Vertebrates carry multiple genes homologous to *hh*, including ***Sonic hedgehog*** (*Shh*), *Indian hedgehog* (*Ihh*), and *Desert hedgehog* (*Dhh*) (51). *Ihh* has been identified in mice, humans, and chicken, and its expression is detected in the developing midgut, lung, and cartilage of the bones. During bone morphogenesis, *Ihh* is expressed in prehypertrophic chondrocytes and controls the balance between ossification and proliferation through a second signal, parathyroid-related protein (PTHrP), which is secreted by perichondrial cells. Ectopic expression of *Ihh* leads to the ectopic induction of PTHrP. Misexpression of *Ihh* or PTHrP results in the disruption of bone development: cartilage elements are broadened, and the bones fail to ossify. On the other hand, premature ossification and insufficient growth of the bones are associated with loss of function of PTHrP or PTH/PTHrP receptor. The genetic analysis of PTHrP-mutant mice indicates that PTHrP is epistatic to *Ihh* and demonstrates that the differentiating prehypertrophic chondrocytes express *Ihh* to induce PTHrP expression in the adjacent perichondrium. The induced PTHrP signal acts as a negative-feedback cue on chondrocytes expressing PTH/PTHrP receptors, to ensure the proliferative status of the cells, and suppresses their early differentiation (52, 53). The mouse *Dhh* gene is involved in spermatogenesis and is proposed to support the survival of sperm cells (54).

2.1. *Sonic hedgehog (Shh)*

Shh is the best-studied *hedgehog* molecule because it is expressed early in embryogenesis and patterns multiple processes during development. These include the establishment of left-right asymmetry in early embryogenesis, specification of ventral neuron fate in the central nervous system, patterning of the dorsal-ventral axis of somites, establishment of the anterior-posterior axis, outgrowth of the limb buds, and eye development. *Shh* expression is first detected in the 8.0 days postcoitum (dpc) mouse embryo, prior to the first somite formation, in the node and the node-derived cells of the head process, which underlies the neural plate. As embryogenesis progresses and the embryo axis extends caudally, *Shh* is detected in the notochord, an extension of the head process, and in the floor plate cells overlying the notochord in the ventral midline of the neural tube. The timing of *Shh* expression in these midline structures matches the inductive activities manifested by the notochord and the floor plate (51, 55). Misexpression and explantation experiments have demonstrated that Shh secreted from the notochord induces the differentiation of floor plate cells and that Shh from both the notochord and the floor plate specifies the ventral neuronal differentiation in the brain and the motor neuron fate in the spinal cord (56-58). Misexpression of *Shh* by the Wnt-1 promoter in mouse embryos results in ectopic floor plate cell differentiation in the dorsal neural tube, as demonstrated by the expression of the floor plate cell marker, *HNF-3b* (hepatocyte nuclear factor 3b) (51). Treatment of neural tube explants with *Shh* conditioned medium also leads to induction of *HNF-3b* (56). Ablation of notochord, loss of *Shh* function, or antibody blockage experimentation provides further evidence that *Shh*, synthesized in the underlying notochord, is required for the induction of floor plate cell differentiation (58-60). The LIM (*l*in-11, *I*sl1, *m*ec-3) homeodomain protein, *Islet-1* (*Isl-1*), is an early ventral neuron marker. Neural tube explants, grown in contact with floor plate tissue or in *Shh*-conditioned medium, acquire ventral neuron fate by expressing *Isl-1*. However, explants from various levels of the neuraxis acquire different identities and express a number of different genes in addition to *Isl-1*, depending on their position along the neural axis. For example, when treated with *Shh*, neural plate cells caudal to the forebrain (rhombencephalon and spinal cord) express both *Isl-1* and *SC1*, which is characteristic of motor neurons, whereas explants from forebrain express *Isl-1* and *Nkx-2.1*, markers that are characteristic of ventral forebrain neurons. The ability of *Shh* to induce different types of ventral neuron fates along the rostrocaudal axis of the neural tube suggests that an early pre-pattern of positional information exists that dictates the differential response to *Shh* (56, 57).

In addition to the patterning of CNS, *Shh* also specifies the dorsal-ventral polarity of somites. Somites originate as spherical balls of epithelial cells derived from paraxial mesoderm flanking the notochord and neural tube. As development proceeds, somites undergo dorsal and ventral differentiation, giving rise to ventral-medial mesochymal sclerotome and dorsal-lateral epithelial dermomyotome. The sclerotome differentiates into axial skeleton including the vertebral column and ribs. The dorsal dermomyotome is subdivided into medial and lateral compartments, which give rise to epaxial (deep back) and hypaxial (limb and body wall) muscles, respectively. The dermis of the back is derived from the superficial epithelial cells that comprise the dermotome. *Shh* is required for both sclerotome differentiation and dermomyotome proliferation. Grafting notochord or floor plate on the dorsal somite enhances sclerotome formation and suppresses dermomyotome formation, suggesting that a substance secreted from the notochord and floor plate specifies ventral sclerotome differentiation (61, 62). Misexpression of *Shh* in the chick dorsal somite results in the dorsal expansion of *Pax-1*, a sclerotomal marker, and down-regulation of the dermomyotomal marker *Pax-*

3 (63) (see Pax Genes). Furthermore, mouse explants co-cultured with *Shh*-expressing cells have increased levels of *Pax-1* and decreased *Pax-3* expression, supporting the hypothesis that *Shh* from axial structures induces ventral sclerotomal cell fate (64). The differentiation and survival of dorsal-medial myotome cells require the inductive functions of both *Shh* from notochord/floor plate and the *wingless* homologue *Wnt* gene products that are derived from the dorsal neural tube (65-68).

The vertebrate limb evolves from both the lateral plate and the lateral edge of the somite. Mesochymal cells from the dorsal-lateral somite adjacent to the presumptive limb bud migrate laterally and give rise to the future limb musculature, and cells from the lateral plate proliferate and develop into the remaining limb tissues, including the bones and tendons. Limb development is a dynamic process orchestrated by multiple inductive signals from the posteriorly located zone of polarization activity (ZPA), the dorsal ectoderm, and the apical ectodermal ridge (AER) that abuts the anterior-posterior axis of the limb, at the distal tip where the dorsal and ventral surfaces meet. *Shh* is expressed in the ZPA and has been shown to establish anterior-posterior polarity in the limb and promote limb outgrowth (69). However, *Shh* alone is not sufficient to induce the expression of its target genes, *Bmp-2* and *Hox* gene cluster, which transduce the *Shh* signal to regulate limb patterning and growth (69, 70). The induction of these genes requires an additional signal, possibly **fibroblast growth factor**-4 (*FGF-4*), that is secreted from the overlying AER (71). *Shh* polarizes and maintains a functional AER. In a similar fashion, AER maintains *Shh* expression in the ZPA, establishing a positive feedback loop and an interdependence between these two inductive signaling centers (71). *Shh* and *FGFs* act together to induce the expression of *Bmp-2*, which relays a signal to induce or maintain *Hox* gene expression (71). Examination of lung and eye development indicates that *Shh* is also an inductive and mitogenic signal governing the growth and differentiation in these organs (72, 73).

3. Comparison of *hedgehog* Signaling in Flies and Vertebrates

The *hh* signaling cascade is well conserved between vertebrates and flies. Homologues of both *ptc* and *smo* have been identified in mammals, and their functions are conserved. Mutations in the mammalian *ptch* and *smo* are associated with familial and sporadic basal cell carcinoma, suggesting that these two homologues function as **tumor suppressor** genes (31, 74-76). Three homologues of *ci* exist in vertebrates: *Gli1, Gli2*, and *Gli3*, which exhibit distinct and overlapping expression patterns during development (77-80). Experiments with *Gli1* antisense and *Gli1* ectopic expression in different systems have shown that Gli1 is the major transcriptional activator that mediates the *Shh* signaling pathway, whereas Gli3 functions as a repressor (81-85). The function of *Gli2* overlaps both *Gli1* and *Gli3* in different developmental processes (85, 86). Mutations in *Gli1* are associated with glioblastoma and skin cancer (87), and those in the *Gli3* gene cause a dominant extra-toe phenotype in mice and are associated with Greg cephalopolysyndactyly syndrome in humans (88-90), suggesting that *Gli1* and*Gli3* function as tumor suppressors. The negative regulation of *Shh* signaling pathways by PKA is also conserved in vertebrates. Ectopic expression of a dominant-negative PKA mutant in the murine dorsal neural tube results in the ectopic expression of *Shh* target genes such as *HNF-3b, path*, and *Gli1*, and the suppression of the dorsal neuronal cell marker *Pax-3* (91). PKA activity has also been shown to antagonize the *Shh* signaling pathway in developing somites (64). Although the *hh* signaling pathways are conserved in most of the systems examined, there are differences between the vertebrate and Drosophila systems. The regulation of CI proteolysis in flies makes CI both an activator and a repressor, whereas in vertebrates it appears that the activation and repression functions are separated into two distinct genes, namely *Gli1* and *Gli3*, respectively. The level of the activated form of CI is regulated post-translationally in flies, whereas the Gli levels are regulated transcriptionally in vertebrates. Continued analysis of these important regulatory cascades will undoubtedly increase our understanding of developmental signaling pathways, their similarities, and their evolutionary divergence.

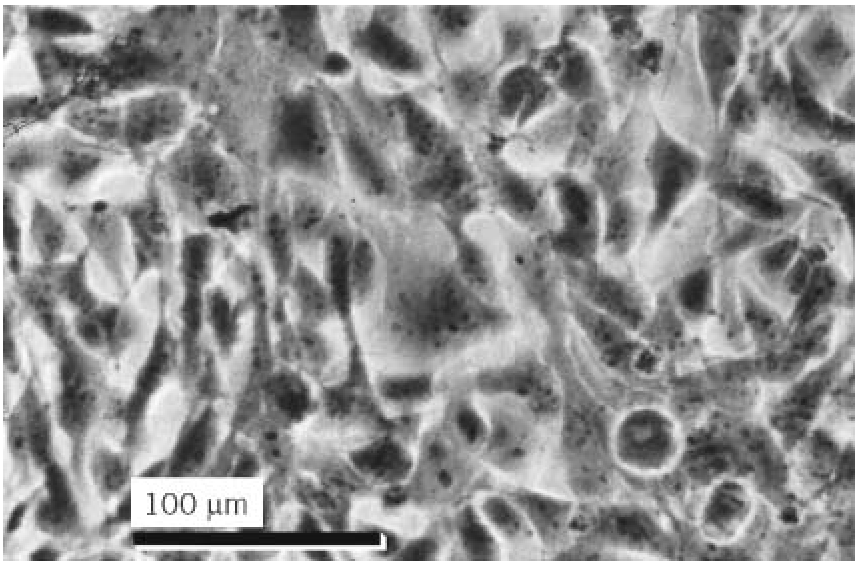
HeLa Cells

The HeLa cell line was originated by George Gey and co-workers in 1952 (1) from a cervical adenocarcinoma from a 31-year-old Afro-American female. It has proved to be a very vigorously growing cell line and is one of the most extensively used cell lines in the world. It is lodged at the American Type Culture Collection (ATCC) as CCL-2. It is even more extensively used than many people realize, because it is also guilty of cross-contaminating more cell lines than any other. HeLa was also the first human cell line to be cloned, when HeLa-S3 was isolated by Puck in 1956 (2). HeLa-S3 (Fig. 1) is in the ATCC catalogue as CCL-2.2. HeLa cells were originally propagated in a combination of human and calf serum (see Serum Dependence), but it has been shown that human serum is not necessary, and they are usually maintained in Eagle's Minimal Essential Medium supplemented with 10% fetal bovine serum. HeLa-S3 can be propagated in suspension using low-calcium medium (3).

Figure 1. Sub-confluent culture of Hela-S3 cells. Phase contrast, Olympus CK microscope, 20× objective.



1. Properties

HeLa is a continuous cell line with an **aneuploid** and heteroploid karyotype containing a number of marker chromosomes (4). It expresses the A subtype of glucose-6-phosphate dehydrogenase, which is present in Negroes and absent in Caucasians. The cells are cytokeratin positive, confirming their epithelial origin, contain **papilloma virus** sequences (HPV-18), and have low expression of p53 and normal **retinoblastoma** proteins (5). They have a short population doubling time (18–22 h) and high plating efficiency (60–80% in monolayer).

2. Usage

HeLa cells have been used for propagation and assay of **viruses** and have been shown to be susceptible to **poliovirus**-1,2,3, **adenovirus**-3, encephalomyocarditis, and coxsackievirus B[5]. They have been used in molecular studies (6, 7), in somatic hybridization analysis of senescence (8) and invasion (9), in fermentor culture for biotechnology (10), and for the development of serum-free media (11). As they are deficient in gap-junction communication, they have been used for transfection analysis of gap-junctional proteins (12). They have also been used for studies on molecular signaling (13).

HeLa-S3, a clone of HeLa (2), is one of the more rapidly dividing of the HeLa strains and can be grown in suspension with mechanical agitation. Because it is less well attached than the parental strain, mitotic cells are readily detached by shaking the flask, following partial cell-cycle blockade induced by short-term storage at 4°C, (14, 15). H-HeLa is a subline suitable for the passage and titration of rhinoviruses (16).

3. Cross-Contamination

HeLa was the first human cell line to be propagated widely in a large number of laboratories throughout the world. It is also a vigorously growing cell line with a high plating efficiency and is, therefore, ideally placed to cross-contaminate other cell lines. That this happened was first demonstrated many years ago by **isoenzyme** analysis (17) and subsequently by chromosomal analysis (18). Combined with more recent studies of DNA **fingerprinting**, it is now clear that a large number of continuous cell lines established in the 1960s and 1970s were cross-contaminated with HeLa cells, including lines such as KB (19) and Hep-2 (19, 20), which are still in regular use. The most serious aspect of this is that, although continued use may be quite acceptable in certain circumstances, few authors acknowledge that these lines are HeLa-contaminated, suggesting that a large part of the scientific community is still unaware of this problem, over 30 years after it was first revealed (21). Reports published by the ATCC (22), and the European Collection of Animal Cell Cultures (ECACC) (23), have confirmed that a significant proportion of cell lines in common use may be HeLa cross-contaminants.

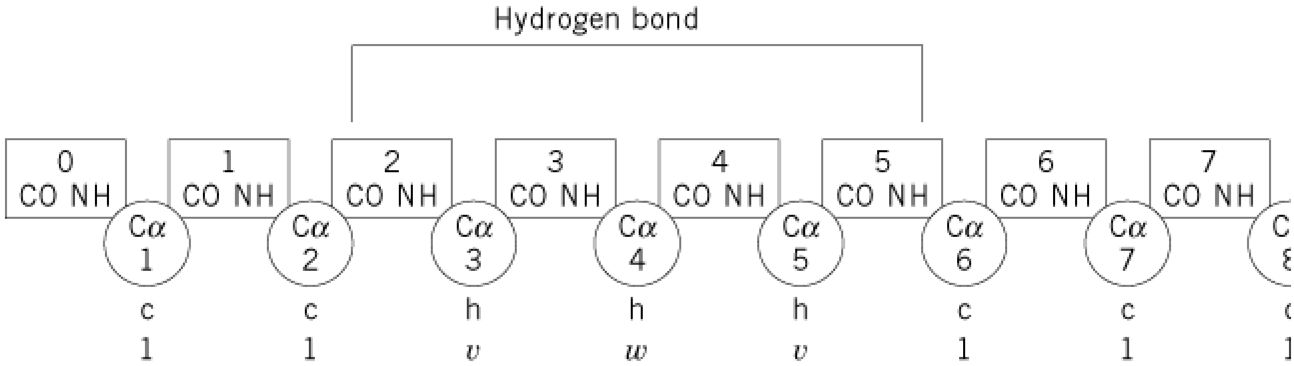
Helix–Coil Theory

Unlike many equilibrium folding–unfolding reactions in proteins that can be described adequately by a simple two-state folding mechanism, a-helix formation in polypeptides is not a simple two-state reaction from fully helical molecules to fully unstructured, or random coil, peptides. This multistate behavior results from mixtures of partially helical molecules, primarily with the ends of the peptide "frayed." From the architecture of the a-helix, this is easy to understand. The ends of an a-helix are different from positions in its center because at the *N*-terminus the NH groups, and at the *C*-terminus the C=O groups, are not paired in hydrogen bonds, which are important for stabilizing the helical conformation. Therefore, under optimal helix-forming conditions, the population of helical molecules represent a distribution of partially helical states. Several models, based on simple statistical mechanics, have been developed to describe the macroscopic properties of the system. Collectively, these are known as *helix–coil theories*, although helix to random coil (or nonhelical structure) is a more accurate description of the models.

The two most popular models for the helix–coil transition in peptides were developed independently by Zimm and Bragg (1) and by Lifson and Roig (2) in the late 1950s and early 1960s (see Zimm–Bragg Model and Lifson–Roig Model). The two models share similar features, with a few important differences. For each model, helix formation is a function of three basic parameters: (i) the chain length or number of residues in the polypeptide, (ii) a helix propagation parameter (*s* or *w* value), and (iii) a helix nucleation parameter (s or v^2). In each model, a single unit or residue can exist in only one of two possible conformations [helix or coil (*h* or *c*)] in the Lifson–Roig treatment, and the statistical weights (*v* or *w*) reflect the microscopic equilibrium constant for the transition between *h* and *c*. Helical residues, *h*, flanked on both sides by other *h* residues are assigned a weight *w*, whereas *h* residues at the ends of a stretch of *h* residues are assigned a weight of *v*. The nucleation parameter (v^2 in the Lifson–Roig treatment) reflects the "penalty," considered primarily entropic, to order three consecutive residues into a stabilized helical segment. Figure 1 illustrates this for the simple case of a helical peptide with one hydrogen bond stabilizing the helical conformation. The energetic difficulting in nucleating the a-helix imparts a degree of **cooperativity** to helix formation. Enumeration of all possible combinations of *h* and *c* residues for a polypeptide chain of a given length, along with the assigned statistical weights, provides the partition function for the system. The partition function can then be used to calculate average properties of the population, notably the fraction of helical residues, the average length and number of helical stretches, and other characteristics of the population.

Figure 1. Depiction of a peptide with one helical hydrogen bond formed. The squares represent the backbone peptide bo with the appropriate side chains. The C_a; groups are numbered, and the conformation of each residue is denoted as either peptide, the statistical weights are defined according to the Lifson–Roig model, using the coil state as a reference (weigh weight *v* and internal helical residues *w*.



The helix propagation parameter, *w* or *s*, is most closely akin to the helix propensity for a given residue. These helix propensities have recently been measured for all twenty amino acids found in proteins (see Alpha-Helix Formation). The Lifson–Roig model is also amenable to modification (3, 4) to include the energetics of other helix-stabilizing interactions, such as *N*- and *C*-capping and the interactions between side chains. A quantitative determination of these parameters, in conjunction with the Lifson–Roig model for the helix to coil transition, provides a reliable estimate of the amount of helix present in a peptide of any sequence.

Helix-Turn-Helix Motif

The helix-turn-helix motif was first identified as a conserved sequence element in the repressors encoded by the lambdoid phages of *E. coli* and *Salmonella typhimurium*. Subsequently this element has been found in a large variety of DNA-binding proteins, both in prokaryotes and in eukaryotes, and shows a very high degree of structural conservation. This DNA-binding domain consists of two short a-helices that usually are separated by a glycine residue. This amino acid in concert with its neighbors acts as a flexible hinge allowing the polypeptide chain to bend between the two helices so that they can make hydrophobic contacts with each other. These contacts preserve the relative orientation of the two helices and result in the formation of a compact tertiary structural domain. The distal helix lies in the DNA major groove and the proximal helix contacts the sugar-phosphate backbone. Although the structure of this domain is highly conserved, the orientation of the recognition helix within the major groove is quite variable. This feature suggests that the motif is a structure that possesses a rigidity which is necessary for precise sequence recognition.

Related to the prokaryotic **helix-turn-helix** fold are protein folds of essentially the same fundamental structure, but which contain longer turns or loops. These eukaryotic variants include the homeodomain fold, which contains both a helix-turn-helix element and a short extended minor groove-tracking sequence, the POU-specific domain, and the helix-wing-helix fold. The latter fold contains an extended b sheet immediately following the recognition helix and is typified by hepatocyte nuclear factor 3 (HNF3) and the globular domain of the linker histones, H5 and H1. Whereas the prokaryotic proteins usually bind as homodimers and bind to palindromic DNA targets, the eukaryotic counterparts normally bind as monomers.

Helper Plasmid

In the context of genetic transformation of **plants**, a helper plasmid is a **plasmid** present in Agrobacterium that provides functions required by the **bacteria** for transferring foreign **DNA** to a plant cell. They have been extremely important in plant genetic engineering. Generally, helper plasmids are derivatives of the Ti plasmid that contain an active virulence region, but from which the T-DNA has been removed.

Central to the concept of developing the binary vector system for *Agrobacterium*-mediated plant cell transformation was the finding that the **genes** contained on the T-DNA are not required for its transfer to the plant cell, that this function is provided by gene products of the virulence region of the Ti plasmid, and that they are trans-acting (1). In practice, this means that foreign DNA to be transferred to the plant cell can be **cloned** between the T-DNA border sequences in any plasmid that is stable in *Agrobacterium*. Then, such a plasmid, known as the binary vector, can be transferred to *Agrobacterium* that contains a helper plasmid by **conjugation**, electroporation, or transformation (see Transfection). Helper plasmids are based on deletion derivatives of Ti plasmid that lack the T-DNA. The helper plasmid provides the functions required for transferring the foreign DNA located between the T-DNA borders of the binary vector to the plant cell. The most widely used binary vector/helper plasmid system is the pBin binary vector (2) used in combination with the LBA4404 helper plasmid (1).

Helper Virus

Some **viruses** require the gene functions of other viruses to replicate. The viruses that rescue such replication-deficient viruses are known as helper viruses. Adenoviruses, herpes simplex virus 1 and 2 (HSV-1, HSV-2) (see Herpesvirus), cytomegalovirus, and pseudorabies virus are helpers for adeno-associated viruses (AAVs), dependoviruses of *Parvoviridae* family. In addition, hepatitis B virus is a helper virus for hepatitis D virus, and most standard viruses are helpers for their deletion mutants, which are called defective interfering particles. Defective viruses and their helper viruses are usually closely related in many replication processes (see Rous Sarcoma Virus (RSV)). It is now considered, however, that the helper functions are not simple and that they involve the interaction between virus and cells in addition to between defective virus and helper virus.

Genetic analysis of helper functions has been most extensive for adenoviruses. Five regions of the adenovirus genome are required for a permissive AAV infection. They are the E1A, E1B, E2A, E4, and VA regions. The E1A region is required for the *trans*-activation of the AAV p5 and p19 promoters. The E1B-coded 55-kDa transforming protein and the E4 gene product, a 35-kDa protein, are both required for the efficient accumulation of AAV messenger RNAs. Their role in AAV replication is believed to be to stabilize the AAV mRNAs and assist their transport to the cytoplasm. The E2A gene product, an adenovirus DNA-binding protein, and the adenovirus VA RNAs are required primarily for the efficient translation of AAV mRNA to produce the viral capsid protein.

Although a helper virus is necessary for fully permissive AAV infection, helper virus genes appear not to be directly involved in AAV DNA replication. AAV DNA replication may use primarily cellular factors that exist in cells. The role of helper virus gene products may stimulate the synthesis of cellular genes that are required for AAV DNA replication.

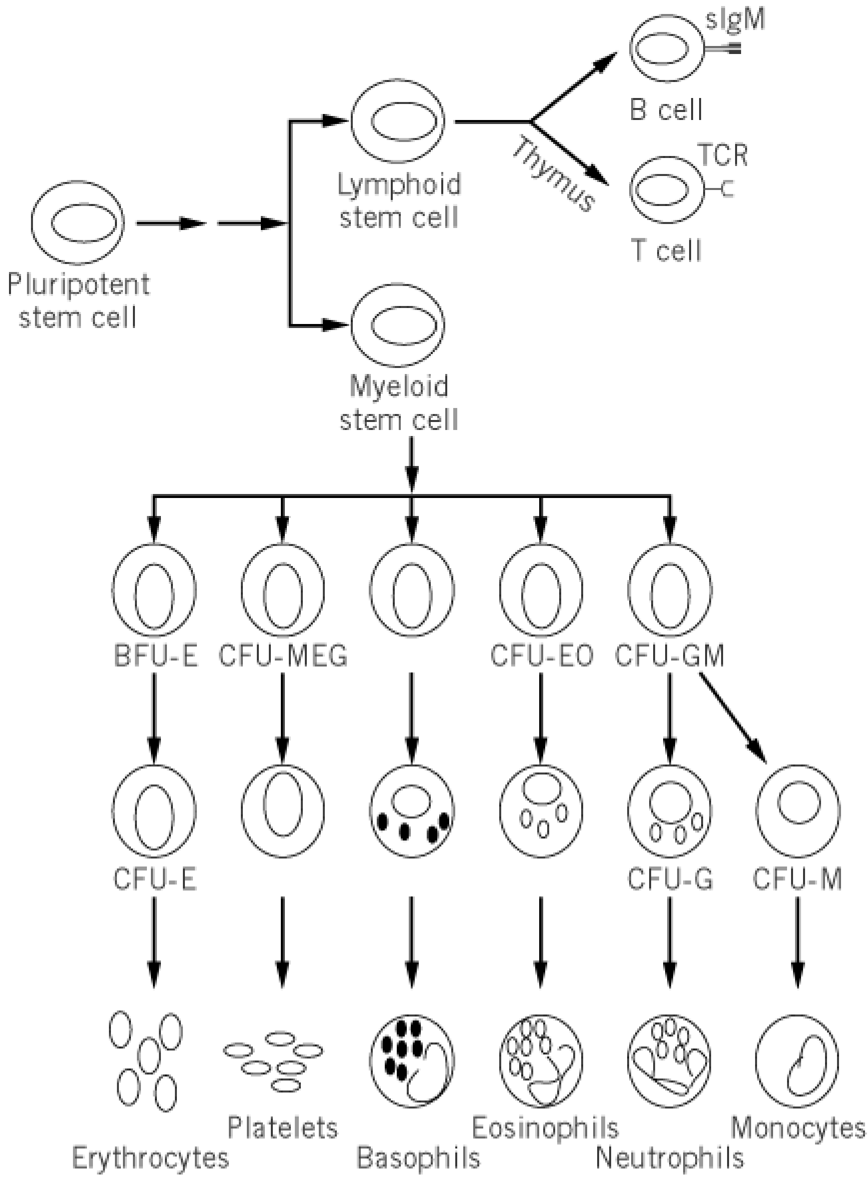
Hematopoiesis

Hematopoiesis is a dynamic process in which blood cells of at least eight distinct lineages must be continually replaced from a population of pluripotent hematopoietic stem cells throughout the life span of the animal. The hematopoietic stem cell is a relatively rare cell, estimated to be approximately 0.001% of nucleated bone marrow cells. Stem cells are normally quiescent, in either the G0 or G1 phase of the cell cycle. Hematopoiesis involves the progressive restriction of the developmental potential of hematopoietic progenitors, with a concomitant increase in their proliferative capacity. Conversely, the self-renewal capacity of hematopoietic progenitor cells progressively decreases with the restriction of their developmental potential, with most mature cell types having short life spans and little or no proliferative capacity. In order to produce the correct numbers of mature blood cells, this balance between proliferation and differentiation of hematopoietic progenitors must be tightly controlled. Perturbation of this delicate balance can result in leukemogenesis or in anemias, immunodeficiencies, and other cellular deficiency disorders.

The existence of hematopoietic progenitor and stem cells can be inferred by the progeny they produce. Transplantation of lethally irradiated mice with cells from syngeneic donors has been the classical approach to demonstrate the presence of repopulating hematopoietic stem cells. The first 4 to 6 months after engraftment is characterized by clonal fluctuations in stem cell proliferation and differentiation, followed by the emergence of a stable hematopoietic system, dominated by a small number of totipotent clones. In addition, the extensive self-renewal capacity of these cells can be demonstrated by their ability to reconstitute recipient animals after serial transplantations. Competitive repopulation assays, in which two genetically distinct populations of bone marrow cells are transplanted together into the same recipient, can be used to determine the effects of a specific genetic alteration on the viability of repopulating hematopoietic stem cells.

The earliest restriction in developmental potential of hematopoietic stem cells involves the generation of putative lymphoid- and myeloid-restricted stem cells from the pluripotent myeloid-lymphoid stem cell. Myeloid-restricted stem cells can be detected by the classic spleen colony assay. In this assay, limiting numbers of bone marrow cells are injected into lethally irradiated recipient mice, giving rise to the formation of macroscopic hematopoietic colonies in the spleen within eight days, each derived from a single progenitor cell. These cells, termed CFU-S (colony-forming unit-spleen), are pluripotent and can give rise to all hematopoietic cells of the myeloid lineage. They possess only limited self-renewal capacity, as measured by their ability, on retransplantation, to give rise to secondary spleen colonies. In addition, CFU-S cannot readily confer hematopoietic repopulation and long-term survival of recipient mice. Additionally, progenitor cells that form spleen colonies at day 12 to 14 after transplantation are more potent in terms of repopulating ability than are day 8 CFU-S cells, suggesting that the spleen colony assay detects a range of cells that differ in their proliferative or repopulation potential.

Figure 1. Schematic of adult hematopoiesis.

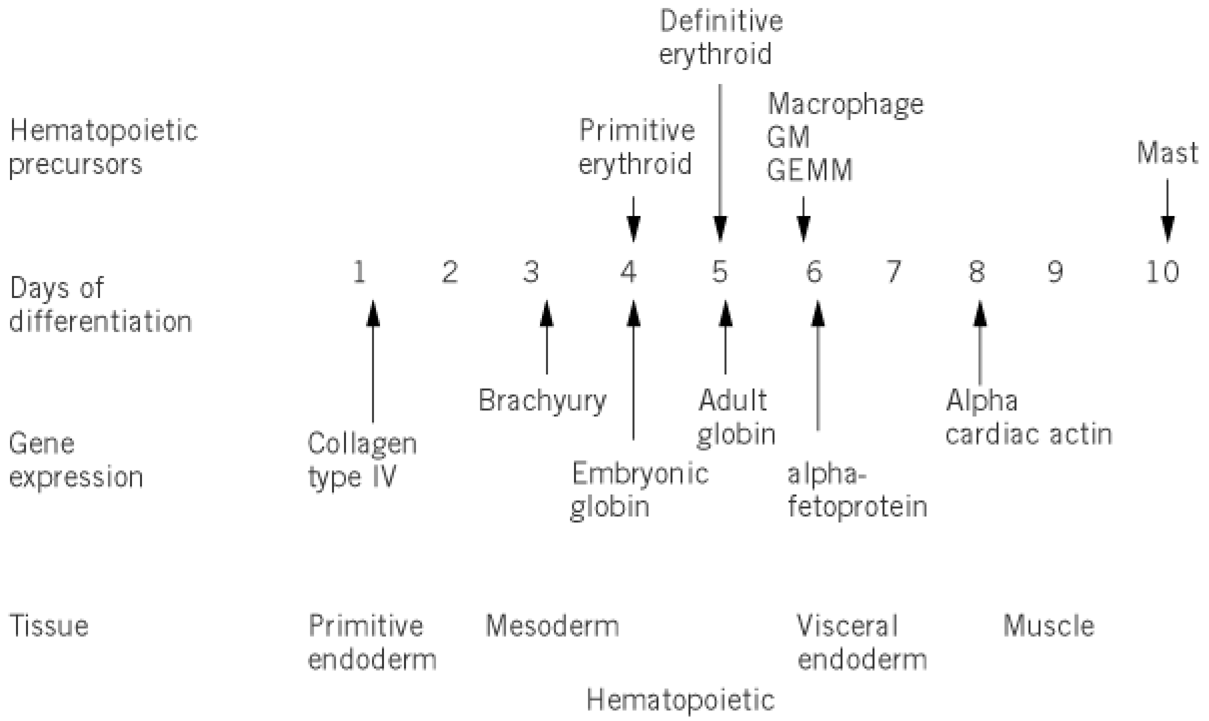


The presence of more restricted hematopoietic progenitor cells can be demonstrated by their ability to form colonies of differentiated blood cells in a semisolid medium in the presence of hematopoeitic growth factors. Multipotential hematopoietic cytokines, including interleukins IL-3 (multipotential CF), IL-4, and granulocyte/macrophage colony stimulating factor (GM-CSF), are capable of supporting the proliferation of multilineage progenitor cells, resulting in the formation of colonies containing multiple hematopoietic lineages. Lineage-specific growth factors, such as erythropoietin, granulocyte CSF (G-CSF), or macrophage CSF (M-CSF or CSF-1), enhance proliferation and differentiation of committed progenitor cells forming colonies of nucleated red blood cells, neutrophils, and macrophages, respectively. A final group of cytokines, including IL-6, IL-11, and Steel (stem cell factor, c-kit ligand), act synergistically with the multilineage and lineage-specific cytokines to enhance colony formation in culture by shortening the G0 period of the hematopoietic progenitors.

During mouse embryogenesis, the first visible sign of hematopoiesis appears in the extraembryonic mesoderm of the day 7.5 yolk sac in the form of blood islands. These blood islands contain primarily primitive erythrocytes, which are large, nucleated cells expressing embryonic hemoglobin, although adult globins are synthesized and accumulate in these cells at later stages of development. Cells of the monocyte-macrophage lineage also appear in the yolk sac. Although the differentiated hematopoietic cells found in the yolk sac are restricted to cells of the erythroid and macrophage lineages, progenitor cells found in the yolk sac at later stages of development can differentiate into various hematopoietic lineages *in vitro* and have been reported to be capable of forming CFU-S *in vivo*, demonstrating the multipotency of these cells. Furthermore, repopulation of recipient animals with yolk sac–derived hematopoietic cells has been reported, suggesting the presence of repopulating hematopoietic stem cells within the yolk sac environment.

Around day 10 of embryonic development, the primary site of hematopoiesis switches from the yolk sac to the fetal liver, the main site of fetal hematopoiesis. The fetal liver produces predominantly cells of the definitive erythroid lineage, expressing adult hemoglobins, as well as some myeloid and lymphoid cells. Various progenitor and stem cells, including CFU-S and pluripotent hematopoietic stem cells capable of long-term repopulation of recipient mice, are all present at a high frequency in the fetal liver. The fetal liver remains the primary erythropoietic organ until shortly before birth, when the major site of hematopoiesis shifts, once again, to the bone marrow. Within the intersinusoidal spaces of the medullary cavity of the bone, hematopoietic cells are found closely associated with the stroma. These cells directly influence hematopoiesis through cell–cell interactions and the production of cytokines, forming a microenvironment that supports blood cell production.

Figure 2. Time course of embryoid body development. Gene expression and presence of hematopoietic precursors are shown.



It has long been accepted that, during embryogenesis, the hematopoietic stem cells (HSCS) that originate in the yolk sac migrate to the fetal liver to initiate the second wave of hematopoiesis. However, recent findings of hematopoietic cells in the para-aortic splanchnopleure of mouse embryos prior to colonization of the fetal liver (1-3) suggest the possibility of another source of hematopoiesis in the embryo proper. It is unclear at this time whether the cells involved in primitive hematopoiesis in the yolk sac are precursors to the cells involved in definitive hematopoiesis or whether definitive hematopoiesis develops independently in the embryo proper. Transplantation studies using the adult mouse as a recipient demonstrated HSC activity in the aorta, gonads, and mesonephros (AGM) region of the embryo at day 10, followed by the fetal liver and yolk sac on day 11 (3, 4). These studies suggest that the first definitive HSCs arise in the AGM region and migrate to the fetal liver to establish definitive hematopoiesis. However, transplantation studies utilizing newborn or embryonic mice as recipients demonstrated the presence of HSCs contributing to definitive hematopoiesis in the yolk sac as early as day 9 (5), lending support to previous models. Although the origin of definitive hematopoiesis remains in debate, microenvironment is clearly a crucial element in the regulation of HSC potential.

The study of murine hematopoietic development, and the role of the microenvironment in this process, has been greatly facilitated by the establishment of *in vitro* model systems in which embryonic stem (ES) cells are differentiated to form cells of the hematopoietic system. Coculture of ES cells with primary bone marrow stroma or stromal cell lines results in the formation of a variety of hematopoietic cells including those of the erythroid, myeloid, B, and T cell lineages (6-8). Additionally, if the leukemia inhibitory factor is removed from the medium and the cells are grown in suspension, ES cells will form primitive embryonic structures termed *embryoid bodies* (EBs), which contain a vasculature and closely resemble the visceral yolk sac of the post-implantation embryo. These EBs contain many differentiated cell types, including those of the hematopoietic system, easily detectable by the appearance of visible blood islands containing red blood cells with hemoglobin.

ES-derived EBs express many genes that serve as markers of tissue restriction and lineage commitment during hematopoietic development (9-11), including the full complement of globin genes in the correct temporal order (12). EBs also contain precursors of the primitive erythroid, definitive erythroid, macrophage, neutrophil, and mast cell lineages, as demonstrated by colony-forming assays (10, 11, 13). Later in EB development, differentiated megakaryocytes, neutrophils, eosinophils, and mast cells also appear (14). Additionally, ES cell-derived EBs contain B and T cell precursors (15) and markers indicative of B and T lymphoid cells (16).

The *in vitro* differentiation of ES cells into cells of the hematopoietic system has been utilized to address the question of the origin of primitive versus definitive hematopoiesis. It remains unclear, however, whether primitive and definitive erythrocytes develop from common or distinct precursors in this system (17, 18). Recent evidence from Xenopus suggests the presence of bipotential primitive-definitive hematopoietic progenitors in the vertebrate embryo (19). However, the detectability of primitive erythrocytes in the yolk sac prior to the appearance of hematopoietic progenitor and stem cells in that tissue indicates that the traditional hierarchy of adult hematopoiesis may not apply in the context of primitive hematopoiesis.

The molecular events that regulate the development and maintenance of the hematopoietic system are beginning to come to light. A great deal of the work that forms the basis of this knowledge has been elucidated using the mouse as a model system. The combination of naturally occurring mutations and those generated by homologous recombination in ES cells has produced a battery of mutant ES and mouse lines, which have been instrumental in revealing the molecular biology of hematopoiesis. Furthermore, *in vitro* differentiation of homozygous mutant ES cells has provided additional information regarding the specific role of the targeted genes during hematopoietic development. Some of the genes that have been identified as essential for the development of hematopoietic stem cells during embryogenesis, or the functioning of these cells in the adult, are listed in Table 1.

Table 1. Hematopoietic Mutants

Disrupted Gene	Encoded Protein	Model	Phenotype

CBFa2 (AML1) (42)	Runt homology domain (RHD) TF[a]	KO mice	Block in definitive hematopoiesis
			Stem cell defect
CBFb (43)	Subunit of CBF	KO mice	Same as CBFa2
EKLF (32)	Zinc finger TF	KO mice	Block in definitive erythropoiesis
EpoR (29, 30)	Erythropoietin receptor	KO mice	Block in definitive erythropoiesis
Flk1 (27)	RTK	KO mice/EBs	Stem cell defect
GATA-1 (36, 37)	Zinc Finger TF	KO mice/EBs	Block in primitive erythropoiesis
			Block in definitive erythrocyte maturation
GATA-2 (38, 39)	Zinc Finger TF	KO mice/EBs	Stem cell defect
Kit (20)	RTK	*Dominant White Spotting (W)*	Stem cell defect
			Macrocytic anemia
			Mast cell deficiency
Myb (40)	Myb domain TF	KO mice	Reduced definitive erythroid and myeloid precursors
PU.1 (Spi-1) (41)	Ets domain TF	KO mice	Block in definitive erythroid maturation
			Stem cell defect
Rbtn2 (31)	LIM domain TF	KO mice/EBs	Block in erythroid maturation
Shp-1 (22, 23)	Tyrosine phosphatase	*Motheaten (me)*	Increased myelopoiesis
Steel (20)	Ligand for *c-kit*	*Steel (Sl)*	Same as *W*
Tal-1/SCL (33-35)	Basic HLH TF	KO mice	Lack of erythroid and myeloid precursors

[a] Key: TF, transcription factor; RTK, receptor tyrosine kinase; KO, knockout; EBs, embryoid bodies.

The process of hematopoiesis is controlled by a number of hematopoietic growth factors, which bind to specific cell surface **receptors** and generate a complex series of intracellular signaling events. These signaling events culminate in changes in **gene expression**, which direct the cell toward proliferation or differentiation. The major strategy by which hematopoietic cells interpret extracellular signals is through the activation of receptors that either possess intrinsic **tyrosine kinase** activity or are coupled to cytoplasmic proteins with tyrosine kinase activity. Several of these receptors have been shown to play a role in the regulation of hematopoietic stem cells and to be crucial for the proper development of the hematopoietic system. Naturally occurring mutations in the receptor tyrosine kinase, c-kit (*W*), and its ligand, steel factor (*Sl*), have uncovered an important role for this signaling pathway in the regulation of hematopoietic stem cells (20). In addition to macrocytic anemia and mast cell deficiency, hematopoietic cells from *W* mice show defects in spleen colony formation and in long-term reconstitution of lethally irradiated recipient mice. In contrast, *Sl* mutant mice have a defective microenvironment that is unable to support the growth of normal stem cells. Genetic and biochemical analysis has revealed two other naturally occurring mutations that form part of the Kit-Steel signaling pathway (21). These mouse loci, *motheaten* (*me*) (22, 23) and *micropthalmia* (*mi*) (24, 25), encode a protein tyrosine phosphatase (Shp-1) and a basic helix-loop-helix transcription factor (MITF), respectively.

Gene targeting strategies have also led to the identification of several hematopoietic receptors that are essential for normal hematopoietic development. One of these receptors is Flk1, a receptor tyrosine kinase that binds *vascular endothelial growth factor* (VEGF). Mice homozygous for a mutation in Flk1 lack both mature endothelial and hematopoietic cells (26). In addition, Flk1 -/- ES cells do not contribute to primitive or definitive hematopoiesis *in vitro* or *in vivo* (27), demonstrating a close association between the molecular and cellular regulation of vasculogenesis and hematopoiesis. Gene targeting of STK, a tyrosine kinase receptor of the Met family isolated from a hematopoietic stem cell cDNA library, has demonstrated a role for this receptor in the negative regulation of macrophage activation and nitric oxide production during a cell-mediated immune response (28).

A second class of cell surface receptors that are important for hematopoietic differentiation contains the cytokine receptors, which signal through the Jak/Stat pathway. An example of this class of receptors, which effects the proliferation and survival of erythroid progenitors, is the erythropoietin (epo) receptor. Mice homozygous for mutations in epo or the epo receptor die at embryonic day 13 from a failure of definitive fetal liver erythropoiesis (29, 30). Committed BFU-E (burst-forming unit-erythroid) and CFU-E (colony-forming unit-erythroid) progenitors are present in these mice, suggesting that the epo signaling pathway is necessary for the proliferation and survival of CFU-E progenitors but not for erythroid lineage commitment.

The signaling events generated in response to the engagement of hematopoietic receptors by their respective ligands culminate in changes in gene expression, which direct the cell toward proliferation or differentiation. Genetic analysis in mice has also revealed several transcription factors that are essential for the development of hematopoietic precursors. Collectively, these transcription factors regulate the expression of hematopoietic-specific genes that are important for the differentiation of multiple blood cell lineages from the pluripotential hematopoietic stem cell. Some of these factors are specific for the development of the erythropoietic lineage (GATA-1, EKLF, Rbtn2), suggesting a role in erythroid commitment and/or maturation. Other factors play a more global role in regulating the proliferation versus differentiation of primitive hematopoietic progenitors (PU.1, GATA-2, Myb, SCL/Tal-1). Interestingly, these studies suggest that primitive and definitive hematopoiesis are controlled by somewhat distinct molecular mechanisms. Disruption of genes encoding Rbtn2 (31), SCL/Tal-1 (32-35), GATA-1 (36, 37), or GATA-2 (38, 39) block both primitive and definitive erythropoiesis, whereas mutations in c-myb (40), PU.1 (41), EKLF (32), and CBF a and b (42, 43) affect only definitive erythropoiesis.

The list of mouse mutations effecting the development of the hematopoietic system is growing rapidly. Furthermore, many mutations exist that result in mild alterations in the regulation of adult hematopoiesis rather than in a complete block in hematopoiesis. This finding suggests some redundancy in the pathways that ultimately culminate in proliferation and differentiation of hematopoietic cells. The generation of mice with mutations in multiple genes involved in the regulation of hematopoiesis will be instrumental in the characterization of hematopoietic signaling pathways, as well as in the identification of points at which these pathways intersect.

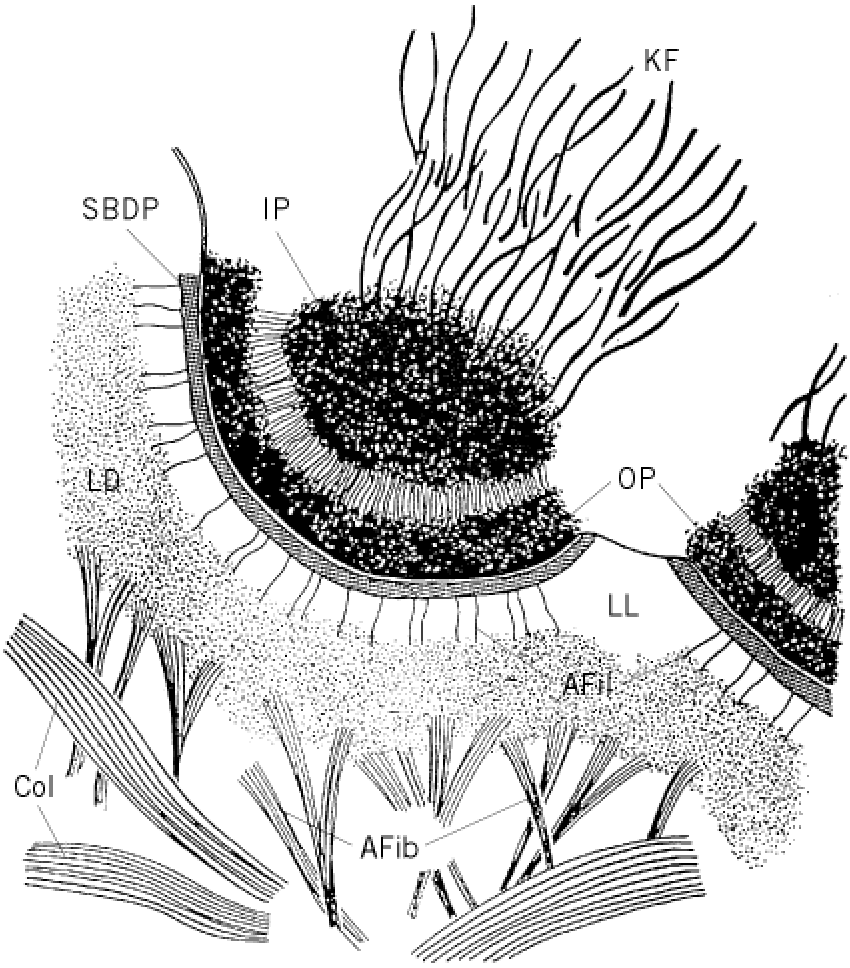
Hemidesmosomes

Hemidesmosomes are cell junctions that are recognized by their ultrastructural appearance (Fig. 1). Located at the basal cell surface, their most prominent feature in cross section is a dense outer plaque closely applied to the inner surface of the plasma membrane (1). The outer plaque is separated by a less dense region from an inner dense plaque, from which intermediate filaments extend into the cytoplasm. The whole structure forms a circular membrane domain of no more than 0.5 micrometres in diameter and approximately 150 nm deep from the plasma membrane to the inner surface of the inner plaque. The extracellular face of the hemidesmosome is in contact with the lamina lucida of the basement membrane. This region is characterized by the presence of fine anchoring filaments that extend from the plasma membrane across the lamina lucida to the lamina densa. In some sections a linear density called the sub-basal dense plate is seen in the lamina lucida, closely associated with the extracellular face of the hemidesmosomal plasma membrane. Particularly in the epidermis and amnion, the matrix beneath the basement membrane contains numerous banded structures, called anchoring fibrils, which insert into the lamina densa. In favorable sections, filamentous continuity between the anchoring fibrils and the anchoring filaments can be observed. This means that there is continuity of structure in epidermis from the dermis right through to the intermediate filament cytoskeleton of the epidermal cells, in which the hemidesmosome itself provides the transmembrane connection. Such continuity appears to be essential for strong adhesive binding of the epidermis to the dermis, because genetic defects leading to absence or abnormality of anchoring fibrils, anchoring filaments, hemidesmosomes, or basal cell keratin filaments give rise to blistering diseases involving loss of adhesion between the epidermis and the dermis (see below). Although hemidesmosomes appear to resemble half **desmosomes**, they are in fact quite different structures, with a unique and distinct molecular composition (2).

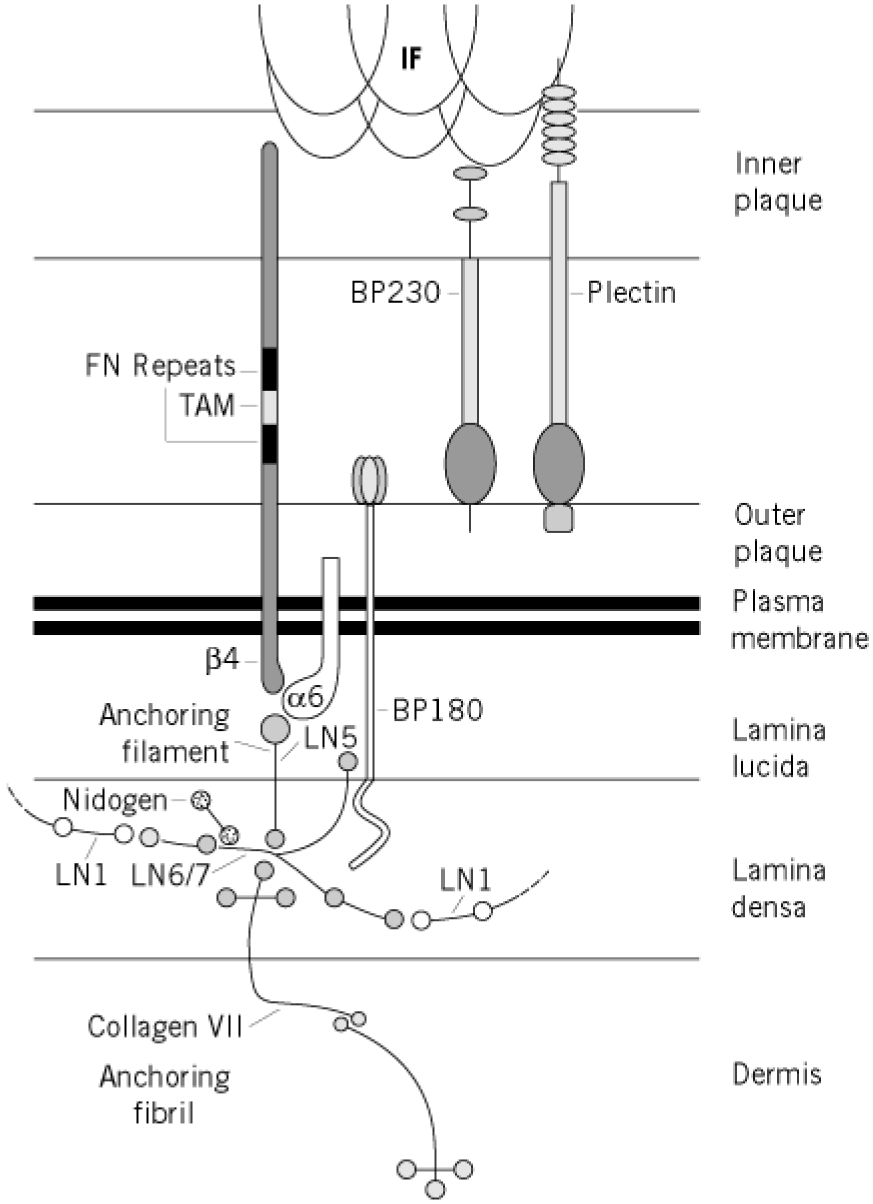
Figure 1. Drawing of an epidermal hemidesmosome seen by electron microscopy. Afib = anchoring fibril; Afil = anchoring filament; Col-dermal collagen fiber; IP = inner plaque; KF = keratin filaments; LD = lamina densa; LL = lamina lucida; SBDP = sub–basal dense plate.



The major molecular components of hemidesmosomes are shown in Figure 2 . The principal adhesion molecule is a6b4 integrin (3), a heterodimer that is extremely abundant on the basal surface of epidermal cells. The b4 subunit is unique among integrin b subunits in having an extremely long cytoplasmic domain of approximately 1000 amino acid residues. The extracellular **domains** of the integrin subunits lie in the lamina lucida of the basement membrane, and their cytoplasmic domains in the hemidesmosomal plaque. The other adhesion molecule is bullous pemphigoid antigen 2 (BPAG2 or BP180), a Type 2 membrane protein whose amino-terminus lies within the desmosomal plaque and the carboxy-terminus in the basement membrane (4). BPAG2 is also referred to as collagen XVII, because it has collagenous repeats in its extracellular domain. a6b4 integrin binds to the truncated **laminin** molecule, laminin 5, which is covalently complexed with laminin 6 or laminin 7 (5). Laminin 5, together with the extracellular domain of BP180, constitutes the anchoring filaments. Laminin 6 and 7 interact with other laminins in the basement membrane and also with nidogen, which links them to other basement membrane components. In addition, they bind to the specific component of anchoring fibrils, collagen VII (6). The anchoring fibrils descend from the lamina densa of the basement membrane into the underlying dermis. The principal plaque components of the hemidesmosome are bullous pemphigoid antigen 1 (BPAG1 or BP230) and plectin (7, 8). Both are members of the plakin family, which also includes desmoplakin, envoplakin, and periplakin of the **desmosome** . BP230 and plectin are believed to be involved in linking between the hemidesmosomal plaque and the intermediate filaments. Although not shown in the diagram, direct interaction between plectin and a6b4 integrin has been demonstrated (9).

Figure 2. Diagrammatic impression of the molecular composition of a hemidesmosome employing information from a

number of sources. a6 = a6 integrin subunit; b4 = b4 subunit; BP180 = 180kDa bullous pemphogoid antigen (BPAG2); BP230 = 230kDa bullous pemphigoid antigen (BPAG1); FN = fibronectin; IF = intermediate filaments; LN 1, 5, 6, 7 = laminins 1, 5, 6, and 7; TAM = tyrosine activation motif.



A number of human diseases have been extremely important in elucidating the composition and function of hemidesmosomes. In the **autoimmune** blistering disease bullous pemphigoid, **antibodies** against BPAG1 and 2 are commonly found. Those against an extracellular juxta membrane epitope of BPAG2 have been shown to be pathogenic (10). A number of genetic diseases, collectively known as epidermolysis bullosa (EB), affect basal cells of epidermis and epidermal-basement membrane adhesion. EB simplex involves the basal cell keratins, K5 and K14 (see Keratins). Such mutations disrupt the assembly of the basal cell intermediate filaments and result in cell breakage at a level above the hemidesmosomes (11). The junctional form of EB (EBJ) involves mutations in the a, b, or g chains of laminin 5 or in $a_6 b_4$ integrin (12). This is a lethal disease resulting in epidermal detachment at the level of the basement membrane. EB dystrophica results from mutations of the anchoring fibril component Type VII collagen (13). Anchoring fibrils fail to form, and the epidermis becomes detached below the level of the basement membrane. The importance of plectin in hemidesmosomes has been revealed by the disease EB with muscular dystrophy (14). Here attachment of intermediate filaments from the hemidesmosomal plaque occurs in basal epidermal cells, resulting in epidermal blistering. This is followed later in life by muscular weakening, arising from absence of plectin from the submembrane cytoskeleton of skeletal muscle fibers. Null mutations of a6b4 integrin, plectin, and BP230 produce phenotypes consistent with the defects found in human disease (15-18). This work suggests that BPAG1 forms a similar function to plectin in attaching intermediate filaments to the plaque. The BPAG1 null nutation revealed an additional function for this molecule in the nervous system (17). BPAG1–/– mice develop severe dystonia, resulting in abnormal limb positioning and loss of involvement through muscle and nerve regeneration. This is reminiscent of a hereditary neurodegenerative disease of mice called *dystonia musculorum (dt/dt)*. *dt* is allelic with BP230. It appears that alternative splicing of the amino-terminus of BPAG1 in the nervous system promotes interaction with actin, and its absence results in disorganisation of the neuronal cytoskeleton (19). It is noteworthy that the dermal epidermal junction requires extremely strong adhesion of cells to the extracellular matrix. This may be why hemidesmosomes have two adhesion molecules and two molecules to bridge between the plaque and the intermediate filaments.

