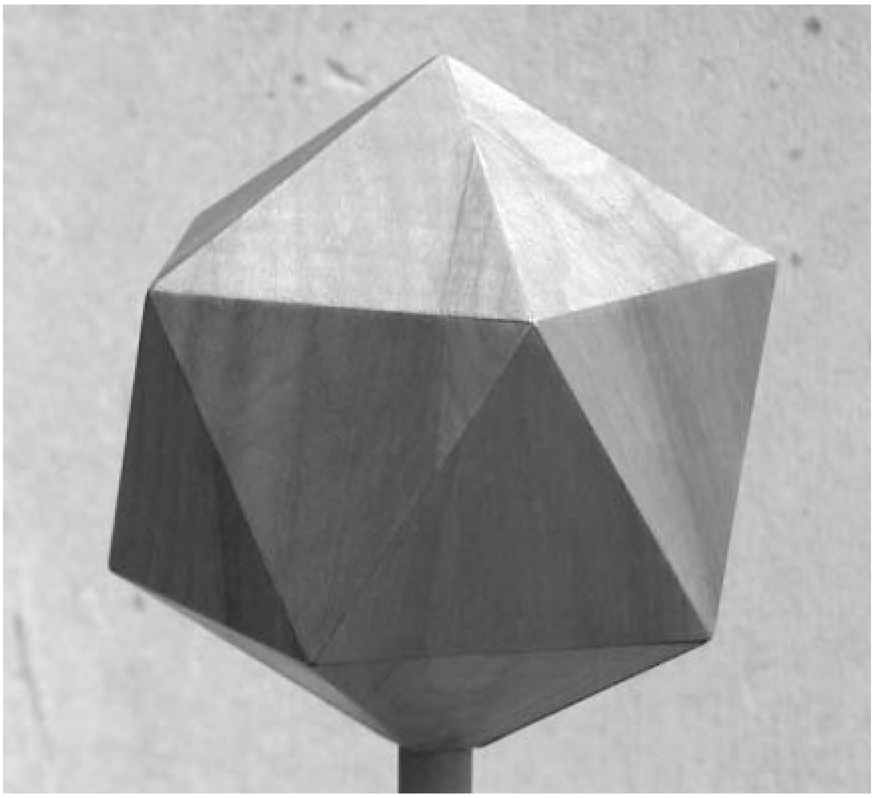
Structurally somewhat more complex examples of helically symmetric viruses are the filamentous bacteriophages, such as phage M13. The major protein subunit of these viruses is arranged in what might best be described as a small number of helices running in parallel up a cylindrical tube. The circular single-stranded DNA genome of these viruses is stretched the length of the helical tube. The filamentous phages have small numbers of copies of additional virus-encoded proteins present on the ends of the virions. These have roles in virion assembly and in **virus infection** (3).

Many enveloped viruses, for example, influenza virus, have their genome—single-stranded RNA in the case of Influenza—wrapped in a helical array with a virus-encoded protein. The resulting flexible nucleoprotein rods are enclosed in the viral envelope, one such structure for each of the eight different genome segments in the case of influenza.

2. Icosahedral Symmetry and Quasi-Equivalent Packing

An icosahedron (Fig. 1) has 20 faces, each an equilateral triangle. Its symmetry is defined by axes of rotational symmetry, each passing through the center of the icosahedron: five-fold axes passing through the corners, three-fold axes passing through the centers of the faces, and twofold axes passing through the centers of the edges. Strictly speaking, an icosahedral virus capsid is not an icosahedron; instead, its protein subunits are related to each other by the symmetry axes of an icosahedron. However, thinking of the protein subunits as lying on the surface of an icosahedron provides a convenient way to visualize and discuss the structure of the capsid, as well as a reasonable approximation to the truth. To make an icosahedrally symmetric capsid, we place three identical protein subunits on each face of the icosahedron, symmetrically arrayed about the center. These subunits will necessarily also find themselves in symmetrical relations with their fellows around all the five-, three-, and twofold axes of the icosahedron, and inspection of a model of such a structure shows that all of the subunits lie in equivalent relationships to their neighbors.

Figure 1. An icosahedron.

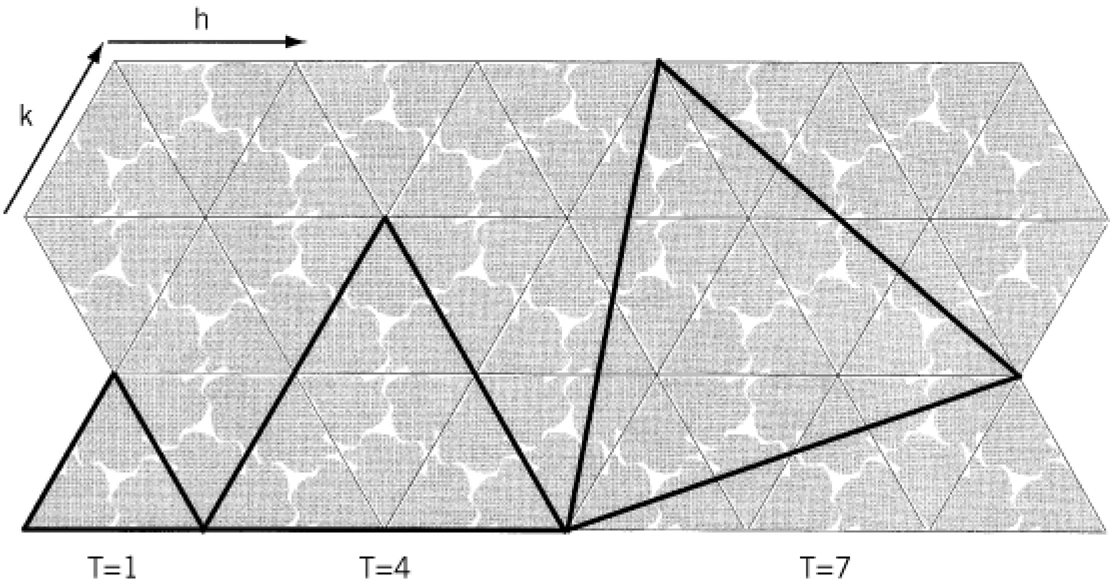


Current knowledge of virus structure allows us to see that some small virus capsids—for example, the Parvoviruses—can be adequately described as such 60-subunit icosahedrally symmetric structures. However, it was already clear by about 1960 that the majority of “spherical” viruses are too large and have too many subunits to be so described. Because there is mathematically no way to make a larger structure while preserving strict equivalence in subunit packing, it was not clear that this way of describing capsid structure would be applicable to most viruses. However, Caspar and Klug (4) proposed a clever extension of Crick and Watson's ideas that has provided a framework for understanding and describing the great majority of spherical virus capsids. Caspar and Klug introduced the idea of “quasi-equivalence” in protein subunit packing. In a nutshell, they suggested that if the requirement for equivalence were relaxed—but not abandoned entirely—it would be possible to make much larger capsids with identical protein subunits, containing multiples of 60 subunits.

A simple way to imagine the process of making a larger capsid is to start with a 60-subunit capsid as described above, group the subunits together into the pentamers that surround each corner (fivefold axis) of the icosahedron, and move those pentamers away from the center to a larger radius. Caspar and Klug's insight was that there are certain ways to fill the resulting spaces between the pentamers with *hexamers* of the same subunit that preserve, at least approximately, the geometrical packing arrangements among all of the subunits in the structure.

A more systematic way to describe this process, shown in Figure 2, is to consider constructing an icosahedron from a piece of paper that has a hexagonal lattice of “protein subunits” printed on it. (Experience has shown, in fact, that the most effective way to understand the concepts described here is to actually take scissors in hand and to construct and examine some capsid models.) The simplest way to make an icosahedron from such a sheet of paper is to cut out 20 of the small triangles in the lattice that each contain three subunits, and join them together into an icosahedron. This icosahedron will have 60 subunits, equivalently packed, and will be identical to the 60-subunit structure described above. It is possible, however, to cut larger triangles out of the paper and use them as the faces of the icosahedron; as long as the corners of these larger triangles fall on the intersection points of the lattice, the resulting icosahedron will be biologically sensible and geometrically acceptable. The figure shows an example of such a larger triangle encompassing four of the small unit triangles. If 20 of these are cut out and assembled into an icosahedron, the structure will have $4 \times 60 = 240$ protein subunits. The subunits in this case are not all equivalently packed—some are in pentamers and some in hexamers, and there are other subtle differences in their geometrical relationships to their neighbors—but the basic relationships between subunits are nonetheless preserved: They are quasi-equivalent. The faces of this icosahedron are said to be “triangulated” into the four unit triangles, and the structure as a whole is said to have a “triangulation number” (T) of 4. The figure also shows a somewhat more complex way of defining the icosahedral face, in which the edges of the icosahedral face are not parallel to the lattice lines. In the example shown, the area of the face is equal to the area of seven small triangles, and the corresponding icosahedron is given the triangulation number 7. More generally, the triangulation number of any icosahedron can be calculated from the formula $T = h^2 + hk + k^2$, where h and k are the number of steps along the lattice in the **h** and **k** directions required to go from one corner of the icosahedral face to another. The “allowed” triangulation numbers derived in this way are a subset of the integers and form an infinite series that starts 1, 3, 4, 7, 9, 12, 13,¼.

Figure 2. A hexagonal lattice of protein subunits with indications of how they can be fit into a strictly equivalent virus capsid ($T = 1$) or into two different kinds of quasi-equivalent capsids ($T = 4$, $T = 7$). The irregular wedge-shaped objects, of which three are packed into each small triangle, represent protein subunits. The bold triangles show the faces of the capsid icosahedron for the three indicated triangulation numbers. The **h** and **k** unit vectors are used to calculate the triangulation number, as described in the text.



3. Icosahedral Virus Capsids in Nature

As the structures of actual virus capsids have been determined in increasing numbers and in increasing detail over the past 30 years, the general predictions of the Caspar and Klug theory have largely been confirmed. At the same time, there are now many examples of "variations on the theme"—features of the structures that are not explicitly predicted by the theory, but are not at odds with its basic concepts. In addition, there are at least two examples of structures that should not have occurred. The definitive test of how the capsid structure is organized is a high-resolution structure by X-ray crystallography; however, it is often possible to get useful information from lower resolution structural measurements. For example, the hexamers and pentamers of the capsid subunit often cluster in such a way that they can be seen by electron microscopy as a distinct morphological unit, called a **capsomere**. Examining the geometrical relationships among the capsomeres on the surface of a capsid can lead to a good idea of the triangulation number of the capsid.

Parvoviruses, as mentioned above, have 60-subunit $T = 1$ structures (5). The same is true for the small f**X174, bacteriophage**, but in this case there are two proteins present in 60 copies each, rather than only one (6). Here we can think of the heterodimer as the basic building block, with 60 copies of that heterodimer arranged with $T = 1$ icosahedral symmetry.

$T = 3$ capsids, the first group that requires that quasi-equivalence be invoked, are especially well-populated, with examples from plant, animal, and bacterial viruses. Tomato bushy stunt virus (TBSV), the first of this group to be solved to atomic resolution, conforms quite well to the expectations of the theory, having 180 chemically identical subunits, each of which occupies one of three similar but nonidentical positions in the $T = 3$ lattice (7). One set of subunits in TBSV, those occupying the "C" position, send an end of their polypeptide chain toward the threefold symmetry axes, where they intertwine with the corresponding parts of the two symmetrically related subunits. This was the first of what are now several examples of capsid proteins interdigitating and intertwining with their neighbors; this is presumed to provide mechanical strength to the capsid. Poliovirus (a Picornavirus) has a structure very similar to that of TBSV, including the positioning of subunits and even the fold of the polypeptide chains within those subunits, but in this case the three quasi-equivalent positions are occupied by three similar but chemically distinct proteins (8). We might imagine that two of the three coding regions encoding these three proteins were the result of gene duplication in an ancestral virus that, like TBSV, had only one capsid protein gene. A slightly different variation on this theme is found in Cauliflower Mosaic virus (a Comovirus), in which the three quasi-equivalent positions are occupied by two proteins, one of which consists of two very similar **domains**, each occupying one of the three quasi-equivalent positions. These last two examples can be regarded either as slightly noncanonical $T = 3$ structures or as $T = 1$ structures made of 60 copies of the heterotrimer (Picornavirus) or heterodimer (Comovirus).

Many capsid structures with larger triangulation numbers have been identified and characterized. Among these are lambda phage, **P22 phage**, bacteriophage HK97, and others ($T = 7$), **T4 phage** and Reovirus ($T = 13$), Herpesvirus ($T = 16$), and Adenovirus ($T = 25$). The largest triangulation number that has been definitively determined is that of the algal virus PBCV1 ($T = 169$). A particularly instructive example is provided by bacteriophage P2 and its satellite phage P4. The P2 capsid protein assembles into a $T = 7$ shell; but in the presence of P4, which does not encode its own capsid protein, the P2 capsid protein assembles into a $T = 4$ structure, just big enough to enclose the P4 genome. This is accomplished through the agency of a P4-encoded protein that associates transiently with the P2 capsid protein during assembly and directs it into the $T = 4$ geometry (9).