Hemizygote

The notion of *hemizygosity* has historical importance in bacterial **genetics**. After the early demonstration by Lederberg of genetic recombination in *Escherichia coli* and the extension of genetic analysis to include a much wider range of unselected markers, a number of complicated anomalies of chromosome segregation began to appear showing that this bacterial system is unconventional. A particular segment of the chromosome of one of the parents, identified by a pair of linked markers, was virtually missing from the **heterozygotes** generated initially and failed to appear in their haploid progeny. These initial **diploids** were incomplete (*hemizygous*). It was first wrongly thought that the missing segment was eliminated from them after their formation. The phenomenon was even given the name of *postzygotic exclusion* . Analysis of this phenomenon led to the discovery of sexuality in bacteria and to the notion of circular chromosome, which resolved the difficulties. To avoid confusion, the term *merozygote* should be used instead of hemizygote for these incomplete and transient heterozygotes.

The term hemizygote should be restricted to a diploid cell or individual in which one of the two copies of a given **gene** has been lost either by deletion or loss of a chromosome. Heterogametic species, in particular human males, are said to be hemizygous for genes located on the X-chromosome and not on the Y-Chromosome (and vice versa).

Hemoglobin

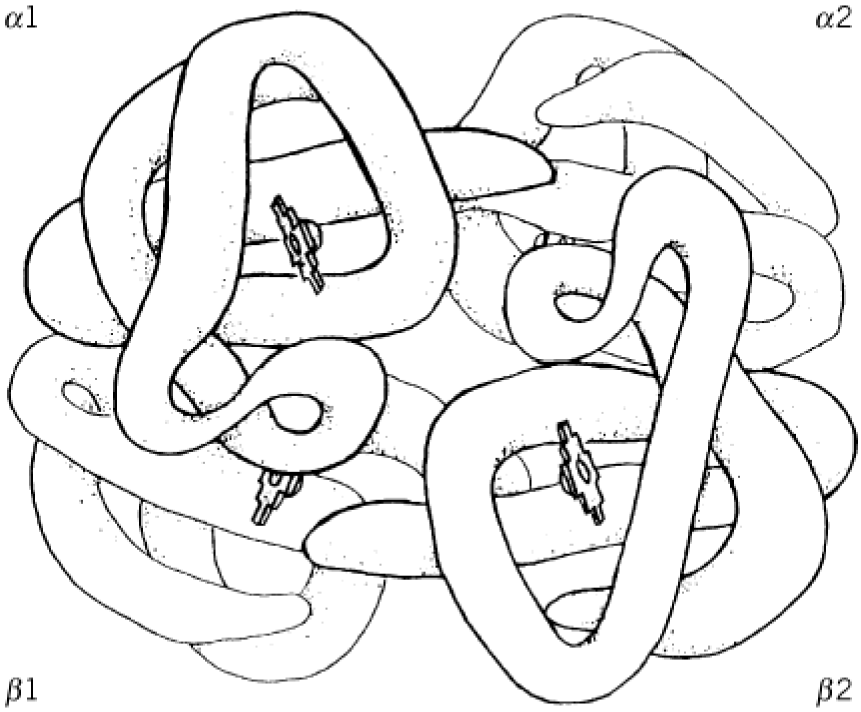
Hemoglobin (Hb) is one of the heme-containing oxygen-binding proteins, that generally contain a globin polypeptide chain and a protoheme IX **prosthetic group** that contains a ferrous iron atom. It is found in circulating fluids (blood or hemolymph) of animals, where its fundamental function is transport of molecular oxygen. Its **phylogenetic** distribution is wide, but somewhat capricious. All of the vertebrates, except icefish, have a Hb within their red blood cells that is a tetramer made up of two pairs of two different subunits, each a globin polypeptide chain that contains one heme group. In contrast, invertebrate Hbs are strikingly variable, in their architecture and size, and also in their function. They can be either intracellular or extracellular. Generally, an intracellular Hb is relatively small, whereas extracellular Hbs have a molecular mass ranging from 250 to 3500 kDa. The latter are polymeric and are dissolved directly in the blood plasma, hemolymph, or coelomic fluid. The invertebrate extracellular Hbs have been known traditionally as *erythrocruorins*, but this term lost its significance when it became apparent that there is no particular distinction between the subunits of the extracellular and of the vertebrate Hbs in their prosthetic group, amino acid sequence homology, or three-dimensional protein structure, the globin fold.

1. Vertebrate Hemoglobin

1.1. Structure

The adult form of human Hb, HbA, is composed of two a-subunits and two b-subunits, each of which has one bound heme group (Fig. 1). The a- and b-chains consist of 141 and 146 amino acid residues, respectively. All of the vertebrate Hb chains have similar numbers of residues and homologous amino acid sequences. All adopt very similar globin folds comprised of eight **alpha-helices**, designated A through H, although a-chains lack a-helix D. Early in development, related polypeptide chains replace the a- and b-chains.

Figure 1. The structure of the vertebrate hemoglobins. The molecule is a tetramer composed of two pairs of a- and b-subunits. The a- and b-chains are homologous, have similar globin folds, and each has a bound heme group. How the individual chains are distinguished is described in the text.



Within the a_2b_2 tetramer, there are relatively few contacts between the pair of a-subunits and the pair of b-subunits, whereas contacts are extensive between the unlike subunits (Fig. 1). If the a-subunits are designated a1 and a2, the b-subunits are numbered so that the distance between the heme iron atoms of the a1/b2 pair is shorter than that in the a1/b1 pair. Because of symmetry, the a1/b1 pair is identical to a2/b2, and a1/b2 is the same as a2/b1 (see Quaternary Structure and Oligomeric Proteins). The tetrameric assembly is stabilized by weak noncovalent bonds, by many van der Waals interactions, a few hydrogen bonds between unlike subunits, and several salt bridges between the two b-subunits.

1.2. Ligand Binding
One molecule of O_2 binds to the sixth coordination site of the iron atom which is on the distal side of the heme group (see Globins and Myoglobin). The heme pocket in the globin fold provides a highly **hydrophobic** environment that maintains the heme iron atom in the ferrous state. Oxidization of the iron atom to ferric to produce methemoglobin destroys its ability to bind oxygen. Upon binding oxygen, the quaternary structure undergoes an extensive change in the relative orientations of the four subunits, especially due to changes in the a1/b2 and a2/b1 interfaces. This switch between two alternative quaternary structures is believed to be involved in the **cooperativity** of oxygen binding. Hb was the primary inspiration of the **concerted model** of allostery, and it remains one of the proteins that best fits that model.

Several other classes of ligand are bound at other specific sites on the deoxy quaternary structure of hemoglobin. These ligands include protons (see Bohr Effect), carbon dioxide, chloride ions, and 2,3-diphosphoglycerate (2,3-DPG). As the ligands bind more avidly to the deoxy form of Hb, they compete in effect with oxygen for binding, and the presence of one of these ligands affects the binding of the others.

1.3. Physiological Function

The physiological functions of vertebrate Hb are (1) transport of oxygen from the lungs to peripheral tissues; (2) transport of carbon dioxide and enhancement of its transport by the blood plasma; and (3) pH regulation (acid–base balance) of the blood.

The transport of oxygen by Hb is well described by its oxygen dissociation curve (or oxygen equilibrium curve), which expresses the dependence of oxygen saturation of Hb (Y) upon the partial pressure of oxygen (P_{O2}) at chemical equilibrium (Fig. 2). The general features of this curve are (1) its sigmoid shape and (2) its shift to the right to higher oxygen partial pressures at higher temperatures or in the presence of the nonheme ligands that bind specifically to deoxy-Hb, protons, CO_2, Cl^-, and 2,3-DPG. The sigmoid shape of the binding curve is ascribed to stepwise enhancement of the oxygen-binding affinity:

$$\mathrm{Hb} + 4\ \mathrm{O_2} \leftrightarrow \mathrm{HbO_2} + 3\ \mathrm{O_2} \leftrightarrow \mathrm{Hb(O_2)_2} + 2\ \mathrm{O_2} \leftrightarrow \mathrm{Hb(O_2)_3} + \mathrm{O_2} \leftrightarrow \mathrm{Hb(O_2)_4} \tag{1}$$

and

$$\begin{aligned} Y &= \frac{[\mathrm{HbO_2}] + 2[\mathrm{Hb(O_2)_2}] + 3[\mathrm{Hb(O_2)_3}] + 4[\mathrm{Hb(O_2)_4}]}{4([\mathrm{Hb}] + [\mathrm{HbO_2}] + [\mathrm{Hb(O_2)_2}] + [\mathrm{Hb(O_2)_3}] + [\mathrm{Hb(O_2)_4}])} \\ &= \frac{K_1 p + 3K_1K_2p^2 + 3K_1K_2K_3p^3 + K_1K_2K_3K_4p^4}{1 + 4K_1p + 6K_1K_2p^2 + 4K_1K_2K_3p^3 + K_1K_2K_3K_4p^4} \end{aligned} \tag{2}$$

Here, $p = P_{O_2}$and K_i (i = 1,2,3,4) are the intrinsic oxygen **association constants** for the *i*th molecule to bind. If the four heme groups of a_2b_2 Hb were equivalent and independent of each other, $K_1 = K_2 = K_3 = K_4$, which would produce a hyperbolic oxygen dissociation curve, like that of myoglobin (Mb) (Fig. 2). Mb is a monomeric globin that contains a single heme group. In contrast, HbA gives a sigmoidal curve in which $K_1 < K_2$, $K_3 \ll K_4$and the ratio of K_4 to K_1 is 500 (2) (Fig. 3). This cooperative binding of oxygen produces the sigmoid curve, in which apparent interactions between the four heme groups of the molecule are mediated by conformational changes in the protein (3). The sigmoidal shape of the oxygen-binding curve contributes to increasing the difference in oxygen saturation between arterial and venous blood and enhances the amount of oxygen released at the tissues (Fig. 2).

Figure 2. Oxygen dissociation curves for hemoglobin (Hb) and myoglobin (Mb). The oxygen concentration is specified by its partial pressure in mm of Hg. The dissociation curve for the monomeric Mb has the expected hyperbolic shape, whereas that for Hb is sigmoid, indicating positive cooperativity in binding the four oxygen molecules by each Hb tetramer. The dissociation curve for Hb is shifted to the left or right upon changing the solution conditions or temperature, as indicated, whereas that for Mb is insensitive to changes in conditions, except for the temperature. The middle of the three curves for Hb is for standard conditions: 37°C, pH 7.4, 40 mm Hg CO_2, and 5 mM 2,3-DPG. The partial pressure of oxygen for arterial blood, 100 mm Hg, and that for mixed venous blood, 40 mm Hg, produce a difference in oxygen saturation of 23%, whereas there would be a much smaller release of oxygen for a hyperbolic curve like that of Mb.

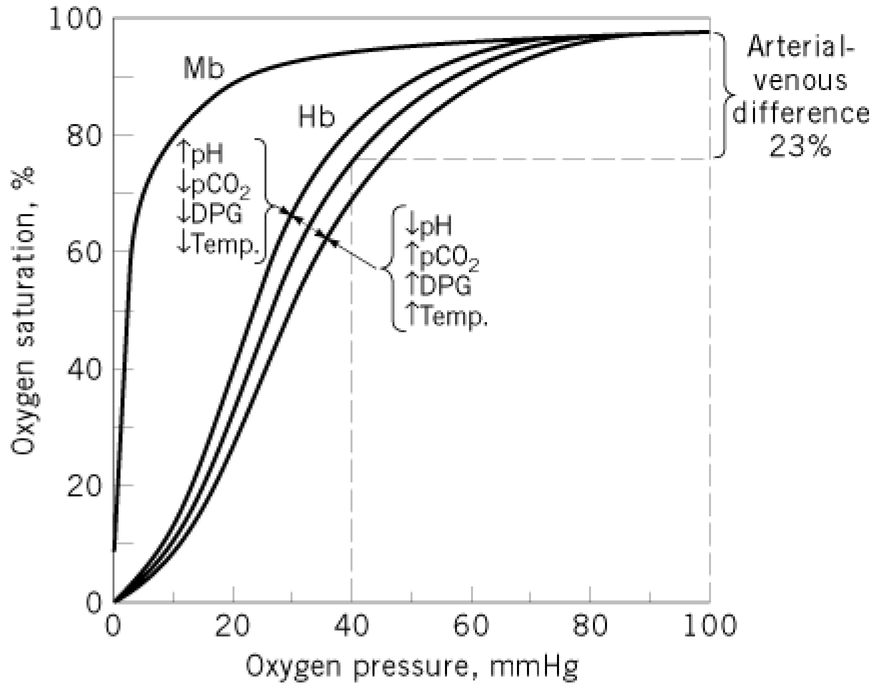


Figure 3. Changes in oxygen affinity of human hemoglobin with oxygen binding at the four heme groups and those upon addition of the cofactors 0.1 M $Cl^{-}$and 2 mM 2,3-DPG. The abscissa indicates the *i*th oxygen molecule to bind, and the ordinate gives the logarithm of the intrinsic association constant for the *i*th step. Open circles correspond to the absence of cofactors, closed circles to their presence. The four-step oxygen binding is illustrated schematically below the graph. Squares and circles represent deoxy and oxy subunits, respectively. Data taken from K. Imai (1982) *Allosteric Effects in Haemoglobin*, Cambridge University Press, London.

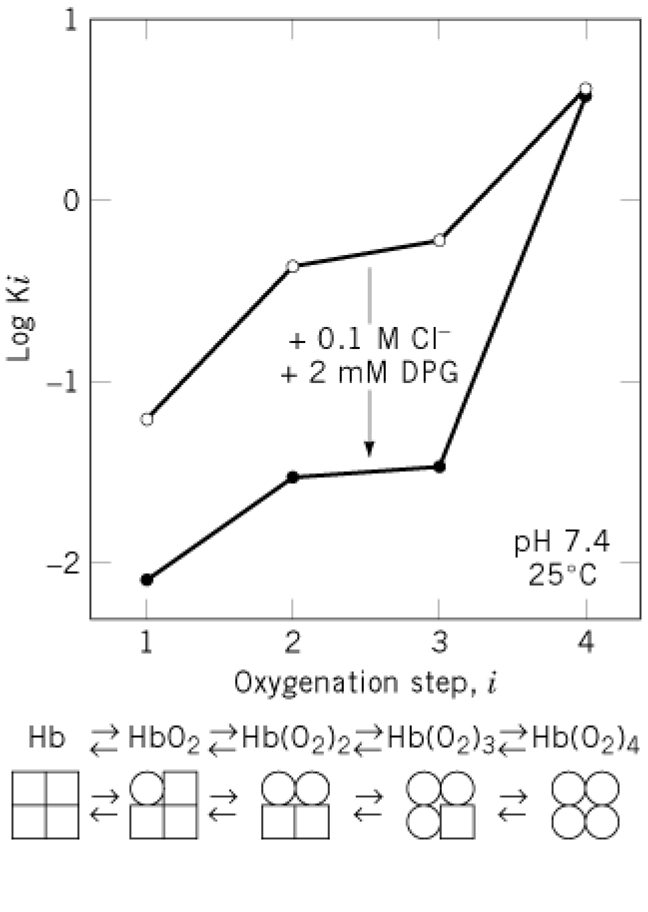

Under physiological conditions, the nonheme ligands lower the oxygen affinity and increase the cooperativity of oxygen binding by HbA. The effect of these ligands on the intrinsic binding constants, K_i, is not uniform with respect to i (Fig. 3). The shift of the oxygen binding curve to higher partial oxygen pressures, that is, the lowering of the overall oxygen affinity upon acidification or upon increasing the CO_2 concentration or temperature has physiological consequences because this enhances the release of oxygen at the peripheral tissues, where such changes result from active metabolism. The effect of pH on the oxygen affinity is known as the Bohr effect. In some cases of chronic hypoxia found in anemia, chronic heart and lung diseases, etc., there is an increase in the intracellular concentration of 2,3-DPG, a decrease in Hb's oxygen affinity, and consequently an enhancement of oxygen release at tissues (4).

Carbon dioxide produced in tissue cells diffuses into the red blood cells and reacts with water, catalyzed by carbonic anhydrase:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+HCO_3^- \tag{3}$$

The HCO^-_3bicarbonate ions thus produced move to the blood plasma in exchange for chloride ions and are transported to the lungs. Reaction 3 is greatly shifted to the right when Hb absorbs the protons produced. Moreover, dissolution of the carbon dioxide is greater in the tissue capillaries than in the alveolar because of the uptake of protons upon oxygen release by Hb:

$$HbO_2 + \delta\ H^+ \leftrightarrow Hb(H^+)_\delta + O_2 \tag{4}$$

This oxygen-linked proton binding known as the Haldane effect is the reciprocal expression of the Bohr effect. The release of oxygen in the tissue capillaries enhances the uptake of protons by Hb, thereby causing a further shift of Eq. 3 to the right. Part of the CO_2 is transported linked directly to Hb as a carbamino moiety:

$$Hb(O_2) - NH_2 + CO_2 \leftrightarrow Hb - NHCOOH + O_2 \tag{5}$$

where $–NH_2$is the a-amino groups of the a- and b-chains. This CO_2 binding is also oxygen-linked. Dissociation of oxygen in tissue capillaries enhances the CO_2 binding by Hb, increasing the CO_2 content of the venous blood. The remainder of the CO_2 is dissolved directly in the blood plasma. The major portion (85%) of the total CO_2 is transported as bicarbonate, 10% as the carbamino form, and the remaining 5% as free CO_2. Consequently, as a result of its allosteric properties, Hb plays a key role in CO_2 transport and oxygen transport.

The properties of HbA described here also apply to other vertebrate Hb, except for some slight differences. In some species, 2,3 DPG is replaced by other cellular metabolites, such as ATP, GTP, or **inositol pentaphosphate**, and CO_2 is replaced by bicarbonate ion.

2. Annelid Hemoglobins

Annelida possess giant extracellular HB of molecular mass 3500 kDa. The molecular architecture is a hexagonal bilayer whose diameter is about 30 nm and whose thickness is about 20 nm. The molecule is composed of 12 identical spherical protein units, known as “submultiples,” six of which make one hexagonal layer. These submultiples are assembled to make up an entire molecule using many linker subunits. The submultiple is composed of 16-kDa globin subunits that have the same globin fold as the vertebrate Hb subunits, but the linker subunits are unrelated, heme-free polypeptide chains. The extracellular Hb from the earthworm *Lumbricus terrestris* has been most extensively studied. Its submultiple is a dodecamer composed of three copies of each of four different kinds of globin chains, and 12 such dodecamers are assembled with 36 linker chains and approximately 57 tightly bound calcium ions. Consequently, there are $12 \times 12 (= 144)$heme groups in each molecule. Some of the globin and linker chains have attached carboyhydrates, which are thought to contribute to stabilization of the quaternary structure through their noncovalent, **lectin**-like binding (5, 6).

Annelid Hbs demonstrate a striking diversity of oxygen-binding properties. Most demonstrate a Bohr effect and cooperativity of oxygen binding like those of vertebrate Hb, and sometimes of even greater magnitude, but others have none. The annelid Hb do not respond to cofactors, such as 2,3-DPG or other organic phosphate compounds. Instead, their oxygen affinity is increased by divalent calcium and magnesium ions, which are abundant in the annelid blood. There is some evidence that the functional allosteric unit of annelid Hb is the submultiple.

3. Hemoglobins of Other Species

A great variety of Hbs are found in lower organisms. They can be (1) one-domain monomers, that have a single globin chain of about 16 kDa and one heme group; (2) polymers of such single-domain monomers; (3) two-domain polymers; and (4) multiple-domain polymers. Most of the single-domain monomer Hbs are present in the cytoplasm. Some are in noncirculating cells, whereas others are in coelomic cells of annelida, such as *Glycera*. Although those in noncirculating cells do not apparently participate in oxygen transport, they are still classified as hemoglobins. Leghemoglobin is a monomeric Hb contained in the cytoplasm of root nodules of legumes. It has an extremely high oxygen affinity, which is important for the completely removing of traces of oxygen from the symbiotic bacteria, because nitrogen fixation is a strictly anaerobic process. Consequently, the function of leghemoglobin is to eliminate oxygen, rather than to supply it to tissues.

Finding the single-domain Hb from the gram-negative bacterium *Vitreoscila* was the first indication that the evolutionary origin of globins may date back to the common ancestor with prokaryotes. Hbs isolated from **yeasts** and *Escherichia coli* have two domains, one of which is a globin chain and the other a flavoprotein. The NADH reductase activity of the second domain prevents the heme iron of the first domain from auto-oxidizing to maintain its capability of reversibly binding oxygen. *Chironomus* larvae possess Hbs that are polymorphic in various species, tissues, and developmental stages. Among the 12 Hbs of *C. thummi thummi*, seven exist as homodimers, four as monomers, and one as a monomer or dimer (see Chironomus). The nematode *Ascaris lumbrodoides* Hbs consists of two-domain globin chains, one of which has lost the ability to bind heme. Hbs from nematodes, including *Ascaris*, have extremely high oxygen affinities. The brine shrimp *Artemia salina* Hbs have a molecular mass 250 kDa and are composed of two polypeptide chains, each containing eight heme-binding domains. The blood clam *Scapharca inaequivalvis* has intracellular homodimeric and heterotetrameric Hbs, which bind oxygen cooperatively. The most conspicuous feature of these Hbs is that their globin chains have an additional a-helix at their N-terminus and that the E and F helices are external, exposed to solvent, whereas the G and H helices are internal, involved in subunit interactions. Thus, the clam Hb tetramer is “back to front” relative to the vertebrate Hb tetramer.

The various species of Hb demonstrate oxygen affinities that vary 26,000-fold. The lowest affinity, measured by the value of the partial pressure of oxygen at half saturation, is 26 mm of Hg, that of human Hb at 37°C, whereas that for the highest affinity is only 0.001 mm Hg, for *Ascaris* Hb at 20°C. The species-dependence of the oxygen affinity of Hb is a manifestation of its adaptation to the environments that the organisms inhabit. All of the Hbs have the same protoheme IX heme group, so this tremendous variation in oxygen affinity arises from species differences in the amino acid sequences of the globin moiety. How this is accomplished is not known.

Hemoglobin Mutations

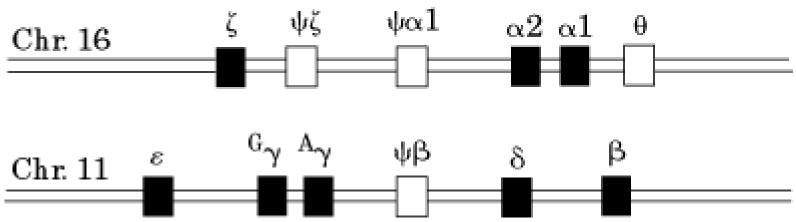
The study of human hemoglobin mutations opened the era of molecular genetics. In 1949, Linus Pauling and colleagues first described the alteration of the electrophoretic mobility of hemoglobin (Hb) by the **sickle cell** anemia mutation. The basis for the more positive electrical charge of sickle cell hemoglobin (Hb S) was not known, but the fact that it was a property of individual Hb molecules led Pauling to designate sickle cell anemia a molecular disease. In 1956 Vernon Ingram demonstrated that the charge difference is due to substitution of valine for glutamic acid in position six of the b-globin peptide chain. This observation was the first to prove that mutations can alter the amino acid sequence of a polypeptide chain and, by extension, it was proposed that the normal function of **genes** is to specify the primary structures of proteins, a hypothesis that is well established now.

It is no accident that the initial connection between mutations and protein structure emerged from studies of Hb. In higher animals, Hb is the protein that is most readily available in relatively pure form. In the case of mammals, a lysate of washed red cells can be used for Hb classification without further purification. Hb levels are measured as part of routine clinical examinations, and persons with diminished synthetic ability or with functionally aberrant Hb are likely to be identified and studied further. Hb is probably the protein that has been most extensively studied worldwide for genetic variations, and the array of mutations known is remarkable in number and in effect.

1. The Globin Loci

A hemoglobin molecule in vertebrates is tetrameric and consists of two each of two globin subunits. The folded tertiary structure of each globin chain binds one molecule of heme. The two kinds of globin subunits in Hb A, the major human adult Hb (actually present from birth onward), are labeled a-globin and b-globin. The a-globin polypeptide chain consists of 141 amino acid residues, and the b-globin chain has 146 residues. The molecular structure can be written a_2b_2. An additional adult Hb, designated Hb A_2, comprises 2.5% of the total. Its molecular structure is a_2d_2, so Hb's A and A_2 differ only in having different “b-like” globins. Other Hb's present at various stages of human development are fetal Hb's, $a_2{}^Gg_2$ and $a_2{}^Ag_2$, and embryonic Hb's, $a_2\varepsilon_2$, $z_2\varepsilon_2$, and z_2g_2. All of the globin chains resemble each other in amino acid sequence and folding pattern and are similar to myoglobin of muscle, which occurs as a monomer. Genetically, the a and z genes form a cluster on human chromosome 16, and the b, d, ^Gg, ^Ag, and e genes form a cluster on chromosome 11 (Fig. 1). All of the functional genes have three **exons** and two **introns**. In addition to the functional genes, there are several pseudogenes.

Figure 1. Diagrams of the organization of the a-globin complex on chromosome 16 and the b-globin complex on chromosome 11. Functional genes are in black. Gene sizes and relative positions are not drawn to scale.



The globin genes constitute a gene family that, along with myoglobin, evolved from a single ancestral gene through gene duplication and evolutionary **divergence**. Recent duplication has occurred in the case of the two a genes, which are identical, and the two g genes, whose products differ by a single codon. The b and d genes are also similar.

An interesting feature of the globin genes is the similarity in order of expression during development with order on the chromosomes. During the embryonic period, the z, ε, g, and a genes are actively transcribed, forming $z_2\varepsilon_2$, z_2g_2, and $a_2\varepsilon_2$ Hb's. The primary Hb during the fetal period is a_2g_2. At about birth, but not as a result of birth, production changes to a_2b_2 and a_2d_2 . The molecular basis for these switches has not been established.

2. Mutations of Hb Genes

Over 500 different mutations have been observed in the Hb loci, exemplifying almost every known mutational mechanism. Those involving the b locus are especially apparent, because this locus becomes active at birth. If a mutation is limited to the b locus, embryonic and fetal development should be normal. In contrast, the a locus is active from the embryonic period. A major defect in its function is likely to interfere with fetal development and lead to abortion. The same is true of the g loci. Defects in function that are limited to the d locus are likely to go unnoticed because of the small amount of Hb A_2 normally made.

The phenotypic consequences of Hb mutations can be classified roughly into four categories: (1) complete absence of a gene product, (2) normal function but diminished amount, (3) abnormal function with or without diminished amount; and (4) normal function and amount. The first group includes genetic deletions, which can extend over two or more loci. Single base-pair substitutions can produce any of the four effects, depending on the site of the substitution. The inability to produce adequate amounts of Hb is known as thalassemia.

3. Absence of a Gene Product

The classical examples are the a- and b-thalassemias that involve deletions of all or part of the a and b genes, respectively. (See Thalassemia.) Other causes are frameshift mutations that involve insertion or deletion of one or two nucleotides, which switch the reading frame. Unless these changes occur very near the C-terminal end of the polypeptide, no recognizable product is produced. Several such mutations, known in the b globin gene, result in b thalassemia.

Single nucleotide substitutions also lead to complete absence of a gene product. In a number of thalassemia mutants, a nucleotide substitution in the coding region of a gene introduces a stop codon, producing a truncated, nonfunctional, and unrecognizable gene product. If a nucleotide substitution occurs at a critical site in a regulatory region, transcription of the gene may not occur. This has been shown in several cases of thalassemia, in which substitutions in the TATA box and other 5′ sites interfere with transcription. Substitutions in the 3′ **poly-A** site leads to absence of product, presumably by interference with translation .

One unusual cause for the absence of b-globin is nonfunction of the switch mechanism that causes transcription to change from the g genes to the d and b genes. In such cases, the g genes continue to function, and transcription of the d and b genes is not initiated. The major Hb is a_2g_2 (fetal Hb or Hb F), and the condition is known as hereditary persistence of fetal hemoglobin. The Hb F is synthesized in amounts adequate for normal function, and homozygotes for this mutation are normal. The responsible mutations occur in two regions. One is a site between the g genes and the d gene. The other sites are in the **promoter** regions of the g genes.

4. Diminished Amount of a Normally Functional Hb

Mutations outside the coding regions of genes substantially suppress transcription without obliterating it completely. Several nucleotide substitutions in the promoter region of the b-globin gene do that, resulting in very low amounts of normal Hb A (so-called b^+–thalassemia). A number of substitutions in the coding region also reduce the amount of globin. In some instances, the globin is quite functional. Hb C results from the substitution of lysine for glutamic acid in residue six of the b-chain. This does not interfere with function but the amount of Hb C produced is less than that of Hb A. Hb C is widespread in West Africa and offers some protection against falciparum malaria. Another polymorphic mutant, Hb E, occurs widely in East Asia and appears to protect against malaria also. Hb E results from a change in codon 26 of the b gene, near the boundary between exon 1 and intron 1. There are several cryptic splice sites in this region. In the case of the Hb E mutation, a cryptic splice site in codon 25 is substantially activated, and only a portion of the primary transcript is spliced correctly. Presumably this mechanism occurs in a number of other mutations that have not been studied so extensively.

5. Functionally Abnormal Globins

The prime example of a functionally abnormal Hb is **sickle cell** Hb (Hb S). Hb S transports oxygen normally. However, in the deoxygenated state, the Hb S molecules aggregate to form long crystal-like structures that disrupt the red cell. The cause is substitution of a **hydrophobic** valine residue in place of glutamic acid in residue six of the b-globin polypeptide chain. This causes the N-terminal part of the b chain to fold differently, leading to aggregation.

Other examples are the mutations that cause **methemoglobinemia** . These involve amino acid substitutions in the heme-binding region. In normal hemoglobins, the Fe of the heme is stabilized in the Fe^{2+} state, which is required for O_2 binding. In Hb M mutations, the Fe is predominantly in the more stable Fe^{3+} form (methemoglobin, metHb). The amount of Hb M made is normal. Therefore a heterozygote has approximately half normal Hb A and half Hb M. Such a person is essentially normal, comparable to a person who is heterozygous for b-thalassemia. The high level of metHb gives them a gray-blue color, however. Hb M mutations are rather rare, and homozygotes have not been observed. Presumably, they would be lethal.

6. Mutations Normal in Function and Amount

The list of these mutations is not extensive because they normally escape detection unless populations are screened. An interesting example is Hb Lisbon, which results from the substitution of aspartic acid for glutamic acid at residue 23 of the a_1-globin. This rare human variant is the standard “wild-type” form in gorillas. All other amino acids are identical in the a_1 globins of the two species.

Another interesting normal variation is the tandem duplication of one of the a-globin genes in populations in the southwest Pacific. Having five copies of the a-globin genes rather than four is a harmless variation.

Hemophilia

Hemophilia is the term used to describe uncontrolled bleeding, which may range from mild (bleeding after surgery or significant trauma) to severe (spontaneous bleeding into joints, muscle, and internal organs). Most examples are attributable to one of the two classic inherited hemophilias: the sex-linked disorders hemophilia A and hemophilia B. The most common of these is hemophilia A, which is caused by mutations in the **gene** on the human X-chromosome coding for the blood coagulation cofactor molecule, factor VIII (see Blood Clotting). Hemophilia B is caused by mutations to another X-chromosome-encoded gene, that for the zymogen of the blood coagulation serine proteinase factor IX. Less common congenital bleeding disorders are caused by mutations in the genes coding for other proteinase components of the blood coagulation system (factors VII, X, XI, and prothrombin), the cofactor molecule factor V, fibrinogen, and the serpin a_2-antiplasmin. Other causes of bleeding are due to defects in platelet aggregation caused by mutations in the genes coding for the integrin a_{IIb} b_3 (glycoprotein IIb-IIIa, the platelet-fibrinogen binding site), the cell adhesion molecule von Willebrand factor, or its platelet binding-site glycoprotein Ib-IX.

The molecular basis of both hemophilia A and B has been studied extensively. Historically, bleeding defects have provided the basis for defining the reactions of the blood coagulation pathways and, more recently, elucidating of structure–function relationships in the coagulation factors. Hemophilias A and B have also been valuable models in the study of mutational mechanisms. All possible types of gene disruption have been detected, including point mutations, deletions, insertions, duplications, and inversions, and they can lead to either absence of the protein, reduced levels of protein, protein with reduced functional activity, or nonfunctional protein.

In various populations, the frequency of hemophilia A is 1 in 510×10^3 male births. Over 80 point mutations in the factor VIII gene have been detected. Of these, 27 cause severe hemophilia and are mainly nonsense mutations, while 29 cause moderate to severe hemophilia and all are missense mutations. The most functionally interesting of the latter are those that lead to normal levels of protein but with severely reduced activity, that is, with reduced specific activity, which account for 5% of the total point mutations. These are all mutations of the Arg residue at the P1 position, immediately preceding the peptide bond to be cleaved, of the thrombin cleavage sites of factor VIII, and involve the hypermutable CpG dinucleotide (which is susceptible to 5-methylcytosine deamination) (see CpG Islands).

The frequency of hemophilia B is one-sixth that of hemophilia A. More than 300 point mutations have been detected, 40% of which lead to factor IX with reduced specific activity; these mutations affect all the **domains** of factor IX. The mutations that can be most readily rationalized in structure–function terms include those leading to abnormal post-translational modification of the Gla domain (ie, generation of **g-carboxyglutamic acid** and b-hydroxyaspartic acid residues), mutation of the arginine residues at the proteolytic activation sites, and mutations affecting the active-site serine residue. Over half of these mutations are in CpG dinucleotides, with C → T or G → A transition mutations.

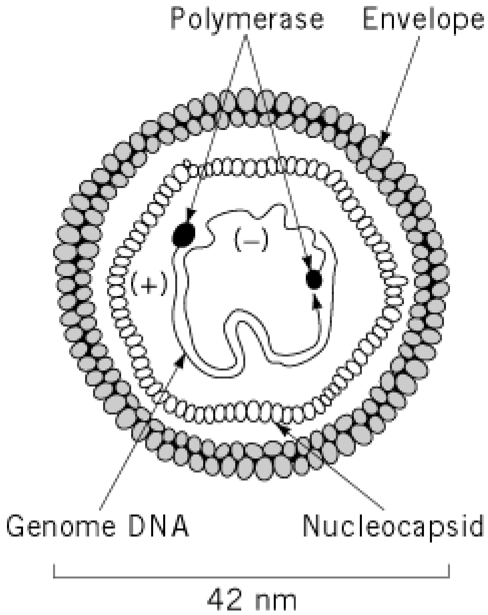
Hepatitis B Virus

Hepatitis B virus (HBV) is one of the hepadnaviruses and causes acute, self-limited or persistent infection that can potentially be passed vertically from carrier mother to infant, or horizontally by the percutaneous and transmucosal exchange of infected blood and body fluids. Persistent infection by HBV is often associated with chronic liver disease that can lead to the development of hepatocellular carcinoma (HCC). The neonatal transmission route is thought to be an important mechanism for HBV persistence because of the immunological immaturity of the infected host. The concomitant infection is usually self-limited, with clearance of virus particles from the liver and blood and the development of lasting immunity to reinfection.

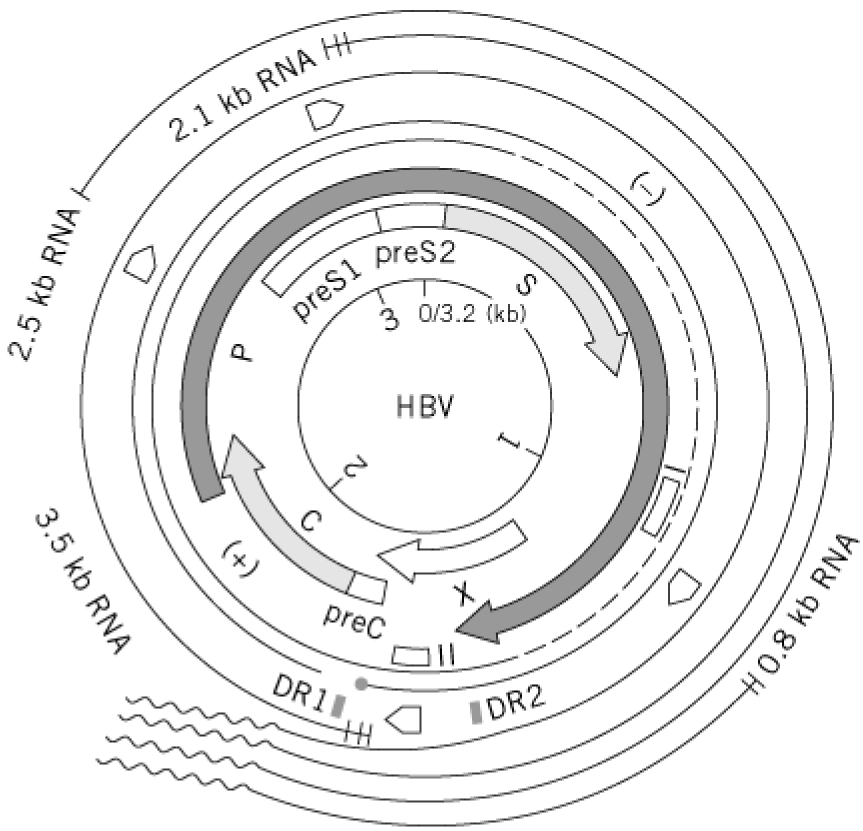
HBV is a spherical particle, 42 nm in diameter (Fig. 1). The genome of HBV is a circular DNA duplex of 3.2 kbp that replicates by **reverse transcription** (see HIV (Human Immunodeficiency Virus) and Rous Sarcoma Virus (RSV)) of a pre-genome RNA and contains a single-stranded gap region of variable length in one strand. DNA replication and transcription of viral genes and the mechanism of virion assembly within infected hepatocytes have been unraveled so some extent, but less is known about the virus–cell interactions that control virus attachment, uncoating, and entry into susceptible cells, as well as the integration of HBV DNA into the host cell genome. Although viral sequences implicated in the interaction of the virion with the cellular membrane are located in a variable region of the amino-terminal part of the pre-S1 domain, the cellular receptor for HBV has not yet been fully characterized.

Figure 1. Schematic diagram of a hepatitis B virus particle.



Nucleotide sequences and those amino acid sequences deduced from HBV DNA from different virus subtypes (adw, adr, ayw, ayr) have revealed a compact, overlapping coding organization of the genome, where the entire genome is coding (Fig. 2). Four open reading frames (ORFs) are localized on one viral strand in the same transcriptional polarity. Two of them, the C and S regions, specify structural proteins: the 183-residue nucleocapsid protein HBcAg and the 226-residue envelope major protein HBsAg, respectively. The smallest ORF, X, codes for a trans-acting 154-residues regulatory protein that interacts with various cellular proteins and may play a major role in hepatic cell transformation. Overlapping these coding regions, the largest ORF, P, encodes a viral polymerase of 843 residues, which is necessary for viral replication and has activities of **DNA polymerase**, **reverse transcriptase**, plus ribonuclease H. This overlapping of the P region is a characteristic feature and, with its unusual overlapping of coding and regulatory sequences (such as **promoters**, two specific enhancers, and a poly A termination signal), makes this virus unique. In addition to the central homologous region, two strong homology blocks in the amino- and carboxy-terminal parts of the X protein might correspond to a conservative selective pressure for functional activity of the X as a *trans*-regulator, and of the viral ribonuclease H encoded by *C*-terminal sequences of P, which overlap with the 5′ end of the X protein.

Figure 2. Genetic organization and transcription map of the hepatitis B virus genome. The HBV DNA was derived from virus of the adr subtype, with a nucleotide sequence of 3215 bp. The positions of promoters and two enhancers are indicated by and *f*, respectively. The four different transcripts are indicated with a poly(A) tail (~). The terminal protein domain of polymerase (•) is attached to the 5′ end of the minus strand (—). DR1 and DR2 represent 11-bp direct repeats.



Another important characteristic of HBV is a high mutation rate due to the lack of a proofreading function of the reverse transcriptase that replicates its genome. This may increase the production of mutated variants during persistent infection, which enables the virus to escape from the host immune response or enables a growth advantage of mutant viral genomes. Substantial nucleotide and amino acid sequence heterogeneity in different isolates of HBV, plus specific mutations in the HBV genome in individual patients, have been observed, and partially deleted HBV genomes have also been observed in human hepatocellular carcinoma. However, there is no experimental evidence that these defective HBV genomes might harbor oncogenic potential, nor that any particular HBV subtype might be more oncogenic than others. Comparison of the HBV genome with those of animal hepadnaviruses reveals extensive homologies among mammalian hepadnaviruses (WHV, GSHV), which share a basically identical genomic organization.

The antibody response to HBV envelope antigen (HBsAg) is well characterized to be **T-cell-dependent** and plays an important role in clearance of the circulating virus and preventing their attachment and uptake by susceptible hosts. The role of the antibody response to the nucleocapsid (HBcAg and its derivative in serum, HBeAg) and nonstructural proteins (X and P) in HBV pathogenesis is less clear yet. Persistent infection of HBV is mainly caused by a weak antiviral immune response that cannot kill or cure all of the infected cells. Alternatively, chronic hepatitis may be caused by an inappropriate T-cell response that can kill but cannot cure the infected hepatocytes without enough production of cytokines to clear the infection.

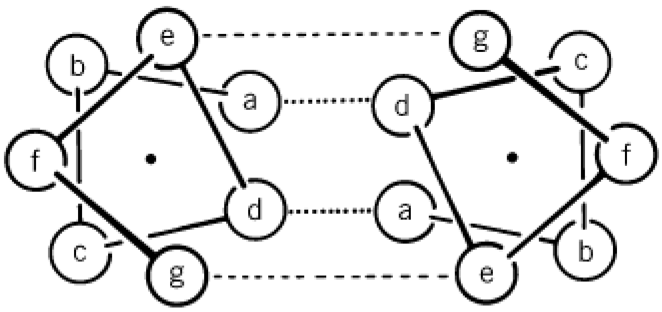
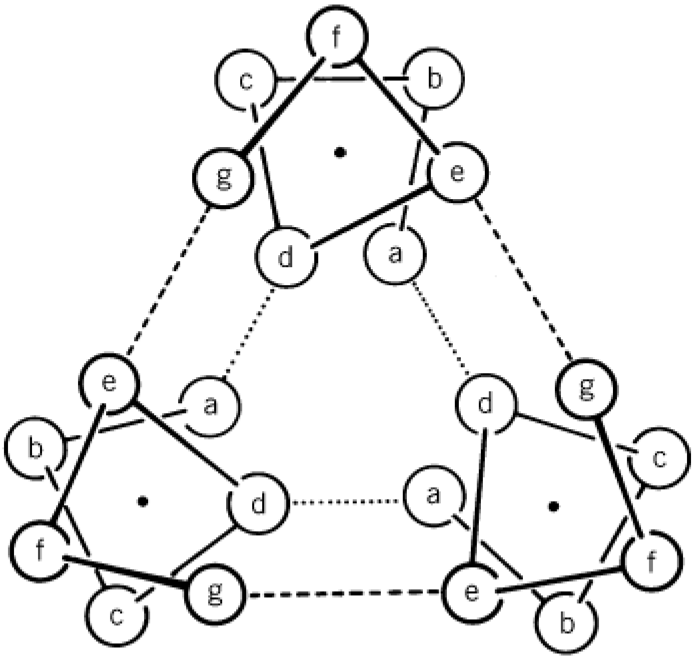
Heptad Repeat

Fibrous proteins of the a-type, as well as many globular proteins, contain a heptad repeat of the form $(a–b–c–d–e–f–g)_n$ in which nonpolar amino acid residues are found with high probability in positions *a* and *d*. Regions displaying a heptad repeat invariably have the a**-helix** conformation and give rise to a **coiled-coil** molecule in which the apolar residues in *a* and *d* in several chains pack in a regular manner along the axis (1) (Fig. 1) (see also Cytokeratins). Electrostatic interactions between charged residues in positions *e* and *g* of adjacent polypeptide chains help to specify the relative orientation and axial stagger of the chains. Various positions within the heptad repeat are not occupied equally by different amino acids (1-3), and this has provided the basis for distinguishing between two- and three-stranded coiled-coils in fibrous proteins (4). Consider the *a*, *d*, *e*, and *g* positions in turn. Leucine, lysine, asparagine, and arginine residues occur more commonly in position *a* in two-stranded coiled-coils than in three-stranded ones, whereas the reverse is true for alanine, glutamine, serine, and threonine. In the *d* positions, leucine is favored in two-stranded coiled-coils, but isoleucine, serine, threonine, and valine are found more commonly in the three-stranded conformations. In *e* positions, glutamic acid, isoleucine, and glutamine are more commonly observed in two-stranded ropes than three-stranded ones, but the reverse is true for phenylalanine, leucine, serine, tryptophan, and tyrosine. Finally, in position *g*, glutamic acid, glutamine, and arginine are favored in two-stranded ropes, whereas isoleucine, leucine, asparagine, tryptophan, and tyrosine occur significantly more frequently in three-stranded coiled-coils.

Figure 1. Heptad repeat seen in axial projection for two- and three-stranded a-helical coiled-coils. Residues in positions *a* and *d* are generally apolar and are shielded from water as a result of systematic close packing along the axis of the rope-like structure so formed (dotted lines). Interchain ionic interactions are also possible, the most common type being those that occur between oppositely charged residues in positions *e* and *g* (dashed lines).(From Ref. 66, with permission.)





Groupings of amino acids also clearly provide a means for distinguishing one multichain coiled-coil from another (Table 1). These figures indicate, for instance, that in two-stranded structures the acidic residues occur very infrequently in position *a* but quite commonly in position *d*. In contrast, basic residues are found commonly in *a* but much less so in *d*. In three-stranded coiled-coils, the preferences for the charged residues are almost reversed in these positions. In all cases the *a* and *d* positions are occupied by apolar residues at a frequency of about 75%. In three-stranded structures the occupancy of charged residues in positions *e* and *g* is reduced, and the occupancy of apolar residues is increased. This trend continues as the number of strands in the coiled-coil rope increases.

Table 1. Percentage of Apolar (ap), Acidic (ac), and Basic (ba) Residues in Positions *a*, *d*, *e*, and *g*

Position	Group	Two-Stranded Structure	Three-Stranded Structure
a	ap	72.6	77.5
a	ac	1.4	3.1
a	ba	13.8	2.2

d	ap	76.1	79.3
d	ac	6.3	1.0
d	ba	3.8	3.9
e	ap	16.9	20.9
e	ac	27.9	22.9
e	ba	23.7	22.5
g	ap	20.0	25.8
g	ac	32.3	22.7
g	ba	19.0	17.3[a]

[a] Acidic residues (ac) are aspartic acid and glutamic acid; basic residues (ba) are arginine and lysine; apolar residues (ap) are leucine, isoleucine, valine, methionine, phenylalanine, tyrosine, and alanine.

A run of consecutive heptad repeats is frequently interrupted, sometimes by a region of sequence with different structural characteristics and sometimes by the insertion/deletion of a few residues in an otherwise perfect and continuous heptad substructure. Analysis shows, however, that the vast majority of such discontinuities fall into one of three categories (5): (i) the deletion of three residues (a " *stutter*"), (ii) the insertion of one residue (a "*skip*") which is structurally equivalent to two stutters, and (iii) the deletion of four residues (a " *stammer*"). Stutters lead to a local unwinding of the coiled-coil structure, whereas the stammer results in a local overwinding. A skip thus leads to a longer distance axially over which the coiled-coil is partially unwound.

Hermaphrodite

In the animal kingdom, natural selection has promoted the development of two opposite sexes, the male and female genders. In most species, individuals belong to either sex, developing either a female **phenotype** with female external genitalia: a uterus, tubes, and two ovaries, or, depending on the presence of a testis-determining factor, a male phenotype with male external genitalia: epididymis and a testis (see Sex). In a hermaphrodite, either in a true hermaphrodite or pseudohermaphrodite , elements of both genders are present in one individual. Some nematodes are physiologically true hermaphrodites (eg, *Caenorhabditis elegans*). Here, the molecular switch to determine whether a male or hermaphrodite is formed depends on an X-chromosome counting system (1), which involves primarily the xol-1 (2, 3) and tra-1 (4) genes. In mammals, however, male and female organs are not normally present in one individual.

Due to the severity of the aberration, different types of hermaphrodites can be found. The clinical appearance of a hermaphrodite is characterized by intermediate sex forms of the external genitalia and **germ line** cells. Gonads that diagnose a true hermaphrodite are ovary and testis, or a combination of the two, the ovotestis. The combination of an ovary and ovotestis is most commonly found in hermaphrodites, followed by the combination of two ovotestes. When close to an ovary, the tubes and rudiments of an uterus are most commonly detected; when close to a testis, a vas deferens and an epididymis are present. In some cases, however, with a lower frequency of appearance, the opposite gender organs, or none, are developed: Tubes and uteri and/or vas deferens and epididymis are found, together with an ovotestis. This can occur because sex differentiation is highly dependent on hormones. As sexual organs are formed from primordial **germ cells**, as well as from soma cells, the gonadal sex does not fit to the genetical and/or cytological sex under certain circumstances.

Besides true hermaphrodites, there are also pseudohermaphrodites, in which all other organs are female but a testis has developed. Due to the higher temperature in the body than in the scrotum, these cells are prone to the development of cancer and will be removed.

Regarding the karyotype of hermaphrodites, those with a Y-Chromosome are more likely to develop a testis than those without. The ovotestis contains both ovarian and testicular cells. The ovarian cells are in many cases normal, and primary follicles are also found. In contrast, the testicular cells show histological aberrations in true hermaphrodites, regardless of whether these cells are found in a testis or an ovotestis.

Regarding the hormone production of hermaphrodites, they are characterized by normal levels of estrogens and gestagens. However, the levels are also dependent on the amount of normal ovarial stroma present in the hermaphrodite. Spermatogenesis does not occur, but testosterone is produced, although it does not reach the levels of normal males. The reduced amounts are responsible for the virilization. There is only one case reported in which a hermaphrodite became a father. However, there are hermaphrodites that are fertile after removal of the testicular tissue and can give birth to children. This certainly does not depend solely on the presence of an ovary, but also on a physiological development of at least one of the tubes and of the uterus. Interestingly, all children born from female hermaphrodites were male. Roughly half the hermaphrodites were identified before the third year of life, but many hermaphrodites were identified only during or after puberty.

During embryogenesis, germ cells become either spermatogonia or oogonia, depending on their genetic constitution. The **genotype** sex normally determines which type of gonads are developed. Further differentiation depends on the hormonal secretion of the gonads themselves, which consequently determines the **phenotypic** sex. The primordial gonad develops to an ovary, and the inner and external genitalia also tend to feminize, so long as the production of male hormones is not stimulated. In the case of secretion of male hormones, especially testosterone and mullerian inhibiting hormone, mullerian ducts do not develop; instead, wolfian ducts are formed that change the fate of the organs, and epididymis, vas deferens, and seminal vesicles evolve.

In cattle and goats, a special situation is found in a male and female twin. Due to the transfer of anastomosae, the development of mullerian ducts is inhibited in the female twin, which results in an infertile female. The external genitalia are female, but the uterus is rudimentary or missing. The male twin is fertile under normal circumstances. Apart from these special cases in twin births in cattle and goats, the biological reason for pathological hermaphroditism in mammals is still unclear.

Other genetically determined disorders related to gender are the Turner (X0) syndrome (5, 6) and surplus X-chromosomes, such as the XXY constitution (Klinefelter syndrome), which can now be detected using **PCR** techniques (7). Due to the absence of the Y-chromosome, the Turner syndrome is mostly linked with a female phenotype, although a mild masculinization has been reported (8). An additional X-chromosome leads to infertility and a reduced IQ. Additional Y-chromosomes, as found in XYY karyotypes, lead to extreme tallness, but not necessarily to crime, as was assumed in former times. In every case, the presence of a Y-chromosome leads automatically to a male phenotype, regardless of how many X-chromosomes were inherited. However, it must be kept in mind that it is not the Y-chromosome itself that triggers the development of male fate, but the SRY gene (see Sex). Mutations within this gene can disrupt its function and consequently lead to female development, even though a Y-chromosome is present.

Herpesvirus

Herpesviruses are large DNA **viruses** whose genomes consist of a large linear double-stranded DNA molecule, 125 kbp to 229 kbp in length. Their hosts range from lower vertebrates to humans. At present, approximately 100 herpesviruses have been isolated and at least partially characterized. In humans, five viruses [herpes simplex virus 1 (HSV-1) and 2 (HSV-2), varicella zoster virus (VZV), human cytomegalovirus (HCMV) and Epstein–Barr virus (EBV)] have been identified as members of the herpesvirus family, *Herpesviridae*. In the past decade, however, three new herpesviruses, namely, human herpesvirus 6, 7, and 8 (HHV-6, HHV-7, and HHV-8), were isolated from healthy people and AIDS patients. These human herpesviruses are responsible for a wide variety of diseases.

Although herpesviruses share common features in their structure, gene organization, replication style, and so forth, the family *Herpesviridae* is further divided into three subfamilies, *Alphaherpesvirinae*, *Betaherpesvirinae*, and *Gammaherpesvirinae*. *Alphaherpesvirinae* includes HSV-1, HSV-2, VZV, pseudorabies virus, equine herpesvirus 1 (EHV-1), and so on. They have a relatively short replication cycle, induce cytocidal damage in infected cells, and establish latency primarily in sensory ganglia. *Betaherpesvirinae* includes HCMV, HHV-6, HHV-7, and so on, and is characterized by its restricted host range, long replication cycle, and slow spread of infection from cell to cell in culture. They can establish latency in lymphoreticular cells, secretory glands, kidneys, and other tissues. *Gammaherpesvirinae* contains EBV, HHV-8 (Kaposi's sarcoma-associated herpesvirus), herpesvirus saimiri (HVS), and so on. They replicate in lymphoid cells, and latency is frequently demonstrated in lymphoid tissue. A most important feature of this subfamily is that some are associated with naturally occurring malignant tumors.

The virions of herpesviruses consist of four morphological elements: an inner core, an icosahedral capsid with 162 capsomers, a surrounding amorphous layer, known as the tegument, and an envelope containing a number of **glycoproteins**. The tegument of the HSV virion is known to contain about 20 distinct structural proteins, some of which have important regulatory functions for the initiation of viral replication. The genomes of eight human herpesviruses have been entirely sequenced, and the complete DNA sequences are also available for several animal herpesviruses, including EHV-1, EHV-2, HVS, and mouse CMV. Although the number of viral genes encoded in the genomes varies, a set of approximately 40 genes is conserved in all herpesviruses. These encode capsid proteins, envelope glycoproteins, proteins involved in DNA cleavage/packaging, and enzymes such as **DNA polymerase**, DNA helicase, DNA primase, uracil-DNA glycosylase, dUTPase, ribonucleotide reductase, and protein kinase. The herpesvirus genomes contain a number of accessory genes that are dispensable for viral replication in cell culture. For example, 45 of 84 HSV genes have been shown to be nonessential. These accessory gene products are supposed, however, to be important for viral growth and spread in their natural hosts.

The principal strategy of herpesvirus replication is similar in all of them and can be summarized as follows: (i) Fusion of the virion envelope with the plasma membrane occurs at the cell surface in a pH-independent manner; (ii) viral capsids with a portion of the tegument are transported to a **nuclear pore**, where viral DNA is released into the nucleus, circularized, and then **transcribed** by cellular **RNA polymerase** II; (iii) viral gene expression is coordinately regulated and sequentially ordered in a cascade fashion; (iv) viral DNA replicates by a **rolling circle** mechanism, and unit-length viral DNA is cleaved from newly synthesized concatemers and packaged into preformed empty capsids; (v) full capsids pass through the inner and outer membranes of the nuclear envelope by budding and reenvelopment and associate with tegument proteins in the perinuclear region; (vi) enveloped virions accumulate in the endoplasmic reticulum and then mature in the Golgi apparatus; and finally, (vii) mature virions are released into the extracellular space by exocytosis.

All herpesviruses have the ability to persist in their natural hosts throughout life. During latency, the viral genomes are present in the form of an **episome** in the nucleus, and only a small subset of viral genes is transcribed. The synthesis of specific viral proteins appears to be essential for some herpesviruses to maintain latency, but not for others. Various stimuli, such as stress and immunosuppression, induce reactivation, which triggers viral replication and shedding of infectious virus. The molecular mechanism of herpesvirus reactivation remains to be elucidated.

Heterochromatin

The term *heterochromatin* was originally used to describe chromatin that stained intensely with particular dyes. This is in contrast to the rest of chromatin, which stained less well and is called euchromatin. Heterochromatin comes in two varieties, constitutive, which is permanently heterochromatic, and facultative, which can change its state. The chromatin regions of centromeres and telomeres are examples of constitutive heterochromatin. In contrast, the inactive X-chromosome (see Barr Body, X-Chromosome Inactivation) and the vast bulk of inactive chromatin in any chromosome are composed of facultative heterochromatin.

The most common observed consequence of heterochromatin formation is the repression of transcription, either in the heterochromatin itself or in regions of chromatin adjacent to the heterochromatin domain. The variability in gene expression at the border of the heterochromatin is described as "position effect variegation." Three explanations have been offered for this phenomenon. The first is that special proteins, such as heterochromatin protein 1 (HP1, see following text), cause heterochromatin to adopt its distinct structure and that these proteins can "spill over" into regions of normal chromatin and exert repressive effects on gene expression. The second is that heterochromatin represents the sequestration of chromosomal domains in specialized nuclear compartments from which the transcriptional machinery is excluded, for example, the chromocenter. The third applies only to *Drosophila* and other insects with polytene chromosomes in that, following placement adjacent to heterochromatin, a gene undergoes fewer rounds of replication than normal. Fewer copies of the gene would cause a concomitant reduction in transcription. Most investigators accept that heterochromatin-specific proteins diffuse onto normal chromatin and thereby influence the gene expression of juxtaposed genes. Although initially defined from work on insects, there is an increasing body of evidence that heterochromatin domains exist in all eukaryotic chromosomes, including those of yeast. Moreover, it is clear that metazoans have used this type of chromosomal organization for the developmental regulation of gene expression.

An approach to the molecular basis of heterochromatin formation has been to look for mutations in *Drosophila* or more recently in *Saccharomyces cerevisiae* that enhance or suppress position effects on gene expression (modifiers of position effect variegation). Modifiers of position effect variegation include mutations in the genes encoding the chromosomal proteins involved in forming heterochromatin. Using this approach, the gene encoding a nonhistone protein, HP1, was identified (see Chromocenter). Mutations of the HP1 gene reduce position effects on gene expression (1). HP1 is preferentially associated with the heterochromatin regions of polytene chromosomes. Other proteins homologous to HP1 include Polycomb, which is also chromatin-associated and from genetic experiments it is known that it influences the expression of many genes in normal chromatin (2). Neither HP1 nor Polycomb interacts with DNA directly, but they presumably recognize some aspect of nucleosome or chromatin fiber structure. Recent experiments reveal that certain proteins that affect position effect variegation, for example, SUV38H1, are histone methyltransferases that selectively modify lysine #9 in histone H3 (3), and that the resulting modified histone is a preferential target for binding by HP1 (4). Combined with earlier data that overexpression of this enzyme leads to HP1 redistribution from heterochromatin (5), as does the histone hyperacetylation via inhibition of histone deacetylases (6), these data strongly support a model that idiosyncratically modified nucleosomes form a landing pad for HP1. Polycomb and HP1 share a common amino acid sequence known as the chromodomain (chromatin modification) (see Chromocenter). This domain is highly conserved through evolution and can be found even in yeast. For example, the *S. pombe* SW16 gene encodes a chromodomain protein. The SW16 protein is involved in the assembling the chromosomal domain containing the transcriptionally silent mating type cassettes.

Position effect variegation also depends on the presence of normal levels of the histone proteins and posttranslational modifications of the N-terminal tails of the core histones, such as acetylation. The histones are needed for forming nucleosomes and for subsequently forming higher order structures. Acetylating the N-terminal tails alters the interaction of the histones with DNA and, potentially, the folding of nucleosomal arrays. Position effect variegation also depends on proteins that recognize nucleosomal arrays, but not naked DNA, such as HP1 and Polycomb (see Position Effect). HP1 is associated only with inactive chromosomal regions, but Polycomb interacts with at least 50 different sites within *Drosophila* chromosomes, including developmentally important loci encoding homeodomain proteins. However, mutations in a second gene family that interacts with the histone proteins allow genes associated with Polycomb to remain active. Thus, Polycomb is likely to exert its effects on gene expression via chromatin structures dependent on the histone proteins (7, 8).

Position effect variegation is recognized now as a universal phenomenon in eukaryotic chromosomes. Genes integrated into yeast chromosomes near the silent mating loci or close to the telomeres are repressed in a way that reflects their proximity to these sites in the chromosome. This silencing effect spreads over at least 5 to 10 kbp of contiguous DNA, but not as much as 20 to 30 kbp in yeast. As in *Drosophila*, the genes influencing the position effect in yeast encode structural components of chromatin or enzymes associated with the modification of chromatin (see Position Effect).

Examples of mammalian chromosomal regions that contain heterochromatin are also the centromere and the telomere (9). The telomeres of mammalian chromosomes have an unusual chromatin structure in which nucleosomes are closely packed (see Telomere). Mammalian telomeres consist of the sequence $(TTAGGG)_n$ repeated for 10 to 100 kbp. Heterochromatin at the centromere contains tandemly repeated simple sequence “satellite” DNA, for example the a-satellite DNA at the human centromere (see Centromeres). This a-satellite heterochromatin plays a structural role by mediating attachment of the kinetochore. In these instances, specialized heterochromatin structures have an important architectural role and protective function in the chromosome.

Occasionally, an entire nucleus becomes heterochromatinized. One example is the inactivation of the erythrocyte nucleus in chicken. Here the special linker histone variant H5, which represses transcription and compacts nucleosomal arrays very effectively, accumulates. Histone H5 is more arginine-rich than the normal linker histone H1 found in somatic cells. This increase in arginine content probably strengthens the interaction of H5 with DNA and stabilizes chromatin structure. In this instance, the assembly of a specialized heterochromatin structure reflects the terminal differentiation of this particular specialized cell type.

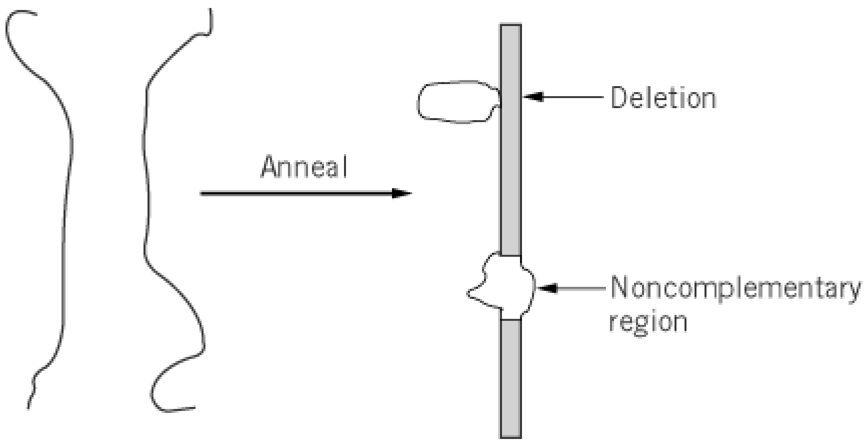
Heteroduplex

Two single-stranded nucleic acid polymers with at least partial complementarity can form duplexes with stretches of double helix, corresponding to the regions of nucleotide sequence homology, interleaved with unpaired stretches, corresponding to noncomplementary regions. Two types of single-stranded loops are introduced by noncomplementarity in the heteroduplex (Fig. 1). A loop in only one of the strands indicates a deletion. A loop composed of single-strand regions in both strands indicates a region of sequence incompatibility. A heteroduplex can be composed of two DNA strands, one DNA strand and one RNA strand, or two RNA strands. *In vivo*, heteroduplexes (DNA–DNA) can arise in the process of recombination or as a consequence of errors (mismatches) in DNA replication (DNA–DNA) or transcription (DNA–RNA). Hybridization of nucleic acids of different origins leads to heteroduplexes *in vitro*.

Figure 1. Loops in a heteroduplex indicate either a deletion or a region of noncomplementarity in the two strands.



The level of sequence homology in the heteroduplex can be evaluated by monitoring the change in ultraviolet **absorbance** on heteroduplex formation or by selective enzymatic digestion of single-stranded regions, followed by hydroxyapatite chromatography. These techniques are analogous to those used for studies of reassociation kinetics (1).

Electron microscopy can used to visualize the regions of sequence homology in the heteroduplex, even though nucleic acids are not sufficiently dense to be easily observable directly in the electron microscope. The heteroduplex is spread on the surface of the electron microscope grid. Heavy metals and proteins are applied to the nucleic acid by one of several techniques, thereby making the polymers visible in the electron microscope.

Heterokaryon

A *heterokaryon* is a combined cell with two separate **nuclei**. Pontecorvo (1) who worked with the **fungus** *Aspergillus nidulans*, which lacks a sexual cycle, observed that genetic recombination occurs during cell division in **mitosis** and employed it in the genetic analysis of fungi. If asexual **spores** from two genetically dissimilar strains of a filamentous fungus are planted very close together on the surface of a solid medium, the emerging hyphae fuse at points of contact. This fusion is followed by the transfer of nuclei from one hypha to the other, so that *heterokaryons* are formed whose hyphae contain nuclei from both strains. As the heterokaryotic hyphae grow, the nuclei multiply independently.

When asexual spores are formed, however, each initial sporogenous cell receives only one nucleus of one type or the other. Subsequent multiplication of these cells thus produces chains of spores. Each chain consists of genetically identical spores, homokaryons, although the spores of adjacent chains may differ in phenotype. Very occasionally, however, two of the nuclei in the heterokaryotic hyphae fuse to form a single **diploid** nucleus. This nucleus multiplies as such and is incorporated into spores in the same way as the haploid nuclei, so rare chains of diploid spores arise which, on subsequent germination, yield diploid individuals. If the haploid parental strains differ in complementary nutritional requirements, eg, one of genotype Ab (requiring B in the growth medium) and the other aB (requiring A), the diploid nucleus (Ab/aB) will possess genetic determinants to synthesize both and B substances needed for growth of the parents. Therefore the existence of diploid spores can be recognized and cultures obtained from them by plating on media lacking the growth factors A and B (2).

Cell fusion is usually carried out by treating a suspension of cells with some inactivated **viruses** or with polyethylene glycol, to alter the plasma membrane of cells so that they are induced to fuse with each other.

Heterokaryons provide a way of mixing the components of two separate cells to study their interactions (see Hybrid Cell).

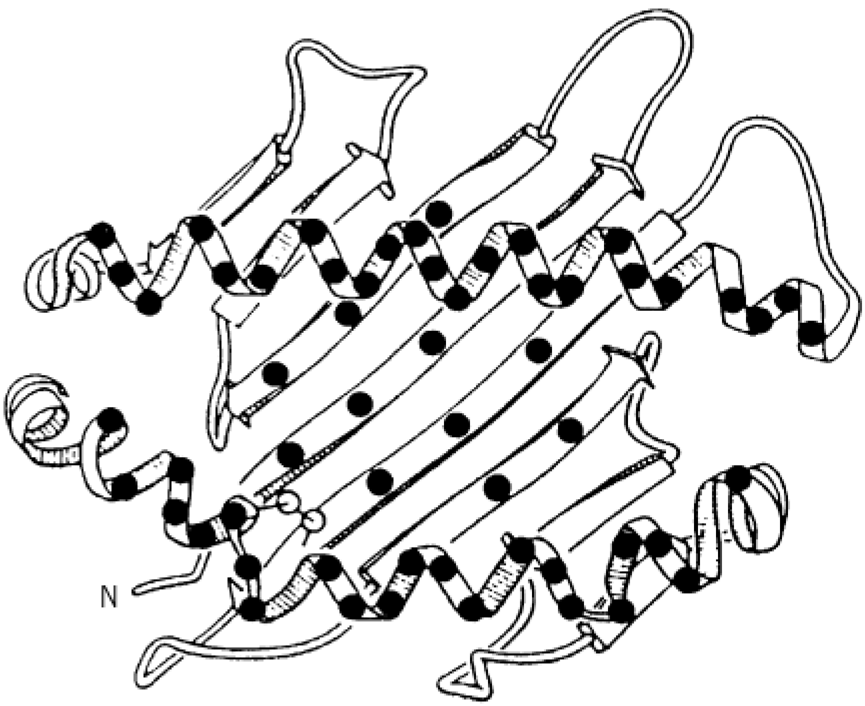
Heterosis

Heterosis is the phenomenon in which **heterozygotes** exhibit superiority of fitness over homozygotes . This superiority often occurs in the areas of viability, longevity, fecundity, and resistance to disease. Therefore, heterosis is sometimes referred to as “hybrid vigor”. Heterosis occurs when two different, often **inbred** strains are crossed. The effect of homozygous deleterious alleles is reduced in the heterozygotes produced through the cross. The increase in vigor may be due to overdominance or superiority of the heterozygote for particular gene differences, or to the introduction of favorable dominant alleles to loci previously homozygous for deleterious recessive **alleles**. Therefore, the terms “heterosis” and “overdominance” are used interchangeably; both confer heterozygotes with an evolutionary advantage over homozygotes.

When survival or reproduction is lowered with recessive alleles, such alleles are eliminated faster from inbred homozygous populations than from outbred, heterozygous populations. Homozygous deleterious alleles will first increase, and then natural selection will tend to remove the deleterious alleles, resulting in less genetic variation and greater average fitness as the heterozygous alleles increase. However, deleterious recessive genes will not be totally eliminated by selection, because they will not be exposed to selection in the heterozygotes.

The major histocompatibility complex (MHC) genes in humans and mouse are known to have extremely high numbers of alleles (Figure 1) (1). Since the number of alleles is much greater than expected if the alleles were all equivalent functionally, it has been long speculated that positive selection is operating on these complex genes. By making combinatorial sets of different alleles, an organism can become resistant to viral infection, which confers superiority of fitness over the homozygote. Thus, the MHC genes are counted as one example of overdominance.

Figure 1. The protein structure of the MHC human protein, HLA Class IA. The residues involved in binding antigen are shown by the closed circles (1).



Hughes and Nei (2) examined the numbers of synonymous and nonsynonymous substitutions in the MHC genes. They found that the number of nonsynonymous substitutions, which change the amino acid, was significantly greater than that of synonymous substitutions in the **antigen**-recognition sites, even though the opposite occurred elsewhere. They concluded that positive selection, most probably by overdominance or heterosis, is operating only on the antigen recognition sites.

Heterotrimeric G Proteins

Heterotrimeric G proteins are **GTP-binding** regulatory proteins that amplify, integrate, and transmit information from cell-surface receptors to cellular signaling proteins, known as effectors. G-protein signaling pathways are found in all eukaryotes; but they have been best studied in animals, where their number is greatest. Animals express over a thousand G-protein-coupled receptors that bind a variety of ligands: biogenic amines and lipids, **peptides**, **protein hormones**, odorants, and other compounds. Fungi use G proteins to convey signals from receptors for pheromones and nutrients, and higher plants may use G proteins in response to pathogens or light.

G proteins convey information by traversing a tightly controlled cycle of GTP binding and hydrolysis. G proteins are activated when GTP binds to the Ga subunit; but GTP binding is extremely slow, unless it is promoted by an agonist-bound receptor. GTP-activated G protein can then bind and activate the effector. Activation is terminated when the G protein hydrolyzes bound GTP to GDP, which does not activate (see Gtpases). Signal amplitude is thus a balance between receptor-stimulated GTP binding and GTP hydrolysis.

G proteins are defined by their GTP-binding a subunits, which are primarily responsible for selective recognition of receptors and effectors (Table 1). Vertebrate genomes encode about 20 Ga subunits, while ***Caenorhabditis*** *elegans* has closer to 30. Plants and fungi have only one or two. Diversity is further enhanced in some cases by alternative splicing of RNA transcripts. Ga subunits form heterotrimers by reversible binding to Gbg dimers. Vertebrates express at least 5 Gb's and 12 Gg's. Although possible combinations of Gb with Gg and of Ga with Gbg dimer are limited by both their cellular expression and intrinsic affinity, the potential number of heterotrimers still numbers over 100. Gabg trimers are bound firmly to the inner face of the plasma membrane, with the exception of transducin in photoreceptor membranes. Membrane attachment depends on Gbg, although Ga subunits are somewhat **hydrophobic** and are further modified by two lipid groups (see Membrane Anchors).

Table 1. Heterotrimeric G Proteins in Animals[a]

Family	Ga Genes	Splicing Products
s	s	2 “long,” 2 “short”
	olf	
i	i1	
	i2	
	i3	
	z	
	o	A,B
	t1 (transducin)	
	t2 (transducin)	
	g (gustducin)	
q	q	(3 in *Drosophila*)
	11	

	14
	15 / 16 (orthologous)
12	12
	13
	con (concertina, *Drosophila*)

[a] This list is most representative of vertebrates, although flies and roundworms also have members of each family. In the roundworm *C. elegans*, for example, there are also 13 "worm-specific" Ga subunits that are expressed primarily in sensory neurons (57). Ga subunits have been identified in the coelenterates, but not yet in sponges or protozoa. Ga subunits in fungi and plants do not fall neatly into any of the animal classes.

The Gabg trimer is quite stable, with **dissociation constants** (K_d) for release of Gbg estimated at 10^{-9}M or less. GTP binding decreases this affinity and drives dissociation, to form free Ga-GTP plus free Gbg. Thus, activation of a Ga by receptor-promoted GTP binding also releases an active Gbg subunit, which regulates a distinct spectrum of effectors. Activation of Ga allows Gbg to generate a second signaling output that can be subsequently quenched by Ga-GDP.

1. Ga Subunits

Ga subunits are globular proteins with molecular weights in the range 39 to 44 kDa (1). They are based on two discrete structural **domains**. The GTP-binding domain, formed by the *N*-terminal and *C*-terminal thirds of Ga, has a tertiary structure and amino acid sequence similar to the small monomeric G proteins (see GTP-Binding Proteins), and it is therefore referred to as the ras-like domain, in analogy to $p21^{ras}$. The middle third of the Ga sequence folds into a discrete **a-helix**-rich domain that acts in part as a cover to the GTP-binding site. Ras-like domains and helical domains can be expressed separately in bacteria and will associate with each other in solution (2). The linkage between the two domains is crucial. The more *C*-terminal linker peptide is also one of three "switch" regions that undergo profound conformational change upon activation; it is referred to as switch I. It resides near switch II, which is totally in the ras-like domain. The switch regions are involved in the binding of Gbg, a family of related proteins known as regulators of G-protein signaling, or RGS proteins, and effectors (1). The second major interaction site involves the *N*- and *C*-termini of Ga proteins, which are close together in the folded structure. This region is involved in recognition of receptors and effectors, Gbg, and RGS proteins. In the inactive heterotrimer, the *N* -terminus of Ga lies as an a-helix along the side of the Gb subunit. The *N*-terminus is apparently quite flexible, however, because its conformation or orientation is apparently different in the abg trimer, free Ga-GDP, or activated free Ga or when bound to an RGS protein.

The *N*-terminal helix of Ga contains two important covalent lipid modifications. The terminal amino group of Ga subunits is blocked by lipid: in the Ga_i family by a **myristoyl** amide group that is added shortly after translation; in Ga_s by an unidentified but hydrophobic modification; and in the Ga_q family by an unidentified modification. In addition, a cysteine residue close to the *N*-terminus is linked to a **palmitoyl group** in all Ga's except Ga_t. In contrast to myristoylation, palmitoylation occurs through a thioester linkage and is therefore reversible. Palmitoyl groups turn over in cells and, in several cases, palmitate turnover is promoted by G-protein activation, so that depalmitoylation follows G-protein activation and repalmitoylation ensues thereafter. Myristoylation and the unknown modification of Ga_s are important for establishing high-affinity interactions with effectors, Gbg, and RGS proteins. The regulatory roles of palmitoylation are less clear. Palmitoylation contributes to the overall hydrophobicity of Ga's, and the absence of palmitate may explain in part the solubility of Ga_t (3). Palmitoylation contributes to membrane attachment, but it is unclear whether this contribution reflects interaction with a specific anchoring protein (Gbg perhaps) or merely an increase in hydrophobicity. It also enhances the affinity for Gbg and decreases the affinity for RGS proteins (4).

Ga-GTP regulates effectors that include enzymes that synthesize or degrade second messengers, **ion channels**, protein **kinases**, regulators of small G proteins, and transport proteins (Table 2). The list is growing constantly. Thus far, it appears that individual Ga subunits have relatively restricted ranges of effector targets. Thus, Ga_s stimulates **adenylyl cyclase** (5), but other targets have not been identified. G_t stimulates cyclic GMP phosphodiesterase (6). G_q family members all stimulate **phospholipase C**-b's (7), and there is one report of G_q stimulation of Bruton's **tyrosine kinase** (8). Ga_i is relatively unique in that it can inhibit two different effectors: several of the adenylyl cyclase **isoforms** (5) and, at least in some cases, some of the same K^+ channels that are stimulated by Gbg (9).

Table 2. G-Protein-Regulated Effectors[a]

Effector	a	bg	GAP
Adenylyl cyclase	s, i↓	↓	–
Cyclic GMP phosphodiesterase (PDE)	t		"co-GAP"
Phospholipase C	q		+
GIRK K^+ channel	i↓		
PI-3-kinase			
Ca^{2+} channel		↓	
Rho GEF	13(12)		+
Protein kinases	q?	↓	
Transporters	?	?	

[a] The arrows indicate whether the activity is increased or decreased by the G protein. Question marks indicate uncertainty of direct interactions. GAP activity of effectors has not been assayed in all cases. Cyclic GMP PDE is shown as a co-GAP because it potentiates the GAP activity of RGS9. The list of known G-protein-regulated effectors is constantly growing.

2. Gbg Subunits

Gbg is a stable heterodimer of a ~35kDa Gb subunit and a ~8kDa Gg subunit, which fold and associate shortly after translation. Nascent Gb will denature if g is not present, and, once formed, Gbg can only be dissociated under denaturing conditions. In the native dimer, Gb is a torus of seven pie-wedge domains known as a b-propeller, because each wedge is composed almost exclusively of **b-strands** . The sequence of Gb is a sevenfold repeat of the "WD40" motif. However, each blade of the propeller is not one individual WD repeat, but is composed of roughly half of each of two adjacent repeats. The ~8kDa Gg subunit is extended across the face of the b-propeller, and the Gg *N*-terminus binds the *N*-terminus of Gb in an extended coiled coil. Gbg binds to Ga along the face of the b-propeller opposite to Gg, with the central hole in the propeller aligned with the switch II region of Ga. The other substantial Ga–Gbg contact is between the *N*-terminal a-helix of Ga and the edge of Gb (10-12). Specificity in Gbg dimer formation is still poorly understood, and most Gbg dimers form readily. In mammals, Gb_{1-4} are strikingly **homologous** to each other, and Gb_5, the most divergent, is still identical in over 50% of its residues. Gg's are much more diverse.

Although Gbg subunits were initially considered to be nonspecific inhibitors of G-protein activation, it is now clear that they regulate as many or more effectors as do the Ga's (Table 2) and fulfill many other signaling functions as well (12). Gbg can either stimulate or inhibit different isoforms of adenylyl cyclase, activate PIP $_2$-specific phospholipase C-b, open K^+ channels and close Ca^{2+} channels, and either activate or inhibit both **tyrosine kinases** and **serine/threonine protein kinases** . New Gbg-mediated functions are being discovered regularly. Gbg regulates effectors when it is released from the Gabg trimer upon activation, reflecting the preferential binding of Gbg to the inactive, GDP-bound Ga. Full dissociation of Ga-GTP from Gb may actually be an extreme outcome of a conformational change that alters the Ga–Gbg interface to allow Gbg to regulate effectors while remaining in physical contact with Ga.

In addition to controlling effector proteins, Gbg exerts multiple regulatory effects directly on Ga's. First, Gbg is required for stable membrane attachment of Ga. Gbg binds tightly to bilayers, in part because of *C*-terminal prenylation of the g subunit (see text below). Sprang proposed a plausible orientation of Gabg with respect to the bilayer, so that both the prenylated *C*-terminus of Gg and the lipid-modified *N*-terminus of Ga can interact directly with lipids (10). Next, Gbg is essentially required for regulation of Ga by receptors, in part by anchoring and orienting Ga with respect to the membrane surface. Anchoring Ga at the membrane surface increases its local concentration at the receptor several thousandfold, increasing its apparent affinity for the receptor proportionately. Direct effects of Gbg on receptor–Ga interactions are also likely. Last, Gbg binds preferentially to Ga in its inactive, GDP-bound conformation, thereby slowing dissociation of GDP from Ga. Gbg is thus a GDI (GDP-dissociation inhibitor) for its Ga partner, suppressing the basal signal output when there is no stimulatory input from the receptor (see text below). Gbg generally decreases the rate of dissociation of GDP from Ga about 10-fold, and even greater effects may occur in cells. Through a combination of these mechanisms, Gbg can facilitate the appropriate activation of a Ga by receptor and suppress its basal activation, thereby decreasing the background signal while permitting a rapid and efficient response to agonist.

Gbg contributes to agonist-dependent desensitization of receptor signaling by recruiting members of a family of protein kinases that phosphorylate G-protein-coupled receptors to initiate their desensitization and down-regulation. G-protein-coupled receptor kinases (GRKs) selectively **phosphorylate** agonist-liganded receptors at one or more serine or threonine residues in the *C*-terminal region or in the third cytoplasmic loop. Phosphorylation recruits scaffolding proteins, known as *arrestins*, which both inhibit interactions with Ga and link receptors to nascent clathrin-coated pits to initiate their endocytosis (13, 14).

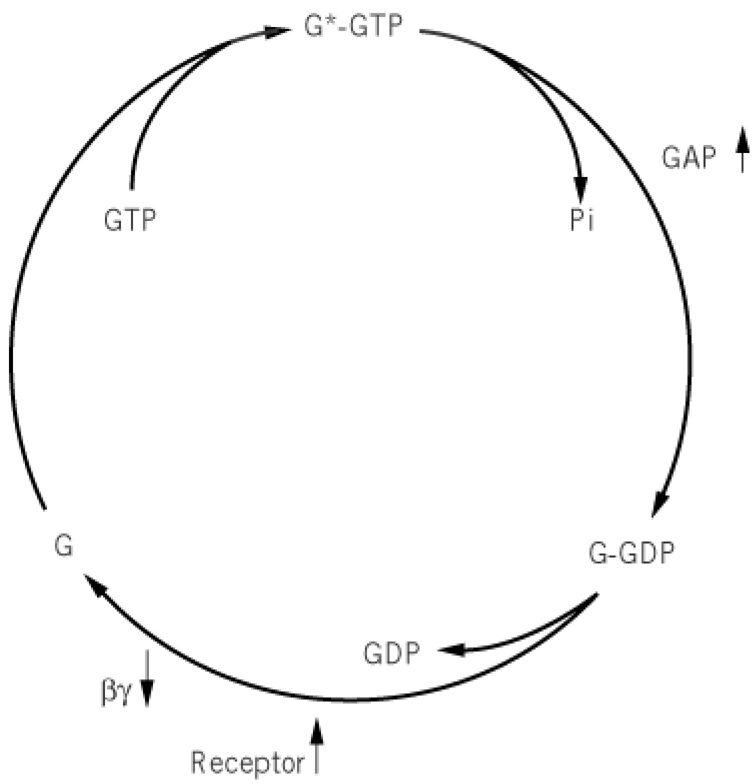
The selectivity of Gbg among receptors, Ga subunits, and effectors—and the structural basis thereof—remains unclear. It has not been possible to isolate abg trimers with a unique subunit composition except from specialized cells. One exception, Gb_1g_1, is found exclusively in photoreceptors and interacts well only with Ga_t, but such selectivity is unusual. *In vitro* studies have usually failed to observe marked selectivity of Gbg dimers in any context. The results of cellular studies have been mixed. Most notably, Kleuss et al. (15, 16) found that suppression of individual Gb or Gg molecules by microinjection of **antisense** messenger RNA leads to receptor-selective inhibition of Gbg signaling functions.

In addition to its controlled release from Ga, the availability and activity of Gbg is also controlled independently. Phosducin, a ubiquitously expressed protein that is unrelated to Ga, binds Gbg with high affinity and blocks its interactions with other proteins. Phosducin is thought to act as a Gbg chelator, and its ability to bind Gbg is regulated by protein kinase A-catalyzed phosphorylation (17). Phosphorylation of phosducin decreases its affinity for Gbg, thereby regulating Gbg in response to cellular cyclic AMP. Gbg is also known to bind both actin and **calmodulin**-Ca^{2+}, but it is unclear whether these interactions actually convey regulatory information to or from Gbg.

3. Regulatory GTPase Cycle

The regulatory GTPase cycle, proposed by Cassel and Selinger in 1977 (18, 19), provides the biochemical mechanism of G-protein signaling. Its kinetic parameters determine the rates of signal initiation and termination and the signal amplitude, both basal and agonist-stimulated (Fig. 1). Each step is tightly controlled. A G protein traverses the GTPase cycle relatively quickly with respect to the duration of the signal that it mediates, undergoing repeated activation, deactivation, and nucleotide exchange. The signal amplitude is therefore proportional to the fraction of time that the G protein spends in the GTP-bound, active state. The amplitude can be increased by accelerating GDP release and GTP binding or by inhibiting GTP hydrolysis. Similarly, the amplitude is decreased by inhibiting nucleotide exchange or by stimulating GTP hydrolysis. The rate of steady-state GTP hydrolysis and the fractional activation of the G protein at steady state are therefore independent: A G protein can cycle quickly or slowly, while maintaining either a high or low fractional regulatory activity.

Figure 1. The regulatory GTPase cycle. GTP-binding proteins are converted by binding GTP to the active state G*–GTP such that they can in turn bind and activate effector proteins. Activation is terminated by hydrolysis of bound GTP to GDP, usually a slow process that is accelerated by GTPase-activating proteins, GAPs. The inactive G–GDP complex is relatively stable unless nucleotide exchange is catalyzed by a receptor. The inactive, GDP-bound state is stabilized by Gbg subunits.



3.1. GDP–GTP Exchange

The release of bound GDP and the binding of GTP is a slow process in which the initial release of GDP is rate-limiting under physiological conditions. *In vitro*, dissociation of GDP can take minutes to hours, and a G protein retains a molecule of bound GDP after purification. Once the GDP has dissociated, GTP binding is fast under most experimental conditions. Association rate constants are estimated at 10^6 to $10^8 M^{-1} \cdot min^{-1}$, so the binding of GTP at a 50 μ *M* cytosolic concentration takes place in a second or less. Activation of the G protein subsequent to binding of GTP is also fast, although a GTP-bound but nonactivated Ga subunit can be prepared at low temperatures or in the absence of divalent cations. Unliganded G proteins can be prepared *in vitro*, although harsh conditions may be required to strip the GDP (20).

G-protein-coupled receptors initiate signaling by accelerating GDP/GTP exchange. Agonist-liganded receptor initially binds to G-GDP to form a transient low-affinity complex of receptor, G protein, and GDP, from which the GDP dissociates [(a) in equation 1]. In the absence of added guanine nucleotide, the resulting receptor–G-protein complex [(b) in equation 1] is itself relatively stable; this maintains the nucleotide binding site in an “open” conformation. In the presence of GTP, a second transient complex, receptor–G–GTP [(c) in equation 1] forms and activates the G protein. At this point, the receptor can dissociate (to leave free, activated G protein) and is itself free to catalyze further G-rotein activation. In cases where receptor-catalyzed GDP/GTP exchange occurs much more rapidly than G-protein deactivation, a single agonist-bound receptor can maintain the activation of multiple G-protein molecules and consequently generate considerable signal amplification. In specialized cells, such as photoreceptors, several thousandfold amplification can be achieved in this way (21).

$$\mathrm{R + G{\cdot}GDP} \rightleftharpoons \underset{(a)}{\mathrm{[R{\cdot}G{\cdot}GDP]}} \overset{\mathrm{GDP}}{\rightleftharpoons} \underset{(b)}{\mathrm{R{\cdot}G}} \overset{\mathrm{GTP}}{\rightleftharpoons} \underset{(c)}{\mathrm{[R{\cdot}G^{*}{\cdot}GTP]}} \rightleftharpoons \mathrm{R + G^{*}{\cdot}GTP}$$

Formally, receptor-catalyzed GDP/GTP exchange reflects the **negative cooperativity** of binding of receptors and guanine nucleotides to G proteins: Each decreases the G protein's affinity for the other, and the decreased affinity appears as an increased rate of dissociation (22). According to this mechanism, a receptor can accelerate the exchange of any guanine nucleotides, and it is the high cellular ratio of GTP to GDP that drives exchange in the physiological direction.

GDP/GTP exchange is also modulated by Gbg, which exerts two separate effects in the GTPase cycle. First, Gbg is a GDP-dissociation inhibitor (GDI) for Ga subunits. By stabilizing the binding of GDP to Ga, Gbg decreases the frequency of spontaneous GDP/GTP exchange and thus suppresses background noise in G-protein signaling pathways. Gbg can also inhibit receptor-stimulated GDP/GTP exchange and thereby inhibit G-protein signaling. Release of Gbg when one G protein is activated can inhibit the activation of another, with the extent of inhibition determined by the relative affinities of the two Ga's for Gbg. Second, and in seeming contrast to its inhibitory effects, Gbg is essentially required for the activation of G proteins by receptors. As discussed above, this effect reflects the membrane anchoring role of Gbg, but it may also have a direct regulatory component.

3.2. GTP Hydrolysis

Ga subunits catalyze hydrolysis of bound GTP by facilitating direct attack by water on the g phosphoryl group, and GTP hydrolysis is followed quickly by dissociation of inorganic orthophosphate (1). The intrinsic rates of hydrolysis of bound GTP vary markedly, however. For G_s, G_i, and G_o, GTP hydrolysis proceeds with a rate constant of 3 to $4 min^{-1}$, such that the active state has a half-life of 10 to 15 s. G_q is somewhat slower, with a half-life of 1 min. G_z is slowest, with a half-life of about 7 min. These rates are still much faster than those of the small, monomeric G proteins, evidently because the helical domain of heterotrimeric G proteins provides a catalytically important arginine residue that the small GTP binding proteins lacks.

If GTP hydrolysis is the primary deactivating event in G protein signaling, the rate of hydrolysis of bound GTP observed *in vitro* should be commensurate with the rate of signal termination upon removal of receptor agonist. This is true in some systems, such as adenylyl cyclase. In others, however, physiological termination of a signal is much faster than the rate at which G-protein-bound GTP is hydrolyzed by the appropriate G protein *in vitro* (23). This discrepancy was resolved by the discovery of GTPase-activating proteins, GAPs, which accelerate the hydrolysis of Ga-bound GTP up to several hundredfold (24).

The first GAP for a heterotrimeric G protein to be identified was also a G-protein-regulated effector, and two such effectors are now known to have GAP activity. Phospholipase C-b's both are regulated by G_q and act as a G_q GAP. PLC-b1 binds Ga_q-GTP with a K_d of ~2nM and increases its rate of hydrolysis more than 50-fold (24, 25). A G_{13}-regulated effector, a GEF for the monomeric G protein rho, is also a G_{13} GAP (26). The second group of G-protein GAPs comprises the RGS proteins. About 30 mammalian RGS proteins have been identified, and RGS proteins are found throughout the eukaryotes. They are GAPs for members of the G_i and G_q families, but with a specificity that is otherwise still poorly understood. RGS proteins have not been demonstrated to have effector activity, although definable functional domains of many RGS proteins outside the conserved GAP domain suggests that they may have other functions. The binding interface between RGS proteins and the switch II region of Ga subunits is similar in overall structure to that between GAPs for the small, monomeric GTP-binding proteins and their targets. However, GAPs for the small G proteins contribute the necessary arginine residue that is provided by the helical domain in Ga subunits (1).

The physiological functions of G-protein GAPs are still largely speculative. GAPs can obviously inhibit G proteins by decreasing the lifetime of the active state, and one role of inducible RGS proteins is attenuation of G-protein signals. The yeast RGS protein Sst2p, which is induced by the **mating** factor signaling pathway, is clearly a feedback inhibitor that is induced by mating factor and serves to turn off the mating response after its induction. GAPs are also clearly required for fast responses to the removal of agonists, and they contribute indirectly to the speed of the stimulatory phase of the GTPase cycle also (24, 27, 28). Such kinetic effects are more likely functions for the GAP activities of effector proteins.

4. Mechanism-Based Tools for G-Protein Research

Knowledge of the regulatory GTPase cycle has led to the development and use of highly specific tools for modulation of G-protein function in cells and *in vitro*. These tools include guanine-nucleotide analogs, bacterial toxins, and a wide array of mutations that can interrupt or alter specific reactions in the GTPase cycle.

4.1. Guanine Nucleotides

Nonmetabolizable analogs of GTP and GDP are used both as manipulators and as probes of G-protein signaling. Prototypes are GTPgS and Gpp(NH)p, GTP analogs that bind and activate G proteins but do not undergo chemical hydrolysis. Because they bind with relatively high affinity (particularly GTPgS), they lock G proteins in the active state. In cells and in membranes, they activate slowly in the absence of agonists, but more quickly in response to receptor-mediated nucleotide exchange. [^{35}S]GTPgS is also the standard radioligand used for quantifying G proteins. The Ga-[^{35}S]GTPgS complex is efficiently trapped on nitrocellulose filters, providing a convenient assay method. GDPgS, which mimics GDP and also binds tightly to Ga subunits, blocks activation and acts as a signaling antagonist. All three compounds are quite useful for intervention in G-protein pathways, but they have little, if any, selectivity among different G proteins, from the small monomeric G proteins through to the heterotrimeric G proteins. Greater specificity can be achieved by using a specific receptor agonist to accelerate nucleotide exchange, so that in a short time interval only the G-protein target of that receptor will bind the nucleotide. An alternative to nonhydrolyzable GTP analogs, a combination of Al^{3+} and F^-, activates heterotrimeric G proteins directly by binding as the AlF^-_4 ion to the Ga-GDP complex in place of the g-phosphoryl group of GTP. Al/F thus converts G-GDP to the active form. While activation by Gpp(NH)p or GTPgS requires nucleotide exchange, Al/F activates almost immediately. Moreover, Al/F is selective for heterotrimeric G proteins and does not bind to monomeric G proteins under normal conditions. **X-ray crystallographic** studies showed that GDP/Al/F $_4$ is not a true analog of GTP, but instead is an analog of the octagonal bipyramidal transition state that occurs during GTP hydrolysis (1). The reason that small monomeric G proteins do not bind Al/F is that they are such poor GTPases that they have low affinity for the transition state structure, although they can bind Al/F if a GAP is present to stabilize the transition state (29).

4.2. Toxins

Cholera toxin and pertussis toxin are widely used in G protein research because they are highly specific probes for G_s and for G_i or G_o, respectively. They **ADP-ribosylate** the a subunits of these G proteins with distinct chemistry, specificity, and effect, and they can be used both *in vitro* and in cells. Cholera toxin, after entering the cell through the endocytic pathway, catalyzes the ADP-ribosylation of an arginine residue at the GTP-binding site of Ga_s, thereby blocking the hydrolysis of bound GTP. G_s that has been ADP-ribosylated by cholera toxin is thus constitutively activated by cellular GTP. Cholera toxin is a specific activator of G_s signaling pathways because the cognate arginine residue in other Ga subunits is ADP-ribosylated much less efficiently. Pertussis toxin specifically ADP-ribosylates a conserved cysteine residue near the *C*-terminus of Ga_i, Ga_o, and Ga_t, thereby rendering the modified Ga insensitive to receptor. Thus, while the Ga retains its intrinsic regulatory and GTPase activities, it cannot be activated, and its function in cells is consequently blocked. Pertussis toxin is most useful for defining G_i-mediated pathways in cells, because the cysteine target residue is absent in the G_s, G_q, and G_{12} families. Pertussis-toxin treatment of cultured cells can also be used to create a functionally G_i-free background in which to study mutant G_i family members whose target cysteine residue has been replaced.

4.3. Mechanism-Based Mutants in G Proteins

Knowledge of the structure and genetics of the Ga family has yielded a group of reasonably reliable mutations that can be used to block GTP hydrolysis, to compromise GTP binding, or to block interaction with effectors or GEFs (1). Constitutively activating mutations that interfere with GTP hydrolysis are the oldest member of this class; the first is based on a naturally occurring, activating mutation of Gly12 in $p21^{ras}$ that makes it oncogenic. The corresponding mutation in Ga subunits also activates, but usually to a lesser extent. In Ga subunits, mutation of a conserved glutamine residue to leucine or of a conserved arginine (the cholera toxin modification site) to cysteine will produce constitutively active proteins that are expressed at normal levels and are otherwise unaltered. The leucine mutant is also insensitive to the GAP activity of RGS proteins (30). Apparent constitutive activation in cells can also be achieved by mutations that increase the rate of GDP/GTP exchange by destabilizing GDP binding (31). Strong dominant negative mutations in Ga subunits have been based on the mutation of Val17 in $p21^{ras}$. This mutation, which presumably acts by creating a nonactivating Ga that chelates receptors, has been less widely used.

Mutations can alter the specificity with which a Ga recognizes specific receptors or effectors. Experience with chimeric mutations that replace either the *N*- or *C*-terminal few amino acids of a Ga with those of another have permitted the construction of G proteins that can respond to receptors of interest and regulate effectors of interest in transfected cell lines. While the construction of these chimeras is not yet standard, the regions of interest for a specific interactions are reasonably well-defined, and enough mutants have been created to guide investigators in new cases.

5. G-Protein-Regulated Effectors

Heterotrimeric G proteins stimulate or inhibit a wide variety of effector proteins: enzymes that synthesize or degrade second messengers, protein kinases, ion channels, exchange factors for monomeric G proteins and, probably, a fairly large number of transporters (Table 2). As suggested by this list, the structures of effector proteins vary widely: They are either integral or peripheral membrane proteins that can be monomeric, homo-oligomeric, or hetero-oligomeric.

The mechanisms of effector regulation by G proteins also vary widely. Regulation can be stimulatory or inhibitory, additive, or synergistic, and both a and bg subunits independently regulate different spectra of effectors. Moreover, multiple isoforms of individual effectors often display differential sensitivity to regulation by Ga and/or Gbg subunits or by other signaling inputs. Individual isoforms are differentially expressed according to cell type, developmental stage, or acute regulatory signals. Such diversity allows a cell to respond to a single G-protein input with unique second messenger outputs, depending on the array of effector isoforms that it expresses. Last, an effector may also act as a GAP to regulate the GTPase activity of the Ga subunit by which it itself is regulated. A receptor can thus modulate the amplitude and speed of the inputs it receives.

5.1. Adenylyl Cyclase

Adenylate cyclase catalyzes the formation of cyclic AMP, the prototypical and ubiquitous second messenger. Eukaryotic adenylyl cyclase is itself the prototypical G-protein-regulated effector. Its stimulation by the concerted action of hormones and guanine nucleotides led to the discovery of G proteins (32, 33). At least 10 isoforms of adenylyl cyclase are found in vertebrates, all of which are stimulated by the activated form of Ga $_s$. Individual isoforms may be inhibited by the activated form of Ga$_i$, and they may be either stimulated or inhibited by (or insensitive to) Gbg. Cell-specific expression of these cyclase isoforms allows the construction of flexible signaling networks in which receptor-initiated signals to different G proteins can combine additively, synergistically, or negatively, to produce an integrated cyclic AMP signal. In addition to direct G-protein regulation, adenylyl cyclase isoforms can be further regulated by calmodulin, by Ca^{2+} itself, or by phosphorylation by several protein kinases (34). In yeast, adenylyl cyclase is regulated by a monomeric, ras-related G protein in response to nutritional signals (35).

Adenylyl cyclase in animals is a monomeric, integral membrane protein whose architecture is based on a pseudodimeric structure (36, 37). Each half of the adenylyl cyclase molecule is a cluster of six membrane-spanning a-helices, followed by a cytoplasmic domain. The active site and the site of all known regulatory interactions are contained within the pseudodimer of the two cytoplasmic domains, C1 and C2. Both Ga$_i$, Ga $_s$, and Gbg bind to C1:C2 dimers, expressed either separately or when fused. Determinants of sensitivity to G_s, G_i, and Gbg are found in distinct and nonoverlapping binding sites in the C1:C2 pseudodimer. The function of the membrane-spanning domain is unknown. Its apparent similarity to membrane transport proteins suggests that it may have an evolutionary history as a transporter. The possibility that an adenylyl cyclase from paramecium is an ion channel (38) is at least consistent with this idea. It is of evolutionary interest that adenylyl cyclase in yeast, which is stimulated by a ras-like monomeric G protein, is a large (~200kDa) soluble protein that is only vaguely related to animal cyclases in the catalytic domains (39).

5.2. Cyclic GMP Phosphodiesterase

A distinct cyclic GMP phosphodiesterase (PDE) is found in vertebrate photoreceptor cells (rods and clones), where it degrades cyclic GMP in response to light signals to cause the closure of cyclic GMP-gated cation channels (6). Retinal PDE is stimulated by the active form of G_t (transducin), which in turn is activated by the photobleached (meta II) form of rhodopsin, a receptor whose ligand is the covalently bound, light-sensing chromophore retinal. G $_t$-sensitive PDE is a heterotetramer of an ab catalytic dimer and two inhibitory g subunits, to which activated G $_t$ binds. In contrast to adenylyl cyclase, which is activated by the binding of Ga_s, the PDE is stimulated by the dissociation of the g subunits when they are sequestered by Ga_t-GTP. The rhodopsin-G $_t$-phosphodiesterase pathway is also unusual in that its components are expressed at extraordinarily high levels in photoreceptor membranes, where rhodopsin represents about 70% the total membrane protein and G $_t$ is about half of the remainder (40).

5.3. Phospholipase C-<b>b<b>

PIP_2-specific **phospholipase C**-b (PLC-b) isozymes are peripheral membrane proteins that are stimulated either by Ga_q family members, by Gbg, or by both, depending on the PLC-b isoform (7). They hydrolyze PIP_2 to the second messengers **diacylglycerol**, an activator of protein kinase C, and inositol-1,4,5-trisphosphate, which releases stored Ca^{2+} into the cytoplasm (see **Inositol triphosphates**). PLC-bs, approximately 150 kDa in size, are based on a core catalytic domain that is common to all PIP_2-selective PLCs. In addition, the PLC-bs also contain a long, *C*-terminal extension that binds Ga_q and mediates its stimulatory interaction (41). Gbg subunits bind at sites in the *N*-terminal half of the molecule. Differential stimulation of PLC-b activity by Ga or Gbg depends on the isoform. Both *in vitro* and *in vivo*, PLC-b-1 is primarily Ga_q-sensitive; PLC-b-2 and b-3 are also markedly stimulated by Gbg; regulation of PLC-b4 has not been described in detail, but it does respond to Ga_q. In cells, stimulation of Ga_i also can lead to PLC-b stimulation, but the response is mediated by Gbg. Sensitivity of PLC activation to pertussis toxin is therefore indicative of Gbg signaling. PLC-bs were the first G-protein-coupled effectors to be shown to have intrinsic GAP activity, which is specific for G_q, its activator (25). Such intrinsic GAP activity in an effector is presumably involved in rapid temporal control of signaling and in determination of receptor specificity, rather than in autoinhibition (24). The G $_q$ PLC-b pathway, while ubiquitous in animals, is particularly important for vision in mollusks and arthropods, where, in photoreceptor cells, rhodopsin regulates a G_q that in turn stimulates a PLC-b.

5.4. Inward Rectifier K^+ Channels

G-protein-gated, inward rectifier K^+ channels (GIRKs), which are found in heart, neurons, and other cells, cause a cellular hyperpolarization that is particularly important in the control of neurons, cardiac muscle, and smooth muscle. GIRKs are stimulated by Gbg subunits that in most cases are released by stimulation of Ga_i, so that GIRK activation is usually sensitive to pertussis toxin (12). A Ga_i-regulated K^+ channel is either a homotetramer or heterotetramer of members of the GIRK protomer family. Free Gbg binds directly to the GIRK channel, and addition of GDP-bound (inactive) Ga can inhibit GIRK stimulation by binding Gbg and blocking its action. It has been reported that activated Ga_i can inhibit GIRK-mediated currents, although it is not clear how this inhibition relates to the ability of nonactivated Ga_i to chelate bg and thus terminate its activating effect (9).

5.5. Other Ion Channels

Voltage-gated Ca^{2+} channels of the N and P/Q (dihydropyridine-insensitive) type are inhibited by Gbg. These are hetero-oligomeric channels that have a complex quaternary structure of integral and peripheral protein components. The location of the binding sites for Gbg are not known, but are presumed to lie in the b subunit, whose different isoforms determine the sensitivity to Gbg (42, 43). Some voltage-gated Na^+ channels are also stimulated by Gbg, perhaps by a direct binding mechanism (44).

5.6. Protein Kinases

Direct regulation of protein kinases by G proteins was first demonstrated in the yeast *Saccharomyces* *cerevisiae*, where Gbg (Ste4p, Ste18p) released from the Ga subunit (Gpa1p) in response to a pheromone receptor activates an ERK signaling cascade to control the mating response (45). An increasing number of protein kinases are now known to be regulated by G proteins in all eukaryotes, and these signaling pathways are under intense study.

At least three groups of protein kinases are regulated by G proteins, and their activation can lead to control of cell growth, cell differentiation, or acute physiological responses. First, Gbg both stimulates and inhibits different serine/threonine kinases in several MAP/ERK kinase cascades in animals and fungi, and probably in plants too. In the case of Raf1, Gbg probably stimulates the kinase activity directly, but other protein kinases may simply be recruited to their sites of action by Gbg. Second, the G-protein-coupled receptor kinases that initiate desensitization and endocytosis of G-protein-coupled receptors also bind directly to Gbg. Binding to Gbg localizes these kinases to the plasma membrane and facilitates the phosphorylation of receptors, although it is not known whether Gbg actively increases protein kinase catalytic activity (14). In animal cells, activation of G-protein pathways also leads to increased phosphorylation of protein tyrosine residues by a combination of indirect mechanisms and, probably, direct stimulation of the kinases. Both Ga_q and Gbg have been reported to stimulate the activity of Bruton tyrosine kinase (8, 46).

5.7. Phosphatidylinositide-3-kinase

Phosphatidylinositide-3-kinases (PI-3-Ks) catalyze the phosphorylation of PI-4,5-P_2 to PI-3,4,5-P_3, which activates at least one protein kinase and may trigger other cellular responses. PI-3-Ks are heterodimers of a catalytic subunit, which is a member of a conserved family of PI-3-K isozymes and one of a diverse group of regulatory subunits (47). The G-protein-regulated PI-3-K has unique regulatory and inhibitory subunits not closely related to other members of the family. It is stimulated directly by Gbg, and both subunits are required for regulation by Gbg.

5.8. Rho GEF

A guanine nucleotide exchange factor (GEF) for the Rho class of small monomeric G proteins is both stimulated by G_{13} and acts as a GAP for G_{12} and G_{13} (26, 48).

5.9. Transporters

Transporters of Na^+/H^+, glucose, Mg^{2+}, and Ca^{2+} have all been reported to be regulated, positively or negatively, by G-protein signaling pathways (49-52). In some cases, their behaviors are consistent with direct regulation by either Ga or Gbg subunits.

6. G-Protein-Coupled Receptors

G-protein-coupled receptors (GPCRs) bind G proteins at the inner face of the plasma membrane and, in response to extracellular agonists, catalyze the exchange of GDP for GTP. GPCRs make up a huge multigene family of proteins whose members are found throughout the eukaryotes. Genes for GPCRs in humans number about 1000, exclusive of the multiple odorant receptors expressed in olfactory epithelium, and account for over 1% of the total genome. Appropriately, GPCRs respond to a diverse range of agonists: biogenic amines, lipids, peptides, chemically diverse pheromones, nucleotides and nucleosides, protein hormones, Ca^{2+}, odorants and tastants, photons (with the help of an attached 11-*cis*-retinal chromophore), and proteinases (by exposure of endogenous agonist peptides) (53, 54).

The GPCRs share a common overall structure and mechanism of action. They are based on a common core structure, a bundle of seven hydrophobic, bilayer-spanning helices in the plasma membrane. The *N*-terminus, usually glycosylated, is extracellular, and the *C*-terminus is cytoplasmic. Both are of variable length. Interhelix loops are short, with the exception of the third cytoplasmic loop, which links a-helices 5 and 6: It can contain up to about 200 amino acid residues. Thus, while the membrane-spanning domain of GPCRs has a minimal size of less than 30 kDa, receptors range in total size to more than 100 kDa. The high-resolution protein structure of a GPCR is not yet known, but a low-resolution structure is available for visual rhodopsin (55). This structure orients the a-helices with respect to each other; and it distinguishes their packing from that of bacteriorhodopsin, an unrelated seven-helix **proton pump**. The rhodopsin structure has been combined with biochemical data, comparison of similar receptors, and the results of numerous mutagenesis experiments, to produce a useful model of a receptor's hydrophobic core (56).

The amino acid sequences of GPCRs in animals are most highly conserved in the membrane-spanning helices and short loops. Several signature sequences are identifiable in these regions, and receptors closely related by sequence usually bind similar extracellular ligands (54). Animal GPCRs include three subfamilies. The major subfamily accounts for receptors for most ligands, including those for most small molecules, proteins, and many peptides. The other two families are the receptors for glutamate and for a group of peptide hormones. Enough GPCR sequences are now available that it is frequently possible to predict the ligand specificity of a receptor from just its sequence. GPCRs in fungi and slime molds are also based on a bundle of seven membrane-spanning a-helices, but any homology of these receptors to animal receptors or to each other is not obvious. Their evolutionary origins are uncertain. Higher plants probably also use seven-span receptors to regulate heterotrimeric G proteins, but identification of candidate proteins as legitimate GPCRs is not yet certain.

The GPCR family is extraordinarily important to drug design: About 30% of prescription drugs act on GPCRs. Both because of this impetus and because of basic interest in their function and biology, extraordinary efforts have gone toward detailed analysis of these receptors and their ligand-binding sites. Ligand-binding sites have been mapped chemically, by mutagenesis and by the study of responses to structurally defined ligands. Experimental approaches have been complemented by intense molecular modeling. Two general structures have emerged. In receptors for small ligands such as biogenic amines, the ligand-binding site is a relatively deep cleft on the extracellular face of the bundle of membrane-spanning helices. Ligands make contact with residues from multiple helices, and it is thought that these contacts initiate the levering of the helices that constitutes receptor activation. Receptors for other ligands, notably the ab dimeric glycoprotein hormones, have extensive *N*-terminal domains that themselves have ligand-binding activity. These *N*-terminal ligand-binding domains may position the ligand near the external face of the helices to promote helix–helix levering.