Although these large viruses all fit into the general picture envisioned by Caspar and Klug, they are replete with exceptions and extensions to the original picture, and these variations all expand our view of how capsids can be constructed. For bacteriophage T4 and Adenovirus, the proteins that make the pentamers at the five-fold symmetric corners of the capsid are encoded by a different gene from the proteins at the six-fold positions in the remainder of the capsid. This is analogous to the Picornavirus example above and presumably reduces the amount of conformational or bonding versatility demanded of any one protein, at the relatively minor expense of encoding an additional protein. In T4, the major component of the capsid, which occupies the hexamer positions, is, as expected, a hexamer, but in Adenovirus these positions are occupied by *trimers* of the “hexon protein” (10). However, the hexon protein is organized into two similarly folded domains, and the structure of the trimeric hexon is very close to a sixfold symmetric arrangement of those domains.

Some viruses—particularly but not exclusively some of the double-stranded DNA phages—have prolate capsids, which have a standard icosahedral arrangement of subunits, except that the shell is elongated along one of the fivefold axes of symmetry and an extra band of hexamers is inserted around the equator. Thus bacteriophage T4 has an elongated $T = 13$ capsid, and bacteriophage f29 has an elongated $T = 4$ capsid. These structures pose interesting questions with regard to how their length is specified and accurately achieved, but they cause no serious problems for the idea of quasi-equivalent packing.

Most viruses have other capsid subunits in addition to the main, icosahedrally packed, subunit protein. In some cases, these are present in equimolar amounts with the main subunit and packed with the same symmetry. Thus phages l and T4 have well-studied examples of such “decoration proteins”; Herpesvirus has a protein clustered as trimers that fits this description, but is systematically absent from positions immediately surrounding the pentamers. Proteins in this category are known in some cases to provide additional strength and stability to the capsid. Structurally, they can be regarded simply as additional domains of the main capsid protein, albeit ones that are encoded by separate genes and generally join the structure at a different time.

Many capsids also have “minor” proteins that are not arrayed with icosahedral symmetry. The portal protein of the double-stranded DNA phages, for example, forms a grommet-like 12-subunit oligomer that replaces a pentamer at one of the five-fold corners of the icosahedral shell and provides an attachment site for the six-fold symmetric helical tail (11). Adenovirus has a trimeric spike extending out from the shell along each of its five-fold symmetry axes.

The first radical deviation from the expectations of the Caspar–Klug ideas was found in the virion of Papovavirus SV40. The capsomeres of SV40 visible by electron microscopy are arranged as expected for a $T = 7$ structure. However, all of the capsomeres are pentamers of the VP1 subunit (12), including the 60 capsomeres situated at positions of sixfold local symmetry, which would be expected to be hexamers in order to interact quasi-equivalently with their environment. The subunits adapt to this extraordinary state of affairs by having the part of the polypeptide chain that contacts the neighboring capsomere located on a flexible arm corresponding to the *C*-terminus of the subunit. The *C*-terminal arm leaves its home subunit at dramatically different angles in different cases, allowing it to interact with its neighbor in essentially the same way in each case. This it does by invading the structure of the neighbor and forming one strand of a b-sheet structure in that subunit. This might be regarded as a form of quasi-equivalent interaction, but of a sort requiring a much more radical subunit flexibility than envisioned by Caspar and Klug.

Another surprising arrangement of subunits is found in fungal virus L-A and bacteriophage f6. These capsids have 120 identical protein subunits, not one of the "allowed" numbers. These are $T = 1$ structures, built of 60 asymmetric homodimers. The unexpected feature of this arrangement is that the two chemically identical subunits occupy nonequivalent positions. Nonetheless, these capsids, as for those of SV40, evidently function well enough to have survived natural selection (ie, very well indeed), and an understanding of their structures enlarges our view of the capabilities of proteins.

Carbon Isotopes

Carbon is element number 6 in the periodic table and has valence states of 2, 3, or 4 (1). Thirteen isotopes of carbon have been identified (2), ranging in atomic mass number from ^{8}C (half-life = 3 × 10^{-22} s) to ^{20}C (half-life = 0.01 s) (see Radioactivity and Radioisotopes). Two stable isotopes of carbon are found in nature: ^{12}C at 98.9%, and ^{13}C at 1.1% abundance.

The most important radioactive isotope of carbon is ^{14}C (half-life = 5730 years). Carbon-14 decays by beta-minus emission to nitrogen-14, which is stable. Carbon-14 decay yields one beta particle, with an energy of 0.156 MeV maximum, 0.0495 MeV on average. Carbon-14 is produced naturally in the earth's atmosphere by cosmic ray interactions with stable nitrogen-14 according to the reaction $^{14}N(n,p)^{14}C$. Atmospheric $^{14}CO_2$ is inhaled by animals and respired by plants in photosynthesis, incorporating small amounts of carbon-14 in all living organisms. Consequently, carbon-14 dating is useful for determining the age of organic matter such as wood and archeological specimens. Hundreds of different organic molecules have been labeled with carbon-14 as a tracer for studying biochemical processes and are available from commercial suppliers.

Another radioactive isotope, carbon-11 (half-life = 20.38 min), is used in nuclear medicine diagnostics with positron-emission tomography. Carbon-11 decays by beta-plus (positron) emission to boron-11, which is stable. Carbon-11 decay yields 0.98 beta particles, with an energy of 0.960 MeV maximum, 0.386 MeV on average. Positron emission is characterized by twin 0.511-MeV photons that result from the annihilation of a positron and an electron and allow it to be detected externally. Carbon-11 is produced by proton accelerators according to the reaction $^{11}B(p,n)^{11}C$. Carbon-11 positrons are useful for ^{11}C-acetate (3) and ^{11}C-palmitate (3) metabolism kinetic imaging in the assessment of heart disease (4).

Carbon-13 is very useful in studies involving nuclear magnetic resonance (NMR), because it gives an NMR signal, whereas the more abundant isotope, carbon-12, does not.

Carbon-14 was first produced artificially for metabolism studies in 1939. At present, it is produced commercially by neutron irradiation of beryllium nitride or aluminum nitride according to the reaction $^{14}N(n,p)^{14}C$. The low cross section of this reaction and the long half-life of carbon-14 results in low specific activities, which can make carbon-14 labeling of organic materials quite difficult.

Carbon-14 labeling of organic molecules has numerous applications in the biomedical sciences. Examples include studies of glucose metabolism and conversion to $^{14}CO_2$, galactose oxidation, carbohydrate metabolism, the Krebs cycle, **nucleic acid** synthesis and **hybridization**, autoradiography, or fluorography, and for studying many other biochemical pathways. Among the most important carbon-14 compounds used in biochemistry and metabolism studies are the carbon dioxides and monoxide, carboxyl-labeled acids, methanols, cyanides, carbides, formic acids, and cyanamides (5). Carbon-14 is detected by beta-particle liquid scintillation counting, autoradiography, and fluorography.

Carbonic Anhydrase

The enzyme carbonic anhydrase (CA) catalyses the reversible hydration of carbon dioxide to bicarbonate and a proton, using a catalytic zinc ion bound at the active site (1, 2). Carbonic anhydrases are of interest because of their varied metabolic roles, efficient catalytic mechanisms, and high metal ion specificity. The enzyme is found in animals, plants, and bacteria, where it plays roles in respiration, photosynthesis, and CO_2 fixation. Three genetically distinct families of CA proteins have been identified: aCA isozymes, found in all animals; bCA, commonly found in plants and bacteria; and gCA, found in a variety of bacteria (3). Of these classes of CA proteins, the a-CA family is the best characterized. This article provides a brief overview of the metabolic roles and genetic structure of the a-CA human isozymes and describes the catalytic reaction mechanism and metal-binding properties of the high activity, well-characterized human a-CA isozyme II (CAII). Recent work on the b- and g-CA enzymes, which catalyze CO_2 hydration using radically different protein structures, is summarized.

1. Metabolic Function and Genetic Structure of Human a-CA Isozymes

Carbonic anhydrase II (CAII) was first discovered in 1933 in human erythrocytes (4), where it facilitates CO_2 transport in respiration by converting CO_2, released as a metabolic by-product from tissues, to bicarbonate. Bicarbonate is carried by the bloodstream to pulmonary capillaries, where its conversion back to CO_2 is catalyzed by CA for release by the lung. CAII is also expressed in many other tissues, including ocular epithelium, where it plays a role in maintaining intraocular pressure (5). A human genetic disease in which CAII is nonfunctional indicates that this isozyme is also crucial for bone resorption and kidney function (6). Furthermore, the inhibition of CAII by aromatic sulfonamides (RSO_2NH_2) is used clinically to treat glaucoma and altitude sickness (5). Additionally, at least six more CA human **isozymes** with varied activities and locations have been discovered (5). The cytosolic isozymes CAI, CAIII, and CAVI are expressed in high concentrations in red blood cells, **muscle** cells, and salivary glands, respectively. CAIV is a membrane-bound isozyme important for regulating bicarbonate levels in the kidney, whereas CAV is a mitochondrial isozyme. CAVI is secreted by the salivary glands. The exact physiological role of several of these isozymes is still under investigation.

The genomic structure of the human CA isozymes lends insight into their evolution and regulation of their transcription. CAI, CAII, and CAIII have been mapped to chromosome 8q22, CAV and VII to chromosome 16, CAIV to chromosome 17q, and CAVI to chromosome 1 (3). This chromosomal mapping, along with comparisons of DNA sequence homologies, indicates that gene duplication events over 450 million years ago led to distribution of the CA isozymes on four different chromosomes; further gene duplications occurred later, resulting in closely linked isozymes CAI, CAII, and CAIII on one chromosome, and CAIV and VI on another (3). The structures of the various human CA genes currently are being studied to determine the mechanism of their tissue-specific expression. CAI has an unusually long 5′-**untranslated region** containing two **promoters** that direct expression of CAI in erythroid cells and in the colon (7). Other CA genes are also likely to have complex structures to direct their expression in different locations and developmental stages.

2. Catalytic Mechanism and Zinc-Binding Properties of Human CAII

Carbonic anhydrase II is the most thoroughly characterized and most highly active of the CA isozymes, catalyzing the hydration of CO_2 with a rate constant of ~ 10^6 s^1 (1). The crystal structure of CAII reveals a tightly bound zinc ion coordinated by the nitrogen atoms of three protein histidine residues, His94, His96, and His119, located at the bottom of a deep active site cleft (Fig. 1) (8). At physiological pH, a hydroxide ion is also bound by zinc, completing the tetrahedral geometry of the metal site. Residue Thr199 forms a hydrogen bond with the zinc hydroxide, orienting it for efficient catalysis. Catalysis occurs in two main steps (1), initiated by nucleophilic attack of the hydroxide ion on the carbonyl carbon of CO_2 to form bicarbonate.

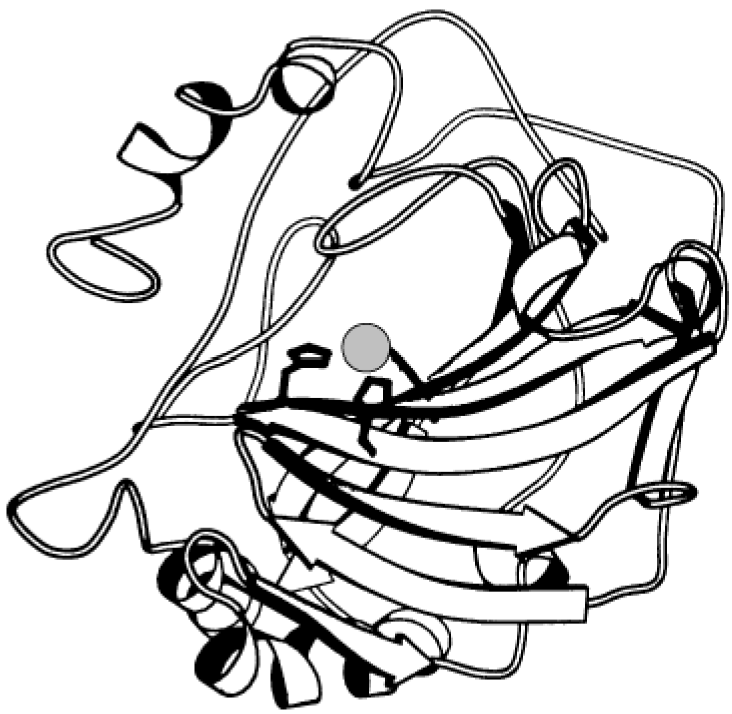
$$\text{E-ZnOH}^- + \text{CO}_2 + \text{H}_2\text{O} \leftrightarrow \text{E-ZnHCO}_3^- + \text{H}_2\text{O} \leftrightarrow \text{E-ZnOH}_2 + \text{HCO}_3^- \quad (1)$$

Water displaces bicarbonate, and the product is released. In the second, rate-limiting step in catalysis (Eq. (2)), the catalytically active enzyme species is regenerated by transfer of the product proton from the zinc-water to protein residue His64. This residue is exposed to solvent and transfers the proton to buffer B:

$$\text{E-ZnOH}_2 + \text{B} \leftrightarrow {}^+\text{H-E-ZnOH}^- + \text{B} \leftrightarrow \text{E-ZnOH}^- + \text{BH}^+ \quad (2)$$

This proton shuttle is essential for rapid catalysis, as transfer of the proton to buffer is much faster than transfer to water. Carbonic anhydrase is one of the few biological systems in which proton transfer can be studied (9).

Figure 1. The crystal structure of human CAII determined by X-ray crystallography (8). It reveals a twisted b-sheet structure in which three histidine residues coordinate the catalytic zinc ion. Figure generated using MOLSCRIPT (13).



Just as the active site of CA has evolved for rapid catalysis, the protein structure is optimized for tight, specific binding of the zinc ion, with a K_d of ~ 2 pM (2, 10) (see Zinc-Binding Proteins). CAII binds only Cu^{2+}, and Hg^{2+} with comparable affinity, and neither of these metals confers catalytic activity to the enzyme (10). CAII has a much lower affinity, with a K_d of nanomolar, for metals such as Co^{2+}, Mg^{2+}, Cd^{2+}, and Ni^{2+}, and only the Co^{2+}-substituted enzyme is active. As the metal binding properties of this protein have been studied extensively, CAII is often used as a model for creating novel metal sites in proteins.

Studies in which site-directed mutagenesis has been used to alter the nature of conserved residues in the zinc site (2) reveal the importance of several factors for high metal affinity. First, in almost all CAII variants studied, the zinc ion retains tetrahedral geometry even if the surrounding protein structure must be rearranged to accommodate new side-chain positions. Second, the distance between the metal and ligand is crucial. Third, conserved residues that form hydrogen bonds with the histidine zinc ligands each contribute modestly to zinc affinity but play a large role in controlling the rates of metal equilibration (2, 11). The histidine ligands, the residues that form hydrogen bonds to these ligands, and the surrounding protein structure contribute to the reactivity and binding properties of the zinc ion.

3. Genetically Distinct CA Families Arose Through Functional Convergence

Examples of the b-CA and g-CA carbonic anhydrase families are only now being discovered and characterized. In an amazing example of evolutionary functional **convergence**, these protein families are completely unrelated genetically to one another and to the a-CA family, yet these enzymes catalyze the same reaction using a catalytic zinc ion (3). The structure determined by X-ray crystallography of a g-CA isolated from **archaebacteria** (12) reveals a trimeric protein containing three active sites; in each active site, a zinc ion is bound at the monomer interface by three histidine residues from different polypeptide chains. As in a-CA proteins, the zinc is bound in tetrahedral geometry, the fourth ligand being a solvent molecule. In this case, a glutamic acid residue located near the zinc ion in g-CA may be the functional analog of Thr199 in human CAII. No structure of b-CA has been solved yet, but phylogenetic and spectroscopic data suggest that the zinc ion may be coordinated by glutamate or cysteine residues rather than histidine (3).

4. Summary

In recent years, the techniques of site-directed mutagenesis and X-ray crystallography have greatly expanded our knowledge of the relationships between protein structure and function in human CAII (2). The structure of CAII appears to have evolved for maximum catalytic activity and metal affinity. Applying these methods to the carbonic anhydrase enzymes that have evolved independently to catalyze the same reaction will give further insight into how protein structure can dictate the reactivity and affinity of metals.

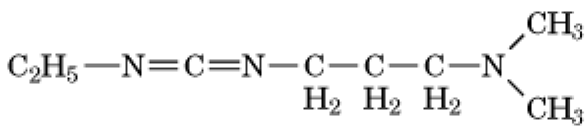
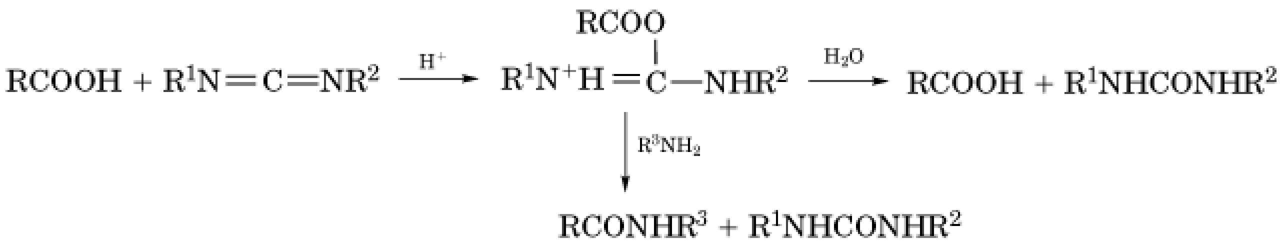
Carboxyl Groups



[I] EDC



A carboxyl group has the formula —COOH. Among compounds that have a carboxyl group are carboxylic acids. A carboxyl group shows relatively weak acidity. Many carboxylic acids are found in nature as free acids or in the form of esters, amides, or salts. Biologically important acids are those found in the metabolic pathways of glycolysis, fatty acids, amino acids, and so on. A carboxylic acid reacts with a base to form a salt and can be reduced to an aldehyde and an alcohol. A carboxylic acid forms an ester with an alcohol, an amide with an amine, and an acid anhydride with an carboxylic acid [see Anhydrides]. Carboxyl groups are not very reactive, and some catalyst or activation processes are required for their reactions.

There are three kinds of carboxyl groups in proteins, the C-terminal a-carboxyl, the b-carboxyl of aspartic acid, and the g-carboxyl of glutamic acid. They have intrinsic pK_a values of 3.8, 4.0, and 4.4, respectively. Carboxyl groups are often employed as catalytic groups in enzymes, and they often play critical roles in **ligand binding**. Thus, carboxyl groups are important in protein chemistry.

1. Chemical Modification of Carboxyl Groups in Proteins

Esterification and amidation are the usual chemical modifications of carboxyl groups (1). Carboxyl groups in proteins are esterified by treating the dry protein with methanol-HCl. However, this method is drastic and not suitable for selective modification of carboxyl groups. Trialkyloxonium salts, such as triethyloxonium tetrafluoroborate, are commonly used for mild esterification of carboxyl groups in proteins (2). Diazoacetyl compounds, such as diazoacetamide, methyl diazoacetate, and *N*-diazoacetylglycinamide, react with carboxyl groups at acidic pH to form esters. Other reagents, such as acid halogen compounds and ethyleneimine have also been used to esterify the carboxyl groups in proteins.

Carboxyl groups are amidated with simple amines after activating the carboxyl groups with water soluble carbodiimides, such as 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) [**I**]. At pH 4.75 to 5, the reaction proceeds as in Scheme 1. Exhaustive amidation is achieved by using high concentrations of both amine (1 M) and EDC (0.1 M) at pH 4.75 under **denaturing** conditions (3). Limited amidation is possible using low concentrations of amine (0.1 M) and EDC (2.6 mM) under mild conditions at pH 5.0 (4). Isoxazolium salts, including Woodward's Reagent K (2-ethyl-5-phenylisoxazolium 3′-sulfonate), can be used in the place of EDC at pH 3 to 5. Amidation is also achieved by ammonolysis of the esters in liquid ammonia at –55°C. In this case, selective amidation is possible starting with a selectively esterified protein (5).

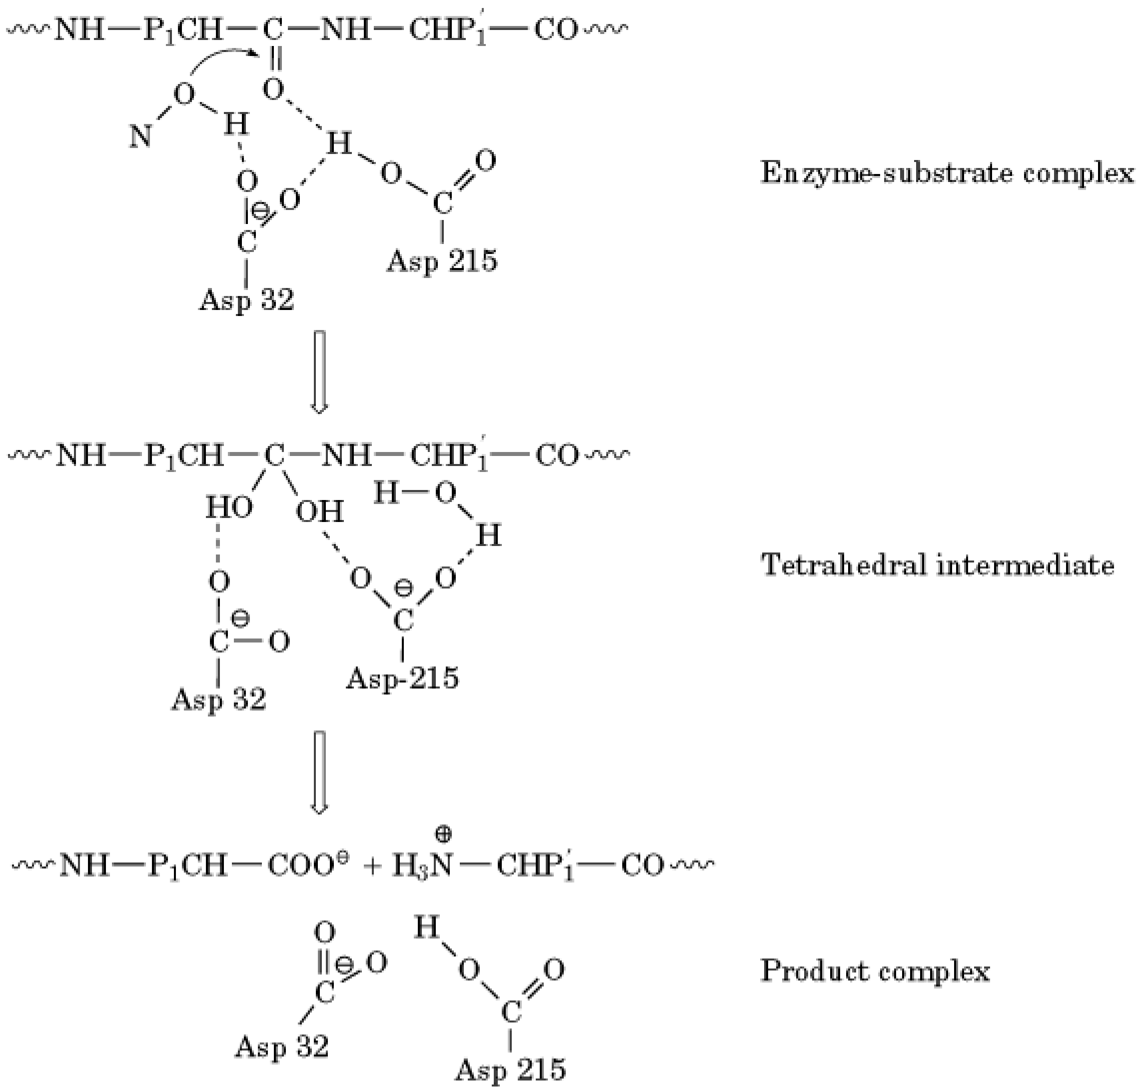
Carboxyl Proteinase

The carboxyl proteinases (E.C. 3.4.23) are also known as *aspartyl proteinases* or *acid proteinases*, so called because the mechanism by which they catalyze the hydrolysis of peptide bonds in proteins (see Proteinases) involves the participation of two carboxyl groups, usually provided by the side chains of two aspartic acid residues (1). The prototypical member of this large family of structurally-related enzymes is the gastric proteinase, **pepsin**, which is optimally active at acid pH. Other members include *rennin* (*chymosin*) from the fourth stomach of the calf; *renin*, a kidney enzyme found in blood plasma; cathepsin D, found in **lysosomes**; numerous fungal enzymes, such as penicillopepsin; and a number of retroviral proteinases from retroviruses, including the human immunodeficiency virus HIV proteinase that is the target of the proteinase inhibitors used in the treatment of acquired immune deficiency syndrome (AIDS). Pepsin and renin illustrate the range of specificity exhibited by proteinases in general and carboxyl proteinases in particular. Pepsin cleaves multiple bonds in virtually all proteins found in the diet, whereas renin cleaves a single bond in its only known biological substrate, *angiotensinogen*—the precursor of *angiotensin*.

Carboxyl proteinases occur in all **eukaryotic** organisms and are important for protein processing and degradation. They are generally synthesized as inactive precursors that spontaneously activate under acidic conditions. Protein and peptide substrates bind to the active site of these enzymes, and one of the carboxylate groups (in the case of pepsin, it is from Asp32) activates a water molecule to attack the carboxyl group of the peptide bond that is to be cleaved (Figure 1). The other carboxyl group, which is protonated (in pepsin, it is Asp215), donates a proton to the peptide nitrogen atom to form an activated intermediate that dissociates into the products. It is believed that this general mechanism pertains to all of the carboxyl proteinases.

Figure 1. Schematic representation of the mechanism of action of carboxyl proteinases. The substrate (top line) binds to the active site of the enzyme [represented by the carboxyl groups of Asp32 and Asp215 (porcine pepsin numbering)] to form an enzyme-substrate complex. P_1 and P'_1 are the sidechains of the main specificity-determining amino acid residues that contribute the -CO- and -NH- groups to the peptide bond that will be hydrolyzed. The carboxylate group of Asp 32 promotes the attack of a water molecule on the carbonyl carbon of the peptide bond, to form a tetrahedral intermediate that is stabilized by transfer of a proton from Asp 215. The intermediate undergoes rearrangement to form a product complex, which subsequently dissociates, thereby regenerating the original enzyme.