In contrast to the external ligand-binding site, the cytoplasmic site on GPCRs that binds and regulates G proteins has been harder to identify. Mutagenesis experiments—mostly the creation of chimeric receptors that use segments of one receptor to alter the G protein specificity of another—suggest that the second and third intracellular loops are the primary components of the G-protein-binding site. Other mutations in the third loop can create constitutively active receptors. In those cases where the third intracellular loop is large, regions near spans 5 and 6 are more important for G-protein regulation, and the central segment fulfills other functions. It has not been possible to identify sequence motifs that determine specificity among G proteins, even when the general regions important for selectivity have been established. This divergence of sequence in receptors that bind the same G protein suggests that receptor subfamilies acquired specificity for extracellular ligands prior to the evolution of the multiple G-protein families.

The process of GPCR activation by ligand is best understood as a conformational equilibrium: An unliganded receptor is usually in an inactive conformation, but the binding of agonist favors the activated state. Partial agonists promote activation incompletely. In any case, the active receptor can catalyze nucleotide exchange on the correct Ga subunit. In constitutively active mutant receptors, an unliganded receptor can catalyze nucleotide exchange. As predicted, these mutants generally bind agonist ligands more tightly than do the wild-type receptor, indicating that they are constitutively in the agonist-favored conformation. The coupling of receptors and G proteins leads to a stereotyped effect of guanine nucleotides on the affinity of agonist binding. As discussed above, binding of an active (agonist-liganded) receptor to G protein drives dissociation of guanine nucleotide to form an agonist–receptor–G-protein complex that can be dissociated by the addition of GTP (or GDP) (equation 1). The receptor–G-protein complex displays higher affinity for agonist than does free receptor. Because addition of guanine nucleotide to membranes drives dissociation of this complex, to leave free receptor and nucleotide-bound G protein, nucleotides are often observed to decrease the affinity of receptors to agonist—but not antagonis—ligands. The nucleotide-driven decrease in agonist affinity has become a useful test for whether a receptor of unknown mechanism interacts with a G protein (22).

Cells regulate their level of response to G-protein stimulation in large part by modulating the expression and activity of the appropriate GPCRs. GPCRs undergo acute desensitization upon stimulation as a result of phosphorylation of serine and threonine residues on their cytoplasmic faces, usually in the third cytoplasmic loop or in the *C*-terminal region. Phosphorylation is catalyzed both by second messenger-activated protein kinases and by a group of GPCR kinases (GRKs). GRKs preferentially phosphorylate receptors in their agonist-bound forms. Phosphorylation limits receptor interaction with G proteins to varying extents. More importantly, phosphorylation helps recruit inhibitory proteins, known as arrestins, which both further inhibit receptor activity and promote receptor-endocytosis and consequent degradation by linking receptors to clathrin, the major coat protein of coated pits (13, 14).

Hfr'S And F-Primes

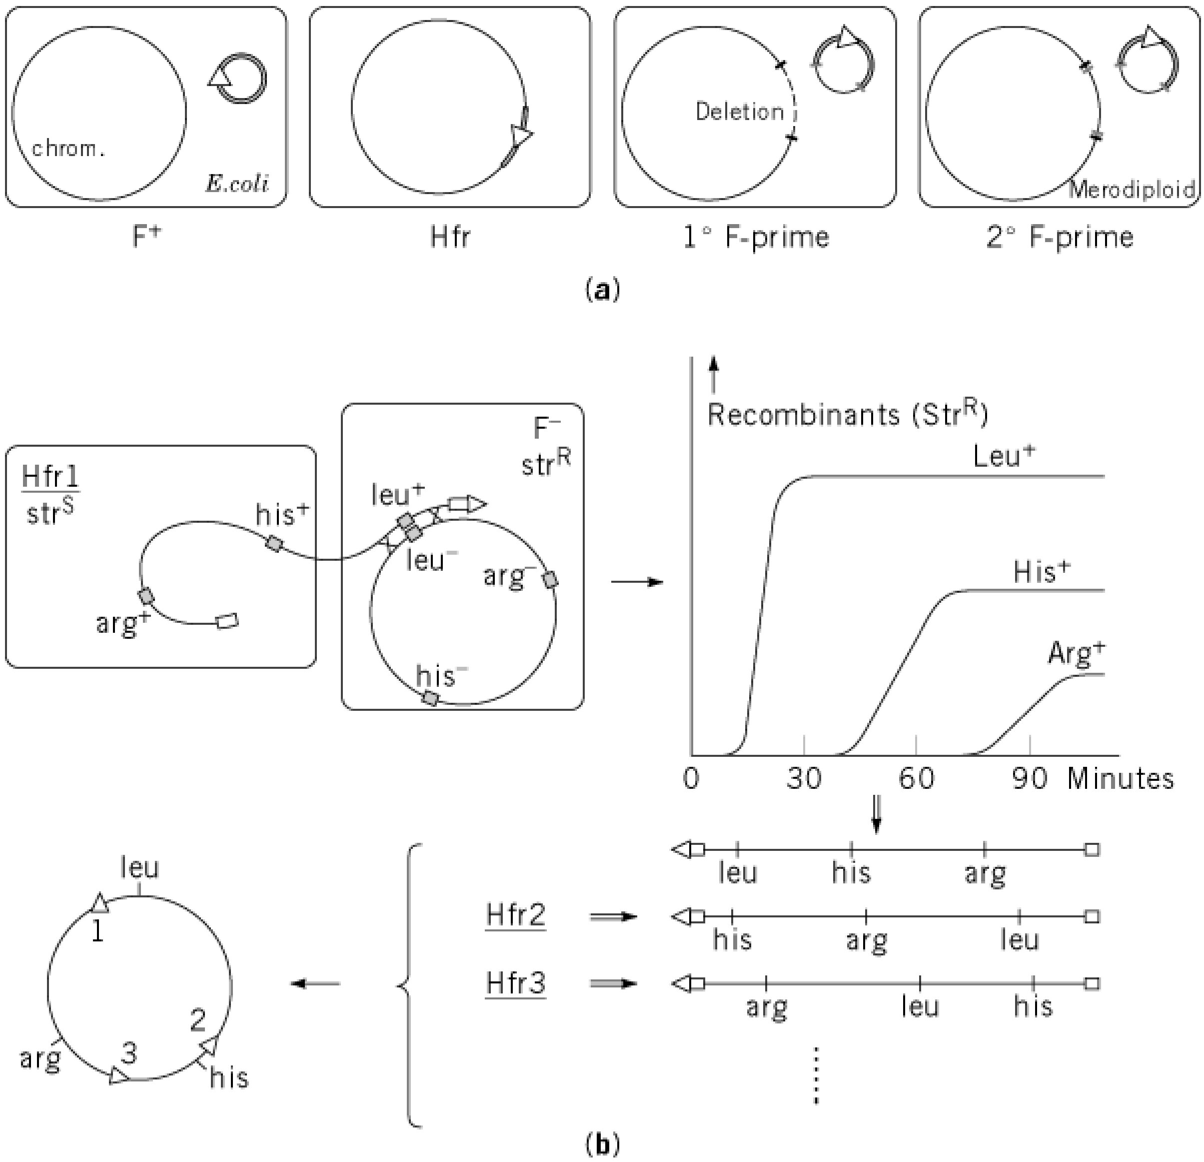
1. Bacterial Sex

Immediately after its discovery by Lederberg and Tatum in 1946 (1), bacterial mating was found to be unorthodox. Conventional sex mixes the entire **genomes** of both parents. But fertile strains of *Escherichia coli* K-12 donated only parts of their chromosomes during mating, transferring them into the other partner, the recipient, to recombine with its genome. The genetic determinant of this donor ability was also unusual: It was able to transfer itself rapidly from cell to cell as an autonomous unit without any associated chromosomal genes. This determinant was named the F (or sex) factor, later shown to be a **plasmid**, and the recombination process it enabled proved to be the key to our understanding of the genetic and physical organization of the bacterial chromosome (see F Plasmid).

2. Hfr's

Cultures of F^+ strains were able to transfer the F factor itself at high frequency to F^- recipients, thereby converting them to F^+ donors, but chromosomal markers were transferred much less efficiently, generating recombinant progeny at frequencies of about one per million parental cells. By chance, certain isolates from an F^+ culture were found with the opposite character: They had virtually lost the ability to transfer donor ability but now generated recombinants at greatly elevated frequencies. They were consequently called Hfr (high-frequency recombination) strains (Fig. 1**a**).

Figure 1. Bacterial genetics by Hfr's and F-primes. (**a**) Genetic donor types. Left to right: An F^+ cell containing the autonomous F plasmid; an Hfr, in which F has integrated into the chromosome; a primary F′ strain, in which F has excised with a portion of chromosome; a secondary F′ strain, diploid for the chromosomal portion carried by the F′ as a result of transfer to a wild-type recipient (ie, merodiploid). The arrow indicates the origin (*oriT*) and orientation of F transfer. (**b**) Mapping by interrupted mating. Following donor-recipient contact, the Hfr chromosome breaks at *oriT* (open arrow) to initiate transfer of a single donor strand into the recipient; concomitant replication in the donor restores its chromosome (not shown). The entering strand recombines with the resident chromosome, replacing the mutant alleles (*leu*, *his*, *arg*) with wild-type counterparts, and recombinants are selected by plating on medium with streptomycin (to stop growth of donors) and without one of the amino acids (to stop growth of nonrecombinant recipients). The recombination frequency declines as distance from *oriT* increases, owing to random breakage, and recombinant formation after sampling is prevented by forced breakage, allowing measurement of distances between *oriT* and the gene. For a given Hfr, the map can be read directly from the time-of-entry data. The combined results from several matings (F^-×Hfr1, Hfr2, Hfr3) showed that the *E. coli* chromosome is genetically circular.



3. F-Primes

Although Hfr strains were generally stable, F^+ “revertant” derivatives identical to the original strain were readily isolated. Some of these derivatives showed an intermediate **phenotype**: They transferred not only the F^+ character at high frequency, but a small set of chromosomal markers as well, so that the normally haploid recipient became merodiploid, that is, **diploid** for only a part of its genome. Such derivatives were termed F-primes (F′; Fig 1**a**).

The physical basis of these early observations is now understood, even if some aspects of the transfer mechanism itself continue to present challenges (see **Conjugation**). The molecular basis of Hfr and plasmid-prime formation was worked out almost entirely using the F plasmid in *E. coli* K12, and we therefore focus our discussion mostly on F. Host gene mobilization involving other plasmids in other bacterial genera conform, in general, to the F pattern. Nevertheless, Hfr's and primes derived from other plasmids justify inclusion in this chapter on the grounds of their utility, and we briefly describe methods for isolating them.

4. The Nature of Hfr Transfer

Wollman and Jacob (2) exploited the one-way transfer of DNA by developing the interrupted mating experiment to map genes (Fig. 1 **b**); in doing so, they revealed the nature of Hfr transfer. Mating is started by mixing cultures of Hfr and F^- strains. Samples of the mixture are taken at intervals and mating pairs ruptured by violent shaking; portions are then plated on agar to select for growth of recombinants. Each Hfr strain introduced its markers into the F^- recipient in a precise order and at a fixed time. Recombination frequencies were greatest for markers transferred early ($\sim10^{-1}$) and declined progressively for later entering markers (to $\sim10^{-5}$); this presumably reflects the sensitivity of conjugal pairs to spontaneous breakage. The results established the linkage relationships of various markers as a simple function of time of entry into the recipient. Moreover, collation of the results from matings with several Hfr strains indicated that the *E. coli* genome consists of a single, circular linkage group (Fig. 1**b**) (3). This striking genetic result has been corroborated by various biophysical means and confirmed by DNA sequencing of the entire genome (4).

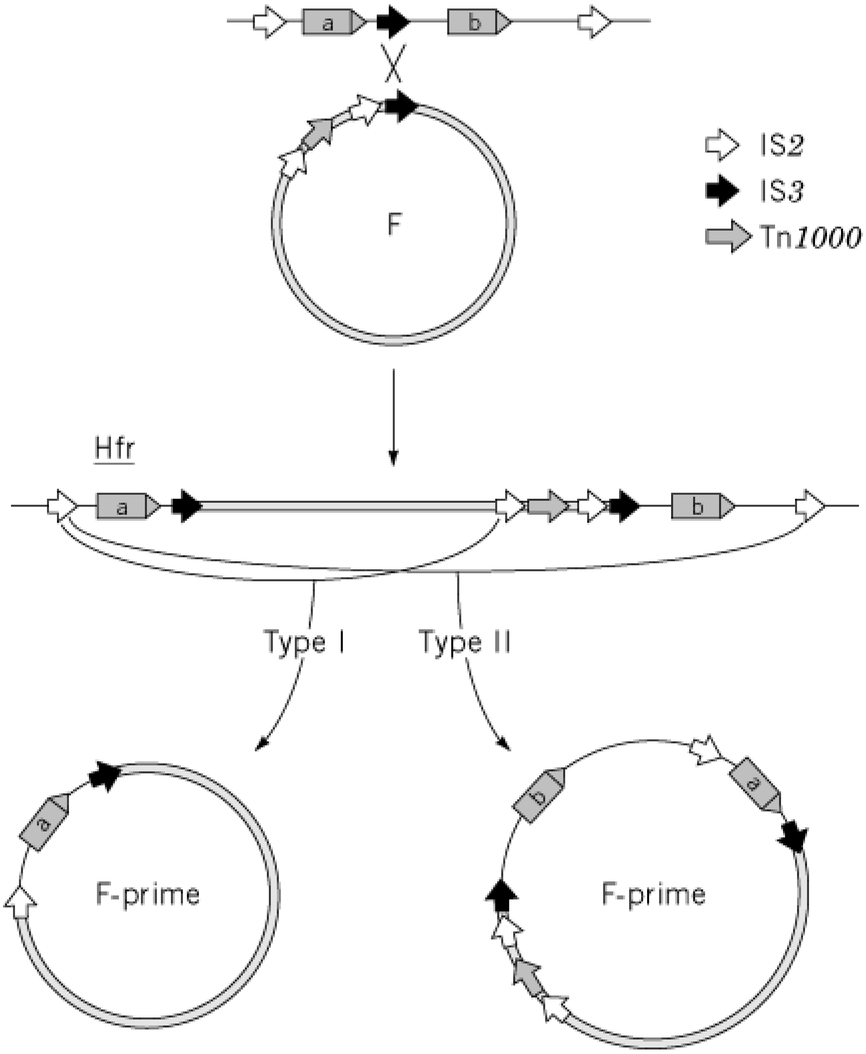
Hfr donors transferred donor ability at only very low frequencies and in association with late-entering markers. This observation, together with the time of entry results, suggested that Hfr strains arose by a single recombinational crossover between a circular F plasmid and a circular chromosome, such that the F was integrated into the chromosome (Fig. 1**a**) (5, 6). During mating, the F is broken to provide the leading end, or origin of transfer (*oriT*), which passes into the recipient, while the genes that encode the mating functions are left at the other end, which is therefore the last, and least likely, to enter (Fig. 1**b**). The order of entry for a given Hfr is determined simply by the site and orientation of F integration into the chromosome. The donor ability of F^+ cultures is then explained by the formation of many different Hfr's, each with F integrated at a distinct site, so that the F^+ population as a whole transfers all markers at about the same rate.

The recombination process is completed in the recipient, where a portion of the linear DNA transferred can be substituted for the equivalent segment of the recipient's circular chromosome by homologous recombination; if different alleles are present in the recombining region, the result is formation of a genetic recombinant.

5. Genesis of Hfr Strains

As more Hfr's were isolated and their points of origin determined, it became clear that certain sectors of the chromosome were favored for insertion of F (7). Moreover, the ability of F^+ strains to generate recombinants was severely reduced in *recA* mutants (8), implying a need for homologous recombination in Hfr formation. The reasons became evident later, when **electron microscopic** analysis of heteroduplexes formed between F and other extrachromosomal DNAs showed that F carries four known transposable elements: Tn*1000*, IS*2*, and two IS*3*s (9). About 13 IS*2*s and 6 IS*3*s are scattered throughout the *E. coli* chromosome, and their locations correspond with the origins of transfer of most Hfr's (10). Thus, homologous recombination via a single crossover between F and the chromosome is the dominant mode of Hfr formation by F (Fig. 2). Nevertheless, other mechanisms exist, as suggested by the isolation of Hfr's in which the F is flanked by copies of Tn*1000*, implying integration by replicative transposition (11).

Figure 2. Hfr and F′ formation. Homologous recombination between a transposable element on F and one on the chromosome, situated between two genes, **a** and **b**, integrates F, while the same process involving a different pair of elements excises it to form an F-prime. Transposition into targets on either the chromosome or the same plasmid creates other varieties of F-prime (not shown; see Ref. 9). Notice how these simple recombination events have changed the relationship of **a** and **b**; the Type I event has placed them on different molecules, while the Type II has reversed their order. This genome has evolved.



It is not only in their role as portable regions of homology that the transposable elements of F promote recombination in *E. coli*. At some point in the evolution of F, one of the IS*3*s transposed into the *finO* regulator gene (12), resulting in constitutive overexpression of the transfer system and the high transfer frequencies that enabled Lederberg and Tatum to find recombinants. F and *E. coli* K-12 thus owe their preeminence in the development of molecular genetics to these transposition events.

6. Genesis of F-Primes

Adelberg and Burns (13) observed that one Hfr “revertant”, which now transferred maleness at high efficiency, had undergone alterations in both its F plasmid and its chromosome, such that each now recombined with the other at very high frequency, as if they retained "memories" of each other. The molecular basis of the memory was in fact an exchange of segments upon excision of F (14, 15).

The various forms that these exchanges take are shown in Figure 2. Once again, the patches of sequence homology provided by the transposable elements play a major role (9). Recombination between two transposable elements, one in F and one in the chromosome, excises a plasmid that now carries one chromosomal flank but has left a dispensable part of itself in the chromosome (16). Plasmids formed in this way are termed Type I F-primes. Alternatively, recombination between chromosomal sequences on both sides of the F integration site creates an undeleted F-prime, termed Type II. Any chromosomal repeated sequence is sufficient: Type II F-primes that arose by recombination between IS5 elements (17) or between **ribosomal** RNA genes (18) have been found. Type I F-primes may also arise by transposition of Tn*1000* into a chromosomal target, with associated deletion of F sequences on the other side of the transposon. Type II RP4-primes might also be formed this way: An RP4::mini-Mu plasmid integrated by transposition can be excised by replicative transposition of one of the bordering mini-Mu elements into chromosomal DNA (19). An unusual event, in which F *oriT* had apparently undergone recombination with certain chromosomal loci, generated Type I F-primes lacking the *tra* operon (20).

F-prime formation has been likened to *in vivo* cloning. There is in principle no limit to the amount of chromosomal DNA that an F-prime can carry, and F-primes carrying up to 30% of the chromosome have been found. In practice however, large F-primes tend to be unstable or growth inhibitory.

Spontaneous rearrangements may be capable of generating a great variety of F-primes from a given Hfr. After excision of the initial F-prime, intramolecular transposition may delete or invert parts of the chromosomal sequence, or the F-prime may reintegrate elsewhere in the chromosome, effectively transposing its chromosomal DNA, only to re-excise as a different F-prime with a new juxtaposition of chromosomal sequences (21, 22). The potential consequences for evolution of the host genome alone are obvious (23), even without considering the possibilities raised by transfer to other species (24-26).

7. Utility of Hfr's and F-Primes

The major use of Hfr's has been the long-range mapping of genetic markers, and circular maps of several **gram-negative** bacteria have been established. How long their utility in this regard will continue is not certain, given the increasing rate at which entire microbial genomes are being sequenced. Hfr mating is still, however, an efficient way to assign new mutations to approximate locations on the chromosome, and it may often be the most convenient way of constructing genetically marked strains.

Whereas Hfr's find their main use in mapping, F-primes have been most important in analysis of function. Transfer of the appropriate F-prime to mutant strains allows tests of complementation and **dominance** at roughly equivalent copy numbers, as illustrated by the central role played by *F′lac* plasmids in deducing the basis of regulated expression of the ***lac*** operon (27). F-primes have also been particularly useful in studies of the biology of plasmids themselves, as surrogates for parent plasmids that confer no readily observable phenotype. Plasmid-primes mobilized by the promiscuous conjugation system of RP4 are used for mutagenesis of many species, as vehicles for delivering transposons or mutant genes for allele replacement (28).

8. Isolating Hfr's

The relatively frequent formation of *E. coli* Hfr strains by F integration is not usually mimicked by other plasmid-host pairs. Therefore various selective methods for isolating strains with integrated plasmids have been developed.

8.1. Treatment with Mutagens

Nitrosoguanidine treatment enabled isolation of Hfr-ColV strains of *E. coli* (29) and Hfr-FP2 strains of *Pseudomonas aeruginosa* (30). Ultraviolet irradiation stimulates Hfr formation by F in *E. coli*. Why these treatments promote Hfr formation is unknown; stimulation of recombination by **DNA damage** might play a part.

8.2. Selection for a Plasmid-Borne Marker Under Conditions in Which the Plasmid Cannot Replicate
Treatment of an *Erwinia* strain carrying F′*lac* with **acridine** orange, which specifically inhibits F replication, led to isolation of an Hfr strain (31). Growth at high temperatures of cells carrying temperature-sensitive (*ts*) IncP plasmids allowed isolation of Hfr's in *P. aeruginosa* (32) and *Rhodobacter capsulatus* (33). Exploiting restricted host range has served the same purpose; Hfr's have been selected after transfer of a hybrid plasmid, containing the ColE1 replicon linked to the RP4 *tra* region, into species of *Rhodobacter* (34) and *Methylobacillus* (35), in which ColE1 cannot replicate. Tn*10*-mediated transposition of the *E. coli* chromosome into a *ts* vector carrying the *tra* region generated Hfr's of any predetermined origin and orientation (36).

8.3. Rescue of Replication-Defective Chromosomes by Plasmid Replicons
Strains of *E. coli* and *Salmonella typhimurium* with *dnaA*ts mutations are unable to grow at 42°C because initiation of chromosome replication is blocked. Temperature resistance results from the integration of plasmids able to assume control of chromosome replication, and this can be used to select Hfr strains. Several R and Col plasmids, as well as F, have given rise to Hfr's in this way (see Ref. 37 for review).

8.4. Incorporation of a Transposon into the Conjugative Plasmid
This approach, which recalls the formation of Hfr's by Tn *1000* transposition, is more generally applicable. Two plasmids in particular have been used to transfer chromosomal DNA in a wide variety of gram-negative bacteria. RP4 carrying either the prophage Mu transposon or its mini-Mu derivative is integrated into the chromosome by replicative transposition, such that the inserted RP4 is flanked on each side by a copy of the Mu element (19). R68.45 carries a tandem duplication of IS21: Cutting between the IS21 elements and pasting into a chromosomal target site integrates the conjugative plasmid, once again flanked by copies of the transposon (38).

8.5. Conjugational Transposons
Conjugation determinants are inserted into a transposon, and strains are selected that carry the transposon at various sites in the chromosome. Each derivative is an Hfr. Yakobsen and Guiney (39) created bipartite Hfr derivatives of *R. meliloti*: Tn5 carrying *oriT* of RP4 was transposed into the chromosome, and RP4 transfer functions were provided by a plasmid, permitting oriented transfer of chromosomal DNA. This approach essentially recapitulates the mobilization of nonconjugative plasmids, such as ColE1, by self-transmissible ones, such as F. Alternative systems in which all the transfer functions are inserted into the transposon have also been constructed (40).

8.6. Transposons as Regions of Portable Homology
Again mimicking natural F integration, this time by homologous recombination, a plasmid carrying a transposable element can be transferred to a recipient that already has the transposable element inserted into its chromosome; growth of exconjugants in conditions restrictive for plasmid replication (temperature-sensitivity, narrow host range, etc.) allows the direct selection of Hfr strains. This approach has been used to obtain Hfr's by integration of F′ *ts*::Tn10 in *S. typhimurium* (41) and R91-5::Tn5 in *Pseudomonas putida* (42). It lends itself both to the generation of banks of Hfr derivatives and to the isolation of individual Hfr's with predetermined origins of transfer.

8.7. Potential Problems
Three potential problems beset the isolation of useful Hfr strains: (i) paucity of insertion sites, (ii) instability, and (iii) deleterious integration. Homology-based integration depends on the chance that the transmissible plasmid and the chromosome have sequences in common, and it also leaves the integrated DNA susceptible to **RecA**- or **resolvase**-mediated excision (43). Fortunately, the transposon-based strategies for Hfr isolation largely overcome these problems: Because transposon

target specificity is usually very low, the range of Hfr's obtainable is, for practical purposes, unlimited; and spontaneous transposon excision is sufficiently rare to permit formation of stable Hfr's. Most conjugative plasmids are of somewhat higher copy number than F, and their integration is often poorly tolerated (32, 43, 44). Here again, a transposon-based strategy solves the problem, because incorporation of transfer functions in a transposon uncouples them from the replicon, as described above.

9. Isolating F-Primes

As in the case of Hfr's, several techniques for isolating particular plasmid-primes have been developed to overcome the limitations of natural mechanisms. One of the earliest used was the selection for early transfer of a marker normally transferred late in an Hfr cross (15). F-primes carrying proximal markers can also be selected by using a *recA* mutant recipient to impair integration of the selected marker (45). This approach has been used to select an R-prime in *P. aeruginosa* (46), and a variation of it in which recombination is prevented by transfer to a recipient of a different species has led to the isolation of many R-primes (eg, Ref. 47). Some recombinants, formed by mating one Hfr strain with another that had been converted to the F^- phenocopy state by prolonged incubation in stationary phase, proved to be “double males,” containing two integrated Fs: recombination between them created F^- primes carrying the intervening DNA (48). A similar event appears to be responsible for the formation of certain R-primes.

The above methods all rely on genetic maneuvers to select spontaneously formed plasmid-primes. A quite distinct method has been used to produce finer gradations in the range of F-primes created. It is based on the essentially random cleavage of host DNA that occurs during **phage P1** infection and consists of simply **transducing** F (or R) DNA into F^- cells (49). It has been used thus far to create shorter versions of existing F-primes, for genetic analysis (50), and to isolate an R′lac plasmid directly by infection of an Hfr strain (51).

10. Prospects

With the radical, and no doubt permanent, shift to physical mapping and sequencing as the preferred means of analyzing genomes, Hfr's and plasmid-primes will now serve mainly as adjuncts to other methods. Even the role of F-primes in genetic complementation has been largely taken over by convenient low copy-number cloning vectors. Nevertheless, these traditional methods should continue to be useful during the initial stages of genetic characterization of new organisms able to host promiscuous conjugative plasmids, such as RP4. Moreover, recent insights into the roles of gene mobilization in the pathogenicity of bacteria underline the importance of understanding the mechanisms of plasmid–chromosome interactions (52). It is not unreasonable to anticipate novel ones. It is also interesting to speculate on giant plasmid-primes as the origin of multichromosome bacteria (53, 54).

Suggestions for Further Reading

55. F. C. Neidhardt et al., eds. (1996) *Escherichia coli and Salmonella. Cellular and Molecular Biology*, 2nd ed., ASM Press, Washington, D.C. Chapters 126–129 in Vol. **2**, Section C provide a comprehensive treatment of the subject, centered on *E. coli*, as well as an exhaustive bibliography.
56. C. Reimann and D. Haas (1993) "Mobilization of chromosomes and non-conjugative plasmids by cointegrative mechanisms."In *Bacterial Conjugation*, (D. B. Clewell, ed.), Plenum Press, New York. An excellent starting point for accessing the available information on conjugal transfer in a wide range of bacteria.
57. W. Hayes (1968) *The Genetics of Bacteria and Their Viruses*, 2nd ed. Blackwell Scientific Publications, Oxford Chapters 22 ("Conjugation") and 24 ("Sex Factors and Other Plasmids") of this textbook is a lucid account of the historical development of the subject, written by one of its pioneers.
58. T. D. Brock (1990) *The Emergence of Bacterial Genetics*. Cold Spring Harbor Laboratory Press, Cold Spring Harbor, New York. Chapter 5 ("Mating") is another historical perspective. The science, enlivened by anecdote, is treated more lightly than in Hayes, but without sacrifice of rigor or clarity.

High Mobility Group (HMG) Proteins

The major proteins of chromosomes and chromatin are the histones, but other, nonhistone chromosomal components are also present, in much lower amounts. The most abundant and best characterized of these is the class of high mobility group (HMG) proteins. (The name is an operational definition coined when the proteins were first isolated in the 1970s as proteins that were soluble in 2% trichloroacetic acid or 5% perchloric acid and migrated with a high mobility in polyacrylamide gel electrophoresis .) HMG proteins in metazoans fall into three structurally and functionally distinct classes: the HMG 1, 2 family, HMG 14 and 17, and the HMG I(Y) family. (The numbering is also a legacy from the past!) They appear to be present in all cells of higher eukaryotes. They are relatively abundant, being present in the nucleus on average at about 1 molecule per 10 to 15 nucleosomes [considerably less for HMG I(Y)]. All have intriguing properties, and their cellular roles are not fully understood, but they are likely to play important roles in **gene** expression. None of the three classes shows specificity for particular DNA sequences; instead, they bind to particular structures in DNA or to chromatin. Both HMG 1,2 and HMG I(Y) have "architectural" roles, and both bind primarily to DNA in the minor groove, although they are wholly unrelated in amino acid sequence and structure. The early work on these proteins is described in a definitive book (1). A recent review (2) gives a comprehensive account of more recent work and is an excellent source of references up to 1996, which in general will not be duplicated here. For more general background, the reader should consult two volumes on chromatin (3, 4).

1. The HMG 1 and 2 Family

In vertebrates this class consists of HMG1 (molecular mass ~25,000Da) and two closely related forms of HMG2, which are a few residues shorter. They are the products of **homologous** genes and show a high degree of evolutionary conservation. They have a tripartite structure consisting of two tandem homologous regions of about 80 amino acid residues (the two DNA-binding "HMG boxes") and a long acidic tail of about 30 (HMG 1) or 20 (HMG 2) consecutive **aspartic** and glutamic acid residues linked to the second box by a short basic region. HMG 1 and 2 bind to DNA with a "structure-preference" rather than a sequence preference. They bind to bent or bulged DNA and to DNA kinked by the antitumor drug *cis*-platin, in preference to linear DNA; they also prefer four-way junctions, **supercoiled** DNA and DNA minicircles, and they stabilize DNA loops (the juxtaposed ends probably resemble crossovers in supercoiled DNA). They bend linear DNA, as shown by the ability to cause circularization (in the presence of DNA Ligaseto join the ends) of short DNA fragments (~80bp) that will not circularize unaided, and they constrain negative supercoils in relaxed circular DNA. The ability to distort DNA, as well as to recognize DNA distortions reflected in these properties, is likely to reflect the *in vivo* role(s) of HMG 1 and 2.

Relatively abundant HMG-box proteins that bind to DNA without sequence specificity also occur in yeast (NHP6A and B), insects (eg, HMG-D and HMG-Z in *Drosophila*; HMG1a and b in *Chironomus*), and plants (HMGa, etc.). In all these cases, the proteins contain only one HMG box and the acidic tail is often shorter than in vertebrate HMG1,2 (eg, 10 residues in HMG-D). All these proteins bind preferentially to distorted DNA substrates (although the *Chironomus* HMG 1a and 1b bind A-T-rich linear and four-way junction DNA with equal affinity). The HMG-box motif also occurs in a large and growing number of sequence-specific transcription factors, as a single copy, with no acidic tail, and embedded in unrelated sequence (5, 6). The first examples were the product of the male sex-determining gene on the mouse Y chromosome (SRY) and the lymphocyte enhancer binding protein (LEF-1). The specificity of these proteins for their DNA targets resides in the HMG box. They also bind to four-way DNA junctions, and they bend linear DNA containing their DNA binding sites (7). The estimated bend angles are ~130° for LEF-1 and ~90° for mouse and human SRY. Proteins with two or more HMG boxes bind DNA with relatively low sequence specificity. These include the **RNA polymerase** I transcription factor UBF (upstream binding factor; 4–6 HMG boxes, depending on source, and a very long acidic tail) and the mitochondrial factors mtTF1 and ABF2.

This diverse group of sequence-specific and non-sequence-specific HMG-box DNA-binding proteins is united by the ability to distort and bend DNA, which is probably central to their biological roles. They are regarded as "architectural elements in the assembly of nucleoprotein structures" (7). Their properties are analogous to those of the bacterial IHF (integration host factor) and **HU proteins**. Indeed HMG-D, NHP6A and HM can all functionally replace HU in *Escherichia coli*, and HMG 1 and 2 can functionally replace HU in facilitating assembly of the invertasome during Hin-mediated recombination .

Protein structures have been determined by NMR for the A and B HMG boxes of HMG 1, the HMG boxes of *Drosophila* HMG-D and the transcription factor Sox4, and for the HMG boxes of SRY and LEF-1 complexed with oligonucleotides. Although there are slight differences that might be significant, the protein folds are all generally very similar, showing that there is no gross change in the HMG-box structure on binding to DNA. The HMG box is L-shaped, the relative positions of the two arms being fixed by a tightly packed **hydrophobic** cluster; Figure 1 shows the A-box of HMG1 (8). The "long" arm contains an *N*-terminal extended **b-strand** packed against **a-helix** III in the *C*-terminal half of the molecule; the "short" arm consists of a-helices I and II. DNA binding occurs on the concave face of the protein, which interacts in the minor groove of the DNA. The SRY/DNA and LEF-1/DNA structures (9, 10) show that the protein partially intercalates into the minor groove and causes the DNA to bend toward the major groove, away from the protein (Fig. 2). The minor groove is also opened up (becomes wider and shallower), forming a larger surface for interaction with the protein, and the DNA is locally untwisted. The protein thus sits on the *outside* of the bend and is very reminiscent of the way in which the **TATA box**-binding protein TBP interacts with DNA. In both structures a bulky hydrophobic residue (Ile in SRY, Met in LEF-1) intercalates between base pairs near the center of the DNA to cause bending. Binding is stabilized by interaction of a basic region *C*-terminal to the box with the major groove opposite the widened minor groove. All HMG boxes are likely to bind to DNA in essentially the same way, except that the role of intercalation in the non-sequence-specific proteins is less clear. Sequence-specific and non-sequence-specific HMG boxes also show characteristic differences in residues at key positions in the *N*-terminal b-strand.

Figure 1. Structure of the HMG box in the A-domain of HMG1 (residues 11-83 of the protein) determined by NMR spectroscopy (8).

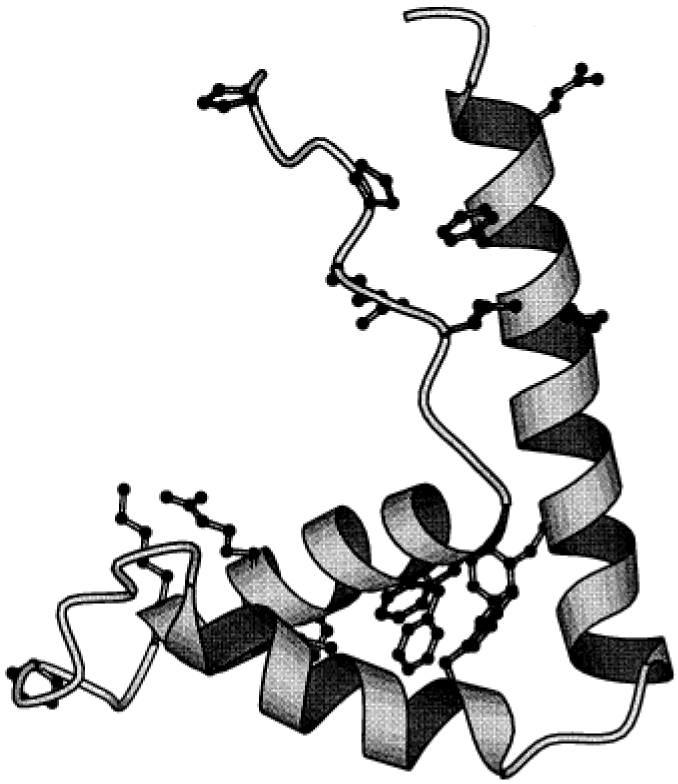

Figure 2. Structure of the LEF-1 HMG box complexed with DNA complex, determined by NMR spectroscopy (10).

The isolated A and B boxes of HMG 1 bend and distort DNA like the entire protein; there are slight differences between them that might be related to the small differences in structure between the two boxes (8). Tandem boxes have a higher affinity for DNA than single boxes and are more effective than single boxes in DNA binding and bending; the basic linker between the boxes and the acidic tail further enhances the affinity (eg, Ref. 11). The acidic tail works in the opposite direction on most DNA substrates *in vitro*, by lowering the affinity of the HMG boxes for DNA, possibly by general charge repulsion, and possibly by interacting electrostatically with the DNA-binding face of the box (es). The acidic tail of HMG-D, however, increases the affinity and selectivity of the protein for mini-circles (<100bp), which are highly constrained and effectively present a "pre-bent" substrate (12); the same is true for HMG 1. Perhaps the tail stabilizes a conformation of the protein that is suited to recognition of a highly predistorted substrate.

Surprisingly little is known for certain about the binding of HMG 1 and 2 to chromatin. Early observations on micrococcal nuclease (**Staphylococcal nuclease**) digestion products of chromatin (3, 4) suggested that HMG 1 and 2 were associated with linker DNA, and that that there was a population of HMG1-containing nucleosomes lacking histone H1. This led to the suggestion that HMG 1 binds to sites normally occupied by H1, but the evidence for this is still circumstantial. However, binding of H1 and HMG 1 to nucleosomes reconstituted on to the *Xenopus* 5 S rRNA gene resulted in similar protection of chromatosome length DNA against micrococcal nuclease digestion (see Chromatin and Nucleosome), which was interpreted in terms of a shared structural role (13). The finding that, like HMG 1, H1 and its globular domain would also bind to synthetic four-way junctions (14) has been taken to reinforce this (the four-way junction is assumed to mimic the crossover of the entering and exiting duplexes around the dyad of the nucleosome). However, it is not clear that the two proteins are recognizing the same features of the four-way junction. Moreover, given the nature of H1 binding to the nucleosome (see Nucleosome or Chromatin), even if H1 and HMG 1 bind in the same general vicinity, the details of their interactions in chromatin would be expected to be very different. *In vivo* evidence for a shared *functional* role in at least some circumstances is more compelling. In *Drosophila* early embryos, where cell division is rapid, H1 is absent and the condensed chromosomes contain HMG-D (which has only one HMG box). At later stages, the chromosomes contain H1 rather than HMG-D, and gene transcription, which was previously absent, starts (15). This apparently reciprocal relationship suggests that H1 and HMG-D may have a common function at different stages of embryogenesis in *Drosophila*, although not necessarily an identical binding site on the nucleosome. Rigorous reconstitution studies are needed to settle the question of how HMG 1 and 2 bind to chromatin. It is, of course, possible that they function only at **promoters** or enhancers, where a nucleosome is absent. For example, by bending DNA they might facilitate the interaction of two proteins, bound on either side of the kink, that is required for some functional purpose; or they could facilitate the binding of a protein that binds best to a DNA bend, by pre-bending the DNA in an essentially catalytic role; or they might also stabilize a DNA loop, such as might be formed to bring enhancer and promoter elements into proximity.

HMG 1 and 2 have been variously implicated in DNA replication, transcription, DNA repair and recombination, and, given their versatility in DNA distortion and recognition of distorted DNA, this is not altogether surprising. In recent *in vitro* studies of V(D)J recombination of immunoglobulin biosynthesis (see Gene Rearrangement), HMG 1 and 2 were found to stimulate V(D)J cleavage (16) and to be components of a stable post-cleavage complex between synapsed recombination signals (17). An obvious question is whether HMG 1 and 2 have roles in transcriptional activation; distinct roles for the HMG boxes and the acidic tails might be envisaged. *In vitro* studies (for references see Ref. 2) have given conflicting answers. It has been suggested that activation might result from stabilization of an activated conformation of the TFIID-TFIIA initiation complex on the promoters of activated genes; or, based on *in vitro* binding assays, that HMG 1 and 2 might act indirectly to promote transcription by promoting the binding of various transcription factors to their cognate DNA binding sites, probably by bending the DNA. *In vivo* results (transfection experiments) show enhancement of transcription by HMG 1 and suggest that the acidic tail acts as a transactivation domain, although this is not the case for the heterologous mammalian HMG 1 expressed in yeast (2). However, HMG 1 and 2 have also been reported to repress transcription by RNA polymerase II *in vitro*—either by interacting with TBP in the presence of a TATA-box-containing oligonucleotide and thus preventing binding of TFIIB and formation of a preinitiation complex, or by acting later, after the assembly of the TBP-TFII promoter complex. There are now several examples of facilitation of transcription factor binding to DNA by HMG 1 and 2, and this seems likely to be important. For example, binding of the progesterone receptor to an oligonucleotide containing the progesterone response element is enhanced ~10–fold by HMG 1 and 2, and HMG 2 stimulates the sequence-specific binding of the octamer transcription factors Oct 1 and Oct 2, by interacting with the POU domains (2). HMG 1 stimulates DNA binding of human HOXD9, by interaction with the **homeobox** domain (18), and of the tumor suppressor p53 (19). Ternary complexes between the transcription factor, HMG protein, and DNA are likely, but in at least some cases the HMG must be only weakly bound, because such complexes cannot be detected by gel electrophoresis.

2. The HMG I(Y) Family

HMG I and Y are isoforms generated by alternative splicing, differing only in HMG Y (96 amino acid residues) having an 11-residue deletion compared with HMG I (107 residues). HMG C (105 residues) is the third member of this family and is related (~50% sequence identity) to HMG I(Y). Like HMG 1 and 2, they appear to function as "architectural" transcription factors, but the two classes are structurally unrelated. The proteins are subject to post-translational modifications, notably **cell cycle**-dependent reversible **phosphorylation**, probably by p34cdc2/cyclin ("cdc2 kinase"). They are expressed at higher levels (~15 to 50 times) in transformed and undifferentiated cells than in differentiated somatic cells, relatively independent of cellular growth rate; there is also a correlation with increased metastatic tumor potential. Further background and references may be found in Ref. 2.

The HMG I(Y) proteins have a distinctive primary structure containing three regions designated "A-T hooks," separated by flexible chain. HMG C is similar in the A-T hook regions, but much less so elsewhere. The A-T hook binds to the minor grooves of A-T-rich sequences, occupying 5 or 6 bp; three tandem AT hooks would therefore occupy 15 to 18 bp of continuous A-T DNA. The **consensus sequence** of the A-T hook motif is -Pro-Arg-Gly-Arg-Pro- flanked by basic residues; the motif also occurs in a number of unrelated DNA-binding proteins in a range of species. The polypeptide backbone structure is predicted to be similar in shape to the drugs distamycin A, netropsin, and Hoechst 33258, which bind to the minor groove of B DNA and can displace HMG I(Y) from A-T-rich DNA. The structural similarity is borne out by NMR spectroscopy (see text below). In addition to minor groove binding—although in completely different ways—HMG I(Y) also shares with HMG 1 and 2 the property of binding to A-rich non-**B-form** DNA, such as four-way junctions, in preference to the corresponding duplexes (20). HMG I(Y) also bends DNA (but in this case bending is attributed simply to asymmetric charge neutralization on one face of the DNA duplex by the basic amino acid side chains in the A-T hook DNA-binding domains) and supercoils relaxed circular DNA in the presence of **topoisomerase** I, probably through strand unwinding, the mechanism of which is unclear. Removal of the negatively charged *C*-terminal domain increases supercoiling by 8- to 10-fold, apparently without affecting the affinity of HMG I(Y) for A-T-rich DNA (2).

Earlier studies suggested a variety of roles for HMG I(Y) proteins (2). More recently, more direct experiments point to a role in transcriptional regulation (negative or positive) of a number of mammalian genes with A-T-rich promoter or enhancer sequences. In positive regulation, HMG I(Y) has been proposed to act as an "architectural" transcription factor that bends DNA and contacts components of a multiprotein complex, as well as promoting contacts between other members. A well-documented example (21) is the involvement of HMG I(Y) in the virus-induced expression of the human b-interferon gene (IFN-b). HMG I(Y) appears, through a combination of DNA bending and protein-protein interactions, to mediate the assembly of a complex containing HMG I(Y) and the transcription factors NF-kB and ATF-2/c-Jun, all bound simultaneously to two separate "positive regulatory domains" (PRDII and IV) of DNA in the 5′ promoter/enhancer region of the b-interferon gene. NF-kB binds to the major groove and HMG I(Y) to the minor groove. The structure of a 39-residue peptide containing the second and third DNA-binding domains complexed with a 12-bp oligonucleotide containing a 5-bp A-T tract from the PRDII element of the b-interferon enhancer has recently been determined by NMR spectroscopy (22) and reveals extensive hydrophobic and polar contacts in the minor groove centered around an Arg-Gly-Arg motif. In contrast to the HMG box–DNA complexes (see text above), the minor groove is not widened and the DNA is not bent. However, this is a short piece of DNA and, although the protein does not directly cause bending at its binding site, as the HMG box does, bending might well be induced outside the binding site and would be apparent only with a longer DNA segment. Principles similar to those involved at the b-interferon promoter are likely to prove a common feature of the role of HMG I(Y) in many systems—for example, in the function of HIV-1 pre-integration complexes (23).

The situation with respect to the binding of HMG I(Y) to chromatin is not clear. The proteins will bind to nucleosome core particles *in vitro*, at up to four molecules per nucleosome, in a noncooperative manner. However, they bind to A-T-rich DNA in preference to mixed-sequence nucleosomes and, as pointed out (2), if A-T sequences were present in the linker DNA—or in a nucleosome-free region—that would probably be the preferred binding site for HMG I(Y) in chromatin. There is an intriguing possible connection between HMG I(Y) and chromatin structure through histone H1 (see Histones). *In vitro* H1 will bind preferentially to A-T-rich fragments of naked DNA, possibly through "-SPKK-" (Ser-Pro-Lys-Lys) motifs in the *C*-terminal tail, and can be displaced by HMG I(Y). In the nucleus, scaffold attachment regions of chromatin are A-T-rich and have been suggested to be focal points for displacement of H1 by HMG I(Y), perhaps leading to "open chromatin" domains (24); in neoplastic cells, greatly increased levels of HMGI(Y) might contribute to altered patterns of gene expression. This is still speculation, but it is highly suggestive that HMG I(Y) co-localize (as shown by immunofluorescence) with A-T-rich scaffold regions in metaphase chromosomes, which contain the interphase scaffold attachment regions brought together (25).

3. HMG 14 and 17

These evolutionarily related proteins are present in all tissues of most higher organisms. Their precise cellular roles are not understood, although various lines of evidence suggest that they facilitate transcription of chromatin, and it now appears that this is at the level of higher-order structure. Early work reported a correlation between DNAse I-sensitivity of chromatin, which itself correlates with transcriptional competence (see Chromatin), and the presence of HMG 14 and 17 (see Refs. 2 and 3 for background). HMG 14 and 17 contain, respectively, 98 and 89 amino acid residues and have a high content of lysine, alanine and proline and a negatively charged *C*-terminal region (although there is no continuous run of acidic residues, as in HMG 1 and 2). They bind to nucleosomes in preference to free DNA through a 30-residue, basic sequence that is conserved within the HMG 14 and HMG 17 classes, but differs in detail between the two (2). HMG 14 and 17, despite their common ancestry, are only 60% identical in sequence and are likely to perform different roles in the cell.

Two copies of HMG 14 and 17 bind cooperatively to 146-bp nucleosome core particles (see Nucleosome) at roughly physiological ionic strength, presumably by recognizing particular structural features. In native chromatin, nucleosomes containing only HMG 14 or HMG 17 are clustered in runs of, on average, six nucleosomes, potentially giving functionally distinct domains along the chromatin fiber, the significance of which is not yet clear (26). The free proteins appear to be unstructured in solution but could well become structured upon interaction with the nucleosome core. Binding of HMG 14 is weakened by **phosphorylation** of Ser 6, which is an early event in the induction of immediate-early genes on mitogenic stimulation (27). Footprinting and cross-linking data have led to a model for the location of the two HMG 14 or 17 molecules on the core particle, in which the HMG proteins are bound by their basic *N*-terminal regions to sites 20 or 30 base pairs from the end of the core particle DNA and then loop under one of the DNA ends to contact, in each case, a major groove adjacent to the dyad on the central turn of DNA (2). This could explain why HMG 14 and 17 stabilize nucleosome core particles, by preventing charge repulsion that would lead to unraveling of the ends. In contrast, HMG 14 and 17 appear to destabilize chromatin higher-order structure in some way, although they do not prevent its formation (2), consistent with the facilitating effect of HMG 14 and 17 on transcription. When tested for activator function as fusions to DNA-binding proteins in yeast, HMG 14 and 17 did not act as classical transcription factors, despite an acidic *C*-terminal region. However, transcription from minichromosomes assembled in *Xenopus* or *Drosophila* embryo extracts was stimulated by HMG 14 and 17, in contrast with transcription from naked DNA, consistent with a role for HMG 14 and 17 in destabilizing chromatin structure (2). Enhancement of transcription from assembled SV40 minichromosomes by HMG14 was interpreted as relief of H1-mediated repression, resulting in unfolding, for which the acidic *C*-terminal region of HMG 14 is needed (28). Specific interactions with the *N*-terminal tail of H3 may be involved (29)—yet another role for the *N*-terminal tails (see Chromatin).

High-Performance Liquid Chromatography (HPLC)

HPLC is a modern high-resolution liquid **chromatographic** technique best described as high-performance liquid chromatography because the essence of the technique is the high resolution of the separations achieved by using uniform microparticulate, chromatographic supports and well-designed equipment. HPLC has also been called high-pressure or high-speed liquid chromatography but these acronyms do not reflect the essential features of the technique.

The development of HPLC has been in several areas including theory, special columns, and equipment. Though the theoretical principles of HPLC were firmly established by Martin and Synge (1) in the early 1950s, HPLC in practice did not appear until the late 1960s because of instrumental problems. Horváth et al. (2) constructed one of the first practical HPLC apparatuses for use in their research on **nucleotides** . Subsequently, dramatic developments in packing materials, particle sizes (as small as 3 µm), narrow-bore columns (as small as 0.5 mm inner diameter for microbore columns) and high column inlet pressures (up to 12,000 psi) have been achieved for high resolution and efficiency.

HPLC is carried out in all classical modes of column chromatography involving a liquid mobile phase. The most important are liquid-solid adsorption, liquid-liquid and organo-bonded partition, **ion-exchange**, **size-exclusion**, and affinity chromatography . HPLC has the advantages over classical liquid chromatography that the columns are reusable, the sample introduction can be automated, flow rates can be controlled precisely, and detection and quantification can be achieved by using continuous flow detectors. These features have led to improved analytical accuracy and precision.

The widespread application of HPLC in biochemical studies is evidenced by countless publications in the field. For example, HPLC is widely used by molecular biologists to isolate **nucleic acids** from synthetic oligonucleotides to natural **plasmids** (see reviews 3, 4 and Chapter 11.1 in 5), and by protein biochemists to purify **peptides** and proteins (see reviews 6–10 and Chapter 11.2 in 5). Those requiring more detailed practical information are directed to the reviews cited previously and also to a number of excellent monographs (5), (11-13).

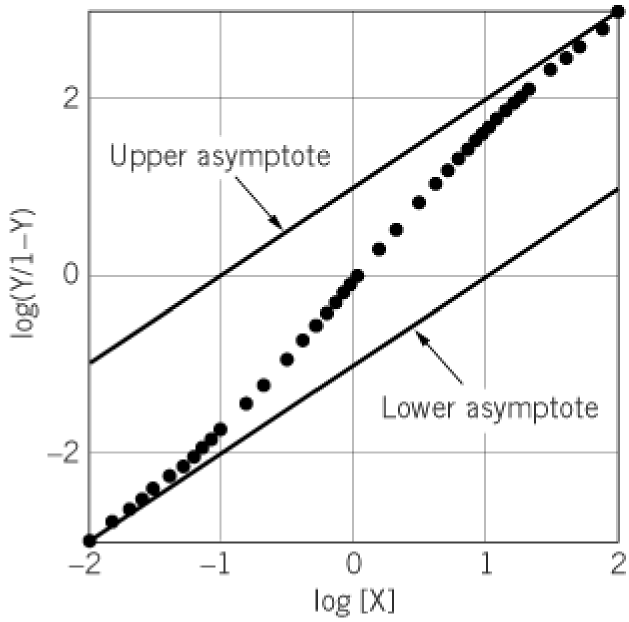
Hill Coefficient, Plot

The Hill coefficient is used to provide a quantitative measure of cooperativity of ligand binding. It is usually estimated graphically from a Hill plot. A hypothetical example of a Hill plot is shown in Figure 1. To construct a Hill plot, y, the fractional saturation of the binding sites by a ligand X, is determined experimentally. The data are plotted as log (y/ 1–y) versus log $[X]_f$. The Hill coefficient,

n_H, is given by the slope of this plot at log $(y/1–y) = 0$—that is, at $y = 0.5$ or 50% saturation of the X binding sites.

Figure 1. Hill plot. A hypothetical Hill plot for positively cooperative binding of ligand X to a macromolecule with two binding sites for X is shown. The data are presented as points, and the limiting asymptotes with slope 1 at high and low extents of ligand binding are shown as lines. The intrinsic stepwise binding constants, K_1 and K_2, given by the intercepts at <rf>log</rf>[X] = 0, are 0.1 and 10, respectively. The Hill coefficient is 1.8.



The value of the Hill coefficient provides two important items of information. First, its value relative to 1 indicates the type of cooperativity. For noncooperative ligand binding, $n_H = 1$. For positively cooperative ligand binding, $n_H > 1$; and for negatively cooperative ligand binding, $n_H < 1$. Second, for positively cooperative ligand binding, the value of n_H puts an upper limit on the numbers of interacting binding sites for X. For example, for a tetrameric protein with four binding sites for X, $n_H \leq 4$.

The Hill plot was initially developed by A. V. Hill in the context of proposing a mechanism for the positive cooperativity of oxygen binding to hemoglobin (1). The central concept of his proposal was recognition that cooperativity in ligand binding requires interactions between multiple binding sites. In the limit that the cooperativity between n binding sites is very strong, then only unliganded and fully n-liganded species of the protein exist. This can be expressed by the binding reaction

$$P_n + nX \rightleftharpoons (P \cdot X)_n \tag{1}$$

An apparent association constant may be written as

$$K = \frac{[(P \cdot X)_n]}{[P_n][X]^n} \tag{2}$$

The fractional saturation, y, is then given by

$$\bar{y} = \frac{[X]^n}{(1/K) + [X]^n} \tag{3}$$

Equation 3 can be converted into a form useful for graphical analysis by taking the ratio of bound sites to free sites, $y/(1–y)$, and taking the logarithm

$$\log(\bar{y}/[1-y]) = n\log[X]_f + \log K \tag{4}$$

Equation 4 is the basis for the Hill plot.

Analysis of the properties of Equation 4 as a function of [X] shows that the slope approaches +1 at both small and large values of y (2-4). These are shown as the lines in Figure 1 that are labeled lower asymptote and upper asymptote, respectively. As described below, in principle these asymptotes provide information about ligand binding. However, accurate determinations of the asymptotes in practice are difficult because they require measurements at very low and very high extents of ligand binding. For this reason, most uses of the Hill plot focus on the slope at 50% saturation with ligand X, the Hill coefficient.

The Hill coefficient can usually be determined with good precision for cooperative binding systems, and it provides an accurate phenomenological description of the cooperativity. For systems with two interacting binding sites for X (eg, dimeric proteins), it may be possible to determine apparent dissociation constants for each site from the Hill plot (see text below). For larger numbers of interacting binding sites, it may be possible to determine the dissociation constants for the first and last ligands bound and the interaction energy between these sites. However, determinations of dissociation constants for other ligand bindings steps are not in general possible. (See Ref. 3 for discussion relative to oxygen binding to hemoglobin.)

To understand the relations between cooperative ligand binding and the Hill coefficient, it is instructive to consider the case of a symmetrical dimer with one binding site for ligand X on each subunit. The stepwise occupancy of the binding sites can be written

$$P_2 + X \overset{K_1}{\rightleftharpoons} P_2X + X \overset{K_2}{\rightleftharpoons} P_2X_2 \tag{5}$$

where K_1 and K_2 are intrinsic stepwise association constants defined by the equations

$$K_1 = \frac{[P_2X]}{[P_2][X]}, \qquad K_2 = \frac{2[P_2X_2]}{[P_2X][X]} \tag{6}$$

The Hill coefficient at $y = 0.5$ is given by

$$n_H = \frac{2}{1 + (K_1/K_2)^{1/2}} \tag{7}$$

For $(K_1/K_2) > 1$, $n_H < 1$, indicating negative cooperativity. For $(K_1/K_2) < 1$, $n_H > 1$, indicating positive cooperativity. The value of n_H cannot exceed 2. The intercepts of the asymptotes in Figure 1, when $\log[X] = 0$ are $\log K_1$ (lower) and $\log K_2$ (upper). Thus they provide values for the intrinsic stepwise binding constants for the initial and final ligand binding steps. Although this is a general result, experimental determination of the asymptotes is in practice difficult. An analogous treatment of cooperativity in the kinetic behavior of a symmetric dimeric enzyme using Weber's approach of coupling free energies (4) has been presented and shows the relations between the magnitude of the coupling free energies and the value of the Hill coefficient (5). A treatment of the Hill coefficient in the context of the concerted allosteric model is presented on page 135 of Ref. 3 .

Hirudin

Hirudin is a protein inhibitor of thrombin in the saliva of the medicinal leech *Hirudo medicinalis* [see Proteinase inhibitors, protein and Serine proteinase inhibitors]. The target enzyme here seems obvious. It is a single polypeptide chain of 65 amino acid residues crosslinked by three disulfide bridges. It combines extremely tightly ($K_I 10^{-14}$M) with thrombin. The crystal structure of a thrombin-hirudin complex reveals that hirudin is not a standard-mechanism canonical inhibitor. The active site of thrombin is embedded in a canyon restricting the entry of many substrates and of most trypsin inhibitors that do not inhibit thrombin. Hirudin blocks the active site, but none of its residues embeds into the S_1 cavity, a hallmark of standard-mechanism canonical inhibition. The highly flexible COOH terminus of hirudin (residues 50–65) binds to the fibrinogen-binding exosite of thrombin. Many hirudin-based drugs block this fibrinogen-binding exosite rather than the active site of thrombin.

His Operon

Energy equivalent to about 41 ATP molecules is required to synthesize one molecule of the amino acid histidine (1). The considerable metabolic cost of histidine biosynthesis presumably accounts for the evolution of multiple strategies to regulate the rate of synthesis of the amino acid in response to environmental changes. Checkpoints regulate both the flow of intermediates through the biosynthetic pathway and the amounts of histidine-biosynthetic enzymes present. Expression of the genes for these enzymes is regulated in bacterial cells by mechanisms that are both general (metabolic regulation, elongation control) and specific (attenuation control, segmental stabilization of the distal part of the messenger RNA).

1. Structural organization of the operon

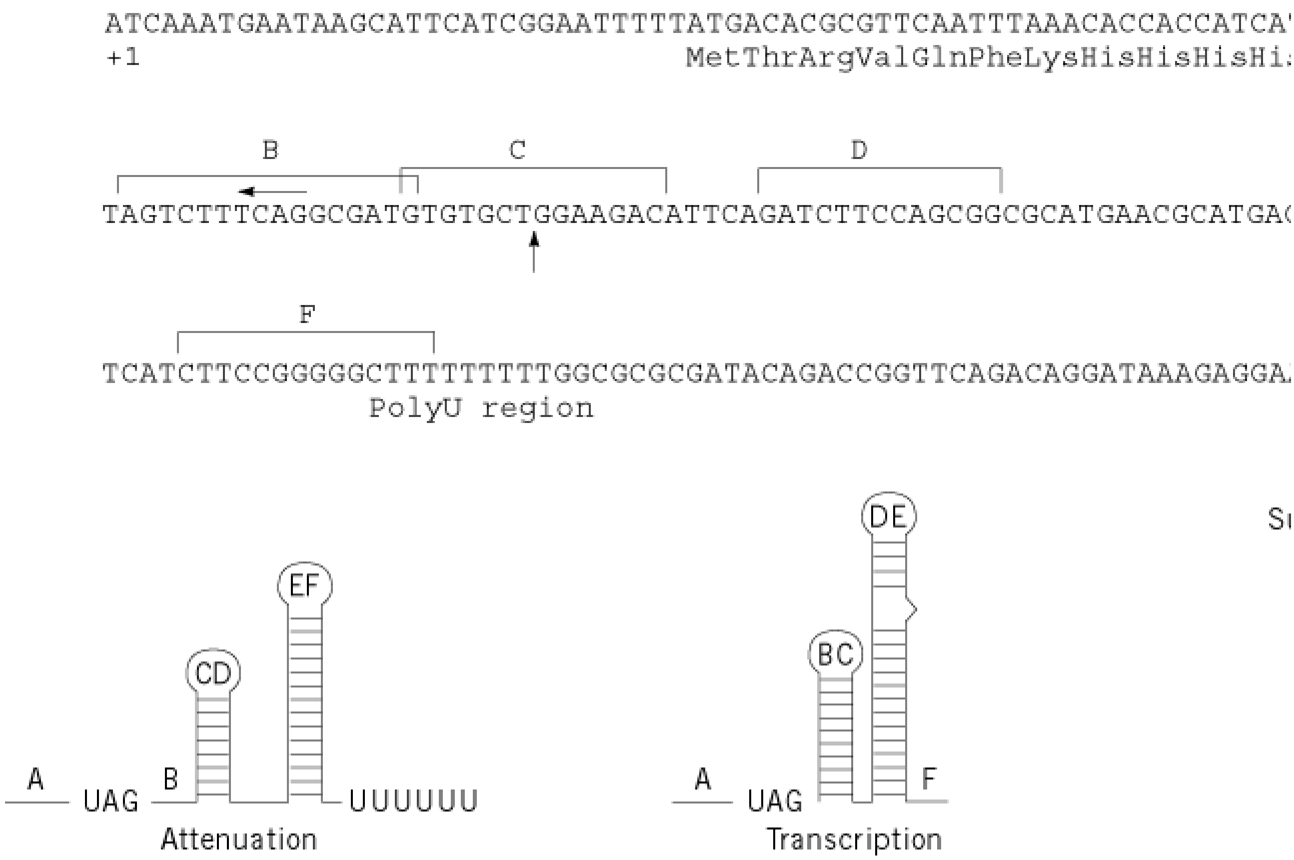
In *Escherichia coli* and *Salmonella typhimurium* the enzymes responsible for the biosynthesis of histidine are encoded by eight genes tightly clustered in a single, large operon (*his* operon). In both species, transcription produces a single polycistronic mRNA about 7300 nucleotides long, extending from a primary **promoter** (*hisp1*) to a Rho-independent terminator. Two weak internal promoters, *hisp2* and *hisp3*, are located within the *hisC* and *hisF* genes, respectively. The structural organization of the operon is essentially the same in the two species, and in both the translational stop codon of each **cistron** overlaps the translational initiation codon of the downstream cistron (2). This organization allows ribosomes to initiate the translation of a new cistron without moving away from the mRNA after terminating translation of the preceding one. Such a translational coupling mechanism probably guarantees equimolar synthesis of the corresponding gene products (3).

2. Control of transcription initiation and elongation

Transcription of the *his* operon is about four-fold more efficient in bacteria growing in minimal-glucose medium than when growing in rich medium. This form of control, called *metabolic regulation*, adjusts the expression of the operon to the amino acid supply in the cell. It is mediated by the “alarmone” guanosine 5′-diphosphate 3′-diphosphate (ppGpp), which is the effector of the stringent response (see Stringency). The alarmone regulates the *his* operon positively by stimulating the primary promoter *hisp1* under conditions of moderate amino acid starvation (4).

In addition to this general metabolic control, *his* operon transcription is specifically regulated by attenuation of transcription, a mechanism in which a regulatory element, located upstream of the first structural gene of the cluster, modulates the level of expression of the histidine biosynthetic enzymes in response to the intracellular levels of charged histidyl-transfer RNA, His-tRNA ^{His} (see Transfer RNA) (5). The *his*-specific regulatory element is transcribed in a 180-nucleotide RNA leader, which exhibits two prominent features: (i) a 16-residue coding sequence including seven consecutive codons specifying histidine, and (ii) overlapping regions of dyad symmetry capable of folding into mutually exclusive, alternative **secondary structures** that signal either transcription termination or antitermination (6, 7). Six RNA segments are involved in base pairing (Fig. 1 A to F) and the stem-loop structure formed by the E and F RNA regions, plus the adjacent run of uridylate residues, constitutes the attenuator, a strong Rho-independent transcription terminator (Fig 1). Translational control of *his* operon transcription is determined by ribosome occupancy of the leader RNA, which in turn depends, given the peculiar composition of the *his* leader peptide, on the availability of His-tRNA ^{His}. High levels of His-tRNA^{His} allow rapid movement of ribosomes up to the B segment; in this case, formation of the C:D and E:F stem-loop structures will result in premature transcription termination (Fig. 1, Attenuation). In the presence of low levels of charged tRNA^{His}, ribosomes stall at the consecutive histidine codons of the leader peptide and prevent the A:B pairing by masking the A segment. Base pairing between the B and C and between the D and E RNA regions prevents formation of the attenuator and determines the antitermination conformation (Fig. 1, Transcription). In the case of severe limitation of the intracellular pool of all charged tRNAs, translation of the leader peptide fails to initiate: under these conditions, the A:B, C:D and E:F stem-loop structures form sequentially, producing a strong transcription termination (Fig. 1, Superattenuation). **RNA polymerase** pauses after synthesis of the first RNA hairpin (A:B). This pausing is believed to synchronize transcription and translation of the leader region by halting the elongating RNA polymerase until a ribosome starts translation of the leader peptide (8). The pause hairpin (Fig. 1) is the only portion of the structure thought to form when RNA polymerase resides at the pause site.

Figure 1. Regulation of translation of the *his* operon messenger RNA. Top: the nucleotide sequence of the leader region *typhimurium* from the transcription initiation site (+1) to the first structural gene, *hisG*. Brackets above the nucleotide se segments (A to F) capable of forming alternative, mutually exclusive secondary structures. The convergent arrows indic structure required for transcriptional pausing at the downstream site indicated by a vertical arrow (see text). The amino a peptide and of the amino-terminal region of *hisG* are shown. Bottom: Schematic representation of the different conform (see text). The run of U's at the 3′ end indicates the formation of the terminator hairpin E:F. The position of the terminati (UAG) in each RNA configuration is also indicated.



Because the absolute amount of charged tRNA^{His} controls the level of *his* attenuation (5), mutants exhibiting high *his* operon expression contain defects in tRNA ^{His} biosynthesis, aminoacylation with histidine, or tRNA ^{His} modification and processing. The *hisR* gene encodes the single cellular tRNA^{His}; and mutations in the *hisR* promoter reduce the total cellular content of tRNA^{His} molecules by about 50% and thereby cause increased readthrough transcription of the *his* attenuator (9). The *hisS* gene encodes histidyl-aminoacyl tRNA synthetase, which aminoacylates tRNA ^{His} molecules with histidine. Mutations that lower the activity of the histidyl-tRNA synthetase or decrease the enzyme's affinity for histidine, tRNA^{His}, or ATP, affect the level of *his* attenuation by reducing the percentage of tRNA^{His} molecules charged with histidine (10). The *hisT* gene encodes pseudouridine synthase I, which catalyzes the formation of pseudouridine residues in the anticodon region of several tRNA species, including tRNA^{His}. Although the undermodified tRNA ^{His} molecules are charged with histidine to the same extent as in wild-type strains, transcription termination at the *his* attenuator is greatly decreased, because the slow rate of translation of the consecutive histidine codons causes stalling of ribosomes (11).

The overall contribution of the internal promoter *hisp2* to the expression of the distal genes of the operon is negligible when transcription proceeds from *hisp1*, because *hisp2* is inhibited by transcription readthrough, a phenomenon known as *promoter occlusion* (12). *hisp2* is also subjected to metabolic regulation, although to a lesser extent than *hisp1*.

Elongation of the *his*-mRNA is modulated by a non-specific mechanism operating at the level of intracistronic *transcription termination elements* (TTEs) (13). These elements consist of cytosine-rich and guanosine-poor RNA regions and are the binding-activation sites of the transcription-termination Rho factor, which is responsible for polar effects in polycistronic operons (14). A premature arrest of translation, produced by nonsense mutations, favors the binding of Rho to the TTE on the nascent transcript. The subsequent interaction of Rho with the elongating RNA polymerase causes a premature release of transcripts. Polarity results, with reduced expression of the genes located downstream from the TTE.

3. Decay and Segmental Stabilization of the *his*-mRNA

The primary 7300-nucleotide *his*-mRNA has a half-life of about 3 minutes in cells growing in minimal-glucose medium and is degraded in a net 5′ → 3′ direction. Three major processed species, 6300, 5000, and 3900 nucleotides long, encompassing the last seven, six, and five cistrons, respectively, are generated in the decay process (12). The 6300- and the 5000-nucleotide RNAs, which have half-lives of 5 and 6 minutes, respectively, have heterogeneous 5′ ends generated by ribonuclease E cleavage (see RNA Degradation In Vitro). The 3900-nucleotide processed RNA species has a unique 5′ end and an uncommon stability, having a half-life of about 15 minutes. This RNA species is generated by specific processing events requiring sequential cleavages by two different endonucleases. RNase E triggers the process by cleaving at a major target site located in the *hisC* cistron, 620 nucleotides upstream of the 5′ end of the processed species. Subsequently, ribonuclease P cleaves the processed RNA species generated by RNase E at a site located 76 nucleotides upstream of the start codon of the *hisB* cistron, producing the mature 5′ end. The observation that the RNase P-catalyzed reaction requires the presence of ribosomes suggests that translation of the *hisB* cistron might favor formation of the structure recognized by RNase P (15).

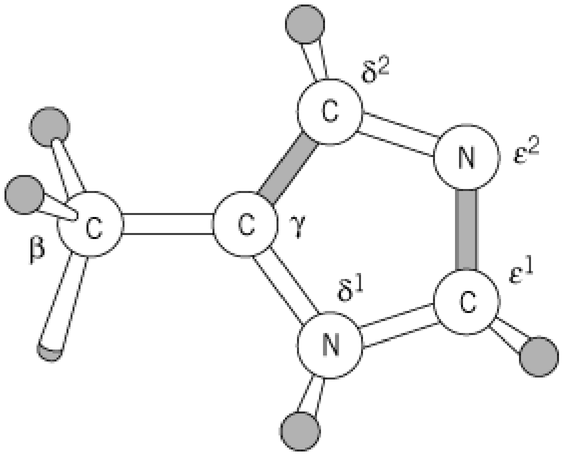
Histidine (His, H)

The amino acid histidine is incorporated into the nascent polypeptide chain during **protein biosynthesis** in response to two **codons**—CAU and CAC—and represents approximately 2.2% of the residues of the proteins that have been characterized. The histidyl residue incorporated has a mass of 137.14 Da, a **van der Waals volume** of 118 Å ^{3}, and an accessible surface area of 194 Å^2. His residues are changed during divergent evolution with average frequency; they are interchanged in **homologous** proteins most frequently with asparagine and glutamine residues.

The side chain of His residues consists of a b-methylene carbon and an imidazole group:

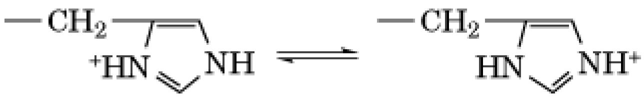


The imidazole groups possesses several special properties that make it extremely effective as a nucleophilic catalyst. It is an amine, which is much more reactive than hydroxide ion in terms of basicity. Furthermore, it is a tertiary amine, which is intrinsically more nucleophilic than primary or secondary amines. The enhanced reactivity of tertiary amines is usually canceled by their greater steric hindrance, but in imidazole the atoms bonded to the two nitrogen atoms are held back in a five-membered ring and cause relatively little steric hindrance. Imidazole has a pK_a value near 7, so it is one of the strongest bases that can exist at neutral pH. A weaker base would have a lower nucleophilic reactivity, whereas a stronger base would be protonated to a greater extent at neutral pH and would be correspondingly less reactive.

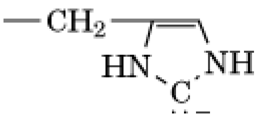
In the nonionized form of the imidazole ring, the nitrogen atom with the hydrogen atom is an electrophile and a donor for **hydrogen bonding**, while the other nitrogen atom is a nucleophile and a hydrogen bond acceptor. Consequently, this one side chain is extremely versatile, almost the chemical equivalent of being ambidextrous. Not surprisingly, His residues are often found at the active sites of enzymes and involved directly in catalysis.

The two nitrogen atoms of the His side chain are designated here as d1 and ε2, but they are also known, respectively, as p and q or as N-1 and N-3. The latter designation is often ambiguous, because biochemists usually assign the number 1 to the nitrogen atom adjacent to the C_g, whereas organic chemists tend to reverse the numbers. The nonionized imidazole ring can exist as two tautomers, with the hydrogen atom on either the d1 and ε2 nitrogen atom. In model peptides, the hydrogen atom is usually predominantly on the ε2 nitrogen atom, which has a pK_a value about 0.6 pH unit higher than that of the d1 atom. The relative affinities of the two nitrogen atoms for protons can vary with their local environment, however, and both forms are found in folded proteins.

The nonionized His side chain is readily protonated, with a p K_a value near 7 at the second N atom, which destroys its nucleophilicity. The positive charge is shared by the two N atoms by resonance:



The $C_{\varepsilon}{}^{1}$ atom, between the two N atoms, is observed to exchange its hydrogen atom slowly with aqueous solvents, indicating that it has a very small probability of being deprotonated:



This hydrogen exchange reaction provides a useful probe of the environments of His residues in proteins. His residues are especially useful in ^{1}H-**NMR** studies of proteins because the hydrogen atom on the $C_{\varepsilon}{}^{1}$ atom is usually well resolved from the multitude of resonances of the other hydrogen atoms in proteins. Its resonance is usually shifted by about 1 ppm to a lower field strength on protonation of the side chain, often making it relatively easy to determine the pK_a values of individual His residues, even in large proteins.

His is one of the residues least favoring the *alpha*-**helical** conformation in model peptides, but it occurs in a-helices in native protein structures slightly more frequently than in *beta* **-sheets** or reverse turns .

The imidazole group is, in principle, capable of undergoing numerous chemical modification reactions, but most of these occur much more readily with **amino** and thiol groups, so very few are suitable for modifying His residues specifically. The imidazole nitrogen atoms have an intrinsic affinity for metal ions, especially zinc, iron, and copper. His residues are frequently involved in binding such ligands to proteins, as in metal-requiring enzymes, **zinc fingers**, myoglobin, and hemoglobin.

Histocompatibility

The transplantation of tissue from one individual to another most often results in an adverse immune reaction between the host and the transplanted tissue, leading to graft rejection. The inclusion of lymphoid effector cells in a tissue graft can lead to graft-versus-host disease as well. These phenomena stem primarily from discordant expression of MHC cell surface molecules encoded by **polymorphic** class I and class II loci of the major histocompatibility complex (MHC). Graft acceptance or rejection is most strongly associated with identity or difference at class I loci, followed by class II and so-called minor histocompatibility antigens, as described below. The clinical evaluation of donor–host compatibility involves "tissue typing" individuals to determine the alleles present at the HLA-A, -B, and -DR loci. In practice, perfect matches at these loci are rare (requiring identity at as many as six independent loci, because **gene** products from maternal and paternal chromosomes are co-dominantly expressed); the majority of transplants rely mainly on the use of immunosuppressive agents postoperatively to increase graft survival. Host individuals are additionally screened for the presence of serum **antibodies** to MHC molecules, arising from prior exposure to non-self MHC through a blood transfusion or pregnancy.

Allograft rejection involves a variety of phenomena; the discussion here is confined to mismatched donor–host class I alleles (whose gene products have often been referred to as "classical transplantation antigens") as the basis for tissue incompatibility. MHC class I molecules present peptide **antigens** to the clonally expressed T-cell receptors (TCRs) of cytotoxic T lymphocytes (CTLs). The composition of the peptides presented by a given class I molecule is influenced by allomorph-specific peptide binding preferences, which in turn are a function of polymorphic amino acid residues found in the peptide-binding region of the class I molecule. Under typical circumstances, CTLs are rendered tolerant to the self class I/self peptide complexes expressed in an individual. The presence of an allograft introduces a new cohort of class I/peptide complexes into the host system, and the array of peptides displayed on the cells of the graft will reflect the binding preferences of the donor's class I allomorphs. Among these allo-MHC/peptide complexes are potentially numerous **epitopes** to which the host individual is not tolerant, thereby marking cells of the transplanted tissue for destruction by circulating CTL.

The cellular immune response to non-self class I/peptide complexes is termed "alloreactivity." The molecular basis for TCR recognition of allo-MHC molecules has long been an area of intensive study and debate in immunology. The preceding paragraph implies a scheme in which allorecognition is a peptide-specific phenomenon and fundamentally similar to the recognition of self class I+foreign peptide. In this view, conserved regions of the majority of class I molecules are themselves likely to provide similar molecular surfaces for contact with the TCR, regardless of the class I allomorph being considered. Specific interactions thus occur between variable regions of the TCR and the class I-bound peptide. There is now considerable evidence to support this model of allorecognition (1). However, allotypic residues on the surface of a class I molecule may also provide critical determinants for allorecognition by some TCR (2), and it is possible that both modes of recognition are utilized in the polyclonal T-cell response to an allograft.

The peptide-based nature of allorecognition also accounts for the involvement of "minor histocompatibility antigens" in graft rejection. Even when genetically nonidentical donor and host are HLA matched, they also manifest differences stemming from the expression of variants of several other polymorphic proteins. A well-known example is the H-Y antigen, encoded on the Y-Chromosome of males, which presents a barrier to successful male-to-female transplantation. This protein is expressed in nearly all tissues and differs in amino acid sequence from its X-chromosome homologue (present in both males and females) (3). Consequently, some H-Y antigen-derived peptides that are presented by MHC class I molecules (3, 4) will constitute novel epitopes in a female host receiving tissue from a male donor, provoking a cellular immune response. The total number of human minor histocompatibility loci and the identity of the proteins they encode remain as yet undetermined.

Histone Acetylation

Acetylation of chromatin by histone acetyltransferases (HATs), using acetyl coenzyme A as the acetyl donor, occurs at the e-amino groups of particular lysine side chains in the *N*-terminal basic tails of the core histones, with varying consequences. Histone deacetylases (HDACs) remove the acetylation. Histone acetylation has roles in chromatin assembly linked to DNA replication, in gene transcription, where the histones are hyperacetylated, and, apparently paradoxically, in heterochromatin (1). In the centric heterochromatin of the polytene chromosomes of the fruit fly *Drosophila* (2) and at the silent mating type loci in the yeast *Saccharomyces cerevisiae* (3), the histones are hypoacetylated, as might be expected, but an acetyl group on Lys12 in the exposed *N*-terminal tail of H4 (see Nucleosome) is essential for heterochromatin formation and may act as a recognition site for the assembly of other heterochromatin proteins. The importance of the pattern of site-specific acetylation, rather than the overall number of acetyl groups, is becoming increasingly clear, but is still poorly understood. Elevated levels of Lys16 acetylation on H4 in the male X-chromosome in *Drosophila* appears to be important, in some way, in **dosage compensation**, which results in a doubling of transcription from X-linked genes in the male (4).

Histone H4 deposited with H3 at the **replication fork** by the core histone **molecular chaperone** CAF-1 (chromatin assembly factor 1) during chromatin assembly is acetylated at Lys5 and Lys12 primarily, by a so-called B-type (deposition-linked) acetyltransferase. Deacetylation occurs soon after deposition. Transcription-related hyperacetylation occurs in chromatin at lysines 5, 8, 12, and 26 in H4, and lysines 9 and 14 in H3. Its role appears to be to "open" chromatin, primarily by destabilizing higher-order structure, thus permitting access by the transcription machinery. Suggestions of the interactions that might be disrupted have come recently from the high-resolution structure of the nucleosome core particle. Because the *N*-terminal tails are not bound within the nucleosome core, acetylation is unlikely to act at this level. The facilitation of **transcription factor** binding due to acetylation observed in *in vitro* assays with mononucleosomes (eg, Ref. 5) may be due to disruption of nonspecific interactions of the histone tails with the DNA gyres, in the absence of any possibilities for higher-order structure formation. Direct evidence that acetylation *per se* does result in increased transcription has come from studies of the *hsp*26 gene reconstituted using a *Drosophila* embryo extract into chromatin with either unacetylated or acetylated histones (6). In nuclei, large domains of chromatin-encompassing active genes appear to be acetylated; this state precedes transcription, and the chromatin is said to be in a transcriptionally competent state. In at least one well-documented case (7), the chicken b-globin gene cluster, the genes are embedded in a domain of greater than 30 kbp, where the histones are hyperacetylated and which shows increased sensitivity to the **nuclease** DNase I (see Chromatin), suggesting a less compact structure.

1. Histone Acetylases

The finding that the *Tetrahymena* HAT, HAT-A, is **homologous** to a yeast transcriptional co-activator, GCN5 (8), solved the mystery of how acetylation might be targeted to particular regions of chromatin. It has since been shown that the acetyltransferase activity of GCN5 (which functions as the GCN5-Ada2-Ada3 complex) is essential for its activator activity (9, 10) and that acetylation occurs in the **promoter** region. GCN5 also functions with Ada proteins in the yeast SAGA complex, which also contains Spt proteins (transcriptional regulators) (SAGA = *S*pt3–*A*da–*G*CN5–*A*cetyltransferase) and is involved in the regulation of many yeast genes. It is now clear (1) that a growing number of proteins known to be transcriptional co-activators and co-activator-associated proteins have HAT activity [eg, p300/CBP, P/CAF (a human homologue of GCN5), the TFIID component $TAF_{II}250$, which is likely to be associated with all promoters during transcriptional initiation, and many others]. (CBP = cAMP response element binding protein; CAF = CBP–associated factor.) Most, including GCN5, function within large complexes, where one subunit recognizes a DNA-bound transcription factor and another has acetyltransferase activity. p300/CBP interacts with transcription factors in many different signaling pathways (eg, nuclear hormone receptors, c-Fos, c-Jun/v-Jun), and acetylation is therefore the end point of many signal transduction pathways. Acetylation of different histones, and different sites within a particular histone, may turn out to require different HATs; GCN5 *in vivo* acetylates preferentially Lys8 and Lys16 of H4 and Lys14 of H3 (11). Histones may not be the only targets of all of the enzymes designated as histone acetyltransferases, for example, HMG 1 and HMG I(Y) are known to be acetylated *in vivo*. The transcription factor/tumor suppressor p53 is acetylated both *in vitro* and *in vivo* by p300, its coactivator. Two general transcription initiation factors, TFIIEb and TFIIF, can also be acetylated by P/CAF and p300 (12). Because the HAT activities that have recently been studied are tethered to sequence-specific DNA binding proteins at promoters (and enhancers), their effect will necessarily be local. It is not clear how this relates to whole domain acetylation over tens of kilobases. One possibility is that the loosening/disruption of the chromatin structure close to the promoter might be transmitted down the 30-nm filament (see Chromatin) through disruption of cooperative interactions, and that the temporarily loosened tails become targets for a pool of untargeted acetylases. There are other possibilities, and this area needs further study. Various models for how histone acetylases and deacetylases selectively affect gene expression have recently been discussed (13).

The first structure of a HAT catalytic subunit (Hat1 from the yeast *Saccharomyces cerevisiae*, which was the first HAT to be isolated) has recently been determined, complexed with acetyl CoA (14); *in vivo* Hat1 exists as a heterodimer with the regulatory subunit HAT2. Hat1's sequence preference for acetylation is Lys12>Lys5, and it acetylates free rather than nucleosomal histones, so it seems likely to be a deposition-related HAT. Nonetheless, Hat1 in both yeast and human cells appears to be primarily nuclear, rather than cytoplasmic as is generally assumed (see Refs. 14 and 15). Hat1 has sequence motifs in common with the GCN5-related superfamily of *N*-acetyltransferases (the GNAT superfamily) and should therefore be an excellent model for the other HATs. Indeed the Hat1 structure explains mutagenesis data on other HATs, such as Gcn5 and CBP; some of the mutations map to the acetyl CoA binding site. The structure of a HAT with a histone or histone tail bound is now needed to reveal the basis of the site specificity of acetylation, which is in the meantime suggested by modeling (14); the structure of a Hat1/Hat2 complex would also be of considerable interest. Hat2 is similar to the p48 subunit of CAF-1 (see Chromatin) and to similar subunits in histone deacetylase HD1 in humans and a related deacetylase in *Drosophila*. These related proteins may be histone-binding subunits.

2. Histone Deacetylases

Histone deacetylases (HDACs) are enzymes that remove acetyl groups, which generally results in repression of transcription. They also appear to be targeted to particular sites by gene regulatory proteins, in this case repressors, in organisms from yeast to mammals. (Intriguingly, the yeast deacetylase RPD3, which is also a repressor of **silencing** at telomeres and mating type loci, specifically deacetylates Lys5 and Lys12 in H4 *in vitro*, consistent with the requirement for Lys12 in an acetylated form for heterochromatin.) Like the HATs, HDACs function in the context of large complexes in which interaction of the HDAC and repressor appears to be mediated by corepressors. In yeast the deacetylase RPD3 is complexed with the corepressor sin3. The mammalian homologue, mSin3, has four paired amphipathic helix (PAH) domains that can interact with several repressors and corepressors. One is the Mad/Max repressor (Mad antagonizes the transcriptional activation and transformation functions of the **Myc oncoprotein**); another is N-CoR, a repressor for the thyroid hormone receptor, which exists in a complex with mSin3A and the mammalian homologue of RPD3. Progress in this rapidly evolving field has been succinctly summarized (1, 16). The finding that the 5-methylcytosine binding protein, MeCP2, recruits Sin3 (17, 18) and a deacetylase suggests a way of ensuring that chromatin in methylated (inactive) regions of the genome remains unacetylated and in a stable higher-order structure.

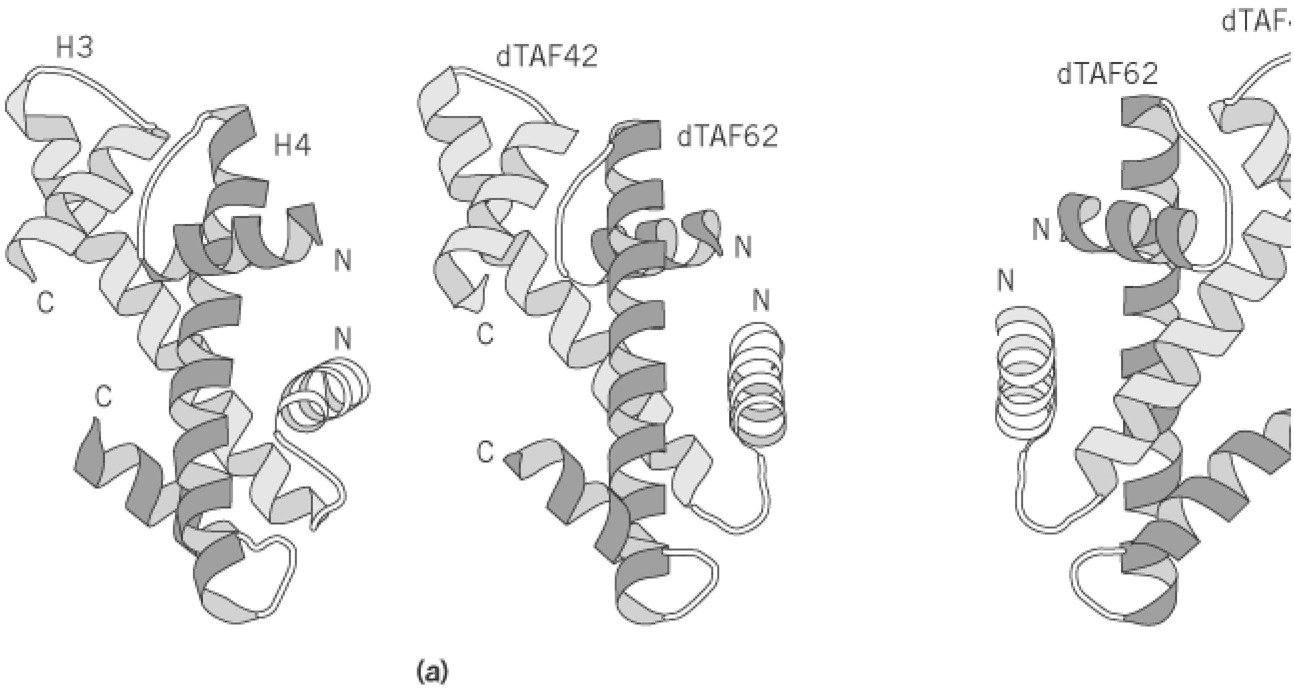
Histone Fold

The histone-fold motif is a protein structure feature common to all four histones that was first revealed in the structure of the core histone octamer (1). The mode of interaction of this motif with DNA, suggested by the octamer structure, is shown in detail in the structure of the nucleosome core particle (2). The histone fold has since been recognized in the structures of several other proteins, spanning the evolutionary range from archaebacteria to mammals, that are involved, like the histones, in **DNA:protein recognition** and protein–protein interactions . Some of the histone-fold proteins thus far identified show little or no sequence homology with the histones (3).

The histone fold consists of a long central a-helix connected by loops to two shorter a-helices. It may have arisen by gene duplication of a **helix–strand–helix motif**, with helix fusion resulting in the long central a-helix (4). The histones in the nucleosome core particle occur as heterodimers through extensive interactions between the two histone folds in a "handshake motif," with extensive **hydrophobic** interactions between the nonpolar faces of the two long amphipathic a-helices. The same basic fold occurs in the homodimeric archaeal histone HMfB (from the hyperthermophile *Methanothermus fervidus*) (5), which shows some sequence similarity to the histones, and in the presence of DNA forms tetramers similar to the H3 $_2$H4$_2$ tetramer (see Histones). In HMfB, however, there are no regions similar to the extensions to the basic fold in H3 that contribute to the organization of the DNA in the nucleosome core particle.

Strikingly, the histone fold has also been found to occur in other proteins. The first reports were for **TATA box**-binding protein-associated factors (TAFs), components of the transcription initiation factor TFIID. The 2 Å X-ray crystallography structure of the complex of TAF(II)42 and TAF(II)62 from *Drosophila* showed that it was a tetramer (a dimer of heterodimers), with the interacting regions (which constitute a relatively small part of the total protein) organized in histone folds similar to those of H3 and H4 (6) (Fig. 1). The finding that human TAF(II)20 (homologous to *Drosophila* TAF(II)30a) probably also contains a histone-fold motif similar to that in H2B (7) (no H2A homologues have been found) led to the suggestion that there is a histone octamer-like TAF complex within human TFIID, composed of a tetramer of TAF(II)80 and TAF(II)31 and two homodimers of TAF(II)20 (in *Drosophila* a tetramer of TAF(II)62 and TAFII42) and two homodimers of TAF(II)30a) (6, 7). Surprisingly, three histone-like TAFs also occur amongst the 20 subunits of the P/CAF acetyltransferase complex (see Histone Acetylation), namely, TAF(II)31, TAF(II)20 / 15 and PAF65a (similar to human TAF(II)80), which resemble H3, H2B, and H4, respectively, and an octamer-like structure has again been suggested (8). The yeast 1.8-MDa SAGA (*S*pt-*A*da- *G*CN5-*a*cetyltransferase) acetyltransferase complex, which is similar to the human P/CAF complex, also contains three histone-fold TAFs with homology to H2B, H3, and H4 as integral components (9), and the Spt3 protein appears to have histone folds in its *N*- and *C*-terminal regions, which have been suggested to interact intramolecularly (10). X-ray crystallography has recently shown that yet another pair of TAFs, human TAF(II)18 and TAF(II)28, which show only weak homology to histones, also form a heterodimer through a histone fold (9). The histone-fold motif thus appears to be widespread, and it may simply be a robust structural motif particularly well-suited to protein dimerization in large complexes. It remains to be seen, however, whether histone octamer-like TAF structures have a particular role to play in processes involving histones. Despite the presence of the histone fold, any interaction of TAFs with DNA is likely, *a priori*, to be different from that in the nucleosome core because the arginine side chains of the core histones that insert into the minor groove of the surrounding DNA are absent; in the case of *Drosophila* TAF(II)42 and TAF (II)62, they are replaced by serine and glutamate. The **four-helix-bundle** interface and the orientation of the two heterodimers within the TAFII tetramer are also different from those in the $H3_2H4_2$ tetramer, although this in itself might not necessarily preclude DNA binding.

Figure 1. Drawings of the histone folds in H3 and H4, and *Drosophila* TAF(II)42 and TAF(II)62. (**a**) The TAF(II)42/TA heterodimer from which the $H3_2H4_2$ tetramer in chromatin is formed; (**b**) the tetramer TAF(II)42 $_2$.TAF(II)62$_2$ (residues TAF62).(Adapted from Ref. 6 and reproduced with permission.)



Although no high-resolution structural data are yet available, it seems likely, on the basis of sequence homology with H2A and H2B, that the histone-fold motif also occurs in two subunits of the trimeric mammalian transcription factor CBF [CCAAT-binding factor (11)] and its yeast homologue HAP (CCAAT boxes are widespread promoter elements; see CAAT Box) and in the human protein NC2 [negative cofactor 2 (12); also known as DRAP1] and its yeast homologue, which repress transcription of class II genes by binding to TBP and to DNA and inhibiting preinitiation complex formation by preventing TFIIB binding. It is striking that the histone fold already present in the *Archaea* has been adapted not only for DNA packaging in eukaryotes but also apparently as a dimerization motif in gene regulatory proteins, which sometimes show little, if any, sequence similarity. This is reminiscent of the “winged helix” DNA-binding motif in the globular domain of histone H5 (see Histones), which is also found in bacterial **cyclic AMP receptor protein** and the liver transcription factor HNF3g, a member of a large family of transcription factors (the

HNF/forkhead family) from several organisms.

Histones

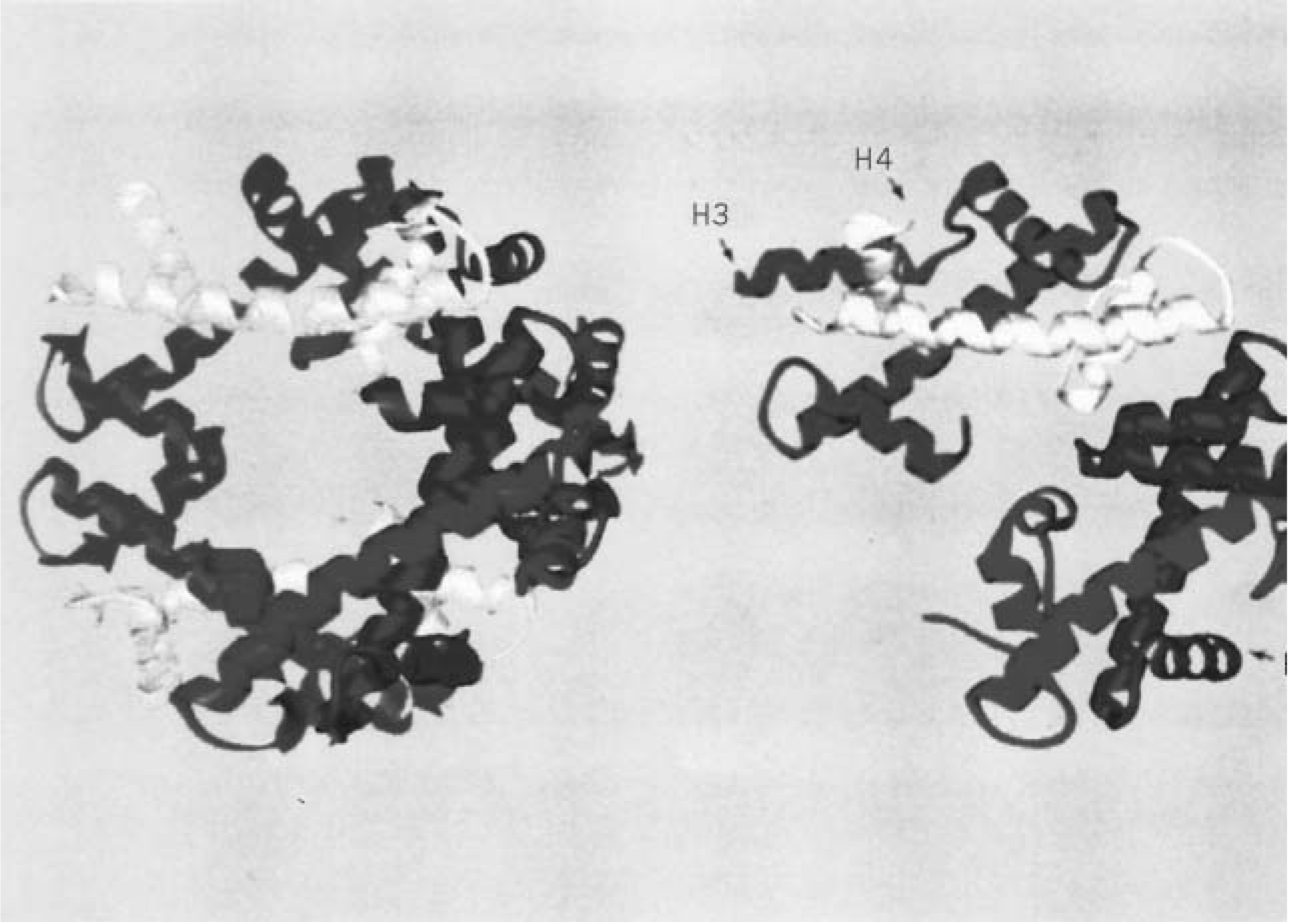
Histones are small basic (positively charged) proteins that are complexed with DNA in the nucleus of almost all eukaryotic cells (not dinoflagellates or mammalian spermatozoa) and serve to package the DNA into nucleosomes in chromatin. It has recently become clear that they also play an important regulatory role in gene transcription and repression. Together, the histones occur in a mass roughly equal to that of DNA. There are five histone types, falling into two functional classes: the core histones (H3, H4, H2A, and H2B) and the larger linker histones (H1 and its variants). Two copies of each of the core histones form the histone octamer that constitutes the protein core of the nucleosome, around which are wound two complete left-handed superhelical turns of DNA. The nucleosome is stabilized by the binding of one molecule of the histone H1 class, which also plays a role in stabilization of the higher-order structure of chromatin. It is becoming clear that H1 may also play a specific role in the regulation of some genes. Both the core histones and H1 undergo dynamic reversible modification. Acetylation of the core histones plays an important role in processes as diverse as transcription, nucleosome assembly, and heterochromatin formation (see Histone Acetylation). Histone H1 is **phosphorylated** during S-phase and mitosis in the cell cycle, and its extreme cell-type specific variants in avian erythrocytes and sea urchin sperm are phosphorylated up until the final stages of chromatin compaction. Two volumes contain a wealth of information about the histones (1, 2).

1. Core Histones: The Histone Octamer

The core histones [molecular masses ~11,300Da (H4) to 15,300 (H3)] show a high degree of evolutionary sequence conservation, consistent with their role as organizing structural components in a common mode of DNA packaging in eukaryotes. Histones H3 and H4 are the most conserved proteins known, with only two (conservative) amino acid differences out of 102 residues between pea and calf H4. All the core histones have high contents of the basic amino acids lysine and arginine (whose side chains are protonated, and hence positively charged, at neutral pH). H2A and H2B are relatively lysine-rich, and H3 and H4 are relatively arginine-rich. The basic residues are unevenly distributed along the amino acid sequence and are concentrated toward the *N*-terminal regions of about 25 to 40 residues. These regions (the *N*-terminal "tails") are implicated in stabilization of chromatin higher-order structure and are essential for a number of vital functions. They are also the sites of several post-translational modifications, including acetylation, which has been well-studied (see Histone Acetylation).

The four core histones exist in chromatin as an octamer that is structurally organized as a tetramer of H3 and H4 ($H3_2H4_2$) and two dimers of H2A and H2B (H2A.H2B). The octamer may be isolated as an entity from chromatin at high ionic strength (eg, 2 M NaCl), which disrupts the electrostatic interactions between the histones and DNA and, in addition, preserves the association of tetramers and dimers (3). At physiological ionic strength, in the absence of DNA, the isolated octamer falls apart into tetramers and dimers. The structure of the octamer, determined to 3.1 Å resolution by X-ray crystallography (4), reveals two distinctive features of the histone associations (Fig. 1). First, the four histones (which have no obvious sequence homology) share a common fold, now designated the "histone fold." This comprises a long central a-helix and two shorter flanking a-helices connected by loops. Second, the histone pairs H3, H4 and H2A, H2B share a common mode of association as heterodimers in a "handshake motif," creating a crescent-shaped structure. Two H3.H4 heterodimers interact through a-helical regions on H3 to form the rather flat tetramer, which resembles a twisted horseshoe; H2A.H2B dimers flank this on each face, through interactions between a-helical regions on H2B and H4. The octamer crystal structure confirmed the presence of a left-handed helical ramp (for DNA binding) on the octamer surface, which had been inferred from earlier work (5), and suggested how the histone fold might form DNA contacts. The details of the interaction of the octamer with DNA have since been observed directly in the high-resolution structure of the nucleosome core particle (see Nucleosome), which also reveals the positions of the histone tails that were not visible in the structure of the octamer alone, because they are disordered. Intriguingly, the histone fold has since been found embedded in much larger proteins, notably several TAFs (TATA-box binding protein-associated factors) and transcription factors (see Histone Fold).

Figure 1. The structure of the histone octamer at 3.1 Å resolution, showing the histone folds (4).



The *N*-terminal histone tails of the core histones are well-conserved, despite being external to the structured core of the octamer, suggesting some structural or functional role. The tails do not appear to be required for nucleosome core integrity and may be removed by **proteolysis** without causing structural disruption. There is good evidence that they play a role, together with the basic tails of H1, in stabilization of chromatin higher-order structure. In the structure of the nucleosome core particle (6) (see Nucleosome) they form few, if any, contacts within the nucleosome core, but are extended from it and are well-placed to interact with neighboring nucleosomes or other chromosomal components. The role of the tails has been extensively studied genetically in yeast (7) (see Nucleosome). It is increasingly recognized that the tails may function as recognition sites for protein factors important for chromatin function. For example, particular sequences in the *N*-terminal tails of H4 (residues 16 to 29) and H3 (residues 4 to 20) are required, together with other proteins (Rap1, Sir2, Sir3, and Sir4) for transcriptional **silencing** (through formation of a more repressed chromatin structure) at yeast telomeres and silent mating type loci (see Chromatin). The amino-termini of H3 and H4 are also required for a1–a2 repression in yeast (a regulatory mechanism involved in distinguishing **diploid** from haploid yeast cells) (8) and for the action *in vitro* of at least one chromatin remodeling machine, *Drosophila* NURF (9).

The *N*-terminal tails are the sites of several types of post-translational modification, the best studied of which is acetylation (see Histone Acetylation). It is involved in transcription and chromatin assembly, the acetylation patterns being different in the two cases, and could also provide additional markers for specific recognition by various partner proteins. The specific acetylation of Lys12 only in heterochromatin in *Drosophila* and yeast could perform such a role. Transcription-linked hyperacetylation, primarily on H4 and H3, is believed to result in relaxation of the repressive higher-order structure by disruption of internucleosome contacts. Crystal contacts in the nucleosome core particle suggest contacts that might be involved (6) (see Nucleosome). Other post-translational modifications have been less well studied and are less well understood (1, 2). Phosphorylation occurs constitutively at the *N*-terminal serine of H2A and, in a small proportion of histones, at Ser 10 and Ser 28 of H3 in response to mitogen stimulation in mammalian cells (10). Phosphorylation and acetylation appear to coexist in the same nucleosomes after mitogen stimulation and might act synergistically to disrupt internuclesomal contacts involving H3 tails and to facilitate transcription. The role of other modifications of the core histones (methylation of lysine side chains, and—in the case of H2B—**ADP-ribosylation**) is unclear; ADP-ribosylation may have a role in DNA repair, probably by disruption of chromatin structure. Also unclear is the role of ubiquitination of lysine side chains near the *C*-terminus of H2A and H2B (ie, covalent attachment of the small protein ubiquitin through an isopeptide linkage), but it appears not to be related to the well-recognized role of ubiquitination as a signal for **protein degradation**.

Core histone variants, the products of distinct genes, are found in all organisms. Their precise role is not clear, but they presumably allow fine-tuning of nucleosome structure and stability for particular purposes. A well-documented example is the developmental pattern of expression of five H2A variants and four H2A variants, which changes through the cleavage, blastula, and gastrula stages of sea urchin embryogenesis (11). Significantly, there is no variation in H3 and H4, which form the structural core of the nucleosome. During spermatogenesis in the same organism, there is a global replacement of somatic H2B with the larger and more basic sperm-specific variant spH2B, which has a long *N*-terminal extension with several "-SPKK-" (-Ser/Thr-Pro-X/Lys-Lys/Arg-) motifs (see text below) and helps in the tight compaction of chromatin in the sperm head. On fertilization, this is phosphorylated and then replaced during subsequent cell divisions with somatic variants. *Drosophila* has two evolutionarily conserved H2A variants: H2A.X, which has a *C*-terminal extension (like wheat H2A1, which has 19 extra residues and binds to linker DNA), and H2A.vD, which is essential for *Drosophila* development and has counterparts in mammals (H2A.Z), chickens (H2A.F/Z), and the ciliated protozoan *Tetrahymena* (hv1), where it is found in actively transcribed chromatin. H2A.Z is interesting because it has an *N*-terminal tail resembling that of H4 and indeed is acetylated more than the canonical H2A, thus providing obvious additional possibilities for regulation of function. For further details, see Ref. 2.

A class of more extreme so-called core histone variants are really hybrid proteins, with a region of histone sequence fused to a wholly unrelated region of unknown function. Two such proteins are the mammalian centromere-specific protein CENP-A (the yeast homologue is CSE4) and macroH2A. CENP-A (molecular mass ~17,000Da) is similar to H3 in its *C*-terminal domain, but has a highly divergent *N*-terminal region and appears to be associated, although not solely, with a- satellite DNA (12). Assuming that it replaces the normal H3, it presumably imparts special properties to centromeric chromatin. MacroH2A is a highly conserved protein in which the *N*-terminal third resembles H2A and the *C*-terminal two-thirds contains a coiled-coil protein dimerization motif. There are two macroH2A subtypes, which are (a) highly conserved and (b) identical in the histone region. It came as a surprise to find that one subtype is localized to the inactive X-chromosome (in mouse) and is distributed throughout the chromatin (13); it is tempting to speculate that the coiled-coil might have a role in protein oligomerization and condensation of chromatin. MacroH2A is thus one more distinctive component of the inactive X-chromosome, the others being heavily **methylated** DNA, hypoacetylated H4, and association with a large ***cis*-acting** nuclear RNA (termed Xist).

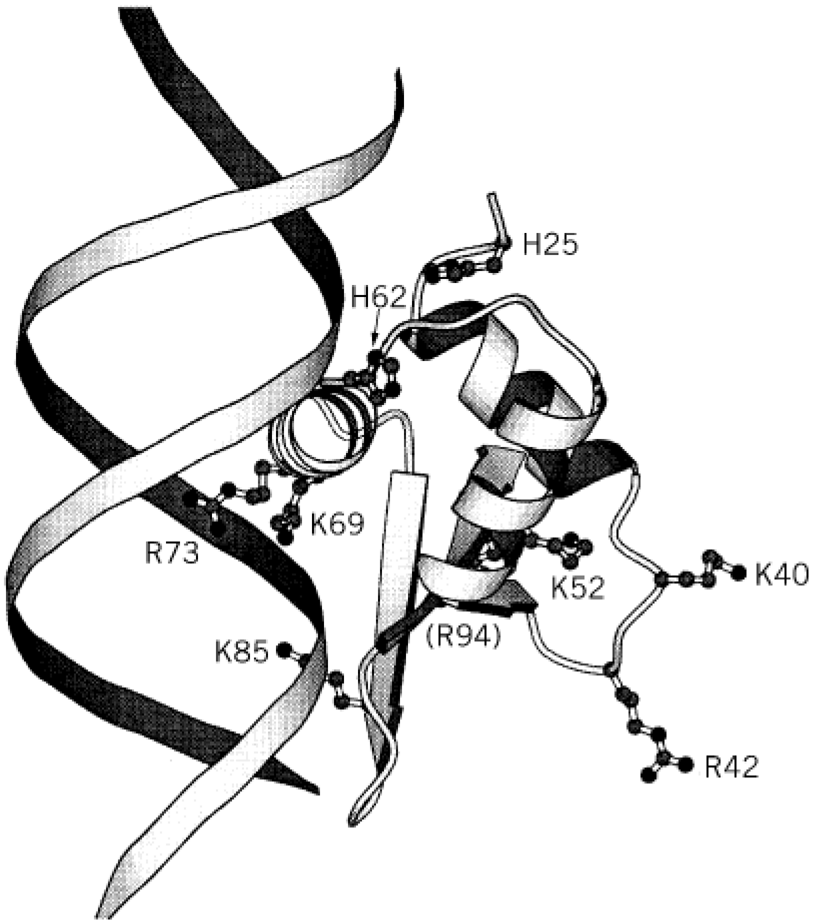
2. Linker Histones/Histone H1

Linker histones (H1 and its variants and subtypes) in higher eukaryotes are larger than the core histones (molecular mass ~20,000 to 25,000 Da) and are particularly lysine-rich. They have a tripartite domain structure, in which a central globular domain of about 80 amino acid residues, which is highly conserved between species, is flanked by basic *N*- and *C*-terminal domains ("tails") that are much more divergent. In the absence of DNA, the tails are disordered and may be selectively removed by proteolysis, leaving the globular domain intact. In a typical mammalian H1, the *N*- and *C*-terminal tails are about 40 and 100 residues long, respectively; the lengths differ in some species-specific and cell-type-specific variants. Nucleosomes released from chromatin by digestion with micrococcal nuclease (**Staphylococcal nuclease**) are rapidly trimmed by further digestion so that the ~200 bp of DNA is reduced to ~166 bp, giving a chromatosome. If H1 is removed before digestion, however, only 146 bp remain protected, as digestion proceeds to the limit nucleosome core particle. The globular domain of H1 alone is sufficient to protect 166 bp, so this is the region of H1 that binds close to the nucleosome core, stabilizing the nucleosome and protecting an extra 20 bp from digestion. The basic *C*-terminal tail (and possibly also the *N*-terminal tail) binds to the linker DNA between adjacent nucleosomes (hence the name *linker histones*), partially neutralizing its negative charge and promoting folding of the nucleosome filament into a higher-order structure, the 30-nm filament; H1 is located on the inside of the 30-nm filament (see Chromatin). The role of H1 is thus to stabilize both the nucleosome and an ordered higher-order chromatin structure. H1 may be phosphorylated (see text below) and poly-ADP-ribosylated; the role of the latter modification is not clear, but it is probably involved in DNA repair .