It is interesting that in carboxyl proteinases such as pepsin and renin, both catalytic carboxyl groups are present in the same molecule. In the retroviral proteinase from HIV-1, which only contains 99 amino acids, two molecules form a dimer with a single active site containing one catalytic aspartic acid from each subunit. The larger mammalian and microbial carboxyl proteinases contain approximately 325 residues and appear to have **homologous** amino- and carboxyl-terminal **domains** that likely evolved from an early gene duplication and **fusion** event. Each domain contributes a catalytically active aspartic acid residue.

A characteristic feature of carboxyl proteinases is their susceptibility to inhibition by pepstatin, an acylated pentapeptide analogue produced by **Streptomyces**. Recently a number of carboxyl proteinase inhibitors have been found useful for the treatment of AIDS, particularly when used in conjunction with other viral enzyme inhibitors. Carboxyl proteinase inhibitors have also been proposed for the treatment of malaria. Two such proteinases are believed to be essential for degradation of hemoglobin in the red blood cell phase of the life cycle of the parasite.

Carboxypeptidases

Enzymes that catalyze the hydrolytic cleavage of the carboxyl-terminal amino acid residue from an oligo- or polypeptide chain are called carboxypeptidases.

One group of these enzymes uses a catalytic mechanism analogous to that of the serine proteinases and, in fact, are inhibited by the prototypical serine proteinase inhibitor, diisopropylfluorophosphate (DIFP). These enzymes are found in the **vacuoles** of higher **plants** and **fungi** and in the **lysosomes** of animal cells, and they presumably participate in intracellular **protein degradation**. Many fungi also secrete serine carboxypeptidases. *Carboxypeptidase Y* (E.C. 3.4.16.1) is a serine carboxypeptidase present in yeast vacuoles (1). It is a very useful enzyme for determining the amino acid sequence of peptides and proteins (see Protein Sequencing), because it can release all C-terminal amino acids, including proline. Moreover, it is active in the presence of **denaturants**, such as urea or sodium dodecyl sulfate (**SDS**), and in the pH range from 4 to 7.

The other group contains metallocarboxypeptidases, which have a zinc ion at the catalytic site (2). The best known of these are the pancreatic enzymes, carboxypeptidases A and B, which are synthesized as largely inactive zymogens, procarboxypeptidases A and B, and stored in the zymogen granules of the pancreatic acinar cells. On ingestion of a meal, they are released into the duodenum through the pancreatic duct, become activated by the action of trypsin, and help digest dietary proteins and peptides. The specificity of carboxypeptidase A (E.C. 3.4.17.1) is toward aromatic and bulky **hydrophobic** amino acids, nicely complementary to that of **chymotrypsin**, which generates peptides with just such amino acids at their C-termini. Similarly, the specificity of carboxypeptidase B (E.C. 3.4.17.2) is toward peptides with the C-terminal basic amino acids arginine and lysine, which can be generated by the action of **trypsin**. The combined action of these endo- and exopeptidases ensures optimum formation of essential amino acids. Carboxypeptidase N circulates in plasma and is a peptidyl-L-arginine hydrolase that is thought to be responsible for the degradation of bradykinin and other hormones.

An important dipeptidyl carboxypeptidase, *angiotensin converting enzyme* (ACE), cleaves C-terminal dipeptides from a variety of substrates, most notably angiotensin I and bradykinin. The former reaction generates angiotensin II, a potent vasopressor, and the latter inactivates a vasodilator. This dual effect on blood pressure has led to the widespread use of ACE inhibitors as antihypertensive agents.

Carcinogen

Translated literally, the term “carcinogen” means giving rise to carcinomas, or epithelial malignancies. In practice, “carcinogen” is used to describe any physical or chemical agent that increases the incidence of tumors in animal models or in human populations. Chemical carcinogens are a diverse group of agents with a range of properties. Much of the early work on carcinogenesis in animal models identified two stages: tumor initiation, thought to involve a mutational event, and tumor promotion, which probably did not. Although this classification of events is still useful in animal studies, it is now recognized as an oversimplification. Cancer develops through a series of stages, which have been exceptionally well-characterized in certain cancers such as those of the colon (1). (An historic perspective on the development of understanding the nature of carcinogenesis is given by Harris (2)). Many of the steps in carcinogenesis involve either mutations or epigenetic changes, with cells gaining a selective advantage and undergoing clonal expansion as a result of activation of **protooncogenes** and/or inactivation of tumor suppressor genes. “Epigenetic” is defined as “all processes relating to the expression (transcription and translation) and the interaction of the genetic material. Epigenetic mechanisms may act at three levels of cell organization: (1) Turn genes off or modulate **protein biosynthesis**, (2) regulate the translation of messenger RNA into proteins, and (3) regulate the topographic distribution and function of proteins.” (3). Metastatic spread of the cancer involves the activation of further oncogenes controlling various aspects of cell adhesion and movement. A scheme showing some of the events involved in various stages of cancer development is shown in Figure 1.

Figure 1. Factors involved in the various stages of carcinogenesis.

INITIATION →	PROMOTION →	PROGRESSION →	METASTASIS
Mutation (exogenous and endogenous factors)	Increased cell turnover (growth factors, hormones, non-genotoxic chemicals)	Genetic instability (mutation of 'normal' oncogenes, suppressor gene loss, chromosomal rearrangements)	Tumor invation (activation of enes for angiogenesis, cell adhesion, proteolysis)

Mutagenicity is the major mechanism for the activation of proto-oncogenes, and most carcinogens are also mutagens. Miller and Miller (4) claimed that the property in common to all the diverse carcinogens is that they either interact directly with DNA or can be metabolically activated to nucleophilic intermediates that are reactive with DNA. While this is certainly true for most carcinogens, there is increasing recognition that not all carcinogens are DNA reactive. For example, inhibitors of topoisomerase II enzymes have been shown to induce human cancers (5), and these act to cause DNA breaks indirectly by poisoning the enzyme (see DNA Topology). A number of carcinogens may act through epigenetic mechanisms. There is also a class of carcinogens that have no action at all on the genetic material (eg, **peroxisome** proliferators, which are thought to work through **receptor** binding and modification of fatty acid metabolism (6)).

While there is no doubt that mutagenic mechanisms are involved in carcinogenesis, there is considerable doubt as to the relative roles of exogenous and endogenous mutagens in the development of human cancers. Exogenous mutagens include alkylating chemicals such as nitrogen mustards and nitrosamines, usually encountered in cancer therapy, and industrial chemicals such as vinyl chloride, dimethyl sulfate, and bis(chloromethyl) ether. Prominent endogenous mutagenic processes include oxy-radical DNA damage, DNA depurination, **DNA polymerase** infidelity, and deamination of 5-methylcytosine.

Casein

Several kinds of phosphoproteins collectively called casein constitute 80% of the protein of cow's milk and 40% of that of humans. Casein is made up of all 20 kinds of amino acids, which is an important characteristic from a nutritional point of view. Skim milk, which is the milk left after the cream is removed, is brought to pH 4.7 to form a precipitate that contains the casein. The supernatant is called whey and contains 20% of the total protein. Electrophoresis at alkaline pH separates casein into the a, b, and g fractions. The a fraction is further separated into a_{s1} and a_{s2}, the common subscript *s* signifying sensitivity to precipitation by the addition of calcium and k-casein. Both a_s-casein and b-casein are precipitated with Ca^{++}, whereas k-casein is not. In milk, these caseins constitute micelles (calcium caseinate-phosphate complex) of a diameter in the range of 30 to 300 nm. The a- and b- caseins are rich in phosphate, mainly in the form of O-phosphoserine residues, and they form a calcium complex that is not soluble, but precipitated. When surrounded by the hydrophilic parts of k-casein in milk, however, it is soluble as large complexes. The g-casein fraction is a heterogeneous mixture primarily of proteolytic fragments of b-casein.

Bovine b-casein contains 209 amino acid residues (with a molecular weight of 23,600) and is very hydrophobic. Five phosphoserine residues are found in the N-terminal region. In milk, the phosphoserine residues are associated with Ca^{++} ions, forming calcium caseinate. b-casein and its partial hydrolysis products present in milk do not have definite three-dimensional structures. They are considered to have a random coil structure that is easily digestible, an advantage of casein as a nutritional protein. The relative casein composition of bulk milk is given in Table 1.

Table 1. Average Casein Composition of Bovine Bulk Milk Samples

Casein Type	Weight %
a_{s1}	38.1
a_{s2}	10.2
b	35.7
k	12.8
g	3.2
Total	100.0

The fourth stomach of ruminating animals (abomasum) contains a proteolytic enzyme called *chymosin*, which liberates a glycopeptide from k-casein at neutral pH. The remaining molecule, called para-casein, reacts with Ca^{++} and then forms an insoluble curd, the source of cheese. The enzyme preferentially cleaves the peptide bond between Phe105-Met106 of k-casein to produce para-k-casein. Humans do not have chymosin, but **pepsin** in the stomach converts k-casein to para-casein to start the digestion of milk in the infant stomach. Chymosin and pepsin are structurally related.

The casein micelle has a complex structure, and the relative disposition of the four subspecies of casein, and especially that of k-casein, has long been the focus of discussion. Since chymosin preferentially digests k-casein, this casein is thought to be on the periphery of the micelle. Recent **electron micrographs** of variously treated micelles show granular structures covering the surface, prompting a suggestion that a casein micelle is composed of smaller-sized submicelles. The idea of a submicellar structure has actually been a long standing one from reconstitution experiments, and by incorporating various observations, a currently accepted model of casein micelles is presented by Holt (1), as reproduced in Figure 1.

Figure 1. Structural model of casein micelles. Reproduced from (1) (Fig. 13, p. 108) with permission.

Secretory vesicles of casein micelles are found abundantly in mammary secretory cells. After the casein proteins are synthesized, they undergo O-glycosylation and **phosphorylation** before being secreted. These changes occur in concert with lactose synthesis by the enzyme known as lactose synthetase. All the enzymes involved in glycosylation, phosphorylation, and lactose synthesis can tolerate Ca^{++} concentrations in the range of 1 *mM*. Accumulation of Ca^{++} in the mammary gland cell, together with phosphorylation of some serine residues, is necessary for the formation of casein micelles.

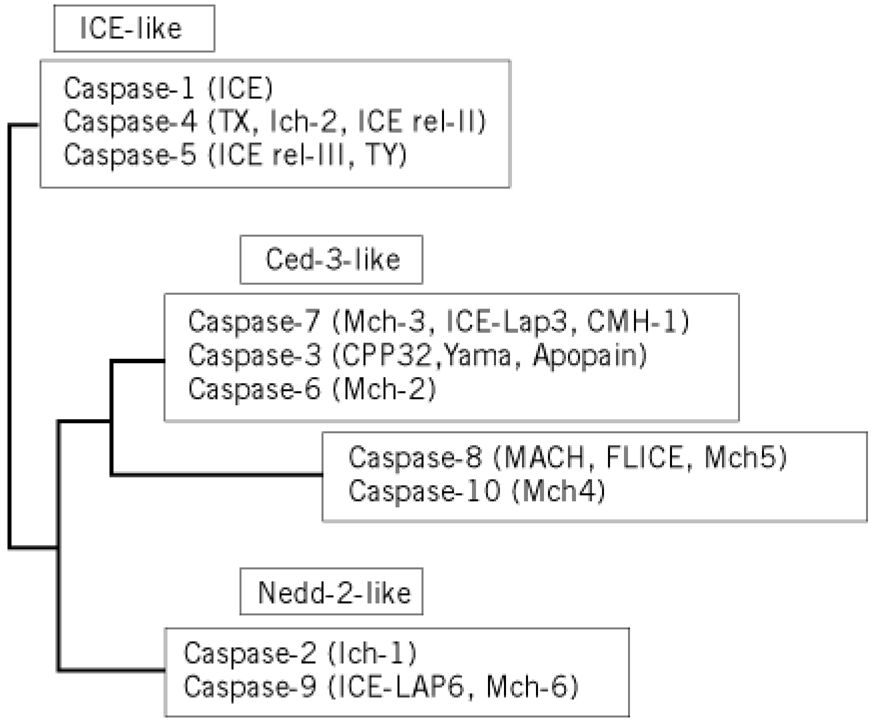
Caspases

Caspases are proteinases involved in apoptosis and programmed cell death. They are mammalian **homologues** of the Ced-3/interleuking-1b converting enzyme (ICE) products of cell death genes (1). The caspase family in mammalian cells currently numbers 14, as shown in Figure 1. They are thiol proteinases that are synthesized as inactive pro-proteins that are processed to a pro-domain and two subunits of approximately 10 and 20 kDa in size. The pro-caspases are inert until proteolytic cleavage of the pro-domain and/or the p10 subunit from the p20 subunit. Caspases share a conserved active-site sequence, -Gln-Ala-Cys-Arg-Gly- (QACRG) or -Gln-Ala-Cys-Gln-Gly- (QACQG), and cleave their substrates at the peptide bond after an aspartate residue; hence, their name- **c**ysteine **asp**artate-specific protein**ases** (1, 2). Caspases cleave specific substrates during apoptosis and are required for the rapid degradation of the cell (2-6); however, none is thought to be critical for apoptosis to occur.

Figure 1. The mammalian caspase family. The various members have been arranged in a phylogeny on the basis of their relative amino acid sequence homologies. The members of the Ced-3-like family of caspases are thought to be the downstream effectors of apoptosis and to be activated in a caspase cascade by the apical members represented by caspases 2, 8, 9, and 10 (1).



Caspases can be divided into subgroups, with each sharing a specific substrate specificity beyond the overall caspase requirement for Asp at the P1 position of the substrate (see Proteinases). Caspases 1, 4, and 5, for example, preferentially cleave after -Tyr-Val-Ala-Asp- (YVAD) sequences and have not been shown to be critical for apoptosis to occur. Caspases 3 and 6, however, are active during cell death and cleave primarily substrates with the sequence -Asp-Xaa-Xaa-Asp- (DxxD). Caspases 2, 8, and 10 are different again and are thought to activate primarily the downstream caspases, such as caspase 3 and 6 (7). This suggests that caspases act in a hierarchy, with activated upstream caspases cleaving downstream caspases and activating them in turn, to generate a *caspase cascade* (4, 8). The apical caspases are proposed to be those with large pro-domains such as caspases 2, 8, and 10. The pro-domains contain a protein structure that facilitates their interaction with other proteins leading to caspase activation, as seen in CD95 (Fas/Apo-1)-induced apoptosis (9).

Cassette Mutagenesis

Cassette mutagenesis involves replacing a wild-type **DNA** sequence with synthetic double-stranded oligonucleotides in order to introduce one or more mutations (1-6). The technique allows saturation of a target amino acid codon with mutations, and can be used to probe the role of that particular residue in a protein and the effect of specific point mutations in it. In their description of the method, Wells et al. (4) synthesized single-stranded oligonucleotides containing different codons over the target in separate pools. Oligonucleotide-**site-directed mutagenesis** procedures are used to generate **restriction sites** that closely flank the target codon in the **plasmid** containing the gene of interest. Use of the appropriate restriction endonucleases permits insertion of the synthetic duplex cassettes. These are designed to restore fully the wild-type coding sequence except over the target codon, and also to eliminate one of the restriction sites. This latter point is important for selection of the clones containing the mutant cassette.

Several variations on the original technique have been developed for specific purposes. For example, Reidhaar-Olsen and Sauer (5) described a combinatorial method, in which they randomized two or three positions by oligonucleotide cassette mutagenesis, selected for functional protein and then sequenced to determine the spectrum of allowable substitutions at each position. They applied the method repeatedly in order to examine the role of different substitutions on the DNA-binding domain of **lambda repressor**. Kegler-Ebo et al. (6) described codon cassette mutagenesis as a way of depositing single codons at specific sites in double-stranded DNA. Using this method, a series of 11 cassettes is sufficient to insert all possible amino acids at any constructed target site.

Catabolite Repression

The ability of glucose to inhibit the synthesis of certain enzymes, referred to as the *glucose effect*, was recognized in **bacteria** at an early date by Monod (1). He observed that when *Escherichia coli* encounters both glucose and lactose, for example, it metabolizes the glucose first and represses the use of lactose, resulting in biphasic growth (diauxie). This phenomenon is due to the repressive effect of glucose on the synthesis of enzymes required for the metabolism of other sugars. Later, the term catabolite repression was introduced as a general name for the glucose effect because compounds closely related to glucose elicited varying degrees of repression of glucose-sensitive enzymes, and the catabolites derived from the repressing compound were assumed to cause the glucose effect (2). Studies on catabolite repression up to the early 1970s brought about the discovery of a positive control system of transcription by cyclic AMP (cAMP) and the cyclic AMP receptor protein (CRP) (also called the catabolite gene activator protein, (CAP)) and led to the concept that catabolite repression is caused by reduction of the level of intracellular cAMP (3). We now know that multiple and different mechanisms are operating, depending on the growth conditions and the target operons, and that the cAMP-dependent mechanism is just one aspect of catabolite repression. Ironically, the preferential utilization of glucose over lactose, the prototype of catabolite repression, is not due to the reduction of the cAMP-CRP complex (4, 5).

Sometimes the term catabolite repression has been used to describe the glucose effect that is independent of the operon-specific regulator, such as the Lac repressor. Here, we shall use it as a general name for the glucose effect as originally defined. According to this view, which is apparently generally accepted, catabolite repression includes all forms of the glucose effect, regardless of their mechanisms. We also concentrate on catabolite repression in *E. coli*. Although several mechanisms of glucose catabolite repression are now understood in *E. coli*, a common feature is that glucose causes catabolite repression ultimately by modulating the activity of transcription factors involved in the regulation of target operons.

1. cAMP–CRP Complex

The best characterized mechanism of catabolite repression involves the regulation of the intracellular concentration of the cAMP–CRP complex. It is well known that the presence of glucose in the growth medium lowers the intracellular cAMP level under certain conditions (3, 6). Cyclic AMP is synthesized from ATP by the enzyme adenylate cyclase. Although the mechanism of regulation of the cAMP level remains elusive, glucose is thought to decrease cAMP by decreasing the level of the phosphorylated form of enzyme IIA^{Glc}, which is involved in the activation of adenylate cyclase. IIA^{Glc} is one of the enzymes of the phosphoenolpyruvate-dependent carbohydrate **phosphotransferase system** (PTS) and is directly responsible for the **active transport** and phosphorylation of glucose (7). Recently, it was discovered that the concentration of CRP is also lowered by the presence of glucose and that this is an additional factor contributing to catabolite repression (8). The decreased CRP is a consequence of the complex autoregulation of expression of the *crp* gene (9). It should be noted that the reduction in the cAMP-CRP level by glucose is usually rather moderate (in the range of several-fold).

2. Inducer Exclusion

The second mechanism of catabolite repression is inducer exclusion, by which glucose lowers the intracellular concentration of inducers necessary for the induction of catabolic operons (7). The target of glucose signaling in inducer exclusion is operon-specific regulators, such as the Lac repressor. The dephosphorylated enzyme IIA^{Glc}, which accumulates in the presence of glucose, binds to and inactivates (for example) the Lac permease, resulting in an increase of the active unliganded Lac repressor (see Lac Operon). Inducer exclusion is a mechanism by which glucose inhibits more strictly the expression of target operons.

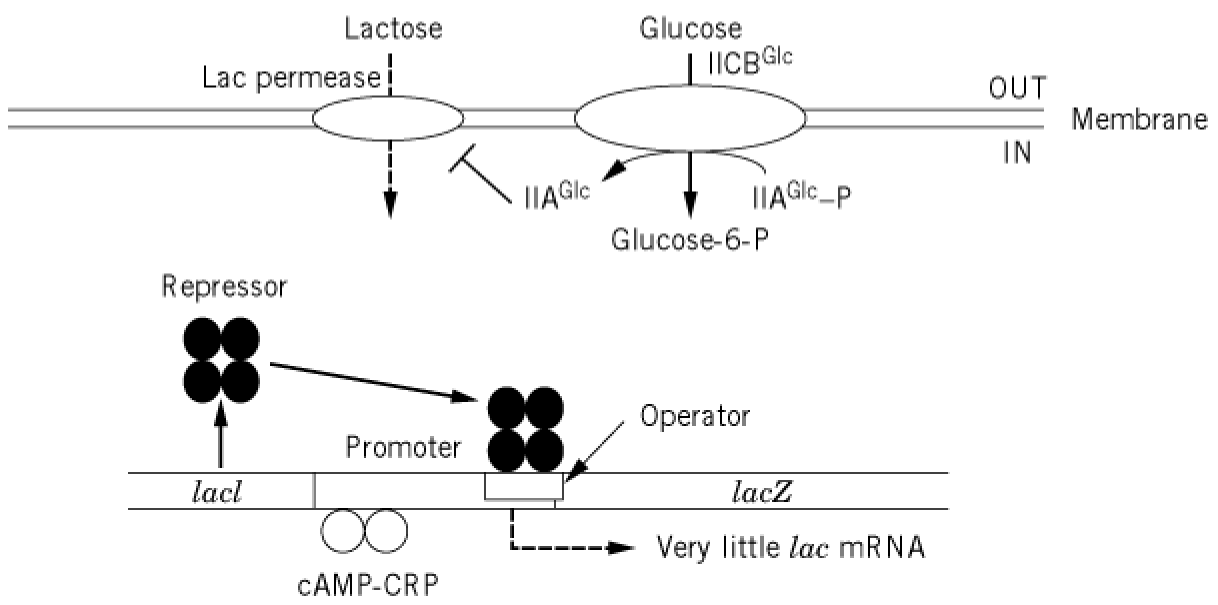
3. Catabolite Repressor/Activator Protein

The third mechanism of catabolite repression is mediated by the catabolite repressor/activator (Cra) protein, which acts as a global regulator of genes encoding enzymes of central carbohydrate metabolism (10). The unliganded form of Cra binds to the operator regions of target operons, causing either activation or inhibition of transcription. The presence of glucose or other PTS sugars produces glycolytic catabolites, such as fructose-1-phosphate, which bind to the Cra protein and cause it to dissociate from the target DNA, resulting in either catabolite repression or catabolite activation.

4. Relationships between the Various Mechanisms

While multiple mechanisms of catabolite repression have been identified in *E. coli*, their signaling pathways appear to be interrelated to each other. For example, the PTS plays a pivotal role in the regulation of the intracellular concentrations of cAMP, inducer, and glycolytic catabolites. In addition, it is particularly important to realize that the contribution of each mechanism varies, depending on growth conditions and the target genes. For example, the Cra-mediated mechanism may play no role in catabolite repression of the *lac* operon, because this operon is not under the control of Cra. An unexpected finding is that the presence of glucose in the lactose medium does not affect the intracellular cAMP level (4). This means that catabolite repression mediated by the reduction in cAMP never happens in glucose–lactose diauxie. The presence of unliganded Lac repressor through inducer exclusion is the principal mechanism for this historical phenomenon (4, 5). Figure 1 illustrates the present understanding of catabolite repression in the glucose–lactose system.

Figure 1. Mechanism of catabolite repression in the glucose-lactose system (4). When both lactose and glucose are present, glucose is transported and phosphorylated by the glucose PTS (IIA^{Glc} + IICB^{Glc}), increasing the concentration of the nonphosphorylated form of IIA^{Glc}, which prevents the uptake of lactose by inhibiting the Lac permease activity. Thus, the concentration of *lac* inducer is very low in the presence of glucose, so the Lac repressor is active and represses transcription of the *lac* operon. It should be noted that glucose does not affect the binding of cAMP–CRP to the promoter, because the levels of cAMP and CRP are not reduced by the presence of glucose.



There are more stories yet to be elucidated before catabolite repression in *E. coli* is fully understood. Further diversity in the mechanism of catabolite repression is known in **Gram-positive** bacteria (11).

Catalase

Catalase, also called *hydroperoxidase*, is a protective enzyme that has been studied for over a century; the concept of a specific protein catalyzing (hence the name *catalase*) the degradation of hydrogen peroxide to oxygen and water first appeared in 1900 (1). Removal of H_2O_2, as shown in the following reaction, avoids unwanted side reactions and prevents the formation of the even more reactive hydroxyl radical:

$$2\ H_2O_2 \rightarrow 2\ H_2O + O_2 \qquad (1)$$

Although the removal of these reactive oxygen species is not essential for growth, catalases do enhance long-term survival in an aerobic environment (2).

A number of developments have spawned considerable interest in the enzyme and spurred extensive studies of both the enzyme and its genes. The first was the simplicity of the "drop test" assay, which involves the visual monitoring of oxygen evolution after the application of a drop of 30% H_2O_2 to the edge of a bacterial colony. Such ease of **phenotypic** scoring has resulted in extensive use of the enzyme as a diagnostic tool for microbiological strain identification. Catalases have been found to be synthesized as part of a variety of **stress response** systems, resulting in their frequent use as indicators of stress response activation. More recently, the catalase–peroxidase family has gained notoriety from its role as the *in vivo* activator of isoniazid into an effective antibiotic in *Mycobacterium tuberculosis* (3). Loss of the enzyme through mutation results in isoniazid resistance, one of the reasons for the increasing spread of tuberculosis.

1. Assay

Two quantitative assay methods are commonly used for catalase activity. One involves the measurement of oxygen evolution using an oxygraph equipped with a Clark electrode (4); the second is a spectrophotometric assay of H_2O_2 by its **absorbance** at 240 nm (5). The two assay procedures produce comparable values in reasonably clear protein solutions, but the oxygraph protocol has the advantage that it can be used for catalase determinations in whole-cell suspensions and in quite turbid extracts. Catalase activity can be visualized on polyacrylamide gels following electrophoresis under nondenaturing conditions (6), producing a clear band in a brown background. This same visualization procedure can be easily modified to visualize peroxidase activities as brown bands on a clear background.

2. Classification

Because of the protection afforded against active oxygen species by catalases, most aerobic organisms produce at least one catalase from among the three main classes of the enzyme. The largest class includes the "typical," heme-containing, monofunctional catalases with either small (~60 kDa) or large (>80 kDa) subunits. The next largest class includes the bifunctional catalase–peroxidases, which are also heme-containing but with sequence similarity to plant and fungal peroxidases. The third and, to date, smallest class includes the non-heme- or Mn-containing catalases. Small-subunit, monofunctional catalases have been found in prokaryotes and eukaryotes but not in an archael species, and the large-subunit catalases are restricted to fungi and bacteria. The catalase-peroxidases are found in **prokaryotes** and **archaebacteria**, and the non-heme-containing enzymes have been found only in bacteria (7).