There are many subtypes and more extreme sequence variants of H1, which all share the same domain organization. These may coexist in the same cell type (eg, there are six H1 subtypes in chicken erythrocytes), and the assumption is that they might stabilize different chromatin higher-order structures. This would be likely to occur only if they were clustered along a chromatin filament, and this indeed appears to be the case for one of the seven H1 variants in the interphase polytene chromosomes in the Dipteran insect ***Chironomus*** *thummi* (14). Information is lacking for other systems or for other H1s in *Chironomus*. There are several instances of changes in linker histone variants during developmentally regulated processes (11, 15). During sea urchin embryogenesis, six distinct H1 subtypes are produced at particular stages; and *Xenopus* has an embryonic form of H1, namely B4, that is very different from the normal somatic H1. The *C*-terminal tail is less basic, and this might result in a less condensed chromatin structure in *Xenopus* embryos, compatible with rapid nuclear division and DNA replication. Extreme variants may also be produced to shut down transcription in particular cell types, and they appear to be associated with more stable chromatin higher-order structures (see Chromatin). For example, in transcriptionally inert mature avian erythrocytes, H5 (which binds more tightly than H1, probably due to its higher arginine content, although it has shorter *N*- and *C*-terminal tails) has largely replaced H1; and in sea urchin sperm, somatic H1 is replaced by a larger and more basic sperm-specific H1, namely spH1, which, together with sperm-specific core histones, is very effective in condensation of the DNA. (In mammalian sperm, histones are replaced by protamines, small arginine-rich proteins, rather than by specialized histone variants.) $H1^{0}$, an H1 variant whose appearance in mammalian cells appears to correlate with terminal differentiation (eg, in neurons), is much more similar to H5 than to H1 in its globular domain.

The globular domains of histones H1 and H5 (GH1 and GH5) can bind to the body of the nucleosome (see text above) and protect an additional 20 bp beyond the core particle length from digestion. The structure of GH5, determined by X-ray crystallography, shows a "winged helix" motif (a variant on the **helix–turn–helix** DNA-binding motif) which is also found in two proteins that bind to specific DNA sequences, namely the liver transcription factor HNF_3g (hepatocyte nuclear factor 3g,) and the prokaryotic protein **cyclic AMP receptor protein** (CRP) (16). It consists of a three-helix bundle with a b-hairpin (or "wing") at its *C*-terminus. Based on the X-ray crystal structures of these proteins bound to DNA, the likely mode of binding of GH5 to DNA, in the major groove, has been deduced. Biochemical evidence points to a second DNA binding site on GH5, and this has been identified on the opposite face of the globular domain (17) (Fig. 2). It is likely that the two sites are occupied in the nucleosome by two of the three duplexes (the central turn and the entering and exiting DNA) that are present in the vicinity of the dyad axis of the nucleosome. Current evidence for bulk nucleosomes (18) suggests that GH5 bridges the central turn, close to the dyad, and one of the entering/exiting duplexes. The orientation proposed would place the *C*-terminal tail of H1 directed toward linker DNA, as expected from various lines of evidence. A different mode of binding of the globular domain to the reconstituted *Xenopus* 5 S nucleosome has been proposed, but it is not yet clear whether this is a special property of the 5 S nucleosome (see Nucleosome). The existence of two binding sites on the globular domain is probably the basis of its preference (over linear DNA) for four-way DNA junctions (19), which mimic a pair of duplexes at the DNA crossover point near the nucleosome dyad.

Figure 2. The structure of the globular domain of histone H5 (GH5) showing the two clusters of basic residues at the two proposed DNA-binding sites on opposite faces of the domain (17). Binding to DNA at one site is by analogy with the structures of HNF3g and CRP (see text).



There is no high-resolution structural information for the *N*- and *C*-terminal tails of H1 or any of its variants. The role of the *N*-terminal tail (~40 amino acid residues in the canonical H1) is unclear, but there is some evidence that it may anchor the globular domain correctly in the presence of the *C*-terminal tail. The basic *C*-terminal tails (~90 to 130 amino acid residues, depending on the variant) have unusually high contents (~50%) of the basic residues lysine and arginine, as well as relatively high contents of alanine and proline. They are essential for chromatin condensation and are believed to bind to linker DNA. They are disordered in the free protein, but they are likely in the presence of DNA to exist as a-helical segments rich in lysine and alanine, the segments being separated by proline residues (20). The proline residues are often embedded in so-called “-SPKK-” sequence motifs (-Ser/Thr-Pro-X/Lys-Lys/Arg-), where the serine is a potential phosphorylation site. There is some phosphorylation at S-phase of the cell cycle and considerably more at mitosis, probably due to the action of the cyclin-dependent kinase, $p34^{cdc2}$ (21). The role of phosphorylation is likely to be to loosen the interactions between the H1 tails and linker DNA, and at mitosis to permit other factors and interactions to drive chromosome condensation. Some members of the repertoire of H1s produced during different stages of sea urchin embryogenesis lack -SPKK- motifs, suggesting that the binding of different H1s may be differentially regulated. Phosphorylation also plays a role in the control of chromatin transitions unrelated to the cell cycle, namely, in the late stages of avian erythropoiesis, or sea urchin sperm spermatogenesis, where there is no cell division and where special histone variants that bind more tightly than somatic H1 (ie, H5 and spH1, respectively) suppress transcription by promoting chromatin condensation. H5 and spH1 are phosphorylated at the -SPKK- motifs (of which there are six copies in the *N*-terminal tail of spH1 and further copies in the C-tail) until the final stage of maturation, when a final dephosphorylation step in the spermatozoon or mature erythrocyte results in the final stage of chromatin condensation and even closer chromatin packing in the sperm head or erythrocyte nucleus; removal of the phosphate increases the net positive charge on the histone and promotes histone–DNA interactions, leading to condensation. An analogous situation exists in the amitotic nucleus of *Tetrahymena* (22).

There are two very atypical H1s, or—in one case—candidate H1, in lower eukaryotes, which lack the characteristic domain organization of the canonical H1. The ciliated protozoan *Tetrahymena thermophila*, which has a transcriptionally active but amitotic **macronucleus** and a transcriptionally inert mitotic **micronucleus**, contains a small, basic, macronuclear protein of 163 residues, designated H1, that appears to share some of the functions of linker histones. (A set of distinctive polypeptides appears to substitute for H1 in the micronucleus.) The macronuclear H1 condenses chromatin in the nucleus, and phosphorylation at 'TPVK' sites results in an increase in nuclear volume, suggesting that phosphorylation loosens interactions with chromatin, as expected (22, 23). It lacks the distinctive globular domain of the canonical H1, however, although its *C*-terminal region has similarities to the *C*-terminal tail of H1. Exactly how the *Tetrahymena* H1 is bound to chromatin is unclear. An unusual, but quite different, domain organization also occurs in a candidate H1 identified from the recently determined complete sequence of the yeast (*Saccharomyces cerevisiae*) genome. Previous attempts to isolate H1 from yeast had been unsuccessful, and one view was that because the linker length of yeast chromatin was virtually zero (chromatin repeat length ~166 base pairs) there was no requirement for neutralization of linker DNA charge or, therefore, for a canonical linker histone. Analysis of the yeast genome revealed an open reading frame (the *HHO1* gene) encoding a protein (Hho1p) with regions of sequence homology to the globular domain of H1, which is regarded as a candidate H1 (24). It has *two* globular domains of about 80 residues, with a basic *N*-terminal extension and a basic connecting linker with some resemblance to the *C*-terminal tail of the canonical H1. Recombinant Hho1p appears to have some of the distinctive properties of H1 in a standard chromatin reconstitution, namely protection of an additional ~20bp of DNA beyond the core particle length against exonuclease digestion (25). Its unique structure, however, means that there are likely to be differences in its detailed mode of binding to chromatin compared with canonical H1, and it is by no means clear at present whether Hho1p functions as a true H1 or is instead a transcription factor with domains homologous to the globular domain of H1 [cf. some TAFs, which have sequence homology to core histones (see Histone Fold); or even $HNF3_g$ which contains the same structural fold as in the globular domains of H5 and H1 (see text above), although in that case there is no sequence homology between the two proteins].

Gene disruptions and deletions have been used to ask whether H1 is essential. Disruption ("knockout") of the $H1^0$ gene in mouse appeared to be without consequence; it is likely, however, that one or some of the six other subtypes compensate (26); in other words, there is functional redundancy. Deletion of the entire complement of somatic H1 genes has not been achieved. Early *Xenopus* embryos contain the unusual H1 variant B4 (see text above) which is later replaced by somatic H1; elimination of B4 had little effect on nuclear assembly or on the development of the organism (27). Deletion of the single gene for the atypical macronuclear H1 of *Tetrahymena* was not lethal, but was not without effect either (23). Vegetative growth, general transcription, and general nucleosome repeat length were unaffected, but there were changes in the nuclear volume (presumably consistent with the role of the protein in chromatin condensation and packing in the nucleus), in the efficiency of meiotic division, and, significantly, in the transcriptional regulation of specific genes. However, although some genes were activated, consistent with the expected repressive role for H1, others were repressed (eg, the CyP gene, which encodes a thiol proteinase). One explanation would be that the binding of the *Tetrahymena* H1 is needed in some nucleosomes to position them in such a way that certain sequences necessary for the binding of activators are exposed. In yeast, deletion of the yeast *HHO1* gene had no detectable effect on cell growth, viability, or mating, or on telomeric silencing, basal transcriptional repression, or efficient **sporulation** (25, 28). It also did not affect transcription of the SW1/SNF-dependent *SUC2* gene or the repression of the silent a1/a2 genes, or activation at a distance of a GAL1 promoter (28). It remains to be seen whether the Hho1p protein is really a *bona fide* H1 or a transcription factor evolutionarily related to the globular domain of histone H1, despite assuming some of the functional properties of H1 in an *in vitro* assay (25). These and other studies suggest strongly that H1 and its variants probably have roles beyond that of simple repression and stabilization of higher-order structure in chromatin. Gene-specific effects of H1 are clear in one well-documented case, namely, the 5 S rRNA genes of *Xenopus laevis*. Replacement of the unusual embryonic variant B4 with the somatic H1 during embryogenesis has been shown to be causal for the selective repression of the oocyte 5 S, leaving the somatic genes active (29). Gene-specific effects of H1, in addition to a general, default, repressive role, may turn out to be more common than might have been imagined.

HIV (Human Immunodeficiency Virus)

Human immunodeficiency virus (HIV), a causative virus of acquired immune deficiency syndrome (AIDS), is a member of the *Lentivirus* genus of the family *Retroviridae* (see Rous Sarcoma Virus (RSV)). The first isolate was reported in 1983 and was named lymphadenopathy-associated virus (LAV). Other isolates, such as human T-lymphotropic virus type III (HTLV-III) and AIDS-associated retrovirus (ARV), were reported in 1984. These HIV isolates were later categorized as HIV-1, because a serologically unique HIV isolate was discovered in 1986 and designated as HIV-2. Great sequence variation, especially in the env gene, is characteristic of HIV, and at least nine subtypes of HIV-1 (A to I) and/or five of HIV-2 (A to E) have been classified.

HIV virions are spherical and about 110 nm in diameter. The HIV virion has a lipid-bilayer envelope, and approximately 72 knobs (spikes) protrude from the envelope. Each knob is composed of oligomeric surface protein (SU:gp120 in HIV-1 and gp130 in HIV-2) and transmembrane protein (TM:gp41 in both HIV-1 and HIV-2). Inside the envelope, the capsid proteins (CA:p24) form the bullet-shaped capsid shell. The matrix protein (MA:p17) is present between the envelope and CA. The nucleocapsid protein (NC:p9) binds to the viral genome. SU, TM, MA, CA, and NC are the major structural proteins. Two identical copies of single-stranded RNA of positive polarity are contained in a HIV virion as the genome. The enzymes proteinase (PR), **reverse transcriptase** (RT) (see Rous Sarcoma Virus (RSV) and Hepatitis B Virus), and integrase (IN) are also contained in the capsid shell.

The genome RNA of about 9.2 kb is, like cellular messenger RNAs, capped at the 5′ end (see Cap) and tailed by poly(A) at the 3′ end. The genome has short direct repeats (R) and unique sequences at both ends (U5 at the 5′ end and U3 at the 3′ end). These sequences are important to form long terminal repeats (LTRs) during replication. The coding sequences of HIV have three major genes of retroviruses: gag, pol, and env. The gag gene codes for MA, CA, and NC; the pol gene codes for PR, RT, and IN; the env gene codes for SU and TM. It is characteristic of HIV to have accessory genes. Two of them, tat and rev, are essential for replication in both HIV-1 and HIV-2. HIV-1 has vif, vpr, nef, and vpu, while HIV-2 has vif, vpr, nef, and vpx instead of vpu as nonessential accessory genes.

The replicative cycle starts with an interaction between the virion and the cell surface receptor. The principal receptor for HIV is the CD4 molecule, which is expressed on CD4-positive T lymphocytes, macrophages, and so on. The CD4-binding sites on the virion are on SU (gp120). The next crucial step after binding is fusion of the virion envelope and the plasma membrane. It has been postulated that an *N*-terminal hydrophobic **domain** in TM is the actual fusion protein, which needs to be exposed by a conformational change in the envelope glycoproteins caused by SU binding to CD4.

Interestingly, an additional cell-surface molecule, actually a chemokine receptor like CCR5 or CXCR4, is needed to initiate the fusion process. These chemokine receptors are referred to as “co-receptors” for HIV infection. Once the nucleoproteins get into the cytoplasm, synthesis of the minus-strand DNA starts using RT and host transfer RNA^{Lys} attached near the 5′ end of the viral genome as a primer. Synthesis of viral DNA is similar to that of other mammalian and avian retroviruses, but lentiviruses, including HIV, start the plus-strand DNA synthesis at two sites; one is a polypurine tract near U3 like many other retroviruses, and the other is a central polypurine tract at the end of pol gene. Double-stranded viral DNA with the LTR (see Rous Sarcoma Virus (RSV)) on both ends is carried to the nucleus as preintegration complex. Presumably, nuclear localization signals in MA and/or Vpr play an important role in nuclear translocation of the preintegration complex. While mammalian and avian retroviruses require cell division for efficient virus production, HIV can infect nondividing, terminally differentiated cells. Linear double-stranded viral DNA is the substrate for IN and the direct precursor of integrated provirus.

Integrated proviral DNA has an LTR on both ends. Full-length viral RNA is transcribed from the U3/R boundary in the 5′LTR to the R/U5 boundary in the 3′LTR, and 5′-capped and 3′-poly(A)-tailed viral RNA serves as both genome RNA and mRNA for translation. The mRNA undergoes complex RNA splicing. The env and accessory gene products are translated from spliced mRNAs. The env gene products (Env) are translated as a precursor protein, gp160, in the rough endoplasmic reticulum, processed to gp120 (SU) and gp41 (TM), and expressed on the cell surface. The gag and pol gene products (Gag and Pol) are translated from unspliced mRNA. The pol gene is not in the same reading frame as gag gene, however, and pol gene products are translated as a Gag–Pol fusion protein by ribosomal frameshifting at the gag–pol boundary. Viral assembly occurs just below the plasma membrane. Virions bud out from the cells, covered by the plasma membrane (viral envelope) with SU and TM. Viral proteinase (PR) digests Gag and Gag–Pol fusion proteins to MA, CA, NC, PR, RT, and IN, and the virions are matured.

Hofmeister Series

The Hofmeister (or *lyotropic*) series, first described by Hofmeister in 1888, is the ordering of ions in their effectiveness in salting out proteins (see Precipitation). Since then, it has been established that the same order is maintained in the effects of these ions on **nucleic acid** and protein stability (see **Stabilization and destabilization by co**), association–dissociation equilibria between macromolecules, enzyme activity, and various other biological and biochemical functions (1). The ordering is as follows:

← Stabilization   Unfolding →
← Salting in   Salting out →

Anions:

$$SO_4^{2-} < CO_3^{2-} < F^- < CH_3COO^- < Cl^- < Br^- < NO_3^- < ClO_4^- < I^- < SCN^-$$

Cations:

$$NH_4^+ < Rb^+, K^+ < Na^+, Cs^+ < Li^+ < Mg^{2+} < Ca^{2+} < Ba^{2+}$$

Anions and cations are essentially independent of each other in these actions, and their effects are additive. For example, it has been found that LiBr is a good salting in agent, whereas NaCl is a salting out agent (2). Reshuffling the ions gives the result that both NaBr and LiCl have no effect on the solubility, in other words, the salting in capacity of one ion (Li^+ or Br^-) is compensated by the salting out characteristic of the co-ion (Cl^- or Na^+).

Holocentric Chromosome

Holocentric or polycentric chromosomes have centromeric heterochromatin (see Centromeres) distributed at multiple sites along the length of the chromosome (1). Organisms with holocentric chromosomes include nematodes, such as *Ascaris*, insects, such as *Lepidoptera*, and **plants** in the genus *Lazula*. Spindle fibers attach along the whole length of holocentric chromosomes (Fig. 1). Sites of attachment of the spindle to centromeric chromatin are interspersed with noncentromeric segments, as in *Ascaris*, or all the chromatin in the chromosome is competent for attachment, as in the coccid bugs (2). In this latter case, centromeric functions are appropriately described as diffuse. In some organisms, like *Lazula*, localized centromeric function might be retained in mitotic chromosomes but shift to different positions in meiotic chromosomes. Mammalian tissue culture chromosomes also persist and segregate when they have multiple centromeres, but in this case only one centromere remains functional (4).

Figure 1. Monocentric and holocentric chromosomes. (a) Monocentric chromosomes have a single site of chromosomal attachment to the spindle. (b) Holocentric chromosomes have multiple sites of attachment to the spindle.

Holoenzyme, Apoenzyme

A number of enzymes rely on the presence of a **prosthetic group** at their active site in order for them to be catalytically active (see Coenzyme, Cofactor). For example, aminotransferases require pyridoxal phosphate. Prosthetic groups are small molecules that are covalently or tightly bound at the active site. They provide groups that the protein component of the enzyme does not possess, but that are essential for catalysis. The enzyme with a prosthetic group bound is referred to as a holoenzyme, whereas after removal of the prosthetic group, the protein component alone is termed an apoenzyme. Thus,

$$\text{Holoenzyme} = \text{apoenzyme} + \text{prosthetic group} \quad (1)$$

The term apoenzyme is also applied to **allosteric** enzymes such as aspartate transcarbamoylase from which the regulatory subunits have been removed.

Homeobox Genes

Homeobox genes play fundamental roles in development and evolution. They are perhaps the best examples of key regulators of gene transcription that are at the heart of the genetic circuitry, regulating different pathways. Homeobox genes have been highly conserved throughout evolution and are involved in the genetic control of the body plan, the determination of cell fate, and several other basic developmental processes. Common among the hundreds of different homeobox genes known today is a highly homologous, 180-bp structural motif, the homeobox . The homeobox encodes a 60-amino acid residue polypeptide chain, the ***homeodomain***, that represents the **DNA-binding** domain of the respective proteins.

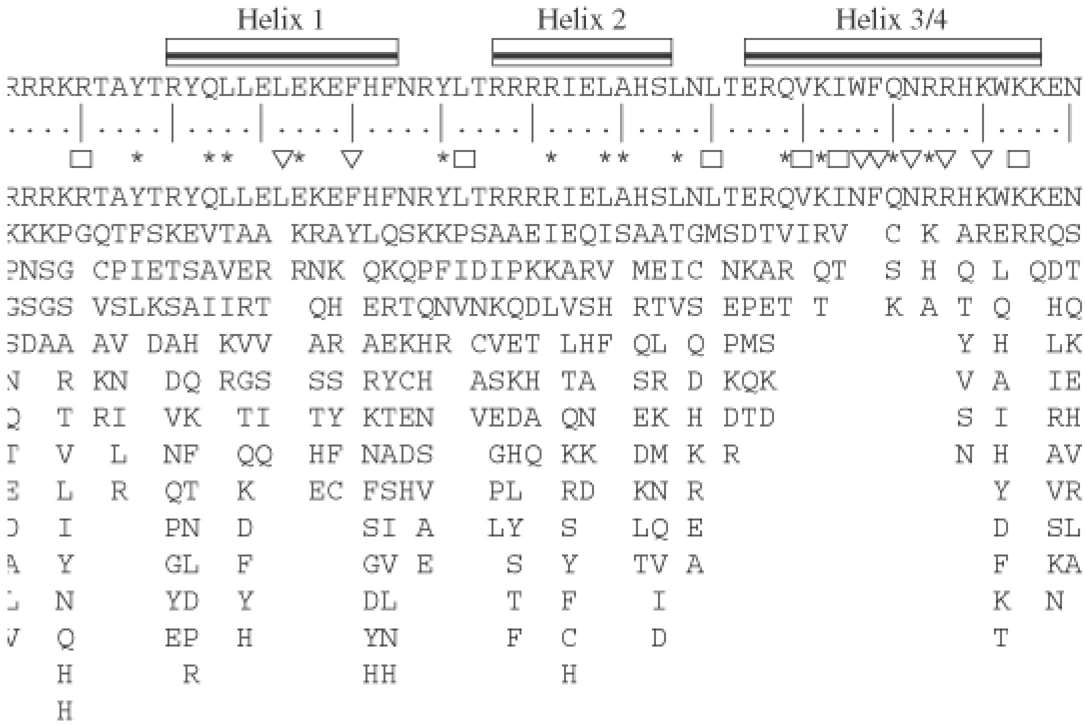
1. History of Homeobox Genes

Homeotic mutations lead to segmental transformations, suggesting that they are involved in the genetic control of a body plan. The first homeotic mutant, bithorax, was discovered in 1915 (1). This *Drosophila* **gene** was later shown to be part of a gene cluster termed the bithorax complex (BX-C) (2). Single mutations in the bithorax complex induced major modifications in the body plan, for example, generating four-winged flies. In 1983, the first homeobox gene locus, *Antennapedia*, was isolated (3), which is part of the ***Antennapedia* complex** (Antp). Comparative sequence analysis of the first three cloned homeobox genes, *Antennapedia*, *fushi tarazu*, and **Ultrabithorax**, established a common DNA motif, coined the homeobox (4, 5). This motif was not confined to *Drosophila*, but was also found in vertebrates, including mice and humans. In 1984, the first homeobox gene in the mouse was **cloned** by cross-hybridization using a *Drosophila* homeobox probe (6).

2. Structure and Function of the Homeodomain

The highly conserved **homeodomain** is typically composed of 60 amino acid residues. Figure 1 shows the amino acid **consensus sequence** based on 346 different homeodomain sequences (7). Comparison of the X-ray crystallography structures of the homeodomains of **engrailed** and other homeobox genes of the yeast **mating-type** proteins revealed a **helix-turn-helix** binding motif (8), suggesting that all homeodomains bind to DNA in the same manner. The three **alpha-helical** regions are composed of residues 10–22, 28–38 and 42–58 of the homeodomain (see Fig. 1). Helix 3, the recognition a-helix, binds to the major groove of DNA, whereas helices 1 and 2 lie close to each other in an antiparallel orientation outside the double helix. Thus, only a small number of residues in helix 3 (in particular, that at position 50) and in the *N*-terminal arm are responsible for the specificity of contacts with the DNA. Furthermore, *in vitro* binding studies with protein extracts of the locus *Antennapedia* showed that the homeodomain binds as a monomer to its DNA-binding site, dissociated only slowly, with an estimated half-life of 90 min (9). Other examples suggest that homeobox proteins may dimerize. Transcriptional regulation of homeodomain proteins *in vivo* was first demonstrated for bicoid, interacting with its target gene hunchback (10-12).

Figure 1. The primary and secondary structures of the homeodomain. The homeodomain contains three well-defined a-helices and a more flexible fourth helix. The schematic illustration of the structure represents a composite derived from the structures of the Antennapedia, engrailed, and MATa2 homeodomains. The amino acid consensus sequence is based on 346 homeodomain sequences. For each position, the amino acid encountered most frequently is listed at the top, while other amino acids are listed beneath in decreasing order of frequency of occurrence. Amino acids occurring fewer than 5 times (1.5%) are not shown. The symbols on top indicate highly conserved positions: ▽ are the most highly conserved positions, with only one or two amino acids found at that position. *ƒ* indicates highly conserved positions with three to five different amino acids found at a particular position, and * indicates conserved positions, with not more than nine different amino acids.



3. HOX Gene Clusters

Homeobox genes are clustered in *Drosophila* and organized in two separate clusters, the bithorax (BC-C, 2) and *Antennapedia* (Antp) complexes (13, 14), and are referred to as *HOM-C complexes* . The genes of these two gene clusters have been termed *HOX genes*. HOX genes play a critical role in pattern formation. The order of HOX genes within each cluster correlates with the temporal order of expression of these genes, which are expressed along the anteroposterior axis of the embryo. Interestingly, homeobox genes with sequence similarity to *Drosophila* **HOX genes** are also clustered in vertebrates. Both humans and mice have four HOX gene clusters, which reside on different chromosomes. They are termed *Hoxa* to *Hoxd* in mice and *HOXA* to *HOXD* in humans (15). Altogether, 38 genes reside in these four gene clusters, and all are orientated in the same 5′–3′ direction of transcription (16, 17). Furthermore, in mammals the order of HOX genes within a cluster dictates the time of expression.

4. Homeotic Mutations

The term *homeotic mutations* actually refers to HOX gene mutations within the homeotic clusters. For example, a homeotic mutation in the *Antennapedia* gene complex transforms an antenna into a leg. A mutation in the *bithorax* gene results in a fly with four wings. A mutation in human HOXD13 results in synpolydactyly. Some of the mouse HOX mutations have been shown to lead to only relatively mild phenotypes. This may be due to functional compensation or to different parallel regulatory pathways.

In a broader sense, homeotic mutations may encompass mutations of all homeobox genes. Homeotic mutations may represent the classic examples of loss-of-function mutations or gain-of-function mutations. It is interesting that missense mutations causing loss-of-function mutations are often concentrated in the homeodomain or in other functionally important parts of the protein. In contrast, nonsense mutations leading to gene truncations are distributed more widely across the genes. Also, a 50% reduction in the gene product (haploinsufficiency) or overexpression may lead to different clinical phenotypes, suggesting that correct dosage is crucial at certain times in development. This was shown for the first time for PAX6, which leads to aniridie when underexpressed and to other severe eye abnormalities when overexpressed (18, 19) (see Pax Genes).

5. Homeodomain Gene Families

Using degenerate oligonucleotide probes or amplification by **PCR**, a wide variety of novel homeobox genes that represent non-HOX homeobox genes have been identified. Some of these “isolated” (“orphan”) homeodomain gene families contain additional highly conserved domains. Examples of these conserved motifs are the **paired-**, **POU-**, LIM-, engrailed-, and **zinc-finger** motifs, which specify the individual classes of homeobox genes. Each of the two independent DNA-binding domains contacts a specific short sequence on the major groove of the DNA double helix. Examples of the homeobox genes with a paired domain include several members of the PAX gene family (PAX 2, 3, 6); POU domain genes are **P**it1, **O**ct1, and **u**nc 86; genes with a LIM motif include the nematode lin-11 and putative human **oncogene** rhombotin1; the engrailed class of homeobox genes includes EH1-5, and a gene with a zinc-finger motif is the human ATBF1 gene.

A homeobox page on the different homeobox genes is maintained by Thomas R. Bürglin and can be accessed via the Internet (site currently unavailable).

6. Homeobox Genes in Disease

In the last few years, gene disruption experiments in transgenic mice, as well as positional cloning in humans, have defined a number of homeobox genes associated with genetic diseases and congenital syndromes. The first human HOX gene mutation, HOXD13, was described in families with synpolydactyly (webbing and duplication of fingers) (20). Here the homeodomain was still intact, and the affected members of these families had an expansion of 7–10 additional alanine residues. RIEG, a bicoid -related homeobox gene, was shown to be involved in Rieger syndrome, a complex human disorder with dental, ocular, and further abnormalities (21). Just recently, the chick and *Xenopus* homologues of RIEG (Pitx2) were shown to determine the left–right asymmetry of internal organs in vertebrates (22). SHOX, a **paired**-related gene, was shown to play a major role in human growth (23), affecting the height in Turner and Léri-Weill syndrome patients, Langer dwarfism, and idiopathic short stature patients. The MSX1/MSX2 family of genes has been found to be mutated in some forms of craniosynostosis (24). PAX2 and PAX6 genes play a role in eye development, and PAX3 in the Waardenburg syndrome, the most common form of inherited deafness (25). Two gene families in particular, Emx and Otx, have been reported to play a role in brain development, and EMX2 mutations, for example, have been associated with schizencephaly (26).

7. Evolutionary Conservation

Because of their fundamental importance in embryonic development, homeobox genes have been highly conserved throughout evolution. Homeobox genes have been found in plants, fungi, insects, and vertebrates. Both the **secondary structures** and tertiary structures of homeodomains of different species have been highly conserved. The two HOM-C clusters in *Drosophila*, and the four HOX clusters in mice and humans, arose by gene duplication and **divergence** from a common ancestral cluster (27). Such a single gene cluster was found in *Amphioxus*, the closest invertebrate relative of the vertebrates.

Functional homology between *Drosophila* and mouse HOX genes has been shown by gene knockout and transgenic mice (28, 29). Most striking are the gene transfer experiments carried out between mouse and *Drosophila*. They demonstrated, for example, that the mouse HOXb-6 gene can induce antennal legs when ectopically expressed in *Drosophila* (30). The ability to compare and extrapolate among species as diverse as *Drosophila*, mice, and humans is also highlighted in experiments with the mutants of eyeless (ey) in *Drosophila*, small eye (Pax6) in mice, and Aniridia (PAX6) in humans, which share a 90% sequence identity in their homeodomains. The murine Pax6 is not only strongly homologous to the *Drosophila* PAX6, but both can induce ectopic eye structures on the wings, legs, and antennae by targeted expression (31).

Homeostasis

Homeostasis is the tendency of an organism to maintain an equilibrium among its internal physiological functions and between the organism and its environment. Metabolism within the cell is regulated to maintain a constant inner environment. Organ systems for respiration, digestion, metabolism, and excretion all work to maintain homeostasis within the organism. Some vertebrates (birds and mammals) also have homeostatic mechanisms to maintain their internal temperatures.

Homeotic Genes

Homeotic genes are required during the development of plants and animals to control the differentiation of repeated homologous structures, such as vertebrae or flower organs. Mutations in homeotic genes result in the transformation of one of these homologous structures into the likeness of another structure normally present in a different position. Although most homeotic genes encode transcription factors (see below), a homeotic gene should be considered as such using anatomical, and not molecular, criteria.

The term “homeosis” was first coined to describe certain spontaneous aberrations seen in the wild in which one part of a homologous series is transformed into the likeness of another (1). In plants, it is frequent to observe these transformations between the different organs of the flower (petals transformed into stamens). In animals, these transformations can happen between appendixes (antenna into leg transformations in insects), parts of a segment (a lumbar vertebra into a thoracic one in vertebrates), or result in the formation of supernumerary organs in more anterior or posterior positions (extra mammary glands). Bateson also included under the term homeosis certain bilateral transformations in which both primordia develop in an animal in which normally only the left or the right primordia gives rise to the adult structure (tusk of the Narwhal; ovary and oviduct of fowl). The first homeotic mutant in animals, *bithorax*, was described in the fruit fly *Drosophila melanogaster* by Bridges and Morgan in 1923. In bithorax mutant flies, part of the metathorax transforms into mesothorax (haltere into wing). Mutations in many genes resulting in homeotic transformations of organs or segments have been isolated in plants, insects, and vertebrates. All these mutant transformations fit within Bateson's anatomical definition of homeosis, and, therefore, the genes that mutate to give such phenotypes are termed “homeotic genes.”

In animals, the concept of a homeotic gene is associated historically with that of homeobox and Hox gene from which it should be distinguished. The association originates from the early studies in *Drosophila* of the molecular nature of the homeotic genes. Genetic analysis had showed that some homeotic genes are in different locations in the genome, but many cluster in two complexes: the Antennapedia complex contains homeotic genes required for the development of the head and the anterior thorax, and the Bithorax complex contains genes required for the development of more posterior segments. Molecular analysis of the homeotic genes of the Bithorax and Antennapedia complexes showed that they encode transcription factors with a common protein domain (2, 3). Because this new protein domain was first found in homeotic genes and was common to all of them, it was called the homeodomain, and the DNA sequence encoding it was called homeobox. Despite this historical link, not all homeotic genes encode homeodomain proteins and vice versa. In animals there are homeobox genes required for segmentation or dorsal-ventral specification that, when mutated, do not result in homeotic transformations. In plants, this lack of correlation is more evident as most homeotic genes are encoded by transcription factors of the **MADS** domain class, and the mutation of homeoproteins like “knotted” does not result in homeotic transformations (4).

According to their similarity, homeodomain sequences can be classified into at least 30 classes (5). The homeodomains encoded by the genes of the Antennapedia and Bithorax complexes are most related by sequence, and homologues of these genes have been found not only in vertebrates and arthropods but also in unsegmented worms like *Caenorhabditis elegans* (6, 7). These evolutionarily related genes are required for the specification of structures along the anterior–posterior axis and have in common the property of being organized in clusters. To reflect this common function and evolutionary origin, the term “Hox genes” was coined. Hox genes are expressed in the anterior-posterior axis of the organism in a collinear order with their location in the cluster. Genes located 3′ in the cluster are expressed in more anterior positions than those located more 5′. Hox genes are homeotic genes; however, certain mutations in Hox genes affect cell properties like migration or cell differentiation, without resulting in clear homeotic transformations.

In plants, the ABC model explains satisfactorily how the homeotic genes form the different organs of the flower (8). According to this model, there are three classes of homeotic genes (termed A, B, and C) acting in combination to form the four flower organs: petals, sepals, stamens, and carpels. These organs are arranged in concentric rings known as whorls. The first (outer) whorl is formed by sepals that express class A genes during development; the second whorl is formed by petals that express A and B genes; the third is formed by stamens that express B and C genes; and the fourth (innermost) is formed by carpels that express C genes. This restricted spatial expression can be represented by the following formula: 1A, 2AB, 3BC, 4C, where numbers represent whorls and letters represent the gene class expressed in those whorls. The ABC model also proposes that the A and C genes repress each other; so, in a class A mutant, C genes are expressed in the region where A genes are normally expressed, and vice versa. In contrast, the mutation of B genes does not affect the spatial expression of A or C genes. With this premise, most of the available expression and mutant data can be explained. In an A mutation C genes will be expressed in all four whorls (1C, 2BC, 3BC, 4C), resulting in a flower expressing C in the outer whorl, which consequently develops as carpels; expressing BC in the second and third whorls, which develop as stamens; and expressing only C in the fourth whorl, which then develop as carpels. With the same logic, a mutation in C leads to a flower composed of sepals, petals, petals, sepals (1A, 2AB, 3AB, 4A). Class B mutants lead to flowers composed of sepals, sepals, carpels, carpels (1A, 2A, 3C, 4C). A triple mutant lacking one gene of each class lacks all the floral organs, and the whorls develop as leaves.

A common characteristic of all homeotic genes is their capability to organize the development of entire segments or structures. To reflect this property, the homeotic genes have been named "selector genes" (9) (and also "identity genes") as they are high in a genetic hierarchy and can "select" what kind of organ is formed in a certain position. Homeotic genes have this property because they control groups of downstream genes, which are ultimately responsible for the shape of the organs by controlling cell behaviors like cell division, adhesion, etc. In *Drosophila*, where more are known, the downstream genes encode diverse proteins, such as signaling molecules, adhesion molecules, transcription factors, etc. (10).

One property that is essential for a homeotic gene is that it is active only in a subset of the homologous series of organs. Where a certain homeotic gene is active is controlled in both plants and animals at the transcriptional level. Only the organ primordia in which a particular homeotic gene is expressed will have the set of characteristics that this gene confers. In a loss of function mutant for this homeotic gene, the characteristics of the organ are replaced with those of another homologous organ. On the other hand, if the function of a homeotic gene is activated in the primordia of a homologous organ that normally does not express it, this organ will have a homeotic transformation.

There is a complex system involved in activating, modulating, and maintaining homeotic gene expression. The best known example is the regulation of Hox gene expression. In *Drosophila* it is the segmentation genes that activate spatially restricted patterns of Hox gene expression (11). Vertebrate Hox gene expression is thought to be initiated by the retinoic acid morphogen (12). Recent studies show that besides the Retinoic acid receptors, the vertebrate caudal homologs are activators of Hox expression in frogs and mice (13, 14). There is a group of genes have been well characterized in both vertebrates and invertebrates that are responsible for the maintenance of Hox gene expression. These are mainly positive regulators, the *Trithorax* genes, and negative regulators, the *Polycomb* genes. Mutations in the Trithorax and Polycomb genes result in homeotic transformations; therefore, they must also be considered homeotic genes. In plants, some genes required for the formation of the floral meristem act as early activators of flower homeotic genes (15, 16). Interestingly, a negative homeotic gene regulator has been isolated in plants that is homologous to a *Polycomb* gene (17).

Most homeotic genes studied to date encode transcription factors, but, as homeosis is an anatomical concept, it is possible that other classes of genes result in homeotic transformations. In fact, the transformations of wing toward notum observed in mutants for the signalling gene *wingless* have been considered a homeotic transformation (18).

Homokaryon

A *homokaryon* is a hyphal cell, mycelium, organism or **spore** of **fungi** in which all the **nuclei** are genetically identical. The alternative situation is a heterokaryon.

Homological Modeling

Proteins that have similar amino acid sequences, or primary structures, adopt the same fold, or conformation of the **polypeptide** backbone, similar tertiary structures. In other words, the relationship of the three-dimensional protein structure to the amino acid sequence (see Protein Structure Prediction) does not have a one-to-one correspondence, but one-to-many. Therefore, when the 3-D structure of one of the proteins encoded by a **gene family** is known, it can be assumed that all of the other **homologous** protein members of the family adopt essentially the same fold. This is a strictly empirical observation that has held valid for natural proteins, and it provides the basis for homological modeling. It is not easy to give a precise numerical threshold, but two proteins with sequences that are identical at 30% or more of the amino acid residues over a span of more than 100 residues, are almost certainly homologous to each other and belong to the same family (1). Again, this is an empirical rule deduced from natural proteins, which have evolved from a common **evolutionary** ancestor by the accumulation of individual mutations, and it need not be applicable to *de novo* designed proteins. In fact, if the sequence is deliberately designed in one step, the fold of a protein can be converted from totally **alpha-helical** to beta-sheet while keeping the sequences 50% identical (2). There is, however, no guarantee that *de novo*-designed proteins will fold to a unique 3-D structure.

Homological modeling begins with alignment of a query sequence against the sequence of a protein homologue of known structure (see Aligning Sequences). The sequence alignment is best performed by a mathematical technique called dynamic programming. The two sequences aligned may contain insertions or deletions (indels) here and there, shown as gaps in one of the sequences. As the sequence similarity decreases, the number of gaps increases, and the entire alignment becomes less certain. If the structure is modeled according to an incorrect alignment, the resulting model will also be incorrect. Thus, a sequence identity of 40 to 50% or more is usually required for accurate homological modeling. Given the sequence alignment, the query amino acid sequence is mounted onto the known structure, which supplies a template backbone, and the necessary amino-acid side chains are replaced according to the sequence alignment.

Once a proper protein of known structure has been found for a query sequence, the main problems of homological modeling are twofold. The first is to fill in any missing polypeptide backbone by generating an appropriate loop structure. The other is to put all of the new side chains into the correct orientation. If the query structure has residues inserted, there is no template for that part of the sequence. The procedure for generating loops should generate additional polypeptide backbone that joins its two termini smoothly to the template structure and also has an energetically favorable conformation. Indels generally occur at the protein surface, so there are few interactions or steric hindrance to guide the structural design. The orientations of the new side chains of interior residues are determined by the packing of all of the atoms within the protein interior. A simple way to incorporate the new side chains is to adjust their conformation against the fixed conformations of nonsubstituted side chains and the polypeptide backbone. The conformations can also be selected from those observed most frequently in known protein structures, collected in “rotamer libraries,” and from those calculated to have the most favorable energies. A “dead-end elimination” algorithm is more advanced (3). More automatically, the simulated annealing method (4) can be applied to the entire model structure, allowing even the backbone conformation to vary, while seeking the energetically most stable and optimum conformation as a whole. Several computer packages for homological modeling are commercially available.

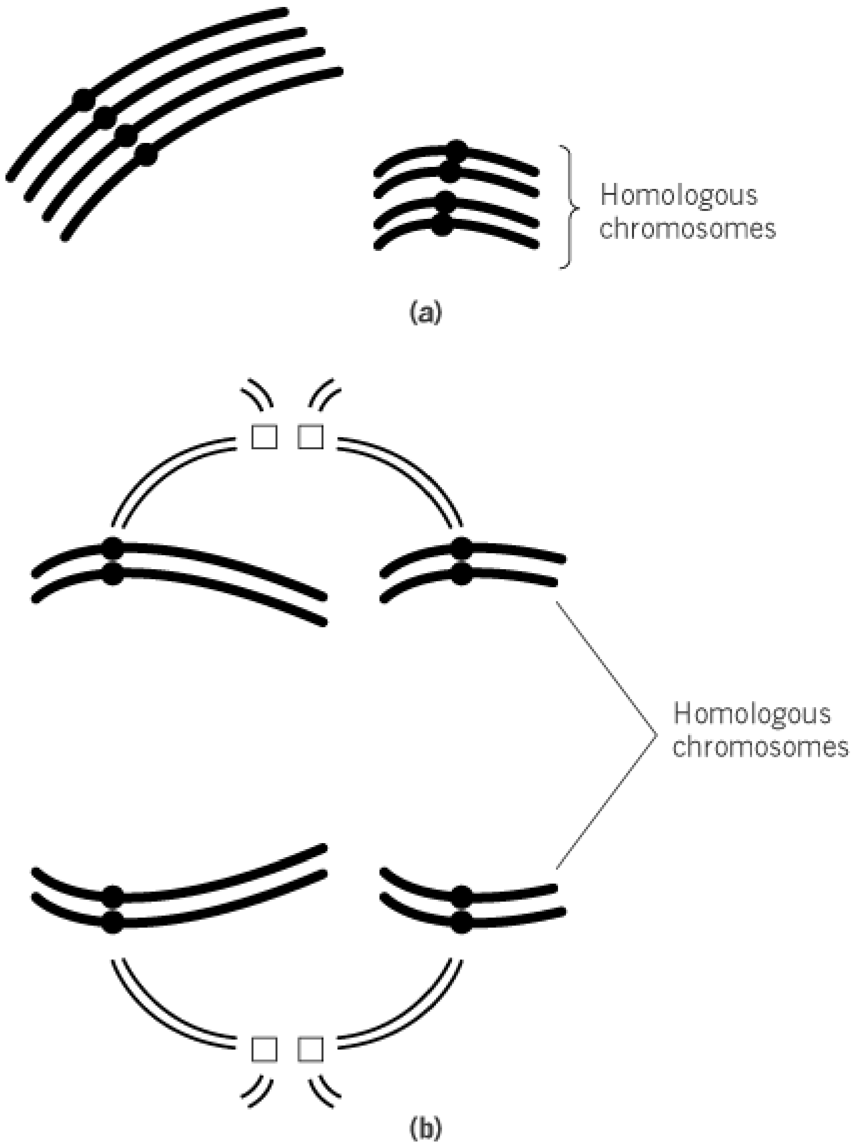
Homologous Chromosomes

Each **diploid** somatic nucleus contains two copies of each chromosome, known as homologues. The existence of pairs of homologous chromosomes is important for providing at least two copies of any particular gene. This provides the cell with two opportunities to generate a functional gene product. However, it also creates the problem of segregating the homologous chromosomes into the **gametes**. Homologous chromosomes always pair during the first meiotic cell division, when they have to be separated to help create haploid gametes (Fig. 1). In certain instances, homologous chromosomes also pair in the somatic **interphase**. This pairing is common in *Dipteran* insects and in some **plants** (1). The techniques of fluorescent ***in situ*** **hybridization** (FISH) and confocal microscopy (see Denaturation Mapping) allow for the definition of chromosomal territories within the nucleus. Homologous chromosomes frequently occupy adjacent territories in insects and plants (2). Nevertheless, homologues do not often pair in the interphase of mammalian cells. Homologous chromosomes are occasionally found in contact with the same nuclear structures, such as the nucleolus or the nuclear membrane, but the distances between homologues are quite variable (3).

Figure 1. Homologous chromosomes during meiosis. (a) Homologous chromosomes align during the pachytene of the first meiotic division. (b) Homologous chromosomes are separated during the anaphase of the first meiotic division.



Pairing of homologous chromosomes in **meiosis** occurs simultaneously with the beginning of chromosome condensation early in the **prophase** of the first meiotic division. In *Coprinus*, a **fungus**, the interaction between homologues, known as **synapsis** begins on the longitudinally aligned chromosomes at points towards the ends of the chromosomes and moves towards the centromere. It is probable that there are specific sites within the chromosome that have evolved to mediate chromosomal pairing (4). How homologous sequences are positioned next to each other during this chromosomal alignment process is also unknown, but recognition of similar nucleoprotein structures is likely to be involved (see Chromocenter). However heterochromatin association does not have a major role in this process, nor do the specialized chromosomal structures found at centromeres and telomeres. The end result of chromosomal adjustment is stable physical linkage of the homologues by the synaptonemal complex (SC) (5). This is a ribbonlike structure consisting of two electron-dense lateral elements (25 nm wide) that are separated by a less dense central region (105 nm wide). The major components of the SC are synthesized during the meiotic prophase. Most of the chromatin is located outside of the SC in loops attached to the lateral elements. The SC has important functions in providing a structural framework for efficient recombination, thereby stabilizing the crossover sites where chromatin bridges form at **chiasmata** (sites of **crossing-over** between homologous DNA sequences). SCs might also introduce constraints on the formation of chiasmata so that they cannot occur too close together. Visualization of SCs under the **electron microscope** after special staining procedures is a useful for revealing any misalignments of chromosomes due to deletions and duplications. This is a useful adjunct to conventional analysis of chromosomal bands.

Homologous Recombination

Homologous, or generalized, recombination requires extensive nucleotide sequence homology between the interacting chromosomes or chromosomal segments. Recombination occurs anywhere within the homologous region, although the frequency varies throughout the region. Near hot spots of recombination, such as the **Chi sites** of *Escherichia coli*, recombination occurs at higher than average frequency. Cold spots, near which recombination occurs at lower than average frequency, are also known.

Homologous recombination plays multiple biological roles. It was first recognized by its production of new combinations of **alleles** from genetically marked parental chromosomes. Later, it was recognized that it plays an important role in the segregation of replicated homologues in the first meiotic division (without further replication sister chromatids subsequently segregate in the second meiotic division). Finally, homologous recombination is the principal method by which double-strand DNA breaks are repaired with fidelity, at least in microorganisms (see DNA Repair).

Homologous recombination can be classified in numerous ways. One way distinguishes reciprocal recombination (crossing over) from nonreciprocal recombination (gene conversion). Reciprocal recombinant types are produced in a single event in the former, but not in the latter. A strict classification requires assessing all of the parental chromosomes entering the event and all of the progeny chromosomes emerging from it. These are most readily assessed in meiosis of certain **fungi** (ascomycetes) that enclose the four products of meiosis, spores, in a sac called an ascus.

Consider a cross between marked parental chromosomes *a b c* and +++. After DNA replication, recombination may occur between a nonsister pair before the first meiotic division. After the two meiotic divisions, four meiotic products emerge.

In gene conversion, an *a*+*c* recombinant chromosome is produced but the reciprocal type, + *b* +, is not. In a crossover, both an *a*++ recombinant chromosome and its reciprocal type +*bc* are produced. Both a gene conversion and a crossover may occur in the same event. In a population of meioses, statistical association of the two events is commonly observed; that is, among the meioses that have a gene conversion at *b*, a higher frequency of crossing over occurs in the *ab* or *bc* interval than in the population as a whole.

Many models have been proposed for homologous recombination. Most models attempt to account for gene conversion and crossing over as alternative outcomes of a common initial event. Common themes in most models of homologous recombination are (1) an initiating break, either single-stranded or double-stranded, in one parental chromosome; (2) the formation of a single-strand end on that chromosome; (3) invasion of the single-stranded tail into the homologous chromosome and the displacement of the identical (or nearly identical) single strand, to form a displacement or D-loop; (4) formation of a more complex joint molecule, such as a Holliday junction; and (5) resolution of this intermediate into one or two progeny chromosomes.

The joint molecule intermediates contain hybrid DNA; that is, DNA with one strand from each parent. If the parental DNA molecules differ genetically in this region, the hybrid DNA is heteroduplex; that is, it contains a noncomplementary nucleotide sequence. If the parental chromosomes differ at a single base pair, the heteroduplex contains a simple mismatch. Mismatch repair converts the heteroduplex to a homoduplex of one or the other parental type and produces a gene convertant. More complex differences between the parental DNA molecules, such as deletions, insertions, or multiple base-pair changes, also produce heteroduplex DNA acted upon by repair enzymes to produce gene convertants. In the absence of such mismatch repair, the heteroduplex DNA is replicated and produces a postmeiotic segregant, that is, a meiotic product that produces two genetic types at the first mitotic division.

D-loops may arise by a single-strand invading tail with a 3′-end, which primes DNA synthesis. Such synthesis is necessary to repair a double-strand break that has been enlarged into a double-strand gap by loss of nucleotides. If the double-strand gap occurs at a site of genetic difference between the parental chromosomes, DNA synthesis templated by the intact chromosome repairs the double-strand gap and produces a gene convertant without mismatch repair.

In many models of homologous recombination, resolution of a Holliday junction in alternate ways gives crossing over (or not) with respect to markers flanking the site of hybrid DNA formation. This feature accounts for the statistical association of crossing over and gene conversion, yet allows for gene conversion without crossing over. These two types of events may, however, sometimes occur by distinct mechanisms. For example, a single-strand invasion without formation of a Holliday junction could readily give a gene convertant, but not a crossover.

Models of homologous recombination can be classified as follows: (1) In breakage-and-reunion there is no loss or resynthesis of nucleotides except for that associated with mismatch repair. This mechanism is exemplified by the Holliday model and, with the addition of limited DNA synthesis, the double-strand gap repair model. (2) In break-copy mechanisms, one parental DNA is broken, and one of its ends primes DNA synthesis (copying) using the other parental DNA as template. This mechanism occurs in recombination of bacteriophages, bacteria, and some types of mitotic double-strand break repair. (3) In copy-choice recombination the initial stage of DNA replication is templated by one parental chromosome, but then replication switches to the other parental DNA at a homologous point. This type of recombination may occur in RNA viruses.

Another type of homologous recombination, single-strand annealing, occurs in the special cases of deletion between direct repeats in a chromosome or in other instances when DNA can be lost, for example, in phage recombination. In this case, a double-strand break may occur between the direct repeats. Resection of one strand at each end exposes complementary single strands that anneal and produce hybrid DNA with one strand from each copy of the repeat. Appropriate trimming of single-strand ends, filling of gaps, and ligations produce a recombinant. This occurs between homologous regions on separate chromosomes if two initiating breaks occur at appropriate places.

Single-strand annealing is an example of a nonconservative recombination event, that is, when two homologous segments or chromosomes interact to produce only one segment or chromosome. In conservative recombination, exemplified by breakage-and-reunion mechanisms, two parental chromosomes produce two progeny chromosomes, one or both of which is recombinant.

Homologous recombination is a complex process promoted, in the cases studied, by multiple enzymes. A central activity, exemplified by the RecA protein of *E. coli*, promotes the association of homologous nucleotide sequences. RecA protein promotes the formation of D-loops from single-strand tails and a homologous duplex. Proteins of related amino acid sequence and function are widespread in many organisms, ranging from bacteria to humans. Other enzymes prepare substrates for RecA protein. For example, the RecBCD enzyme of *E. coli* generates a single-strand intermediate from linear duplex DNA. Other enzymes resolve recombination intermediates into products. For example, the RuvC protein of *E. coli* cleaves a Holliday junction near the exchange point into two separate duplexes. Their nicks are ligated by DNA ligase to produce intact, possibly recombinant DNA molecules.

Homology

Homology is a similarity due to a shared common ancestor in . Therefore, homology is the result of ; in contrast, is a consequence of . Originally, homology was used for morphological characters, such as organs. For example, homologous organs were defined as organs that are related to each other through a common descent, even though now they perhaps exhibit different functions. At the present time, however, the term is used in relation to molecular traits, in particular, **nucleotide sequences** and amino acid sequences.

Any two sequences can be compared by alignment, where maximum similarity is used as the basis of measurement (see). Once the alignment is made, the proportion of identical nucleotides, site by site, can be computed. This proportion is the simplest measure for the “degree of sequence similarity.” When the proportion is statistically significant, it is reasonable to say that the two sequences being compared are homologous, because the probability that the similarity was derived by mere chance is, in most cases, extremely small. In general, if the proportion of identical sites is at least 25–30% in an amino acid sequence, or over 40% in a nucleotide sequence, the two sequences may be said to be homologous. This is because there is an extremely high possibility that this similarity is due to a common ancestor and a very low probability that it occurred randomly. The degree of sequence similarity can then be called the "degree of homology."

By using sequence similarity, one can search for homologous sequences in the nucleotide and amino acid . A given sequence is used as a query sequence and is compared with a sequence in an entry of the database by sliding one site in each comparison, until all possible comparisons have been made. This procedure is repeated for all entries of the database. Only the entries where the sequence homology is statistically significant to the query sequence are noted. This search is called a "homology search." In practice, algorithms called "dynamic programming" are used to make the homology search more efficient.

The homology search is particularly useful for predicting the function of a newly identified gene or protein. This is based on the following logic: In general, conservation of a sequence is known to be stronger for functionally important regions of a protein. If we search a sequence and find a region where conservation is strong, it is reasonable to conclude that the region is functionally important and that the function is possibly shared by the homologous sequences. Doolittle constructed his own public database of amino acid sequences, which were deduced from nucleotide sequences (1). He conducted a primitive homology search by using a viral **oncogene** (*sis*) as a query sequence and then found homology with human (Figure 1). He found that the homology was very high, and for this reason he proposed that the *sis* gene may have a function as a . Following Doolittle's prediction, experiments confirmed the hypothesis (2). In fact, it was found that the *sis* gene was the host gene that was inserted into the viral genome. This was the first report in which a homology search was successful for predicting biological function of an unknown sequence. Since then, the homology search has become a very popular tool in molecular biology.

Homozygote

The **phenotype** of a **diploid** cell may depend upon the interaction of two **alleles** of a gene because a **recessive** gene can express itself only in the absence of its **dominant** allele (note, however, that some genes are neither dominant or recessive). This brings us to two very important words in the language of genetics, *homozygote* and **heterozygote** that describe the general genetic constitution of diploid cells.

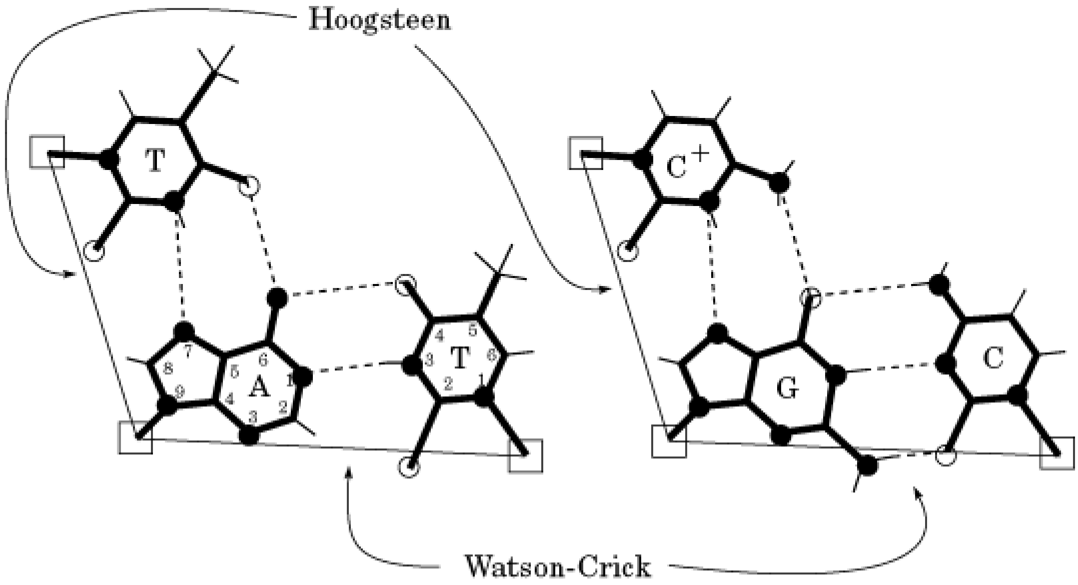
A homozygote is a zygote, or other diploid cell, derived from the union of two **gametes** of identical **genotype**. In practice, however, homozygosity requires evidence from genetic crosses that a particular pair of genes is identical, and it is obviously impossible to prove that *all* the thousands of pairs of genes in what appears to be a homozygous individual are in fact identical. So the words homozygote and heterozygote have a narrower connotation and denote the relationship between specific homologous chromosome regions or genes.

We say that a diploid cell is homozygous for gene *A*, which means that it has the genetic constitution either *AA* or *aa*, or, as it is usually written, *A*/*A* and *a*/*a*, where *A* and *a* are two distinguishable alleles. A cell may be homozygous for gene *A* but heterozygous for gene *B* (*AB*/*Ab*).

Hoogsteen Base Pairing

Nucleic acid bases can form a variety of base pairs. In all canonical duplex structures including B-DNA, A-DNA, and Z-DNA, the so-called Watson–Crick base pairs are found. The Watson–Crick base-pairings of guanine with cytosine and adenine with thymine are shown in Figure 1. The G to C and A to T complementarities are provided by specific hydrogen bond donors and acceptors between the bases. In a G:C base pair three hydrogen bonds are found between G-O6 and C-N4, G-N1 and C-N3, and G-N2 and C-O2 positions, and in an A:T base pair two hydrogen bonds are found between A-N6 and T-O4, and A-N1 and T-N3 positions. The two C1′ atoms within a G:C base pair and an A:T base pair are equidistant (~10.5 Å). Thus the G:C and A:T base pairs in the Watson–Crick conformation are nearly iso-structural, from the point of the view of the sugar-phosphate backbone.

Figure 1. Schematic illustration of the A:T and G:C Watson–Crick and Hoogsteen base pairs. Hydrogen bonds are shown as dashed lines, and the distance between two C1′ atoms (shown as open squares) is drawn with a thin line. The numbering system of the purine and pyrimidine rings is shown.



In earlier crystallographic analyses of nucleic acid base pairs, it was found that an A:T base pair can also adopt a different conformation. Instead of using the N1 position of adenine to base pair with N3 of thymine, the N7 position of adenine was used. This type of A:T base pair was named Hoogsteen base pair (1). A striking difference between those two types of base pairs is that the C1′–C1′ distance in the Hoogsteen base pair of 8.65 Å is significantly shorter than that of the Watson–Crick base pair of 10.5 Å. Therefore the Hoogsteen base pair is not compatible structurally with the Watson–Crick base pair in B-DNA. The incorporation of a Hoogsteen base pair in B-DNA destabilizes the duplex structure. A similar G:C Hoogsteen base pair is not stable unless the C is protonated at the N3 position.

However, certain chemical modifications may enhance the stability of the Hoogsteen base pair. It was shown that the modified nucleoside 3-isodeoxyadenosine (iA) forms a stable base pair with thymine (T) using the Hoogsteen conformation, and the iA:T base pair is fully compatible with the normal Watson–Crick base pair as evident from the stable duplex of $d(CG[iA]TCG)_2$ shown by NMR analysis (2). Another modification which stabilizes the Hoogsteen base pair involves the use of 8-amino-adenine in which the amino group at the C8 position can form an additional hydrogen bond with the O2 of thymine (3). Those modified bases may find applications when the Hoogsteen base pairing is needed in nucleic acid structures.

The binding of protein or drug to DNA may induce alternative base pairs, including Hoogsteen base pair, to form. It has been shown that the quinoxaline bis-intercalator antibiotics triostine A and echinomycin bind to -XCGY- sequences with the drug bracketing the CG dinucleotide base pairs. In the structure of the triostine-CGTACG and triostine-GCGTACGCT complexes, the A:T and G:C$^+$ base pairs adjacent to the quinoxaline rings adopt Hoogsteen base pairs (4). The molecular basis for the Hoogsteen base pair in the structure is to improve the stacking interactions between the quinoxaline ring and the adjacent base pairs. It is likely that such a conformational rearrangement from the Watson–Crick to Hoogsteen base pairs may occur in other biological systems.

An important role for the A:T and G:C$^+$ Hoogsteen base pairs is found in the structure of a nucleic acid triple helix. The formation of a poly(A).poly(U).poly(U) triplex requires that the third strand of poly(U) is bound to the poly(A) strand of the poly(A).poly(U) duplex using Hoogsteen base pairing. The T.A.T. and the C.G.C$^+$ triple base pairs are shown in Figure 1. (Note that the triple C.G.C. base pair is not stable unless the second C is protonated.)

It should be pointed out that Hoogsteen base pairing is not restricted in DNA. In transfer RNA, the nucleic acid bases are often modified and involved in tertiary interactions. For example, in yeast $tRNA^{Phe}$ the nucleotide at position 58 is 1-methyl-adenosine, which is base paired with T54 (5). Because the N1 position of this adenine is methylated, it cannot participate in the normal Watson–Crick base pair. Instead m^1 A58 and T54 form a reverse Hoogsteen base pair. It is likely that those noncanonical base pairs, including Hoogsteen and reverse Hoogsteen base pairs, will be found in higher-ordered RNA structures.

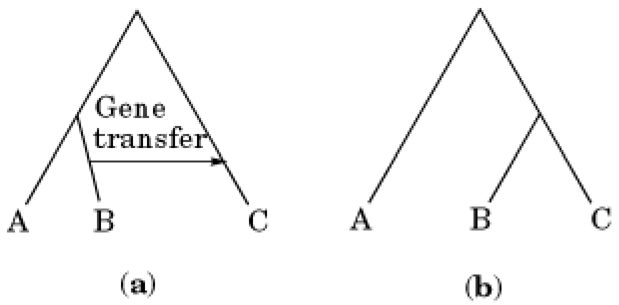
Horizontal Gene Transfer

In general, **genes** are transferred from one generation to the next in a vertical fashion, from parent to progeny through the gametes donated from each parent to form the zygote from which the offspring develops (see Vertical Gene Transfer). In horizontal gene transfer, a gene is transferred from one species to another, often with a **virus** or bacterium acting as the vehicle (Fig. 1). In vertical gene transfer, the genes must originate in germline cells in order to be transferred. In horizontal gene transfer, the gene may originate in a somatic cell, but the receiving cell must be a germline cell in order for the transferred gene to be passed on to the next generation. Strictly speaking, transfers of genes between somatic cells of two species are not called horizontal gene transfer.

Figure 1. Illustration of horizontal gene transfer and how it affects the (**a**) species and (**b**) gene phylogenetic trees.



Horizontal gene transfer is often difficult to detect. It is often suspected, however, when there is marked discontinuity in the phylogenetic tree for a gene, such as the appearance of a gene in one species, but not in any of its most closely related species. Discrepancies between the phylogenetic trees for species and for genes can also indicate that horizontal gene transfer may have occurred.

The **nucleotide sequences** of entire genomes show that horizontal gene transfers must have occurred often. When the complete genome sequences of three representative species from the three major organismic worlds, namely, *Escherichia coli* (Eubacterium), *Methanococcus jannaschi* (Archaebacterium), and *Saccharomyces cerevisiae* (Eukaryote) were compared with each other, approximately 60% of all the genes of the archaebacterial genome are closer to those of the eubacterium than to those of eukaryotes, whereas about 30% of the archaebacterial genes were closer to eukaryotes. The remaining 10% of the genes are archaebacteria-specific (1). Therefore, the archaebacterial genome looks like a mosaic structure, a mixture of genetic material from various genomes. At present, only horizontal gene transfer can explain the mosaic features of the genomes. It implies that a tremendous amount of horizontal gene transfer should have taken place during long-term evolution. Genomes appear to have a robustness that allows major changes in gene order and arrangement without loss of function. This provides an environment in which horizontal gene transfer can occur and provides a source for the emergence of new gene systems and new gene interactions. Thus, the unit of function appears to be the gene, and the positions of genes in the genome have little effect on function. There appear to be only rare examples in which a set of genes must work as a unit. This elasticity of the genome allows it to absorb any disturbances caused by horizontal gene transfer, and it demonstrates the evolutionary significance of the genome itself.

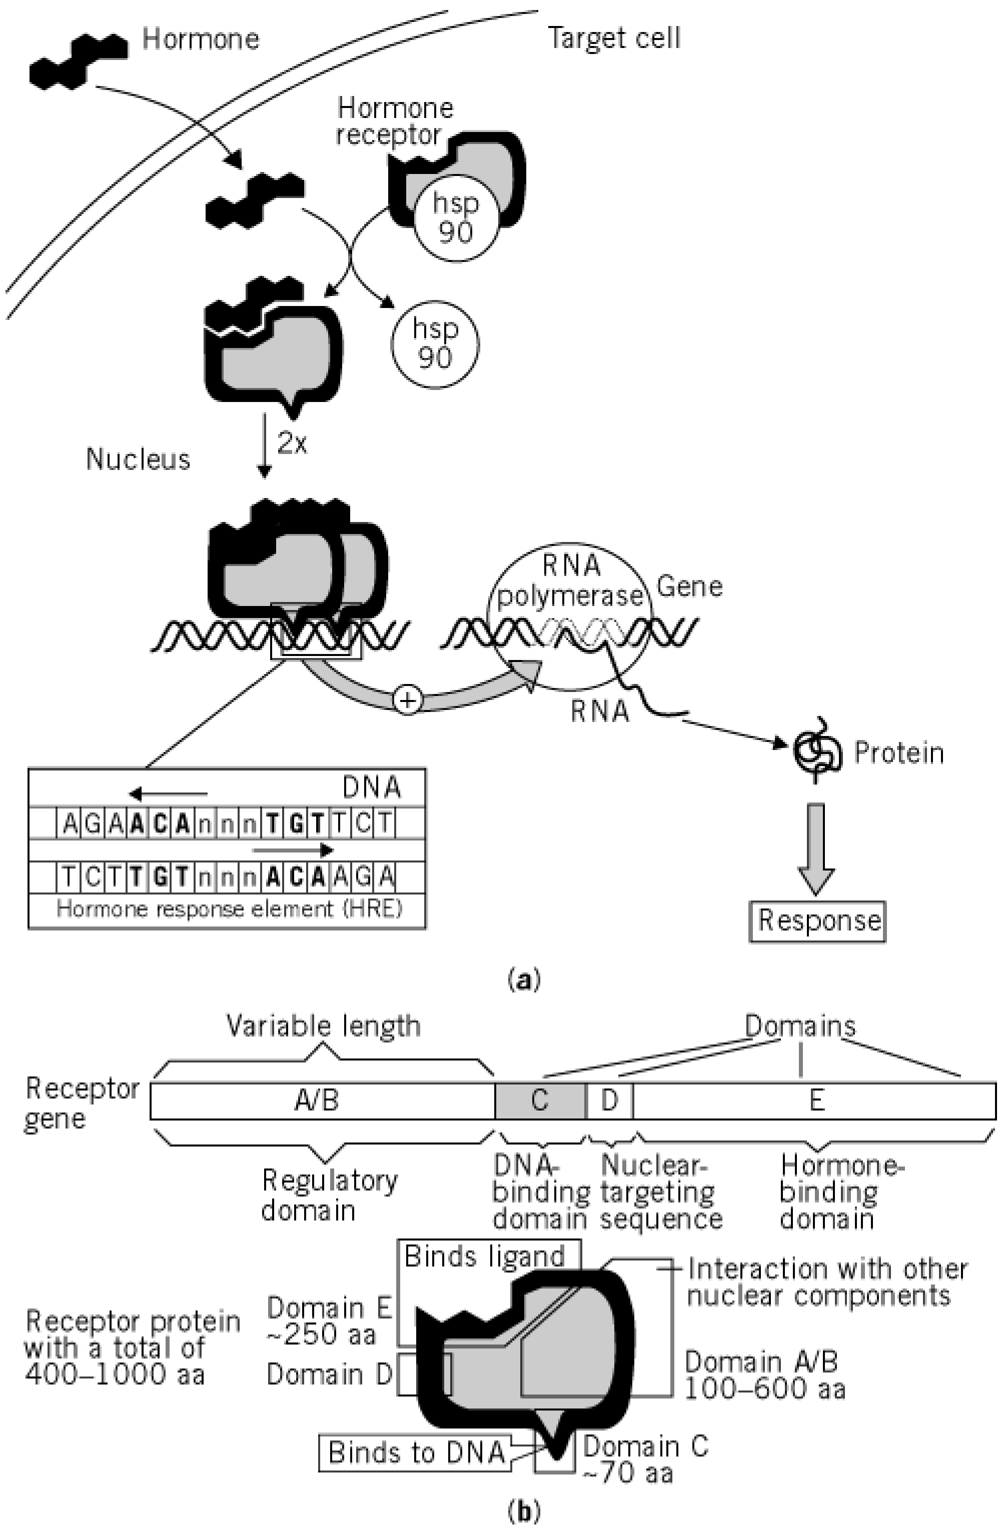
Hormone Receptors

Hormones regulate a wide variety of physiological functions, encompassing intermediary metabolism, growth, and cell differentiation. In contrast to the diversity of their phenotypic effects, they have only two fundamental mechanisms of action, depending on their physical chemical characteristics. The lipophilic steroid hormones and thyroid hormones (vitamin D_2 and retinoic acid have similar modes of action) are **hydrophobic** and primarily act intracellularly, modulating gene transcription, whereas the peptide hormones, adrenaline, and melatonin are hydrophilic and act primarily at the cell membrane, triggering a cascade of signal transduction events leading to intracellular regulatory effects. The first step, and a prerequisite for the elicitation of the hormonal effect of both lipophilic or hydrophilic hormones, is binding of the hormone to its appropriate **receptor** protein. The hormone receptors have the following characteristics: (a) high specificity, so that the receptors can recognize their specific ligand and discriminate between the incoming signals; (b) high affinity for their ligand (K_D values in the range of 10^{-7} to 10^{-10}M); and (c) limited capacity (no more than a few thousand receptor molecules per cell).

1. Lipophilic Hormones

The hydrophobic hormones appear to diffuse across the membrane into the cell (although there are claims of a specific transport mechanism) and bind with high affinity and specificity to their respective receptor protein (see Estrogen Receptors). These receptors, also known as nuclear receptors, belong to a large family of proteins with similar structures, characterized by various functional **domains**, through which the biological activity of the molecule is expressed (Fig. 1). The central DNA-binding domain is responsible for recognition and specific interaction with specific **palindromic** DNA sequences, the hormone response elements. Characteristic of DNA-binding domains are those comprised of two **zinc finger** structures: One is on the amino-terminal side making specific contact with the DNA major groove, and the other is responsible for the specific homodimerization of the activated receptor. Other important domains are (a) the ligand-binding domain, which is at the carboxy terminus of the receptor, (b) nuclear import, export motifs, (c) **heat-shock** protein binding sites, and (d) **transactivation** domains, which can be at either the *N*- or *C*-terminal regions of the receptor. In the absence of hormone, the receptor is complexed to other proteins, such as the heat shock protein hsp90, immunophilins, and smaller peptides. Upon hormone binding, the complex dissociates and the receptor protein is released and forms homodimers, which then bind to the hormone response elements (HREs) (see Hormone Response Elements, Glucocorticoid Response Element). The HREs are enhancer elements that are activated by the ligand–receptor complex. The result of this binding is stimulation (or, in some cases, inhibition) of transcription of the appropriate gene. The mechanism is not yet elucidated, but it also involves interaction of the hormone–receptor complex with other nuclear proteins, such as transcription factors, “adaptor proteins,” “coactivators,” and transacetylases (1-4). The primary transcript is subsequently processed (see RNA Splicing), and the resulting messenger RNA is **translated** into the respective protein. The nature of the protein determines the phenotypic expression of the hormone action: For example, if the protein is an enzyme involved in gluconeogenesis, the blood glucose level will change; if it is a growth factor, cell replication will be affected.

Figure 1. Mechanism of action of lipophilic hormones. (**a**) Mechanism of action of lipophilic hormones. (**b**) Receptors of lipophilic hormones. [From Ref. 10, with permission (slightly modified).]

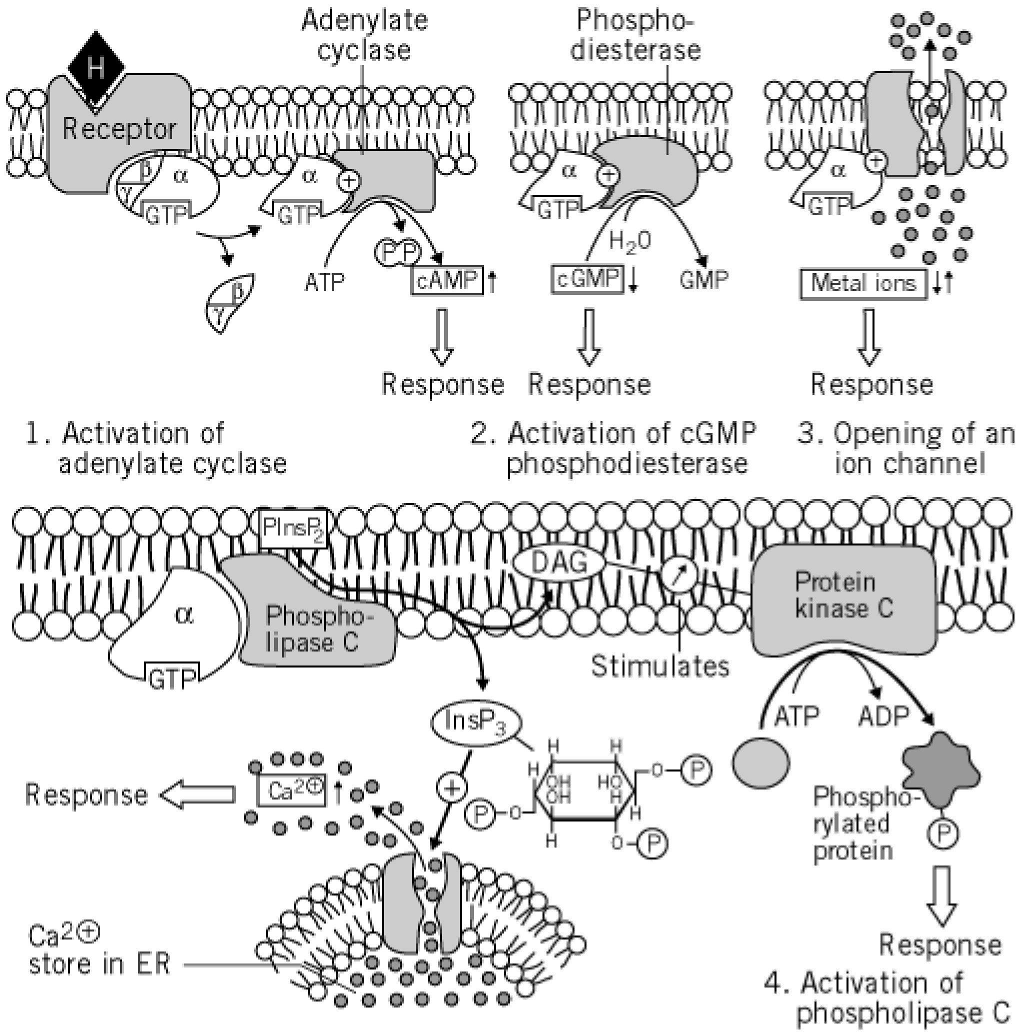


The effects of steroid hormones are usually long-term, needing hours to be exerted. It is becoming increasingly evident, however, that some steroid hormones act very rapidly, by binding to membranes and altering the intracellular concentrations of Ca^{2+}, Na^{+}, and other ions (5). The nature of the membrane-binding sites (eg, whether they are parts of a pore complex) is not known.

2. Hydrophilic Hormones

The hydrophilic hormones are not able to penetrate the cell and instead interact with membrane receptors (see Hormone Receptors) (Fig. 2). Two types of membrane receptors for hydrophilic hormones have been characterized, Type I and Type III. The third type, Type II, represents ion channels, which are mainly regulated by neurotransmitters.

Figure 2. Mechanism of action of hydrophilic hormones. [From Ref. 10, with permission (slightly modified).]



2.1. Type III Receptors

These receptors are integral membrane proteins, with seven **a-helical** domains spanning the membrane, an extracellular domain that is important for ligand recognition, and an intracellular one important for signal transduction. Binding of the cognate ligand induces a conformational change in the receptor that is further transmitted through a family of guanine nucleotide-binding proteins (**G proteins**) associated with the receptor (Fig. 2). The G proteins are trimers of a, b, and g subunits. In the resting state, the a subunit has GDP bound. Interaction of the hormone with the receptor leads to exchange of GDP for GTP on the a subunit and dissociation of the G complex into a separate a-subunit and a b/g dimer. The free a subunit is the effector molecule that activates enzymes involved in the production of second messengers, such as the adenylate cyclases, which catalyze 3′,5′-**cyclic AMP** synthesis from ATP, and **phospholipase C**, which catalyzes the production of inositol 1,4,5-triphosphate (IP_3) and **diacylglycerol** (DAG) from phosphatidyl inositol bisphosphate. Cyclic AMP and DAG are **allosteric** modulators of protein kinases A and C, respectively, whereas the hydrophilic IP_3 reaches the endoplasmic reticulum and acts there by releasing Ca^+_2 from storage sites (6-8). Activation of the protein kinases leads to **phosphorylation** at serine/threonine residues of a large variety of proteins (see Serine/Threonine Kinases and Phosphatases), which are activated in their various functions, such as enzymes, structural proteins, and transcription factors.

The free a subunit of the G protein, due to its intrinsic GTPase activity, hydrolyzes its bound GTP to GDP. When the hormonal stimulus ceases, the GDP is not replaced by GTP, and the G-protein trimer is reconstituted. Consequently, the system thus returns to its initial inactive condition.

2.2. Type I Receptors

These receptors are best exemplified by the insulin receptor. It is composed of two identical a subunits that are extracellular and two identical b subunits, with extracellular, transmembrane, and intracellular domains. The intracellular domains possess intrinsic protein kinase activity. Binding of the cognate ligand induces a conformational change and dimerization of the receptor molecule. This leads to activation of the kinase activity of the receptor and phosphorylation of tyrosine residues within the kinase domain and at other sites of the receptor (see Tyrosine Kinases and Phosphatases). These last sites create docking sites for downstream signal transduction molecules containing **SH2 domains**, which are activated by a variety of mechanisms (eg, tyrosine phosphorylation, conformational changes). Subsequently, by way of intermediate second messenger molecules, they trigger metabolic processes, gene transcription, and DNA replication . The importance of second messenger formation is that the original hormonal signal is amplified by two to three orders of magnitude and that multiple signal effects are integrated by using the same second messenger.

3. Medical Disorders

A series of endocrine diseases result from genetic defects of the receptors for both the lipophilic and the hydrophilic hormones. They are manifested as resistance syndromes, with elevated blood levels of the specific hormone, because the regulatory feedback inhibitory cycle is not functioning. Mutations have been found in various domains of the receptors, leading to partial or total loss of response to hormonal stimuli. In more rare cases, the receptors have lost their function, but in addition they inhibit the action of the wild-type receptor (dominant negative mutants). Table 1 shows an overview of diseases caused by mutations in genes coding for members of the nuclear hormone receptor family.

Table 1. Some Diseases Caused by Mutations in Genes Coding for Members of the Nuclear Hormone Receptor Superfamily[a]

Mutant Receptors	Disease	Remarks
Androgen	Androgen insensitivity syndrome (AIS)	Complete AIS leads to a complete female phenotype.
Glucocorticoid	Glucocorticoid resistance syndrome	Symptoms of fatigue, hirsutism, and hypertension.
Mineralocorticoid	Mineralocorticoid resistance syndrome	Rare autosomal disease, with symptoms of hyponatraemiaand dehydration.
Estrogen	Estrogen resistance syndrome	Only one case with complete resistance has beenreported. Symptoms of incomplete epiphysal closure, prolonged linear growth.
Thyroid hormone	Thyroid hormone	Caused by mutations in the b-

	resistance syndrome	receptor gene.Goiter, learning disabilities, hearing defects, delayed bone maturation, mentalretardation.
Vitamin D_3 (calcitriol)	Vitamin D_3 resistancesyndrome	Severe rickets, secondary hypocalcemia, hyperparathyroidism.

Hormone Response Elements

Lipophilic hormones are able to enter cells and exert their actions by binding to specific **receptors** . Binding of hormones of this type, such as the **steroids**, retinoic acid, thyroid hormone and vitamin D_3, results in the activation of their receptors, which then bind to specific response elements and activate gene transcription . The detailed discussion of this process for one specific hormone and its response elements is provided in Glucocorticoid response element. This article describes the relationships between the different response elements for these various hormones (1).

In each case, the particular response element confers a specific response to a particular hormone because the response element binds only the receptor for that hormone, and not other receptors (2, 3). Thus, the glucocorticoid response element (GRE) binds the glucocorticoid receptor–glucocorticoid hormone complex and hence mediates response to glucocorticoid hormone (Table 1, part a). However, alteration of an A residue at the third position of the palindromic GRE sequence to a T residue converts the GRE into an ERE (estrogen response element), which binds the estrogen receptor–hormone complex and therefore activates gene expression in response to estrogen (Table 1, part a). Similarly, while the glucocorticoid and estrogen response elements have a 3-bp space between the two halves of the response element, the removal of this space to make the two halves of the response element contiguous with one another results in a thyroid hormone response element (TRE) that binds the thyroid hormone receptor. Hence, relatively small changes in sequence can affect the receptor that is bound by the response element and therefore result in it mediating a different pattern of gene expression.

Table 1. Relationships Among Various Hormone Response Elements

(a) Palindromic repeats	
Glucocorticoid	RGRACANNNTGTYCY[a]
Oestrogen	RGGTCANNNTGACCY
Thyroid	RGGTCA——TGACCY
(b) Direct Repeats	
9-*cis*-Retinoic acid	$AGGTCAN_1AGGTCA$
All-*trans* retinoic acid	$AGGTCAN_2AGGTCA$
	$AGGTCAN_5AGGTCA$
Vitamin D_3	$AGGTCAN_3AGGTCA$
Thyroid hormone	$AGGTCAN_4AGGTCA$

[a] N indicates that any base can be present at that position, R indicates a purine ie A or G, Y indicates a pyrimidine ie. C or T. A dash indicates that no base is present, the gap having been introduced to align the sequence with the other sequences.

Although a response to thyroid hormone can be obtained by having the palindromic element illustrated in Table 1, part a, most thyroid hormone response elements are of a different form, in which the GGTCA sequence is directly repeated, with a 4-bp gap between the two direct repeats (Table 1, part b). As with the palindromic elements, the spacing between these direct repeats can affect the nature of the receptor that is bound: Direct repeats with a spacing of 1, 2, or 5 bp produce a response to different forms of retinoic acid, a 3-bp spacing produces a response to vitamin D_3, and a 4-bp space results in a response to thyroid hormone. Detailed structural studies of the different receptors involved have recently revealed the manner in which their different structures allow them to recognize these different response elements specifically (4).

Hence, a family of related response elements that bind a family of related receptor proteins allow different genes to respond to different, but related, lipophilic hormones.

Hormones

Hormones are chemical signaling molecules that regulate metabolism, growth, and differentiation in multicellular organisms (1). Hormones are produced in specialized cells of the endocrine glands and reach their target cells by way of the blood circulation. The term "hormone" is sometimes applied loosely to encompass various other regulatory compounds, including those of lower animals and plants, that show comparable effects. Several hormones (primarily steroid hormones and thyroid hormones) are transported in the circulation while bound to specific binding proteins. These proteins serve as hormone depots, releasing the hormone when needed and also protecting it from rapid inactivation. Most hormones are either steroids (see Steroid Hormones) or peptides and proteins (see Peptide Hormones) (Table 1). Adrenaline, the thyroid hormones, and melatonin are hormones derived from amino acids. In insects and crustaceans, peptide hormones, steroid hormones (ecdysteroids), and sesquiterpenoid derivatives (juvenile hormones) have been isolated.

Table 1. List of Hormones and Sites of Production

Hormones	Site of Production
Steroids	
Glucocorticoids (cortisol, corticosterone)	Adrenal cortex
Mineralocorticoids (aldosterone)	Adrenal cortex
Androgens (testosterone)	Testis
Estrogens (17b-estradiol)	Ovary (follicles)
Progestins (progesterone)	Ovary (corpus luteum)
Calcitriol[a]	Kidneys
Peptide and Proteo Hormones (Partial List)	
Parathormone	Parathyroids
Insulin	Pancreas
Glucagon	Pancreas
Ocytocin	Neurohypophysis
Vasopressin	Neurohypophysis
Melanotropin	Pars intermedia of hypophysis

Somatotropin	Adenohypophysis
Corticotropin	Adenohypophysis
Thyrotropin	Adenohypophysis
FSH (folitropin)	Adenohypophysis
LH (lutropin)	Adenohypophysis
Amino Acid Derivatives	
Thyroxin, triiodothyronine	Throid gland
Adrenaline	Adrenal cortex
Melatonin	Epiphysis

[a] Steroid derivative, not a steroid, but with molecular action like steroid hormones.

The steroid hormones are derived from cholesterol by a series of enzymatic reactions that take place in the cytosol and in mitochondria of primarily cells of the adrenal cortex, ovary, and testis. In some cases, the steroid hormone must be subjected to modification in the target tissue, either to be activated or to produce a more active derivative. The steroid hormones are inactivated mainly in the liver in various ways—for example, by reduction of keto groups or unsaturated double bonds, ring hydroxylation, oxidation of hydroxyl groups, and cleavage of the side chain. They are excreted after being conjugated to sulfuric or glucuronic acids. Most of the peptide and proteohormones are synthesized in the form of precursor proteins (prohormones) and are stored in the endocrine cell. Before being released into the circulation, the prohormones are cleaved to the active hormone. Their inactivation involves **proteolytic** cleavage by intracellular proteinases. The production and release of many hormones is controlled by "tropic" hormones produced by the hypophysis, an endocrine "master" gland; this phenomenon is known as *hormone hierarchy*. The hypophysis responds to chemical signals (metabolites, hormones) from the periphery or to neuroendocrine stimuli from the hypothalamus (liberins, which act positively on hypophysial hormone release, and statins, which inhibit their release). From an evolutionary standpoint, the endocrine system developed earlier than the other two major regulatory systems of higher organisms, the nervous and the immune systems.

The molecular mechanism of hormone action depends on the physical chemical characteristics of the hormones. Steroid and thyroid hormones, which are **hydrophobic**, can enter the cell and bind intracellularly to their respective hormone receptors (2-4). These proteins belong to the superfamily of nuclear receptors and are present in the quiescent cell as complexes with other proteins, among them **heat-shock** proteins. This complex dissociates upon binding of the hormone ligand, the receptor homodimerizes, and it then binds to specific nucleotide sequences, the hormone response elements (HRE). These represent receptor-activated enhancer elements situated at varying distances from the **promoter** of the hormonally regulated genes. Interaction of the hormone–receptor homodimer complex with the HRE results, in a still undefined way, in either stimulation or inhibition of gene transcription, and consequently of expression of the gene. The nature of the protein synthesized determines the **phenotypic** effect. The hydrophilic hormones (peptide and proteohormones, adrenaline and melatonin) cannot enter the cell, but bind to membrane hormone receptors. This results, by way of a **G-protein** effector system, in activation of enzyme systems (eg, adenylate cyclase, **phospholipase C**) generating second messengers, which are **allosteric** effectors of protein kinases primarily (5-7) (see Phosphorylation, Protein). The hormonal effect depends upon the nature of the phosphorylated protein. One class of membrane receptors eg, the insulin receptor, first dimerizes upon binding the hormone and is then autophosphorylated; in this state, it can phosphorylate and activate other intracellular proteins (see Hormone Receptors).

Analogues of hormones can be either more or less potent than the natural hormones, or they can be inhibitors of hormone action; many have been synthesized and used in research or as therapeutics.

The more potent analogues of steroid hormones exhibit higher affinity for the cognate receptor than the natural hormone or greater stability, due to lower rates of inactivation and excretion. Important examples of such analogs are diethylstilbestrol, an estrogen, and dexamethasone and triamcinolone, glucocorticoids. Competitive inhibitors also bind with high affinity to the receptor but cannot elicit the hormonal effect; they can inhibit receptor homodimerization, binding of the receptor to hormone response elements, or interaction of the receptor with the transcriptional machinery. Some such inhibitors (Fig. 1) that have found clinical application include the antiestrogen ICI 182780 used in treatment of breast cancer, the antiandrogen cyproteron in prostate cancer and hirsutismus, and RU486, an antiprogesterone compound used in pregnancy termination.

Hotspot

DNA sequence analysis can be used to reveal the distribution of mutations within a gene due to spontaneous mutagenesis or following treatment by specific chemicals. Such mutation spectra reveal that neither spontaneous nor induced mutagenesis is random, but mutations cluster in specific regions within a gene. Those DNA sites at which a large number of mutants occur are referred to as "hot spots." For example, Halliday and Glickman (1) found that 71% of the 729 spontaneous mutants in the *lac I* gene of *E. coli* carried mutations in a small region (positions 620–632) with base sequence $[5'TGGC3']_3$. In contrast, 98% of ICR-191-induced mutations in the *lac I* gene were +1 and –1 frameshift mutations in runs of repetitive G.C base pairs (2).

There are several possible explanations for genetic hot spots. A trivial one is that there could be a selection bias that favors the detection of mutations at some sites in preference to those at others, but this is probably not true of most observations in the literature. The most likely explanations of most hot spots are unequal distribution of premutational lesions in the gene, differences in processing of lesions in different regions, or some sort of differential DNA repair process. The frameshift mutations produced by N_2-(acetylamino)fluorene (AAF, Fig. 1) provide an example in which the reasons for hot spots have been explored in some detail, especially by Fuchs and co-workers (3). This model carcinogen forms adducts on the C8 position of guanine bases. However, the distribution of AAF-induced mutations fails to correspond to the distribution of AAF adducts in DNA. Only 19% of the DNA adducts appear at the sites of mutational hot spots, even though these sites produce 89% of the mutations (4). Subsequent studies have suggested that these hot spots result from differences in processing of DNA damage at particular sites, with premutational events being more readily converted into a mutation at hot spots than at other sites in DNA.

HU And Related Proteins

The bacterial type-II DNA-binding proteins include the abundant HU and integration host factor (IHF) proteins and the phage-encoded TF1. They are believed to condense their cognate **genomes** by binding at multiple sites and inducing coherent bends. HU and TF1 possess little, if any, binding sequence specificity, but IHF, which is also required for site-specific **recombination, DNA replication**, and transcription, binds at specific sites characterized by a limited **consensus sequence**.

All proteins of this type bind to DNA as dimers and bend the DNA to a substantial extent. In particular, IHF induces a bend angle of at least 160°, and possibly in excess of 180°, within the 2 1 / 2 turns of double helix that comprise its binding site. IHF is normally a heterodimer, while HU can exist either as a homo- or as a heterodimer. In both IHF and HU, the two ~10 kDa subunits intertwine to form a compact core, from which two long beta-sheet ribbon arms extend. These arms track along the minor groove from the inside to the outside of the wrapped DNA, where they terminate at the two substantial kinks. In addition to these interactions via the b arms, IHF also clamps the hairpin by minor-groove contacts with **alpha-helices** from both subunits in the core of the dimer. All the contacts to the DNA are either in the minor groove or are part of an extensive network of electrostatic interactions with the backbone phosphate groups.

The two kinks are induced by the partial intercalation between adjacent base pairs of an absolutely conserved proline sidechain located at the tips of the b arms. In the IHF–DNA complex, the DNA bend is maintained by two distinct mechanisms. On the outside of the bend, the hydrophobic intercalation stabilizes the opening of the minor groove. On the inside, charge neutralization counteracts the enhanced repulsion between the phosphates on opposite sides of the narrowed grooves.

The sequence dependency of IHF binding is determined by the conformation of DNA rather than by base-specific contacts. The “consensus” sequence consists of two short elements separated by approximately half a turn in only one of the two half-sites. The conserved sequence CAA at the kink site can accommodate the severe distortion induced by the protein better than other short sequences, and so is favored.

Hybrid Cell

A heterokaryon, with two separate **nuclei**, eventually proceeds to **mitosis**. This produces a *hybrid cell* in which the two nuclear envelopes have been disassembled, allowing all the chromosomes to be brought together in a single large nucleus. Although such hybrid cells can be cloned to produce hybrid cell lines, the initial hybrid cells are unstable and lose chromosomes. For unknown reasons, mouse-human hybrid cells predominantly lose human chromosomes (see Hybridomas). The loss is random and gives rise to a variety of hybrid cell lines, each of which contains only one or a few human chromosomes. This phenomenon has been used in mapping the locations of genes in the human genome.

Hybrid Dysgenesis

Hybrid dysgenesis is a syndrome observed in *Drosophila* that results from the high-frequency germline transposition of a particular *Drosophila* transposable element called the P element (1). The phenotypes associated with hybrid dysgenesis include a high frequency of mutation and sterility. Hybrid dysgenesis results when males from a strain that contains P elements in its genome are crossed with females from a non-P strain. The lack of high-frequency transposition when P^+ (or P^-) strains are crossed among themselves results from the fact that the P element encodes, in addition to a transposase, an inhibitor of transposition. Thus, hybrid dysgenesis occurs only when the egg is from a P^- strain, lacking the P element and its inhibitor, and when the P-element-containing DNA arrives via sperm without the inhibitor.

Regulation at several levels can account for hybrid dysgenesis. Transposition of the P element is restricted to the germ line because an intact transposase protein is produced only in the germ line. Transposase is encoded by four separate exons whose messenger RNA needs to be assembled by RNA splicing. This splicing event can occur only in the germ line because a somatic protein that binds to Exon 2 RNA near the 5′ splice site inhibits splicing in somatic tissue (2, 3). Another level of control of P element transposition is the transposition inhibitor encoded by the P element itself (1). This inhibitor derives from the P element mRNA, so the transposition inhibitor is related to, but is not identical to, transposase. The mechanism of inhibition appears to involve repression of transcription, which decreases the amount of available transposase.

The high-frequency P-element transposition in the germline that leads to hybrid dysgenesis thus results from the germline-specific synthesis of transposase from the DNA of the sperm of a P^+ male in the absence of a transposition inhibitor; the inhibitor is lacking in the maternal cytoplasm because this fly lacks a P element to generate the inhibitor.

Hybrid Individual

A hybrid is the offspring of genetically different individuals. The term is used often to refer to the offspring of distantly related members of the same species or of closely related species. The potential production of fertile hybrids is a fundamental criterion to assign different individuals, strains, or races to a single biological species.

A *heterozygote* is an individual whose nuclei carry at least two different versions of at least part of the genetic information. The difference may consist in the nucleic acid sequence, the number of chromosomes, or the order of the genes in the chromosomes.

1. Mendelian Hybrid

In a restricted sense, a Mendelian hybrid is the result of crossing two true-breeding strains (homozygotes) (see Homozygote, True Breeding).

A hybrid may involve two **alleles** *A* and *a* of a single gene (a monohybrid *Aa*), or two pairs of alleles at two different genes (the dihybrid *AaBb*), and so on. Hybrids produce characteristic Mendelian segregations in crosses with each other or with their parents (see Mendelian Inheritance, **Crosses**).

Genes that appear in heterozygosis in a polyhybrid may be carried in the same or different chromosomes. The dihybrid *AaBb* is said to be in the *cis-configuration*, or the *coupling* phase, when it contains two dominant alleles on the same chromosome and two recessive alleles on the homologous chromosome of the diploid; to make a graphic distinction, the genotypes of the homologous chromosomes are separated by a slash: *AB/ab*. The dihybrid *AaBb* is said to be in the *trans-configuration*, or the *repulsion* phase, when each chromosome carries a dominant and a recessive allele: *Ab/aB*. When two genes are sufficiently close in the same chromosome, their alleles do not form the random combinations expected from Mendelian inheritance; alleles in the same chromosome tend to remain together.

Hybrids may be larger, more vigorous, or more resistant to adverse conditions than their parents. This phenomenon, called heterosis or *hybrid vigor*, occurs frequently in plants and animals and has led to the commercial production of hybrid seed for agriculture. Depending on the actual techniques that are used, hybrid seed may be too expensive and replaced in practical application by "*double hybrid* seed," the offspring of two hybrids, each with different parents.

Hybridization, Nucleic Acids

Shortly after the discovery of the double helix, it was found that the two strands of DNA could be separated and that duplex DNA could be reformed. Further it was found that DNA from different sources could be combined to form hybrid duplexes (1). Hybridization techniques have become one of the workhorses of molecular biology (2). The properties that promote formation of duplexes from partially or exactly complementary single-stranded nucleic acids are the foundation of hybridization techniques. A requirement for most hybridization experiments is labeled nucleic acid, which provides a detectable signal reporting the quantity of hybrid duplex formed with high sensitivity. Many techniques in nucleic acid chemistry rely on formation of a hybrid duplex composed of single-stranded nucleic acids from different origins.

Hybridization techniques vary markedly in their details, but there are features common to all. Under appropriate solution conditions, two nucleic acid strands with at least partial sequence complementarity can form a hybrid duplex. Each strand may be either DNA or RNA. Most hybridization experiments consist of a minimum of three steps: (*1*) preparation of the target, (*2*) formation of the hybrid duplex, and (*3*) detection of the hybrid duplex. Each step can be technically challenging, and proper procedure requires multiple accompanying control experiments.

The nucleic acids to be hybridized should be free of interfering contaminants. If any of them are part of a duplex, a denaturation step, either by heat or alkali, is included. Frequently, a partial degradation step prior to denaturation is included in the procedure. The degradation is accomplished either by shear or by endonuclease digestion. Selection of the temperature and solution conditions for the hybridization reaction is critical in determining the outcome (see Stringency). Under high stringency conditions, only regions that are highly complementary will form hybrid duplexes. As the stringency is lowered, the fraction of bases participating in hybrid duplexes will increase because of the greater tolerance for defect in sequence alignment under such conditions.

The power of hybridization techniques comes from the dependence of the stability of the hybrid duplex on the extent of complementarity of the constituent strands. The stability of the hybrid duplex depends strongly on solution conditions and temperature, which must be designed carefully to achieve the desired level of sequence discrimination. Most hybridization solutions contain EDTA to bind divalent cations, a polymer utilized to enhance hybrid formation (presumably via an excluded volume effect), and a **denaturant**, usually formamide, in a pH buffered salt solution. The combination of solution conditions (especially the formamide and NaCl concentrations) and temperature defines the stringency of the hybridization reaction. Optimizing the stringency of the reaction is of paramount importance in the success of any hybridization experiment. Defining the optimum depends on the objectives of the experiment. High stringency conditions reduce the stability of the hybrid duplex and select for high sequence homology. Such conditions are used when high target specificity is desired. Low stringency conditions tolerant greater sequence variability. Lower stringency conditions are useful when it is desirable to relax sequence selectivity, such as when probing for a family of related sequences.

When hybridization is performed in solution, the selective detection of hybrid duplexes is difficult. Some progress has been made on this issue by application of fluorescence **energy transfer** techniques; however, selective detection of hybrids remains problematic. This has limited the application of solution hybridization. Its primary application is for formation of heteroduplexes that are subsequently analyzed to determine the extent of sequence complementarity. Another difficulty encountered in solution hybridization is the competition between formation of the hybrid duplex and reformation of the original duplex. There are several approaches to address this problem. For example, when RNA–DNA hybrids are formed, high formamide concentrations (80%) can be used; DNA–DNA duplexes are more destabilized under such conditions. The most common way to circumvent the competitive equilibrium problem is by immobilization of the denatured nucleic acid on a surface. Immobilization prevents reassociation of the denatured duplex. Immobilization of a target nucleic acid forms the basis for a wide variety of probe hybridization techniques. It is in these techniques that the true utility of hybridization for studying nucleic acids is realized.

Traditionally, hybridization reactions have been confined to formation of RNA–DNA and DNA–DNA duplexes. The recent and rapid developments in synthesis of unnatural nucleic acid analogues with base and backbone modifications is expanding the number of possible combinations of duplexes that can be formed. These developments are likely to be exploited in new hybridization reactions. Also, the recent development of triplex-forming nucleic acids for use as probes has expanded the range of reactions that can be usefully included under the heading hybridization.

Hybridomas

Classical seminal studies by Köhler and Milstein in 1975 (1) led to the generation of monoclonal antibodies with defined specificity. Hybridoma methodology was based primarily on fusing murine immune lymphocytes with a malignant myeloma lymphocyte cell line that possessed certain important genetic and biochemical properties. This important methodology was necessitated by the fact that immune antibody-producing B lymphocytes were difficult to maintain as stable cell lines under tissue culture conditions. However, fusion of antibody-producing cells with a malignant myeloma cell line resulted in proliferative cells that can be maintained indefinitely.

Spontaneous fusions between lymphocytes are rare events, so the frequency of fusion was increased to generate large numbers of fused cells by using surface-active agents such as inactivated Sendai virus or the chemical polyethylene glycol (PEG). Upon mixing immune lymphocytes with myeloma cells and the fusing reagent, a selection system was mandatory to eliminate unfused parental cells and to assay for appropriately fused cells that synthesized antibodies with the desired specificity. The tissue culture selection process was dependent on the procurement of myeloma cell lines that no longer synthesized an immunoglobulin and lacked genes for **thymidine kinase** (TK) and/or **hypoxanthine-guanine-phosphoribosyl transferase** (HGPRT). These enzymes catalyze important steps in the salvage pathway used in DNA synthesis by dividing cells. Unfused myeloma cells are unable to proliferate in the HAT selection medium (containing hypoxanthine, aminopterin, and thymidine) because aminopterin inhibited the *de novo* DNA biosynthetic pathway, forcing the cells to use the nonfunctional salvage pathway. Fused myeloma cells proliferate in HAT medium because the immune lymphocytes (fusion partner) furnish the essential TK and HGPRT enzymes for the salvage pathway. Thus, cells that survived incubation with HAT medium represented a successful immune B-cell–myeloma cell fusion, usually on a 1:1 cellular basis. The second phase in hybridoma production was the selection of those fused cells that synthesized and secreted antibody of the desired specificity. This was generally achieved by diluting fused cell populations to a single cell and then generating clones by proliferation of the single cell. The extracellular fluid or media from the single cell and resulting progeny were assayed for the appropriate antigen binding. The methods and techniques used to detect monoclonal antibody activity are usually based upon some variation of the solid-phase immunoassay (eg, ELISA or radioimmunoassay formats).

Hybridoma methodology and consistent generation of relatively large amounts of monoclonal antibodies with defined specificities has proven to be a source of important immunological reagents.

1. The provision of adequate quantities of monoclonal antibody has facilitated the routine determination of primary structures of both the H and L chains at the protein level.
2. Various monoclonal antibodies can be crystallized on a regular basis, providing atomic, 2- to 3-Å resolution structures by **X-ray crystallographic** procedures. In general, **Fab** fragments (four-domain substructures of antibodies, including the variable domains of both chains) with bound ligand crystallize most efficiently. Approximately 100 resolved structures of monoclonal antibodies (Fab fragments) have now been reported.
3. This methodology provides large homogeneous hybridoma cell populations from which messenger RNA responsible for the synthesis of H and L chains can be obtained. Through development of polynucleotide primers, polymerase chain reaction (**PCR**) technology can be used to generate complementary DNA copies for sequencing at the gene level.
4. Gene cloning experimentation with antibody genes has been important in successful site-directed mutagenesis studies. Such studies have been critical in deciphering structure–function relationships governing antibody activity.
5. Hybridoma methodology has led to the development of antibody derivatives, such as single-chain antibodies (2). The latter represent ~25,000–Da structures containing only the variable domains of the H and L chains of a specific antibody molecule. Variable domains constituting single-chain antibodies are usually attached covalently through the use of flexible polylinkers (10 to 15 amino acid residues) that are encoded in the single-chain synthetic gene. Single-chain genes are subsequently incorporated into the appropriate plasmids and expressed in either **prokaryote** or **eukaryote** cell lines.
6. Antigen–antibody interactions can now be studied on a homogeneous basis, yielding important information regarding the thermodynamics of binding.
7. The provision of monoclonal antibodies by hybridoma technology has led to the development of standard diagnostic procedures as well as therapeutically useful immunochemical reagents.

Monoclonal antibodies of defined specificity generated through hybridoma methodology have been used to solve many issues related to structure–function relationships within the antibody molecule. Based on studies with monoclonal antibodies, the property of Fab (active site) segmental flexibility within the IgG class of antibodies was solved. Homogeneous binding at both active sites within a bivalent molecule ruled out **allosteric** effects within antibody molecules. Thus, binding at one active site does not influence antigen binding at the adjacent site. Conformational changes transmitted throughout the molecule subsequent to binding of antigen were dismissed as an explanation for such important phenomena as **complement** binding and fixation. In all cases, the availability of monoclonal antibodies proved important to examine definitively these important questions.

Although hybridoma technology has been the method of choice to produce monoclonal antibodies of defined specificity, new techniques have now emerged. Similar to the construction of single-chain antibodies, gene segments encoding the H- and L-chain variable domains are genetically fused to genes encoding a **bacteriophage** coat protein (3). The engineered bacteriophage infect bacteria, and the resulting phage particles express active antibody products on their surface. The resulting phage display library expresses many different antigen-binding domains. Phage that specifically bind antigen are selected and used to infect bacteria in a second cycle. Each selected phage produces a monoclonal antigen-reactive particle. Primary structures of the variable domains can be determined, and those genes can be fused to the antibody constant region genes to reconstruct a monoclonal antibody. Such genes transfected into myeloma cell lines are expressed, and the antibody products are secreted. Phage display methodology has important implications for the future.

Hydration

The total hydration of a protein (or nucleic acid) is the effective amount of water immobilized by (bound to) a protein molecule or other macromolecule. This consists of a summation of interactions of water molecules with individual sites on the accessible surface of a protein molecule. Such interactions vary from (1) very strong ones, such as water molecules trapped within cavities on a protein molecule and involved in the actual folded structure of the protein, (2) weak interactions, such as water molecules that hydrate charged and other **polar groups** on the surface of a protein molecule; and (3) very weak interactions that comprise water molecules whose rotation or translation is momentarily perturbed by the proximity of a protein molecule (by weak attraction or repulsion). This last type of interaction is primarily **entropic** in nature and reflected by a very small value of the **free energy**. The summation of all these interactions manifests itself as effective binding (ie, immobilization of the water by the protein) that may have a small fractional value at each protein surface site, but which sums up to some whole numbers over the entire molecule.

Total hydration is very difficult to measure, and its values may be a function of the techniques used. X-ray crystallography detects the more strongly interacting water molecules. The NMR technique that detects water molecules whose freezing is perturbed by the presence of the protein (1) and vapor pressure osmometry (2) give similar values of total hydration. These values are of similar magnitude to those obtained from equilibrium dialysis in those cases in which there is total exclusion of ligand from the protein surface. Furthermore, a measurement of site occupancy by the ligand by a contact detecting technique (total binding), when combined with equilibrium dialysis, yields the total hydration (see Eq. 1 of Binding). See also Preferential Hydration.

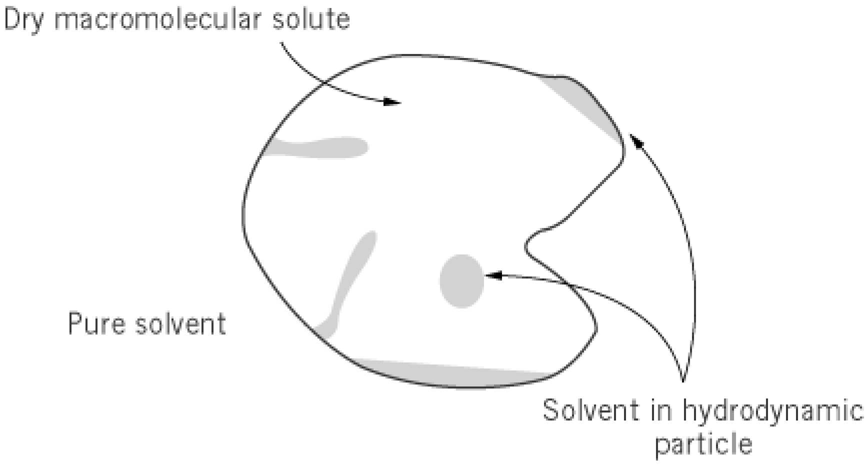
Hydrodynamic Volume

Measurement of the hydrodynamic properties of a biological macromolecule can provide low resolution information about its size and shape. This information can be useful in modeling any interactions in which the macromolecule is involved. Among the techniques used for hydrodynamic measurements are **light scattering, sedimentation velocity** and sedimentation equilibrium centrifugation, and size exclusion chromatography. The hydrodynamic properties of a macromolecule are often expressed in terms of a macromolecular volume (see Stokes Radius). In considering the volume of a macromolecule, however, one must include not only the macromolecule itself but also the role of solvent. Solvent that is “trapped” is an inherent part of a macromolecule and will, therefore, be reflected in measurements of its transport properties. A simple model of hydration of a biological macromolecule is shown in Figure 1. As indicated, water may be bound either at the surface of the macromolecule or in interior spaces. Some solvent molecules may be bound specifically, and others may be simply trapped. In the thermodynamic treatment of this bound water, no distinction is made between the various classes of bound-water molecules. Instead, they are treated as a smooth surface or as internal pools. In any hydrodynamic measurement, these water molecules remain tightly associated with the macromolecule, so the total volume of the macromolecule derived from such studies will necessarily include the bound solvent. A mathematical treatment of hydrodynamic volume in which the bound water molecules are explicitly included is provided here, based on References 1-3.

Figure 1. A cartoon diagram of a macromolecule with bound water. The water can be associated with the surface of the macromolecule or may be accumulated in “pools” in the interior of the molecule. The thermodynamic treatment of this water presented here does not distinguish between these different types of bound-water molecules.



Assume that a given macromolecule has d_1 grams of water bound per gram of macromolecule. If V^*_1 is the average specific volume of this water in cm^3/gm, and if a solution consists of g_1 grams of water and g_2 grams of anhydrous macromolecule, the total volume of the solution can be calculated using the following equation:

$$V_{tot} = (g_1 - g_2\delta_1)\overline{V}_1^{\Delta} + g_2V_2 + \delta_1 V_1^* g_2 \tag{1}$$

where V_{D1} is the specific volume of pure water in cm^3/gm. The first term in the equation is the volume of unbound water; it is assumed to have the same specific volume as pure water. The second term is the volume occupied by the macromolecule; the specific volume of the macromolecule in solution, V_2, is not necessarily equivalent to the specific volume of the pure solid macromolecule. The third term is the volume of bound water. The sum of the second and third terms is the volume of the hydrated macromolecule. This volume can be calculated using the following equation:

$$V_h = \frac{M}{N_0}(V_2 + \delta_1 V_1^*) \tag{2}$$

where M is the **molecular weight** of the macromolecular solute and N_0 is Avogadro's number. Unfortunately, this equation is not very useful, since the terms V_2, d_1, and V^*_1 are not known. These variables can, however, as indicated below, be replaced by those that are experimentally accessible.

The **partial specific volume** of a solute is the change in solution volume when a small increment of the solute is added, at the limit of infinite dilution. This quantity is determined experimentally by measuring the density of a solution as a function of the weight concentration of the solute. The expected result of this measurement can be derived from Equation (1)

$$\overline{V}_2 = \left[\frac{\partial V_{tot}}{\partial g_2}\right]_{g_1,T} = -\delta_1\overline{V}_1^{\Delta} + V_2 + \delta_1 V_1^* \tag{3}$$

This derivation assumes that the macromolecule is sufficiently dilute that the degree of its hydration is independent of its concentration. Using this equation, we can replace V_2 and V^*_1 in Equation (2) to yield

$$V_h = \frac{M}{N_0}(\overline{V}_2 + \delta_1 \overline{V}_1^{\Delta}) \tag{4}$$

The term V_{D1} represents the specific volume of water, which is a pure substance, and can be replaced by its partial specific volume, V_1, which is simply the inverse of the density of pure water. It follows that the hydrated volume of the macromolecule is

$$V_h = \frac{M}{N_0}(\overline{V}_2 + \delta_1 \overline{V}_1) \tag{5}$$

The partial specific volume of the macromolecular solute, V_2, can be measured directly by determining the change in solution volume as a function of added macromolecular solute. The final term is the hydration, and d_1 is an unknown, but it can be reasonably estimated.