3. Reaction

Catalases and peroxidases both degrade H_2O_2 but, whereas catalase employs H_2O_2 as both electron donor and acceptor (reaction 1), a peroxidase uses organic substrates as the electron donor to reduce H_2O_2:

$$H_2O_2 + RH_2 \rightarrow 2\ H_2O + R \tag{2}$$

The catalase-peroxidases catalyze both reactions 1 and 2 at significant rates.

The well-characterized catalytic reaction pathway is a two-step process. First, H_2O_2 is converted to water and an oxyferryl species, compound I, with the iron in the +5 oxidation state but with part of the charge delocalized in a heme cation radical:

$$Heme\text{—}Fe^{III} + H_2O_2 \rightarrow heme\text{—}Fe^{V} = O(cpd\ I) + H_2O \quad (3)$$

Then compound I reacts with a second molecule of H_2O_2 to produce water and molecular oxygen:

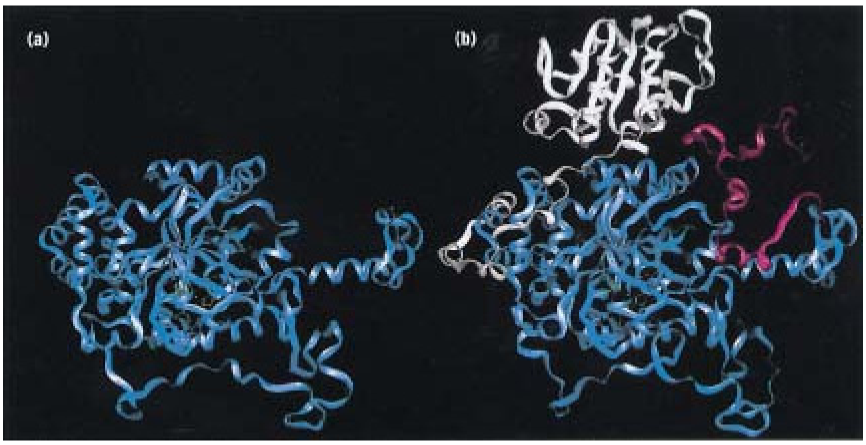
$$Heme\text{—}Fe^{V} = O + H_2O_2 \rightarrow heme\text{—}Fe^{III} + O_2 + H_2O \quad (4)$$

In the absence of a suitable substrate for the reduction of compound I, other intermediates can be formed such as the catalytically inactive compound II.

4. Structure and Properties

Detailed structural information is now available for all three types of catalases. Small- and large-subunit catalases share a common highly conserved core sequence of about 350 residues organized in a b-barrel structure (see Beta-Sheet). This is illustrated in Figure 1 (8, 9), which compares the small subunit of *Proteus mirabilis* catalase (Fig. 1**a**) and the large subunit of *Escherichia coli* HPII (Fig. 1**b**). An *N*-terminal extension of 10–90 residues (colored red in Fig. 1B) and a *C*-terminal extension of 150–170 residues (colored white in Fig. 1**b**), the latter organized in a flavodoxin-like structure, are added to the core structure in the large-subunit enzyme. The tetrameric organization of small-subunit enzymes is sufficiently stable to resist denaturation by organic reagents and to retain activity over a broad pH range from 4 to 11. In large-subunit enzymes, the extended sequences allow the amino terminus of one subunit to be overlapped or trapped by the carboxyl terminus of an adjacent subunit (10), and this interweaving further enhances the resistance of the tetramer to denaturation by heat, **SDS**, and urea.

Figure 1. Comparison of the structures of the small subunit of *Proteus mirabilis* catalase (**a**) (8) and the large subunit of *E. coli* HPII catalase (**b**) (9). The conserved b-barrel core structure is colored blue in both subunits. The 78 additional residues at the *N* terminus of HPII in (**b**) are colored red, and the 195 additional residues at the *C* terminus of HPII in (**b**) are colored white. See color insert.



Besides size, the small- and large-subunit catalases have two other characteristic differences. The first is that small-subunit enzymes contain heme *b*, which in large-subunit enzymes is converted to a *cis*-hydroxy g-spirolactone heme *d* and flipped 180°. The second is that small-subunit, but not large-subunit, catalases contain NADPH (11), which is postulated to have a role in the reduction of inactive compound II. A number of unusual modifications have been identified in catalases, including

1. A methionine sulfone in the active site of the *P. mirabilis* enzyme (12)

2. A blocked cysteine residue in HPII from *E. coli* (13)
3. A histidine–tyrosine bond in HPII

The narrow channel leading to the deeply buried active site of catalases limits access to small substrates and inhibitors, and results in a 10-fold higher apparent $\boldsymbol{K}_{\mathbf{m}}$ for H_2O_2 compared to the non-heme-containing catalases and catalase–peroxidases. Within the catalase active site, a histidine residue immediately above the heme, and an asparagine residue situated to one side, orient the H_2O_2 over the heme iron (12) to facilitate a very fast reaction in both small- and large-subunit enzymes [k_{cat} @ $3.5 \times 10^5\ s^{-1}$ (15) and $1.2 \times 10^5\ s^{-1}$, respectively] as compared to the catalase–peroxidases and non-heme-containing catalases [k_{cat} @ $1.6 \times 10^4\ s^{-1}$ (16) and $3.9 \times 10^5\ s^{-1}$ (17), respectively].

5. Cloning and Expression

The number of catalase enzymes in a given organism varies: one in animals, one or two in **fungi**, one to three in plants, and zero to three in bacteria. The availability of catalase-deficient hosts, the ease of assay, and the development of protocols using oligonucleotide and **PCR** probes have facilitated the cloning and characterization of over 90 catalase genes. Most of the isolated genes are from plants and bacteria, with a small number from fungi and animals. A **phylogenetic** comparison of the core protein sequences has revealed separate branches for the small-subunit enzymes from bacterial, plant, animal, and fungal sources, and one additional branch containing the large-subunit enzymes from both fungal and bacterial origins.

The most detailed studies of catalase gene expression have been carried out in plants and bacteria. In maize, catalase expression is tied to developmental changes during kernel development and seed germination and to environmental factors such as light and growth regulators (18). A multitude of species-specific mechanisms control catalase and catalase–peroxidase expression in bacteria, but two common threads are evident among these expression patterns involving induction either by an active oxygen species such as H_2O_2 or in stationary phase. In most cases, the control mechanisms can be rationalized as either protective responses to oxidative stress or as a means of enhancing long-term survival during metabolic limitation (7, 19).

Catalysis

Catalysis by enzymes starts with the collision between the enzyme E and its substrate A to form an enzyme-substrate complex EA:

$$\begin{array}{ccc} \mathrm{E + A \rightleftharpoons EA \rightleftharpoons EA^*} & \rightleftharpoons & \mathrm{EP^* \rightleftharpoons EP \rightleftharpoons E + P} \\ [\text{ collision clamping }] & \text{conversion} & [\text{ unclamping dissociation }] \\ \text{binding} & \text{catalysis} & \text{release} \end{array}$$

This is a second-order reaction, as it involves two reactants, and the collision rate is equal to $k[E_t][A_t]$, where k is a second-order rate constant. There is a distinct limit to the value of k, as it cannot exceed the diffusion rate (see Diffusion-Controlled Reactions and Turnover Number). Nonproductive complexes can also form as a result of the interaction of a substrate with an enzyme. If the structure of a substrate is complementary to that of the active site of the enzyme, the interaction rate is high and the binding tight. If, however, this is not the case, some of the binding energy has to be utilized to facilitate the interaction through a conformational change or clamping reaction on the enzyme. Binding is the product of the initial interaction and the subsequent conformational change.

After being bound to the enzyme, the substrate must undergo activation. That is, a proportion of the total number of substrate molecules in the ground state must be raised to the transition state. This is a short-lived, unstable species with a structure intermediate between that of the substrate and the product. These activated molecules can fall back to the ground state or be converted to EP^* at a rate that is independent of the structure of the reactants. The activation energy barrier for the conversion of ground-state molecules to transition-state molecules is very much lower for an enzyme-catalyzed reaction than for either a noncatalyzed reaction or chemically catalyzed reaction. In the activated state, the substrate is bound more tightly to the enzyme than it is in the ground state (see Transition State Analogue). If such tighter binding did not occur, there would be no catalysis. In fact, the increase in rate is proportional to the increase in binding. It is for this reason that transition state analogues are potent inhibitors of enzymes. After formation of the EP^* complex, the enzyme undergoes another conformational or unclamping reaction to release the product into the bulk medium and regenerate the free form of enzyme. Such regeneration is an essential part of enzymic catalysis.

Catalytic Antibodies

The concept of *catalytic antibodies* owes its origin to Pauling and Jencks, who proposed that an antibody normally differs from an enzyme by its inability to bind selectively and to stabilize the transition state of a chemical reaction. An antibody that did happen to be specific for a transition state should therefore function like an enzyme and promote chemical catalysis of the corresponding reaction (1). Advances in chemical synthesis and in hybridoma technology to produce monoclonal antibodies have enabled the exploitation of the diversity and affinity of the immune repertoire to develop catalytic antibodies that are elicited against transition state analogues. The binding sites of these antibodies are anticipated to bind substrates structurally related to the transition state and to process them to products through a pathway lower in free energy, and therefore more rapid, than the normal one that occurs in the absence of antibody. By clever design of appropriate transition state analogues, "tailor-made catalysts" should be created to catalyze reactions with no enzymic counterparts. Challenge of the immune system with a transition state analogue to induce a catalytic antibody is a necessary, but not a sufficient, condition to generate an effective catalyst; factors other than high affinity for the transition state, such as precise orientation of catalytic residues and the effective release of reaction products at the active site, also contribute to the overall catalytic efficiency of an antibody. Strategies have evolved to design transition state analogue immunogens that would solicit catalytic functions within the antibody combining site for efficient catalysis.

1. Reactions Catalyzed by Antibodies

There are now approximately 100 reactions that have been catalyzed by antibodies (1-3). These reactions include (*1*) pericyclic processes (oxy-Cope rearrangement, Diels–Alder condensation, Claisen rearrangement), (*2*) elimination reactions (decarboxylation, dehydration, *syn* elimination of HF from fluoroketones, E2 (biomolecular) elimination of benisoxazole), (*3*) hydrolyses (carbonate esters, esters, amide, lactones, enol ethers), (*4*) bond-forming reactions (lactonization, peptide synthesis, cationic cyclization, aldol condensation), and (*5*) redox reactions (ketone reduction, epoxidation, sulfoxide oxidation). Antibodies can catalyze, with high stereo- and regiospecificity, reactions that may not generally be catalyzed by enzymes. This property has appeal in the potential application of antibody catalysis to commercial synthetic and medical uses, such as pharmaceutical synthesis and prodrug activation.

2. The Nature of the Catalytic Site

The active sites of catalytic antibodies elicited by a given immunogen exhibit high sequence homologies and are often structurally convergent (4). These sites harbor shallow clefts complementing the structural and electronic features of the immunogen. The positioning of active site residues in the binding pocket is accomplished by somatic mutation of the germline ancestral antibody arising from an immunological response (5). The germline antibody undergoes a substantial amount of induced-fit conformational change on binding the immunogen. By the process of affinity maturation, the active site residues in the mature antibody become preoriented such that a rigid binding pocket is generated for optimal binding (lock-and-key fit).

3. Nature of Catalysis

Catalysis by antibodies is like that by enzymes, in that it exhibits Michaelis–Menten kinetics in which substrate binding precedes a chemical transformation, followed by dissociation of the product. Kinetic characterization experiments (6) indicate that the antibody-catalyzed reaction recapitulates a number of characteristics expected of an enzyme, but the chemical transformation step is often rate-limiting. The rate enhancement is generally less than that observed for enzymes catalyzing similar reactions. Transition state analogues are only approximations of the true transition state, and they also do not demonstrate the extremely tight binding to enzymes that is predicted theoretically (see Transition State Analogue). Furthermore, antibodies catalyze reactions primarily through restrictions on the translational and rotational movement of substrates, and only to a lesser extent through the active-site acid/base or nucleophilic catalysis that occurs in enzymes. The difference in catalytic efficiency between antibody and enzyme can also be attributed in part to the latter's ability to provide more extensive electrostatic interactions and hydrogen bonding during catalysis through conformational mobility (7).

4. Generation of Catalytic Antibodies

The recovery of catalytic antibodies relies on an efficient means of sampling the immune repertoire and screening for effective catalysts. The murine immune repertoire is estimated to have a diversity of 10^8, and it can be further expanded by immunization. The majority of catalytic antibodies have been derived from hybridomas that generally capture only 0.01% of the immune repertoire. The development of recombinant antibody fragments as combinatorial libraries consisting of $\geq 10^6$ members in **lambda** and in M13 phage has increased the access to the immune repertoire and possibly the recovery of catalytic antibodies. The diversity of an antibody combinatorial library, and potentially the yield of efficient catalytic antibodies, can be further expanded by polypeptide chain-shuffling experiments in which the heavy-chain fragment of a catalytic antibody is allowed to cross with a library of light-chain fragments elicited by the same immunoglobulin, and vice versa (8).

5. Screening for Catalytic Antibodies

Catalytic antibodies have been identified by their high affinities for the appropriate haptens, as well as their catalytic activities for the desirable reactions. Given the often low activity of catalytic antibodies, sensitive but specific methods have been developed for identifying the catalyst. CatELISA is based on screening for the presence of antibody-catalyzed reaction products using product-specific antibodies as primary antibody indicators in enzyme-linked immunosorbent assay (ELISA) (9). An alternative method depends on the catalytic release of a reactive species that can be trapped via covalent modification of the phage-displayed antibody, which then permits the recovery of DNA encoding catalytic antibody clones from the phage particles (10). Another method involves the recovery of antibody clones that sustain growth of **microorganisms**, such as **yeast** or bacterial auxotrophs, through catalysis of essential biological pathways (11). The host organisms, however, may also impose an additional selection on what catalytic antibodies can be recovered from the screen, since the host will not survive expression of antibodies that are toxic.

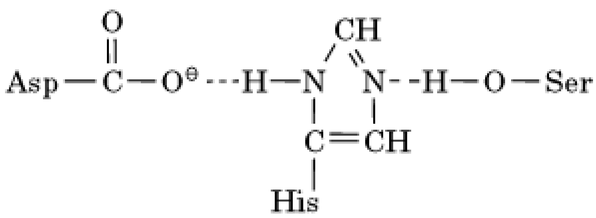
Catalytic Triad

The term *catalytic triad* is used to describe the arrangement of amino acid residues in the active sites of serine proteinases that underlies their mechanism of enzyme action. It was first applied to the active site of **chymotrypsin** when the structure of that enzyme was determined by X-ray crystallography (1). Earlier studies had shown that chymotrypsin could be inactivated by chemical modification of one of its serine residues with the nerve gas, diisopropylfluorophosphate (DIFP). Examination of the enzyme structure revealed that the hydroxyl group of this serine, residue 195, was “activated” by the imidazole group of histidine 57, which in turn was “activated” by the carboxyl group of **aspartate** 102 (Fig. 1). Originally described as a *charge relay system*, these three residues are more commonly called a *catalytic triad*.

Figure 1. The catalytic triad, the hydrolytic apparatus of serine proteinases. It consists of the side chains of an aspartic acid, a histidine, and a serine residue (eg, residues 102, 57 and 195, respectively, in bovine chymotrypsin). In the absence of substrate, the imidazole group of the histidine is unprotonated, but it potentiates the nucleophilic properties of the hydroxyl side chain of the serine. When substrate binds to the active site, the serine proton is transferred to the imidazole group and the oxygen attacks the carbonyl group of the substrate. The resulting positively charged imidazole is stabilized by interaction with the negative charge of the aspartate carboxyl group. The activated serine is also highly reactive toward inhibitors such as PMSF and DIFP.



Similar triads have been observed in both the chymotrypsin and subtilisin evolutionary families of serine proteinases (2), as well as in other hydrolytic enzymes (3). It is remarkable that the bacterial serine proteinase subtilisin has the same geometrical arrangement of aspartate, histidine, and serine residues as chymotrypsin, but all other structural aspects of the two proteins are quite different. This is a classic example of **convergent** evolution. The activated serine interacts with the carbonyl carbon atom of the peptide bond to be hydrolyzed, forming an oxyanion intermediate, which is converted to an acylated serine with release of the amine component of the peptide. Subsequent hydrolysis of the acylenzyme occurs by the reverse reaction in which water substitutes for the activated serine.

Cathepsins

The term *cathepsin* is derived from the Greek word meaning “to digest” and is used to describe a broad range of intracellular proteinases that serve important biological functions. Two major pathways have been identified that control the degradation of cellular proteins. One operates within the **cytoplasm** and is called the **ubiquitin**-mediated pathway. The other functions within specific cellular compartments, especially the **lysosomes**, but also in endosomes and the endoplasmic reticulum. Lysosomes are the major site of intracellular protein degradation (1). They are amply endowed for this function because they contain as many as 20 different proteolytic enzymes and as many other hydrolytic enzymes (eg, **phosphatases**, lipases, **nucleases**, and sulfatases) (1).

The lysosomal proteinases are called *cathepsins*. They are single-chain proteins that range in molecular mass from 20 kDa to about 40 kDa. Typically they have a broad substrate specificity, are optimally active at somewhat acidic pH, and belong to either the thiol proteinase or carboxyl proteinase classes. For no particular reason, they have been designated by letters as cathepsins B, L, H, M, N, S, and T, all of which are thiol proteinases or, more commonly, *cysteine proteinases*; and cathepsins D and E, which are carboxyl (or *aspartyl*) proteinases (2). All of these are endopeptidases, enzymes that cleave peptide bonds in the internal part of a protein. In addition, there are several lysosomal *exopeptidases*, including *cathepsin C*, which removes dipeptides from the amino-terminus of polypeptide chains and is therefore a dipeptidyl aminopeptidase, and at least two carboxycathepsins that are carboxypeptidases. Cathepsin G is a chymotrypsin-like serine proteinase found in neutrophils, and cathepsin R is another serine proteinase found in the endoplasmic reticulum.

The lysosomal cathepsins have been considered to be the most active proteinases in the body, because they degrade four times as much protein as the pancreatic and gastric proteinases combined (3). Much of this is essentially turnover of cytosolic proteins to balance **protein synthesis** and maintain homeostasis. However, cathepsins are also important components of the **immune system**: In order for a foreign protein to generate an antibody response, it must be taken up by a specialized **antigen-presenting** cell and degraded within endosomes. The resultant peptide fragments are then “presented” on the cell surface, where they trigger antibody production (4).

Caudal Protein

Caudal protein (Cad) was identified originally as a **homeodomain** protein in *Drosophila*, but **homologues** have subsequently been found in vertebrates as well. It belongs to the superfamily of **DNA-binding** homeodomain transcription factors. Caudal messenger RNA, which is supplied by the mother in the unfertilized egg; is required for proper segmentation of posterior segments in insects and for the development of the posterior lineage in vertebrates. In *Drosophila*, Caudal has been shown to bind to **promoter** elements and to activate directly the transcription of several segmentation genes. In this process, it cooperates with other transcriptional activators of segmentation genes, eg, Bicoid (another homeodomain protein). At the preblastoderm stage, Caudal protein forms a gradient, which is generated by **translational repression** caused by Bicoid binding to the *cad* mRNA. Although this early function appears to be specific to *Drosophila* (and other long-germ-band insects), the zygotic function of Caudal, specification of the most posterior segments in insects or posterior cell lineage in vertebrates, appears to be conserved throughout the animal kingdom.

The *caudal* (*cad*) gene of *Drosophila* was first isolated as a **homeobox**-containing gene by cross-hybridization to the homeobox of ***Ultrabithorax*** (*Ubx*) and others (1, 2). The *cad* homeodomain shares 58% identity with that of *ftz*, and 53% and 52%, respectively, with those of *Antp* and *Ubx*. During *Drosophila* development, *cad* is expressed both maternally and zygotically. The maternal expression is detected in the **germ line** in nurse cells during **oogenesis**, and its mRNA accumulates in the developing **oocyte**. At the end of oogenesis, the *cad* mRNA is distributed evenly throughout the oocyte. No Cad protein is detected during oogenesis. Cad protein is first detected beginning with nuclear division cycles 6 or 7, just prior to the formation of the syncitial blastoderm. From this stage on to the 13 nuclear cycle, the distribution of Cad protein forms a concentration gradient throughout the embryo and along the anterior-posterior axis, with its maximum at the posterior end. The *cad* mRNA remains uniformly distributed throughout the cytoplasm to the 12 nuclear cleavage; subsequently, it follows the protein gradient, when it is then distributed as a concentration gradient itself. Nevertheless, the protein gradient precedes the mRNA gradient by several nuclear cycles, so that the mRNA gradient is not relevant for the generation of its protein gradient (see below). Following the final nuclear cleavage during cellularization of the blastoderm, the maternally-derived *cad* mRNA disappears, and with it the protein translated from it (1-3).

Formation of the protein gradient from the initially uniformly distributed mRNA is generated by translational repression in the anterior regions of the embryo. Another maternally provided homeodomain protein, Bicoid, binds the *cad* mRNA and prevents its translation (4, 5). This is the only reported example of a homeodomain protein controlling the expression of another homeodomain factor at the level of its mRNA by translational repression. Caudal protein also accumulates in the pole cells during their formation and is present there for several hours of embryogenesis. There is no *de novo* expression in the pole cells, however, and all the protein present was synthesized from the maternally provided mRNA. Formation of the Caudal protein gradient does not depend on zygotic gene expression. In older unfertilized eggs, an anterior-posterior gradient is detected that is similar to that normally present in embryos of the same stage (2, 3). Maternally expressed Caudal has also been reported in other insects, such as *Bombyx mori* (6).

Zygotic expression of Caudal protein in *Drosophila* begins during cellularization of the blastoderm as a stripe in the posterior region of the embryo corresponding to the anlagen of the most posterior segments (the presumptive abdominal segments A9/A10, parts of the telson) and the hindgut. At the extended-germ-band stage, and throughout the rest of embryogenesis, *cad* is expressed in posterior midgut cells, the Malpighian tubules, the anal plate and, at weaker levels, during germ-band extension in pair-rule-like stripes (1-3). In third instar larvae, *cad* is expressed in the Malpighian tubules, the posterior midgut, the gonads of both sexes, and in the anlagen of the anal plates and the hindgut, within the genital (3). Most aspects of the zygotic expression are conserved in those vertebrates that have been analyzed (7-10).

In *Drosophila*, the function of the Caudal transcription factor is required for segment specification in the thoracic and abdominal regions by regulating the transcription of several segmentation genes (11-14). Embryos lacking both maternal and zygotic Cad protein are severely shortened, with variable deletions of many of the thoracic and abdominal segments. Zygotically provided protein can, however, largely rescue these defects. Ectopic expression of Caudal protein throughout the embryo at the blastoderm stage leads to **phenotypes** that are somewhat opposite to the phenotypes observed in *cad*-defective embryos (15). Analysis of the cis-acting elements of several segmentation genes has demonstrated that Cad is directly activating transcription of *fushi tarazu* (11) and other segmentation genes (12-14). Caudal acts in concert with Bicoid, and is partially redundant, in controlling the expression of the downstream targets, the segmentation genes (12, 13).

Embryos from wild-type mothers that lack zygotic function display an absence of parts of the most posterior segments, the terminalia; in particular, the anal tuft, parts of the anal pads, and the terminal sense organs, all structures that are derived from a cryptic tenth abdominal segment, are deleted (2). The isolation and developmental expression analysis of Caudal homologues in vertebrates (7-10) has suggested that this aspect of Caudal function, specification of most posterior segments or posterior lineage in vertebrates, has been conserved throughout evolution. Based on the expression patterns of some of the vertebrate Caudal homologues, additional roles for this subfamily of homeodomain transcription factors have been proposed; eg, participation in rostrocaudal axial patterning or in the development and regeneration of the liver (16, 17). However, all the assumptions of Caudal function (s) in vertebrate development are based purely on the respective expression patterns, and no loss-of-function mutants have been reported to date. Thus, all these proposed roles of vertebrate Caudal homologues await confirmation by the analysis of specific mutants, eg, **knockout** mice, or the potential identification of mutants in other model systems, such as the zebrafish.

Cauliflower Mosaic Virus

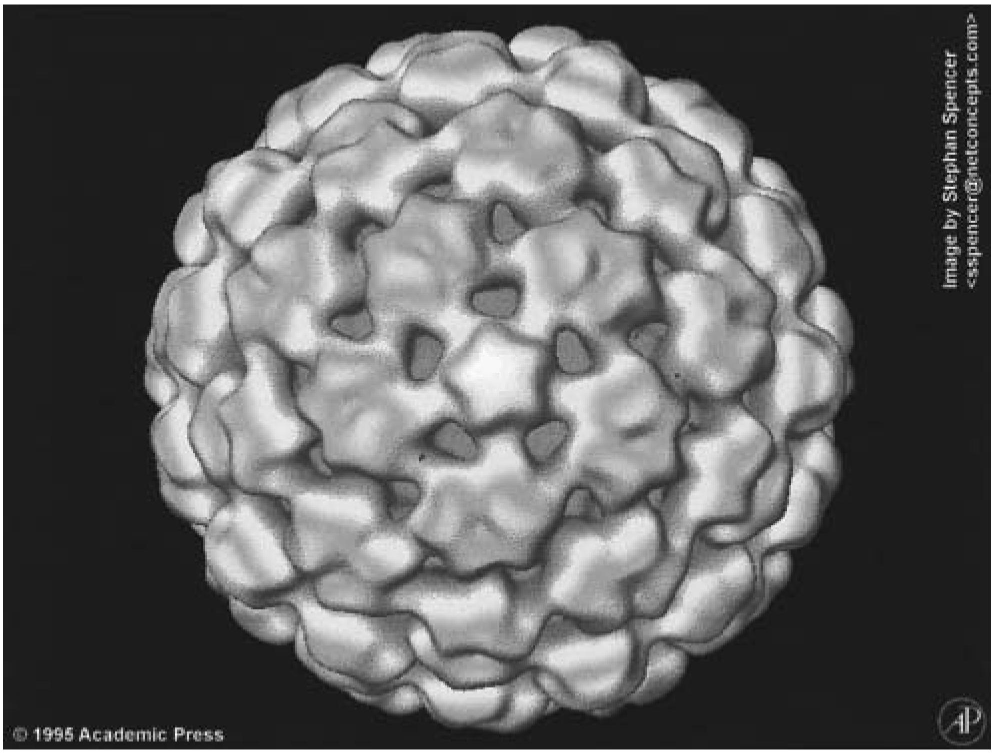
Cauliflower mosaic virus (CaMV) was the first plant **virus** shown to have a DNA genome and the first shown to **replicate** by **reverse transcription**. The virus is found worldwide but only causes significant losses locally. It is transmitted by aphids in the externally borne or stylet-borne manner (see Virus Infection, Plant) and encodes a helper factor that is required for transmission. It has a narrow host range, being restricted primarily to the Cruciferae. CaMV is the type member of the Caulimovirus genus, which contains 11 species and 6 possible members.

This virus has had a significant impact on plant virology and plant molecular biology. The unravelling of the reverse transcription replication mechanism led to the concept of *pararetroviruses* (1, 2). The virus is an important source of gene regulatory elements, which have been used extensively in the genetic manipulation of plants.

1. Virus Structure

CaMV particles are isometric, about 50 nm in diameter (**Fig.** 1). Although the virus particles have been crystallized, X-ray crystallography did not yield detailed information, most probably because of the heterogeneity of the coat protein (3) The structure has been shown by cryoelectron microscopy and three-dimensional **image reconstruction** to comprise three concentric layers of solvent-excluded density (4). The outermost layer is made up of a total of 420 coat protein subunits arranged in $T = 7$ **icosahedral symmetry**; it is the first example of a $T = 7$ virus that obeys the stoichometric rules of icosahedral symmetry. The DNA genome is distributed in layers II and III, together with some of the viral coat protein. The viral coat protein is expressed from **open reading frame** IV (see below) as a 58-kDa precursor molecule that is processed **proteolytically** to several molecular sizes, the major ones being 42 and 37 kDa. The protein in virions is **glycosylated** and **phosphorylated**, and the virions also contain minor amounts of the products of open reading frames III and V.

Figure 1. External structure of cauliflower mosaic virus, viewed down a local five-fold axis.

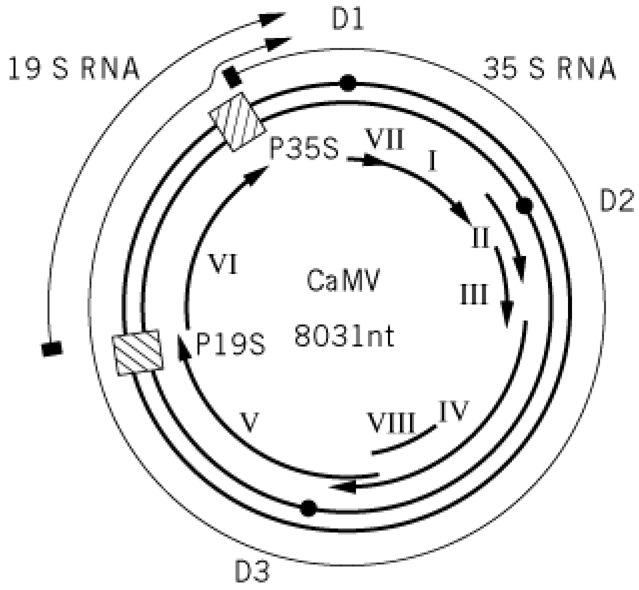


CaMV particles are very stable and are only dissociated at high pH (5) or by digestion of the coat protein with proteinases.

2. Viral Genome

Each virus particle contains a single molecule of circular double-stranded DNA of 8 kbp. The DNA of most isolates of CaMV has three discontinuities (D1, D2, and D3 in Fig. 2), one in one strand (the a strand) and two in the other (yielding the b and g strands); one strain has only two discontinuities, one in each strand. The discontinuities have an unusual structure, with a fixed 5′ DNA nucleotide (with sometimes one or two ribonucleotides attached) and variable 3′ end, overlapping the 5′ end by 10 to 30 nucleotides. They are the sites of the priming of (+)- and (–)-strand DNA replication, and this unusual structure results from viral replication (see below). The DNA has a twisted conformation that, because of the discontinuities, cannot be **supercoiled**, the constraining forces being unknown.

Figure 2. Genome organization of CaMV. The double-stranded DNA genome is represented by the thick double circle, with the discontinuities shown as ●. The promoters for the 35S and 19S transcripts are indicated by ⊠, and the positions of the transcripts are shown by the outer arcs. The inner arcs are the open reading frames I to VIII.



CaMV DNA has six, or possibly eight, open reading frames (ORFs) on the complement to the a strand (**Fig.** 2). ORF I product (37 kDa) is involved in the cell-to-cell movement of the virus, and ORF II product (18 kDa) is the aphid transmission protein (see Virus Infection, Plant). The product of ORF III is a protein of 15 kDa that is processed to 11 kDa and thought to be involved in packaging the DNA genome (6). ORF IV encodes the viral coat protein, which contains the "cys" motif C^{ys-} X_2C^{ys-} X_4 H^{is-} X_4C^{ys-} characteristic of retrovirus *gag* or nucleoproteins and a highly basic lysine-rich region. The viral polymerase (reverse transcriptase +ribonucleaseH) is encoded by ORF V (79 kDa). The product of ORF VI forms the matrix of the inclusion bodies in which virus particles are found embedded in the **cytoplasm** of infected cells. It has several functions, including being the site of the reverse transcription phase of viral replication (7), involved in virus assembly (8), a transactivator during viral expression (see below), and a symptom determinant. No products have been found for ORFs VII and VIII, and it is uncertain whether they are expressed.

3. Transcription and Translation

CaMV DNA is transcribed asymmetrically from the a strand to give a more-than-genome length transcript (the 35S RNA), with a terminal repeat of 180 nucleotides and subgenomic transcript (the 19S RNA) that is the messenger RNA for ORF VI (Fig. 2); the transcripts are **polyadenylated**. There are suggestions of other transcripts, such as one for ORF V (9), but these have not been characterized. **Splicing** events between the leader sequence and an acceptor site in ORF II (10) are essential for virus infectivity. It is possible that these events might form the mRNA for expression of ORF III and, possibly, ORFs IV and V.

The **promoter** for the 35S RNA is well characterized and widely used in the expression of transgenes in plants. It directs constitutive, high-level expression in most tissues of most plant species. The promoter has a modular structure, with regions that control the tissue specificity of expression [reviewed in 11). Nuclear factors have been identified that bind to specific regions of the promoter. The 19S promoter is much weaker than the 35S promoter and is less well characterized.

The CaMV genome also contains the signal sequence for the polyadenylation of both the 35S and 19S transcripts. Due to the terminal repeat, the transcription of the 35S RNA has to pass this signal the first time it is encountered and recognize it the second time. It is thought that the bypass is due to the proximity of the promoter (12).

Translation of the 35S RNA is effected by several unusual mechanisms [reviewed in (11) and further refined in (10)). The leader sequence upstream of ORFI is long (>600 nucleotides) and contains several **AUG** start codons, which could inhibit downstream translation. However, this leader sequence is folded into a complex stem-loop structure, which enables small ribosomal subunits to “shunt” from the 5′ to 3′ end of the leader sequence without scanning the sequence in between; this then opens up ORFI. Translation of downstream ORFs on this polycistronic message is dependent on the presence of a **transactivator**, which is the product of ORF VI, and possibly on the splicing mechanism described above. This process of transactivation seems to enable ribosomes that have translated one ORF to remain competent to translate the next ORF downstream.

4. Viral Replication

The replication cycle of CaMV (Fig. 3) has been studied in much detail, but there are are still several aspects that are not fully understood. Virus particles enter the uninfected cell and are unencapsidated by an unknown mechanism. The viral DNA genome enters the nucleus, where the discontinuities are sealed and the molecule associates with histones forming a minichromosome (Fig. 3, step 2). This is the template for transcription by the host DNA-dependent **RNA polymerase**, giving the 35S and 19S RNAs, which pass to the cytoplasm (Fig. 3, step 3). The 19S RNA is translated to yield the inclusion body protein. The 35S RNA has two functions, being the mRNA for at least the products of ORFs I and II and the template for the reverse transcription phase of replication. There is some evidence that this phase of replication takes place in viruslike particles in the inclusion bodies (7). The first event in reverse transcription is the annealing of the 3′ end of $tRNA^{met}_{init}$ to a site, that of discontinuity 1 (D1), about 600 nucleotides from the 5′ end of the 35S RNA (Fig. 3 step 4). This acts as a primer for the synthesis of a-strand DNA toward the 5′ end of the template. RNaseH activity removes the RNA moiety of the DNA–RNA duplex thus formed and leaves DNA (Fig. 3, step 5) that, because of the terminal repeat of the 35S RNA, is complementary to the 3′ end of the template. Thus, a strand switch is effected, and synthesis of the a strand DNA continues (Fig. 3, step 6). The digestion of the RNA by RNaseH leaves purine-rich regions at the positions of discontinuities 2 and 3 (D2 and D3), which act as primers for the synthesis of the b and g strands (Fig. 3 steps 7 and 8). When the oncoming strand of (+)-strand DNA reaches the next priming site, it displaces the primer and some newly synthesized DNA, resulting in the triple-strand discontinuity described above. A second strand switch occurs at the tRNA priming site between the oncoming a and g strands, allowing the synthesis of the g strand to continue and making discontinuity 1.

Figure 3. Replication cycle of CaMV. Step 1: The input DNA containing discontinuities 1–3 (D1–D3) passes to the nucleus where it forms minichromosomes (step 2). These are the template for the transcription of the 35S RNA (step 3) with terminal repeats r, which moves to the cytoplasm. Priming of the 35S RNA occurs by the annealing of the 3′ end of $tRNA^{met}_{init}$ to the primer binding site (PBS) on the 35S RNA and leads to the synthesis of (–)-strand DNA (step 4). RNaseH removes the RNA of the RNA DNA duplex, leaving the complement to the terminal repeat sequence R (step 5). This anneals to the 3′ end of the 35S RNA, and DNA synthesis continues (step 6). RNAseH activity leaves purine-rich regions ●, which act as primers for (+)-strand DNA synthesis (steps 7 and 8). The oncoming strand displaces the primer sequence, thus giving the characteristic discontinuities, and a second strand-switch is effected at D1 to complete the molecule.

cDNA Libraries

In contrast to genomic libraries, which contain raw DNA sequences harvested from an organism's chromosomes, cDNA libraries are composed of processed nucleic acid sequences harvested from an organism's **RNA** pools (see Complementary DNA (cDNA)). cDNA can be prepared from any RNA source, including in RNA and noncoding RNA, isolated from single cell organisms, cultured metazoan cells, and isolated tissues. cDNA libraries provide a powerful means of examining cell- and tissue-specific gene expression. For example, mammalion cDNA libraries contain only the fraction of sequences that are expressed in the subject tissues at the time of harvest, typically in the range of 10% of the **genes** carried by the genome. Also, cDNA is typically prepared enzymatically from **polyadenylated** mRNA, a population of RNA that has previously undergone post-transcriptional editing and removal of any intervening sequences (**introns**). Whereas genes in genomic DNA are often interrupted by numerous introns, the copy of a gene in a cDNA or mRNA commonly contains an uninterrupted sequence encoding the gene product. Thus, cDNA inserts are directly expressible as both RNA and protein gene products. Vectors used in cDNA libraries often contain expression elements that mediate transcription and translation of the cloned cDNAs.

In constructing cDNA libraries, the goal is usually to represent full-length protein coding sequences for all of the mRNAs expressed in the subject cells or tissue. Thus, it is essential to preserve the integrity of cellular mRNA during extraction and purification protocols. Libraries made from fragmented RNA will not preserve the full open reading frame, rendering the resultant partial clones less useful. Unfortunately, RNA tends to be a transient species by design, as cells have developed complex post-transcriptional mechanisms to regulate gene expression through mRNA decay. The problem is worse in certain tissues, such as pancreas, that secrete large amounts of degradative enzymes as part of their normal function. Though troublesome, the RNA decay problem can be overcome through specialized procedures that seek to inactivate **ribonuclease** enzymes concomitantly with RNA extraction from intact tissue.

Once total RNA is extracted from the subject tissue, the mRNA fraction is purified by annealing to oligodeoxythymidine (oligo-(dT)) cellulose. Oligo-(dT) is a short polymer that hybridizes specifically to polyadenylate. Because the majority of cellular mRNAs are **polyadenylated**, affinity chromatography over oligo-(dT) cellulose provides a simple means to remove contaminating RNA species, such as ribosomal and transfer RNAs, which do not contain poly A tails. The purified mRNA is then annealed to oligo-(dT), which serves as a primer that can be extended by the enzyme **reverse transcriptase** (RT). RT extension thus generates **antisense** DNA copies of the purified mRNA species. Under appropriate conditions, RT can be induced to complete a second-strand DNA synthesis, using the first DNA strand as a template. The result is a collection of double-stranded DNA copies of the parental mRNA population (hence the “c” in “cDNA”). The double-stranded DNA population can then be cloned into an appropriate plasmid or bacteriophage vector to constitute a cDNA library.