Direct determination of the partial specific volumes (V_2 in Eq. (5)) of macromolecules is accomplished by determining the change in solution volume as a function of added macromolecular solute. This can be a difficult measurement and may require a large amount of material. The availability of accurate microbalances can minimize the latter difficulty. Partial specific volumes can also be determined by ultracentrifugation in various mixtures of H_2O/D_2O with varying densities (3). The advantages of this technique are that it as both rapid and requires very little material. The partial specific volumes of proteins can also be reasonably estimated from their amino acid compositions, using estimates of specific volumes of individual amino acid residues (4).

Hydration of biological macromolecules (d_1 in Eq. (5)) has been measured using a variety of techniques, including NMR spectroscopy of frozen samples and **calorimetric** studies. Results from these studies on proteins indicate that the variation in bound water is related to the amino acid composition of the protein. Based on these results, methods for calculating the amount of water bound to a protein from its amino acid composition have been developed. Results of the calculations are in good agreement with the results of experimental measurement (5).

Hydrogen Bond

A hydrogen bond is an attractive interaction between the donor pair X—H and the acceptor atom Y, where H is a hydrogen atom that is covalently bound to an electronegative atom X but attracted to another electronegative atom, Y. The hydrogen bond is commonly represented by a dotted line, as in X—H¼Y. The electron density in the X—H bond is attracted more to X, so X has a partial negative charge and H a partial positive charge, which has been demonstrated by neutron and X-ray diffraction studies of hydrogen bonded crystals. Since the hydrogen bond involves at least three and sometimes four atoms, physically it is characterized by the bond length (—H¼Y—), the angle formed by X—H¼Y, and the enthalpy of formation, D *H*. Typical donors are F—H, >NH, —NH_2, —OH, —COOH, and less frequently, —S—H, → C—H groups. Hydrogen bonds involving C—H are among the weakest. The acceptors are commonly —N, > C=O, —C—F, > NH, > O, and p-electron systems of unsaturated or aromatic hydrocarbons. Examples of hydrogen bonded pairs commonly found in biological structures are [P—OH¼O=P], [O—H¼O=C], [N—H¼O=C], and [O—H¼O—H] (1).

Historically, the presence of associative interactions among certain types of organic and inorganic molecules was recognized in the early 1900s. The remarkable unusual properties of liquid water were attributed to the network of hydrogen-bonded H_2O molecules (for a summary of the early history and references, see Ref. 2). The idea of a hydrogen bond provided an extra valence for the hydrogen atom, which already has a closed electron shell structure. The early observations were summarized in a unified view and presented as the "hydrogen bond" by L. C. Pauling (3).

1. Methods of Detection

For their ease and sensitivity, the vibrational spectroscopy techniques of infrared (IR) and, less frequently, Raman spectroscopy, plus NMR, are the preferred methods for detecting the presence of hydrogen bonds. Neutron diffraction from single crystals gives the most precise elucidation of the hydrogen bond geometry, as it detects the hydrogen atom directly, in contrast to X-ray crystallography, where the presence of a hydrogen bond can be inferred only by the shorter than normal distance between the heavier atoms X and Y (1, 2, 4, 5).

1.1. X-H Stretching Mode in Infrared Spectroscopy

A low frequency shift in IR spectra in the frequency range of 1500–4000 cm^{-1} that is highly temperature-dependent and accompanied by a dramatic increase in absorbance is usually taken as evidence of hydrogen bonds involving O—H or N—H groups as donors. Bending of X—H¼Y bonds in and out of the plane causes absorbance in the region of 1700–1800 cm^{-1} and 400–900 cm^{-1}, respectively. The stretching and bending vibrations of H¼Y hydrogen bonds have much lower resonance frequencies of 50–600 cm^{-1} and less than 50 cm^{-1}, respectively (1). Such spectral changes allow the determination of an equilibrium constant for formation of the hydrogen bond, and its temperature dependence can give the enthalpy of formation. The low frequency vibrational modes make important contributions to the thermodynamic properties of hydrogen-bonded systems.

1.2. Deshielded Proton Signals in NMR

NMR spectroscopy can detect hydrogen bonds because the hydrogen atoms involved are less shielded and consequently resonate at a lower magnetic field. In the case of nucleic acids, these hydrogen atoms are known to have typical chemical shifts of 9–15 ppm downfield of the internal standard (6). If the acceptor group is of aromatic p electrons, the resonance is shifted upfield relative to non-hydrogen-bonded atoms.

1.3. Position of the H Atom by Neutron and X-Ray Diffraction

Neutron diffraction gives the most accurate positions of hydrogen atoms, as they scatter about half as much as C, N, and O atoms. In contrast, hydrogen atoms are barely detectable by X-ray diffraction, and hydrogen bonds are evident primarily from the closeness of the X and Y atoms. On the other hand, there are much more X-ray crystallography data available than neutron diffraction data. The controversy over the existence of weak C—H¼O (or N, S, Cl) hydrogen bonds has been discussed (7).

2. Energetics

2.1. Enthalpy of Formation

The enthalpy of formation of typical hydrogen bonds is commonly determined as the temperature dependence of the association constant for hydrogen-bonded dimers in isolation. The values measured range from a few to 100 kJ/mol, and the majority are in the range 20–30 kJ/mol (Table 1). The bond energy of a hydrogen bond is therefore less than 0.1 that of typical C━C or C━N covalent bonds.

Table 1. Thermodynamics of Hydrogen Bond Formation

Species	–D*H*, kJ/mol	–D*S*, e.u./mol-H bond
Formic acid dimer (gas)	28	18
Acetic acid dimer (gas)	31	18
Propionic acid dimer (gas)	32	18
Stearic acid dimer (liquid)	28	14
Water (gas)	18–21	
Water (liquid)	14	
Methanol (gas)	13–25	
Methanol (liquid)	20	
Ethanol (gas)	17	
Ethanol (liquid)	~17	
Ammonia (gas)	~17	
HF (gas)	28–29	
HCN (gas)	14	

2.2. Hydrogen Bond Potential

Typical potential-energy curves for hydrogen bonds are presented in Figure 1. The first curve (**a**) demonstrates that most common unsymmetric potential, where the H atom is more strongly associated with atom X than with Y. The second curve (**b**) illustrates a symmetric case, where H is bonded equally to X and to Y. As the potential barrier becomes lower, the position of the hydrogen atom becomes sensitive to environmental factors. The third curve (**c**) illustrates the rare case where the potential-energy curve has a single minimum, and the hydrogen bond is truly centric; a good example of this may be found in intramolecular, symmetric hydrogen bonds illustrated in Figure 2.

Figure 1. Potential-energy curves of hydrogen-bonded systems: (**a**) a typical case of an unsymmetric potential, where the H atom is more strongly bonded to X; (**b**) a symmetric case such as Fig. 1**c**; and (**c**) a rare case of a centric potential.

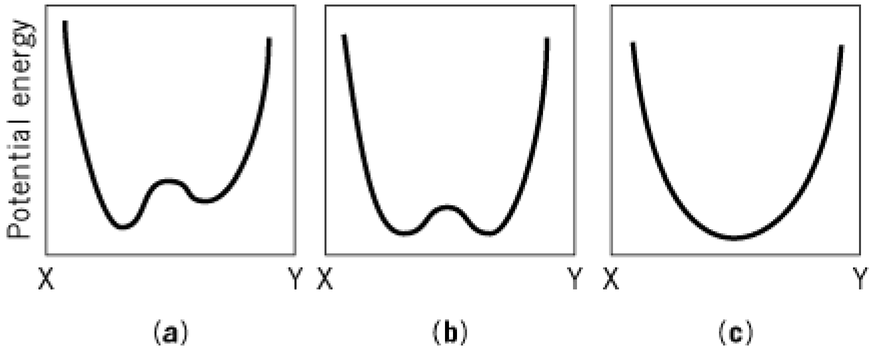

Figure 2. Schematic illustration of various geometries of hydrogen-bonded complexes: (**a**) a strong hydrogen bond between hydrogen fluoride and fluoride anion; (**b**) a cyclic dimer of aliphatic acids; (**c**) a symmetric example of intramolecular hydrogen bonding; (**d**) a hydrogen bond network of water molecules; (**e**) an example of a multi-centered hydrogen bond system. Taken from 9 with permission.

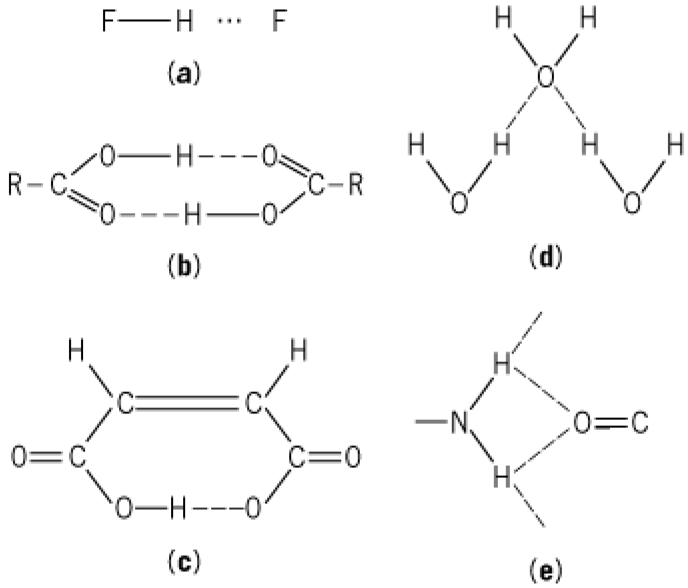
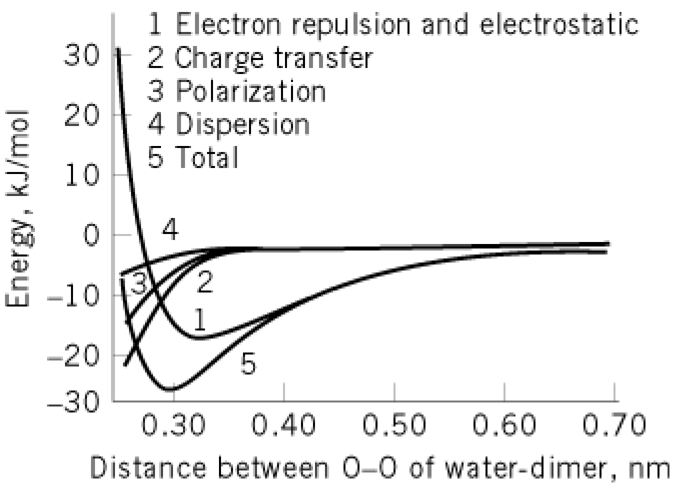


The Morokuma potential decomposes the total hydrogen bond energy into the following terms and evaluates the relative contribution of each term from the distance between the atoms, r: (*1*) electrostatic (r^{-1}), (*2*) polarization (r^{-4}), (*3*) exchange repulsion (r^{-12}), (*4*) charge transfer <rf>exp</rf>($-r$), and (*5*) dispersion interactions ($r^{-6} + r^{-8} + r^{-10}$) (1, 8) (see Electrostatic Interactions and van der Waals Interactions). The dependence of the total hydrogen bond energy calculated for a water dimer in the gas phase is given in Figure 3 in terms of the individual interactions above.

Figure 3. Decomposition of the total hydrogen bond energy of the water dimer, demonstrating an important contribution of the electrostatic term. (Taken from Ref. 1 with permission.)



3. Hydrogen Bond Geometry

The acceptor Y atom of a hydrogen bond often has electrons in lone pairs that are directional, and consequently the hydrogen bond is also highly directional. Because of this property, the hydrogen bond is often a determining factor for the geometry of hydrogen-bonded crystals and in the conformation of polymers. In Figure 2, the geometries of a variety of hydrogen-bonded molecular complexes are presented in simplified forms. The distinction between inter- and intramolecular hydrogen bonds is important for small molecules, because the geometric constraints are more severe for the latter. For small molecules in solution, hydrogen-bonded pairs are constantly changing their counterparts, due to the low potential and activation energies of hydrogen bonds.

3.1. Bond Length

The distance parameters of X—H¼Y hydrogen bonds may be defined in several ways. When the position of the H atom is known, the distance between H and Y is defined as the hydrogen bond length. When it is not known, the distance between X and Y is a less sensitive, but in many cases still a good, guide for the presence of a hydrogen bond. For example, high resolution neutron diffraction studies indicate that nonbonded distances between two O atoms of <0.30 , 0.34, and >0.37 nm correspond to respective hydrogen bond probabilities of nearly 100%, about 50%, and almost 0% (1, 9). The strength of a hydrogen bond is no more than 0.1 that of a common covalent bond, so the geometries of weak to moderate hydrogen bonds are sensitive to their environment. The hydrogen bond distance H¼Y can vary by as much as ±20% from the averages given in Table 2. For example, a compilation of more than 120 bond lengths determined by neutron diffraction studies gave a distribution of O—H distances of 0.095–0.120 nm, of H¼O from 0.120 to 0.200 nm (1).

Table 2. Bond Lengths in Typical Hydrogen Systems

Hydrogen-Bonded Systems	X—H	X—Y	H¼Y	Examples
O—H¼O	~0.100nm	0.275 nm	~0.17	Ice
N—H¼O	~0.090nm	0.299 nm	~0.21	Urea
O—H¼N	~0.110nm	0.278 nm	~0.17	Acetoxime
N—H¼N	~0.090nm	0.308 nm	~0.22	Guanine·HCl·$\frac{1}{2}H_2O$

In the nucleosides and nucleotides, some of the H¼Y distances are as follows (1):

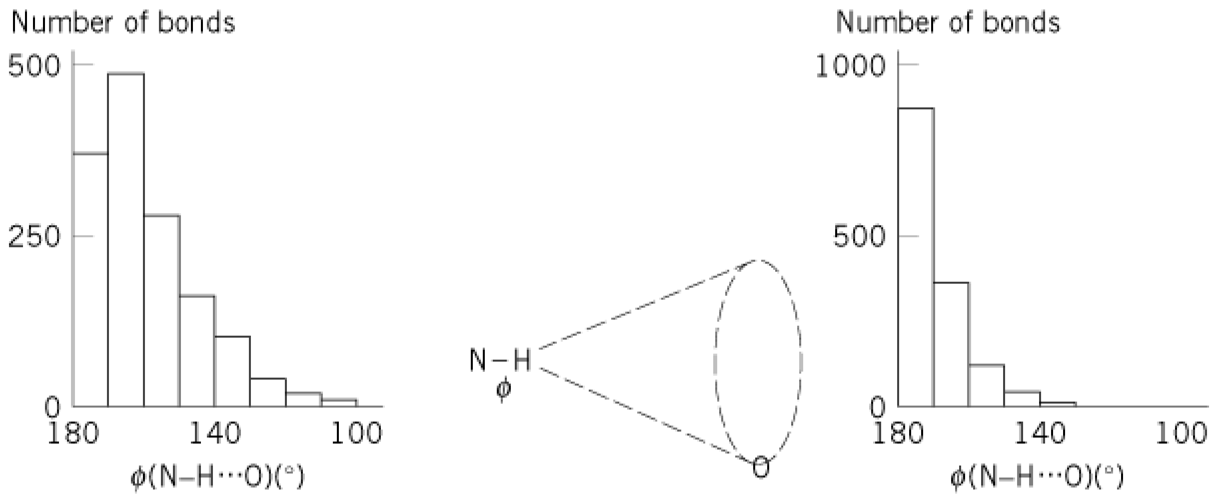
P—OH¼OP	0.155–0.169 nm	
P—OH¼OH	0.165–0.189 nm	
O_W—H¼OP		0.166–0.188 nm
P—O—H¼O_W	0.159–0.168 nm	
Other O—H¼O	0.174–0.218 nm	
N—H¼O=P	0.158–0.189 nm	
N—H¼O=C	0.169–0.232 nm	
N—H¼N	0.173–0.223 nm	
NH—H¼O=P	0.167–	

	0.207 nm
NH—H¼O=C	0.168–0.273 nm
NH—H¼N	0.185–0.276 nm

3.2. Bond Angle

Although the three atoms involved in an X—H¼Y hydrogen bond tend to lie on a straight line, and unless there are two or more acceptors, the final geometry is a compromise of all the environmental factors. A hydrogen bond is therefore sometimes said to be "soft." As a result, the angle formed by the three atoms X—H¼Y is close to 180° for a strong hydrogen bond, and the flexibility about this angle increases as the bond becomes weaker. Bifurcated hydrogen bonds cannot be linear. Figure 4 (10) illustrates the distribution of X—H¼Y angles.

Figure 4. The distribution of hydrogen bond angles. The three atoms involved in the formation of a hydrogen bond have preferred configuration for the hydrogen bond to be most effective. The distribution on the left is normalized with respect to the statistical factor of 2 p sin f. (Taken from Ref. 9 with permission.)



A very good example of the geometry of a hydrogen-bonded dimer is found in acetic acid in the gas phase, which is similar to scheme **b** of Figure 2. The O—H¼O angle is 180°, and the O—H and H¼O bond lengths are 0.104 and 0.164 nm, respectively.

4. Hydrogen Bonds in Molecular Biology

4.1. Hydrogen Bonds in Water

Water is well known to differ from the liquids formed by comparable molecules, such as H_2S, in its higher melting and boiling temperatures, its greater heat of fusion and of evaporation, and in its greater viscosity, properties that are important for life on earth. The hydrophobic effect that is one aspect of the interactions between nonpolar molecules and groups in water is a result of the physical properties of hydrogen-bonded networks in liquid water. When nonpolar molecules dissolve in water, they create a cavity within the hydrogen-bonded network of water molecules, which disrupts the network and forces a rearrangement of the water molecules; this reduces the entropy of the system. It is thermodynamically preferable for the nonpolar molecules to associate, thereby reducing the total area of the water–solute interface and minimizing the disruption of the hydrogen-bonded network of water.

4.2. Hydrogen Bonds in Protein Structure

Hydrogen bonds in folded protein structures are formed primarily (about 90%) between the N—H and C=O groups of the polypeptide backbone, and about 85% of these are in either alpha-helix or beta-sheet . In the a-helix, hydrogen bonds are formed between peptide groups every four residues apart; in the case of b-sheets, every two residues. The average hydrogen bond length (H¼O) is shorter for b-sheets (0.197 nm) than for the a-helix (0.206 nm). Three-centered, bifurcated hydrogen bonds are observed in helices, but are not as common as in small molecules. Polar side chains with hydrogen atoms, such as those of tyrosine, serine, threonine, lysine, arginine, glutamic acid, aspartic acid, glutamine, and asparagine, can act as hydrogen bond donors. Turn structures, such as **beta**- and gamma-turns, are also stabilized by main-chain hydrogen bonds (11, 12). The concept of low-barrier hydrogen bonds has been introduced to explain the fast and efficient proton transfer within and between proteins (13), but their presence, although persuasive in the gas phase, is still controversial and not supported by an NMR study (14).

4.3. Hydrogen Bond Network in the Active Site of Serine Proteinases

A hydrogen bond network was proposed in the active sites of serine proteinases on the basis of the X-ray crystallographic structure of chymotrypsin, so as to explain the unusual chemical reactivity of the serine residue at its active site (15, 16). At neutral pH, the hydroxyl group of an ordinary serine residue is not able to carry out an electrophilic attack on the carbonyl carbon of peptide bonds. That the active site Ser195 residue is in an activated state because of its participation in a hydrogen bond network with Asp102 and His57 has been well accepted. In the process of hydrolyzing a substrate peptide bond, the carbonyl group of the susceptible bond forms a covalent bond with the hydroxyl group of Ser195, to form an acyl intermediate, cleaving the peptide bond, and permitting the amino-terminus of the carboxyl-terminal portion of the peptide to form a hydrogen bond with His57. The amino group is then replaced by a water molecule, which will cleave the covalent bond to Ser195 and the amino-terminal portion of the substrate will dissociate, to complete the proteolysis reaction.

Hydrogen bond networks are also present in the active sites of carboxyl proteinases and in the functions of DNA-binding proteins, such as **zinc fingers**. The importance of hydrogen bonds in the subunit interactions of oligomeric proteins has been discussed thoroughly by Perutz (17).

4.4. Hydrogen Bonds in Nucleic Acids

The importance of hydrogen bonds in **nucleic acids** is twofold. Hydrogen bonds between the bases stabilize the **double-helix** structures of DNA and RNA, but a more important aspect is that hydrogen bonds are formed only between specified pairs of adenine:thymine, A:T (uracil for RNA) and guanine:cytosine, G:C. Formation of hydrogen bonds only between such specified pairs permits the basic mechanism of transmission of genetic information in the nucleic acids. The biological significance of the Watson–Crick model of DNA was in the specific hydrogen-bonding patterns between A:T and G:C complementary nucleotide pairs, which have been amply verified. There are other possibilities of hydrogen bond patterns among the four bases, but, under physiological conditions, the **Watson–Crick base pairs** are the most stable. An important aspect is that the G:C base pair is more stable than the A:T pair, in part because of the greater number of hydrogen bonds.

4.5. Hydrogen Bonds in Carbohydrates and Lipids

Carbohydrate molecules have a large number of —OH groups, all of which are candidates for forming hydrogen bonds. There is no doubt that the conformations of carbohydrates, and especially those of polymeric carbohydrates, are strongly influenced by hydrogen bond formation. Formation of hydrogen-bonded (often three-centered) structures in their fibrous and crystalline states is discussed by Jeffrey (1). The functional groups in lipid molecules that can form hydrogen bonds are limited to the hydrophilic head groups. Consequently, the conformational variation of lipid molecules through hydrogen bond formation is rather limited, compared to the preceding examples.

5. Prospectives

The importance of hydrogen bonds in chemistry and especially in biology is increasingly appreciated because of the advance of our knowledge of the natural and synthetic multimolecular systems known as supra-molecular systems. These complex structures are stabilized by multitudes of weak secondary interactions such as **van der Waals**, **electrostatic**, chelating, and hydrogen bonding interactions. The importance of supramolecular structures resides in the fact, as well as in our expectation, that a structure held together weakly and therefore dynamically will exert more subtle functions than will other developed molecules and molecular systems. The hydrogen bond is based on neutral groups and strongly controls the geometry of the resulting molecular associations, which will be important in controlling the structure and activity of synthetic and hybrid structures once the nature of hydrogen bond is understood more precisely. New methods are emerging for the study of hydrogen bonded systems with completely different perspectives. For example, the strength and specificity of hydrogen bonding can now be measured using scanning probe techniques applied to a group of molecules (18) and at the single-molecule level (19).

Hydrogen Exchange

Hydrogen exchange is the interchange of hydrogen atoms between a molecule of interest, usually a peptide, **protein**, or **nucleic acid**, and water. Usually the exchange is detected because the hydrogens are different isotopes, the normal protium (^{1}H), or deuterium (^{2}H = D), or tritium (^{3}H = T). Designating the two isotopes as H and H′, the remainder of the macromolecule as M, and O as the oxygen atom of water, the reaction can be represented as

$$\mathrm{MH} + -\mathrm{OH'} \rightarrow \mathrm{MH'} + -\mathrm{OH} \quad (1)$$

Hydrogen exchange experiments provide information about the flexibilities of biological macromolecules. These are not static structures but exhibit a flexibility that is often important in their function. They undergo spontaneous thermal fluctuations and folding and unfolding processes, and they may display variations of their conformations. These motions vary with the binding of other molecules, with **allosteric** interactions, and with other environmental influences. All of these affect the rates of hydrogen exchange, whose measurement then helps to elucidate the dynamic structure of the molecule. For example, it is possible to measure the rate of base-pair opening in the DNA **double helix**, which is prerequisite for **replication** and transcription .

Rates of exchange of different types of hydrogen atoms are quite variable. Those attached to oxygen atoms of sugars in carbohydrates or of serine, threonine, and tyrosine residues in proteins exchange so rapidly that they are difficult to measure. Exchange of hydrogens attached to carbon is too slow. Those of most experimental interest are attached to nitrogen, as in the CONH peptide backbone or the asparagine and glutamine $CONH_2$ side chains of peptides and proteins and in the amino (NH_2) and imino (NH) groups of the nucleic acid bases **adenine**, **thymidine**, **uracil**, **guanine**, and **cytosine**. These exchange in milliseconds, or even faster with appropriate catalysts, when free and accessible to the solvent, but much slower, by as much as 10^{12}-fold, when buried in the interior of a macromolecule and inaccessible to solvent. These retardations reveal information about the stability of the folded macromolecular structure. The rate at which exchange actually occurs provides information about molecular dynamics.

1. Rates and Mechanisms of Chemical Exchange in Model Small Molecules

The rate of exchange R_{ex} or the rate of disappearance of MH and the formation of MH′ [Eq. (1)] is given by Eq. (2), where $[\mathrm{MH}]_{eq}$ and $[\mathrm{MH'}]_{eq}$ are the equilibrium concentrations of MH and MH′ and k_{ex} is the rate constant for the reaction (see Molecular Dynamics). For the amide groups of peptides and proteins, it is observed that k_{ex} has the form in Eq. (3), corresponding to acid catalysis by H^+ and base catalysis by OH^-. The catalytic constants are k_H and k_{OH}, respectively, and a term that is usually too small to detect, except in solvents less polar than water, corresponds to water catalysis. For the NH group of a typical amide, $k_H \sim 10^{-1} M^{-1} s^{-1}$ and $k_{OH} \sim 10^7 M^{-1} s^{-1}$. A graph of log k_{ex} versus pH is shown in Fig. 1. This shows a minimum given by Eq. (4), where $K_w = [\mathrm{H^+}][\mathrm{OH^-}] = 10^{-14}\ \mathrm{M}^2$.

$$R_{ex} = -\frac{d([\mathrm{MH}] - [\mathrm{MH}]_{eq})}{dt} = \frac{d([\mathrm{MH'}] - [\mathrm{MH'}]_{eq})}{dt} = k_{ex}([\mathrm{MH}] - [\mathrm{MH}]_{eq}) \tag{2}$$

$$k_{ex} = k_{\mathrm{H}}[\mathrm{H}^+] + k_{\mathrm{OH}}[\mathrm{OH}^-] + k_w \tag{3}$$

$$pH_{min} = \frac{1}{2}\log\left(\frac{k_{\mathrm{H}}}{K_w k_{\mathrm{OH}}}\right) \tag{4}$$

The mechanism of the base-catalyzed reaction involves removing the amide NH hydrogen atom [Eq. (5)], to create the imidate anion (the conjugate base of the amide), which then abstracts an H^+ from water to regenerate the amide [Eq. (6)]. The mechanism of the acid-catalyzed reaction depends on the amide. For the $CONH_2$ side chains of asparagine and glutamine residues, the exchange occurs simply by transient protonation of the nitrogen, which produces an unstable conjugate acid of the amide, followed by removal of a different hydrogen as H^+ [Eq. (7)]. For backbone CONH groups, exchange occurs by attachment of H^+ to the oxygen atom, which is much more basic than the nitrogen (see Kinetics), and produces another conjugate acid [Eq. (8)], followed by removal of H^+ from nitrogen, to produce the imidic acid, the unstable **tautomer** of an amide [Eq. (9)]. Attachment of a solvent H^+ to the nitrogen, followed by removal of H^+ from oxygen, regenerates the amide, but with its H exchanged [Eq. (10)].

$$\mathrm{RC(=O)NHR' + OH^- \rightarrow RC(-O^-) = NR'(imidate) + H_2O} \tag{5}$$

$$\mathrm{RC(-O^-) = NR' + H_2O \rightarrow RC(=O)NHR' + OH^-} \tag{6}$$

$$\mathrm{RC(=O)NH_2 + H^+ \rightarrow RC(=O)NH_3^+ \rightarrow RC(=O)NH_2 + H^+} \tag{7}$$

$$\mathrm{RC(=O)NHR' + H^+ \rightarrow RC(-OH) = NHR'^+} \tag{8}$$

$$\mathrm{RC(-OH) = NHR'^+ \rightarrow RC(-OH) = NR'(imidic\ acid) + H^+} \tag{9}$$

$$\mathrm{RC(-OH) = NR' + H^+ \rightarrow RC(-OH) = NHR'^+ \rightarrow RC(=O)NHR' + H^+} \tag{10}$$

The rates vary with the substitution pattern in the amide (1). Table 1lists logarithms of relative rate constants k_{H} and k_{OH} for various amino acid residues (2). Electron-withdrawing groups increase k_{OH} because they stabilize the negative charge that is created in the imidate anion. They also decrease k_{H} because they destabilize the positive charge created in either mechanism. As a result, pH_{min} [Eq. (4)] is decreased and the minimum in Fig. 1 moves to the left. Rates also increase with increasing temperature. In acid, the activation energy is 14 kcal/mol. In base, at constant pH, the apparent activation energy is 17.5 kcal/mol, but this greater value largely results from the temperature-dependence of K_w.

Figure 1. pH dependence of the value of the intrinsic exchange rate constant k_{ex} for the backbone amide of a typical peptide.

The mechanisms of exchange in nucleic acids are analogous, except that the equivalent of Eq. (7) never contributes. The imino NH groups of uracil, thymidine, and guanine are sufficiently acidic that they can be removed by OH^- at every encounter, in a diffusion-controlled reaction that has a rate constant k_{OH}~$10^{10}M^{-1}s^{-1}$. Weaker bases, such as components of the buffer, also remove these hydrogen atoms. Acid-catalyzed exchange proceeds by protonation of oxygen, followed by deprotonation of the NH, to produce the iminol tautomer (**1**, R = H or CH_3, or **2**; Fig. 2) as a transient intermediate. Acid catalysis for guanine is masked by conversion to the conjugate acid. Exchange of an amino NH_2 group of adenine, guanine, or cytosine is catalyzed by acid and base, and there is also a pH-independent rate near neutrality. The base-catalyzed reaction involves slow removal of an NH by OH^-. The acid-catalyzed reaction involves attachment of H^+ to a ring nitrogen, followed by removal of one of the amino hydrogen atoms by water, to produce an abnormal tautomer (**3**, **4**, **5**; Fig. 2) as a transient intermediate. In the pH-independent region, that NH is removed by OH^- instead of water, to form the same intermediate. In each of these substrates, the acid catalysis is masked at low pH by complete conversion of substrate to its conjugate acid.

Because charged species, either cationic or anionic, must be formed as intermediates, the local environment affects the rate of hydrogen exchange. For example, nearby charges stabilize or destabilize the charged intermediate by electrostatic interactions. These charges include the phosphate backbone of nucleic acids and the side chains of acidic or basic residues in proteins. However, their effect is moderated by ions of salts that screen the interaction. As a result, the intrinsic rates are affected by the ionic strength of the solution. Moreover, the charges on nearby sites titrate with pH, leading to a variability of k_{ex} that is more complicated than in Fig. 1. Another effect on rates arises in less polar solvents, where those charged intermediates are less stable and lead to a reduction in rate. This may also contribute to a retardation of exchange in the nonpolar, **hydrophobic** interior of a protein. It is widely believed that the major retardation of exchange in biological macromolecules occurs when the hydrogen atom is involved in a hydrogen bond to some adjacent group. Generally, that hydrogen bond must be broken to expose the NH to solvent and render it susceptible to exchange. But simple interpretation is confounded by the fact that hydrogen bonding and inaccessibility usually occur simultaneously in folded macromolecules (see Nonpolar).

2. Mechanisms of Chemical Exchange in Macromolecules

An NH group at the surface of a macromolecule and hydrogen-bonded only to water has an intrinsic exchange rate characteristic of a model small molecule. Hydrogen atoms that are protected in the interior of a macromolecule and by internal hydrogen bonding exchange more slowly. The degree of this retardation provides information about the stability of the macromolecular structure and the flexibility that permits exchange.

The process by which inaccessible hydrogen atoms gain access to water so that they can undergo exchange is still a matter of debate, but there are two limiting and extreme models. According to the solvent-penetration model, water and catalytic H^+ or OH^- gain access to the interior of the macromolecule through channels, perhaps generated transiently by conformational fluctuations. Then the rate of exchange is governed by the extent to which those buried hydrogen atoms come into contact with the solvent atoms. According to the other model, called the local-unfolding model, cooperative motion of a segment of the molecule breaks a set of hydrogen bonds and other interactions that hold the macromolecule in its stable conformation. Thereby, the NH groups of that segment are exposed to solvent, where they can undergo exchange. This model agrees nicely with the dynamic nature of macromolecular structure, although it does not explain why exchange is not decreased substantially by incorporating the macromolecule into a crystal lattice, and it is an oversimplification to assume a single unfolded state from which exchange occurs. Macromolecules probably achieve a variety of unfolded states, from those involving only minor local fluctuations to those involving global unfolding.

The local-unfolding model can be analyzed kinetically, as in Eq. (11). Here k_{unfold} is the rate constant for the motion that converts the closed to the open form, k_{fold} is the rate constant for reversion back to the closed form, and k_{ex} is the rate constant for hydrogen exchange, as in Eqs. (2), (3). The general expression for the observed rate constant is given by Eq. (12). Two limiting behaviors can be distinguished:

$$\text{closed} \underset{k_{fold}}{\overset{k_{unfold}}{\rightleftarrows}} \text{open} \xrightarrow{k_{ex}} \text{exchanged product} \quad (11)$$

$$k_{obs} = \frac{k_{unfold}k_{ex}}{k_{fold} + k_{ex}} \quad (12)$$

If $k_{ex} \gg k_{fold}$, then k_{obs} [Eq. (12)] simplifies to k_{unfold}. The rate-limiting step is the opening to produce the locally unfolded state, from which exchange is rapid. Under these conditions, called "EX1," the rate is independent (except insofar as k_{unfold} is pH-dependent) of the concentrations of acid or base catalyst, which enter into Eq. (3). In principle, these conditions can be induced at high pH, where k_{ex} becomes sufficiently large. In practice, it is rare to achieve these conditions for a protein without **denaturation**, and exchange generally occurs from the totally unfolded conformation. In contrast, this is possible for DNA, and extrapolation to high pH or catalyst concentration provides k_{unfold}, the rate at which the double helix breaks the hydrogen bonds and allows an NH group to exchange.

If $k_{fold} \gg k_{ex}$, then k_{obs} [Eq. (12)] simplifies to $K_{op}k_{ex}$, where $K_{op} = k_{unfold}/k_{fold}$ is the equilibrium constant, [open]/[closed], for forming the locally unfolded state. These conditions are called "EX2", and they correspond to exchange that occurs only during that fraction of the time when the macromolecule is unfolded. Because k_{ex} can be approximated by the value (including acid or base catalysis, according to pH) for an appropriate model small molecule (1, 2), then the experimentally determined value of k_{obs} provides an estimate of K_{op}. Moreover, conversion to the corresponding **free energy**, D$G°$ = $-RT \ln K_{op}$, provides a measure of the energy that stabilizes the closed native state of the macromolecule or of the energy required to allow the local unfolding. Alternatively, k_{ex}/k_{obs} (= $1/K_{op}$) can be called a protection factor P, which represents the extent to which exchange is retarded in the native state.

3. Applications

Study of hydrogen exchange has the advantage that the measurement need not perturb the macromolecule and involves only the normal solvent, water. Separate samples can be exposed to a labeling pulse for varying time periods. Then the exchange is quenched by adjusting the pH to trap the label, and the subsequent time course of the loss of label from each site is monitored. The pulse conditions can be chosen to label selectively the sites of interest for the particular application.

Hydrogen exchange has long been used to provide information about the tertiary structures of proteins and about protein dynamics. Characteristic patterns of protection factors are associated with hydrogen atoms in **a-helices** or **b-sheets** . To the extent that hydrogen exchange also involves cooperative unfolding of an entire structural **domain**, all of the hydrogens in that domain should show the same protection factor.

Other aspects that have been investigated include the quaternary structure of proteins and their interactions with small molecules and other macromolecules. For example, selective labeling allows recognizing the segments involved in allosteric transitions in such proteins as hemoglobin. Because exchange of some NH atoms requires local unfolding, the observed rates also provide information about the stability of the native structure and the way it responds to changes in the environment. Intermolecular interactions that have been probed include protein–peptide interactions, enzyme–substrate and enzyme–inhibitor binding, protein–protein interactions, such as those between cytochrome ***c*** and cytochrome *c* peroxidase or between a protein and an antibody or a chaperonin, and protein–nucleic acid interactions.

One of the most recent applications is characterization of transient intermediates in **protein folding**. Exposed hydrogen atoms in a deuterated protein that is undergoing refolding are labeled during a rapid pulse with normal water. Then the pattern of a normal hydrogen isotope trapped in the refolded native protein can be analyzed to infer the structure of the intermediate. This method has been applied to several proteins, including **ribonuclease A**, cytochrome *c*, **barnase**, and hen egg white lysozyme.

For duplex DNA, it is possible to measure k_{unfold}, the rate of base-pair opening. Most rate constants measured are between 2×10^{1} and $2\times10^{3}s^{-1}$, but lower values are evidence of unusual structural features. It is also possible to study the influence of **intercalators** and of **triple helices**.

4. Methods of Measurement

The simplest method for detecting hydrogen exchange is measuring the overall extent of exchange by measuring the isotopic content of the macromolecule. This is achieved by counting the radioactivity of tritium or by UV-visible or vibrational spectroscopy that is sensitive to isotopic content. These methods measure only the total content of isotope, however, and cannot distinguish among the various hydrogen atoms in the macromolecule.

Methods involving various aspects of nuclear magnetic resonance (NMR) distinguish the individual hydrogen atoms in a molecule, and methods for assigning each signal have been developed. Two-dimensional Fourier-transform NMR is especially powerful at spreading out the spectrum so that each site is resolved. Pulse methods have been developed to select only particular nuclei, such as those attached to ^{15}N. Then the simplest method for measuring rates of exchange is transferring the sample to D_2O and watching the disappearance of each NH signal.

Three other techniques utilize the unique capability of NMR to detect exchange and measure rates under equilibrium conditions, when no net reaction is proceeding. The derivatives in Eq. (2) are zero, but an NH remains in an MH site for an average time of $1/k_{ex}$. (1) The signal of an NH that is exchanging with solvent H_2O displays an NMR broadening that increases with the exchange rate, until the signal becomes so broad that it disappears into the base line. (2) The signal of a CH adjacent to an NH is split into a doublet. As the NH exchange rate increases, the doublet components broaden, overlap, and coalesce into a broad single peak that then sharpens. This method provides rate constants for small molecules but is much less suitable for macromolecules, where the CH signals are not resolvable. (3) Various pulse sequences also label H_2O or individual NH signals with a characteristic magnetization (saturation or inversion). As hydrogen atoms exchange among these sites, the magnetization is transferred from one site to another. Analysis of the magnitude and time course of these transfers provides the rate constants for exchange. All of these techniques have the further advantage of not being limited by rapid exchange during mixing.

Mass Spectrometry is used to measure the overall exchange process because the different isotopes slightly alter the molecular weight of the macromolecule. It has only recently been applied to measuring hydrogen exchange rates at individual sites because it is necessary to cleave the macromolecule into small pieces that can be analyzed individually. This must be done under conditions that preserve the label, using enzymes that function at 0°C and at pH_{min} (Fig. 1), and then the fragments are separated and analyzed for isotopic content.

Hydrogen Isotopes

Hydrogen is element number 1 in the periodic table and the most abundant element in the universe. Hydrogen has a valence state of 1 (1); it occurs mainly in nature in combination with oxygen as water in all living organisms and is present in all organic matter.

Three isotopes of hydrogen exist in nature: ^1H (protium, with an abundance of 99.985%), ^2H (deuterium, with an abundance of 0.015%), and ^3H (*tritium* , which exists naturally only in trace amounts) (see Radioactivity and Radioisotopes). Stable deuterium, which was first prepared by Urey (1), is used as heavy water (^2H_2O or D_2O) for contrast variation in **neutron scattering**, altering the density of aqueous solvents, and in studying hydrogen exchange reactions in macromolecules, as well as in moderating (slowing down) neutrons in some nuclear reactors. It is also used as a proton source in nuclear magnetic resonance spectroscopy and imaging.

Among the hydrogen isotopes, only tritium is **radioactive**, with a half-life of 12.35 years (2). It decays by beta-minus emission to ^3H, which is stable. Tritium yields one beta particle per decay, with an energy of 0.0186 MeV maximum, 0.00568 MeV on average. Tritium is produced in a nuclear reactor by irradiation of enriched lithium targets according to the reaction $^6Li(n,a)^3H$, or by irradiation of ^3H gas targets according to the reaction $^3He(n,p)$ ^3H. Tritium is used as an ingredient in thermonuclear weapons, in luminous lighting (airport runway lights, exit signs and luminous paints), and as a tracer in biomedical studies.

Tritium was first made available for biological research by the U.S. Atomic Energy Commission in

1948. The first tritium uptake studies in humans were conducted in 1951. Streptomycin and tetracycline were first labeled with tritium (2), and tritiated water was first used to measure total-body water in 1956 (3). Hundreds of different tritiated compounds are now commercially available in generous amounts and with high specific activity from commercial suppliers. Methods for tritium labeling typically involve exchange, substitution, or addition reactions, such as exchange by heterogeneous catalysis, exchange by homogeneous catalysis, exchange catalyzed by radiation, substitution by chemical reduction, or hydrogenation.

The short range of tritium's weak beta particle, its low toxicity, relatively low cost, and usefulness for high resolution autoradiography make it a convenient choice for tracer studies. A frequently encountered problem is pH-dependent loss of tritium by exchange with solvent water.

In molecular biology, tritium is widely used as a tracer and label for **nucleic acid** precursors. One of the most common tritiated compounds used is ^{3}H-**thymidine**, which may be introduced into the laboratory animal by direct injection or added to excised tissues. The metabolism and uptake of ^{3}H-thymidine is used to monitor DNA replication. Tritiated thymidine has also been used to study the effectiveness of therapeutic drugs that either stimulate or block DNA synthesis, such as chemotherapeutic agents. Tritium-labeled amino acids are incorporated into proteins and are used to follow protein biosynthesis.

The presence of tritium may be determined by liquid scintillation counting or chromatography. In autoradiography, specimens containing tritiated compounds may be coated with photographic emulsion and incubated under refrigeration to expose the emulsion to tritium beta particles. The emulsion is then developed and fixed, and the tissues are stained for microscopy to identify the labeled organelles (4) (see Autoradiography).

Hydrogenase

Hydrogenases are enzymes that catalyze the reversible oxidation of molecular hydrogen and play an important role in the anaerobic metabolism of microorganisms. Hydrogen uptake and production occur in sulfate-reducing **bacteria** and fermentative **anaerobes**, as well as in aerobic **nitrogen-fixing** bacteria, photosynthetic bacteria, and **cyanobacteria** (1). Three distinct categories of hydrogenases have been described:

- *Iron hydrogenases.* With two [4Fe-4 S] centers in addition to a special type of [4Fe-4 S] center.
- *Nickel–iron hydrogenases.* With a nickel center coordinated to a sulfur atom, two [4Fe-4 S] centers, and a [3Fe-xS] center.
- *Nickel–iron-selenium hydrogenases.* With a nickel center coordinated to a selenium atom as well as two [4Fe-4 S] centers.

Hydrolase

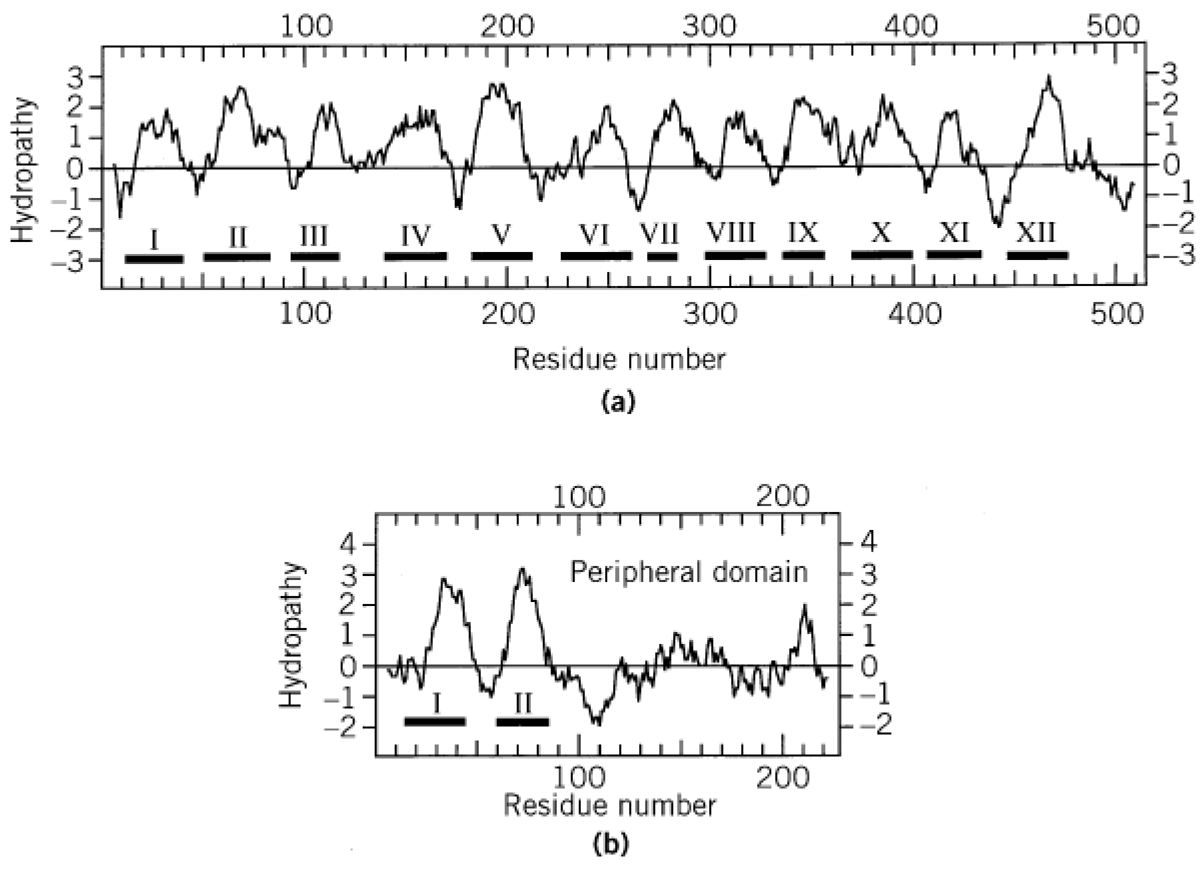
Hydrolases are enzymes that catalyze the hydrolysis of a range of bonds. They frequently show broad specificity, and this characteristic has posed problems in naming them. The systematic name for an enzyme that performs a hydrolytic reaction includes the term hydrolase, whereas the trivial name is formed by the addition of the suffix *ase* to the name of the substrate or the class of substrate on which the enzyme acts. Those hydrolases that act on carboxylic esters, thiolesters, phosphomonoesters, phosphodiesters, phosphotriesters, diphosphomonoesters, **DNA** and **RNA** have been classified as a group that acts on ester bonds. The glycosidases hydrolyze *O*-glycosyl, *N*-glycosyl, and *S*-glycosyl compounds; etherases act on ether and thioether bonds; peptidases hydrolyze aminoacylpeptide, dipeptide, and dipeptidylpeptide bonds. Other categories of hydrolase are the serine carboxypeptidases and serine proteinases, which contain a DIFP (diisopropyl fluorophosphate)-sensitive a serine residue at their active sites, the thiol proteinases, the carboxyl proteinases, and the metalloproteinases There are also hydrolases that act on C—N , rather than peptide, bonds, and the substrates for these enzymes include amides, cyclic amides, linear amidines, cyclic amidines, and nitriles. Other hydrolases act on acid anhydrides and C—C , halide, P—N , S—N , and C—P bonds.

Hydropathy

a -helices can be identified in the primary structure of a membrane protein with a relatively high confidence using hydropathy analysis, in which each residue is assigned a characteristic hydrophobicity value. Hydropathy is a term that refers to the spectrum of amino acid side chains in the hydrophilicity–hydrophobicity scale. It was originally coined by Kyte and Doolittle(1) in an article describing an algorithm that identifies helical transmembrane spans and that came to be widely used. Their scale is based on the transfer free energies from water to vapor of model compounds for the amino acid side chains, as well as on the exterior–interior distribution of amino acids in protein structures. The hydropathy values of some residues were adjusted subjectively by the authors. Another frequently used hydrophobicity scale has been devised by Engelman, Steitz, and Goldman(2). This is a physicochemical scale based on the free energies of transfer from water to oil of amino acid residues that are parts of a helix. These free energy changes have been corrected for unfavorable hydrophilic contributions due to polar atoms and protonation/deprotonation events of charged residues upon transfer to the nonpolar phase. A number of other scales exist. A useful review on hydrophobicity scales has been written by Eisenberg(3), and references to recent literature are provided by Wimley and White(4), who have measured the free energies of transfer of all 20 amino acid residues from the interface of a lipid bilayer to water.

To calculate a hydropathy profile, the hydrophobicity of a chosen number of residues within a window is summed and divided by the number of residues in the window. The resulting score is assigned to the residue in the middle of the window, after which the window is moved on by one residue and the procedure is repeated. An example of a hydropathy prediction is shown in Figure 1. In the cases of bacteriorhodopsin, cytochrome oxidase, and bacterial photosynthetic reaction center, this simple analysis correctly identified the approximate positions of all the transmembrane helices, with no false positives.

Figure 1. A Kyte–Doolittle hydropathy analysis of subunits I **(a)** and II **(b)** of the bovine cytochrome *c* oxidase, with the true locations of the transmembrane helices marked beneath the plot. A window length of 11 residues was used. The *C*-terminal peripheral domain of subunit II is indicated. Helix VII of subunit I is least well predicted. It contains only 17 residues, whereas hydropathy analysis suggested a length of about 26 that partially overlaps the residues seen in the actual helix in the X-ray structure.



Several more advanced methods for prediction of transmembrane helices have been developed. In addition to the hydropathy analysis, these make use of, for example, the observation that deletions and insertions occur in **homologous** sequences only outside the transmembrane sequences. Thus, use of a multiple sequence alignment, instead of a single sequence, as the input for the algorithm improves the prediction. Likewise, the modern algorithms make use of statistical analyses of amino acid preferences within transmembrane helices and in their flanking loops.

The “positive inside” rule has been incorporated into the prediction protocols to determine the orientation of the polypeptide in the membrane. This rule is based on the fact that **arginine** and lysine residues occur more frequently in the loops between transmembrane helices that reside in the inner side of the membrane (and are shorter than 60 residues) than in the loops on the outer surface of the membrane.

Hydrophilic

Most biological molecules contain electronegative atoms such as O, N, or S. These molecules or groups are polar and can act as hydrogen bond acceptors or donors, allowing them to interact more or less strongly with other such polar groups, with groups possessing charges of opposite sign, or with solvent water, which is equipped with partial positive and negative charges. Molecules or groups that bear full electrostatic charges, such as the NH^{+}_{3} and COO^{-} groups of amino acids in neutral solution, are extremely polar and especially difficult to remove from water. Hydrophilicity, or hydrophilic character, provides a quantitative index of a molecule's polarity, by indicating the difficulty of removing it from solvent water.

Hydrophilicity

When biological molecules combine or react with each other, or change shape, their interactions with the solvent change. The noncovalent binding of **ligands** by enzymes, antibodies, and other **receptors**, eg, involve removal of the interacting partners from the solvent to which they were previously exposed; also, the ease of breaking and making chemical bonds depends on the strength of interaction of the reactants and products with solvent. Most biological molecules contain electronegative atoms such as O, N, or S, which can act as hydrogen bond acceptors or donors and allow them to interact more or less strongly with solvent water; they are said to be hydrophilic . The rates and equilibria of most biological processes, including binding interactions and metabolic transformations, are therefore strongly influenced by changing interactions with the surrounding solvent, which typically is ~80% water in intracellular fluid. Many biological compounds are so polar that their removal from solvent water, an operation essential to measuring the strength of their solvation by water, or *hydrophilicity*, is difficult. The very difficulty of measuring hydrophilicity suggests the magnitude of the solvation forces and the potential magnitude of their influence on rates and equilibria.

Hydrophilicity can be defined as the dimensionless equilibrium constant for the transfer of a molecule between the dilute vapor phase, in which intermolecular contacts are negligible, to dilute aqueous solution, in which each solute molecule is completely surrounded by solvent water. The concentration is measured in the same units, such as moles/liter, in each phase. Hydrophilic character is simply $\log_{10}$ of the equilibrium constant for transfer from vapor to water (1). Hydrophilicity and hydrophilic character values provide the simplest measure of a molecule's affinity for watery surroundings, since they do not depend on any reference phase in which the molecule interacts with other partners. In that sense, they differ from hydrophobicity, which involves a second solvent that is immiscible with water, and with which the solute molecule interacts more or less strongly (see Partition Coefficient). Hydrophilic character also differs from solubility, in which the reference phase is the pure solute in liquid or crystalline form: Such an arbitrary reference is of questionable value if different solute molecules are to be compared against each other.

Hydrophilic character can be determined in some cases by measuring the water solubility of a gas under an atmosphere of known partial pressure, or conversely, by measuring the concentration of a solute in the gas space over an aqueous solution of known concentration (Fig. 1). In more typical cases, of the kind often encountered in biological molecules, the concentration of gas in the vapor phase may be too low to detect directly. In such cases, a large volume of carrier gas (usually argon or nitrogen) is bubbled through an aqueous solution of known concentration, then through an efficient trap, which may be water itself. From the amount of solute collecting in the trap, plotted as a function of the measured volume of carrier gas that has passed through the system, it is a simple matter to calculate the concentration of solute in the vapor phase. Using radioisotope labels, UV spectroscopy, or high-field NMR measurements, it is possible in this way to examine molecules as hydrophilic as **peptides** (2) or guanidino compounds (3), and to determine water-to-vapor distribution coefficients as low as 10^{-10}. A scale of such equilibrium constants for simple organic compounds *in uncharged form* is shown in Figure 2. More extreme values are beyond direct measurement. However, there is much evidence to suggest that the free energy of solvation by water tends to be an additive function of a molecule's constituent groups (1), allowing values for complex molecules to be estimated by considering their substituents. From the behavior of methylamine and acetic acid, eg, it can be inferred that the concentration of glycine in the vapor phase, over a 1- *M* aqueous solution, is approximately $10^{-14}M$, even though that value is too low to measure directly.

Figure 1. The equilibrium for transfer of a molecule from dilute aqueous solution to the vapor phase. Hydrophilicity is the reciprocal of this equilibrium constant, and it measures the affinity of a molecule for watery surroundings.

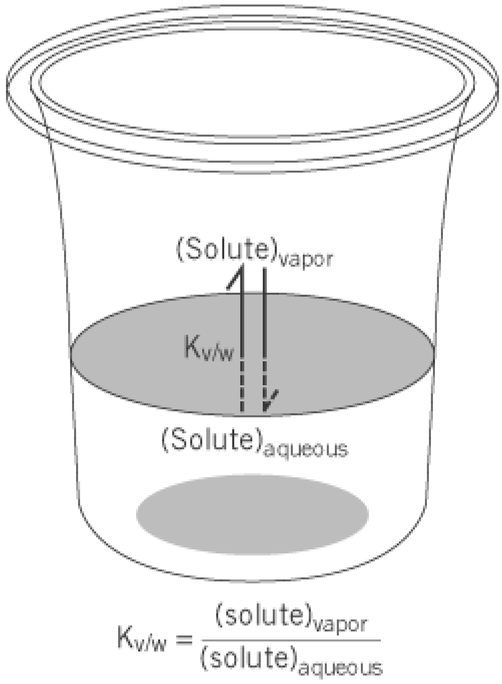

Figure 2. Scale of hydrophilicities for simple organic compounds in uncharged form.

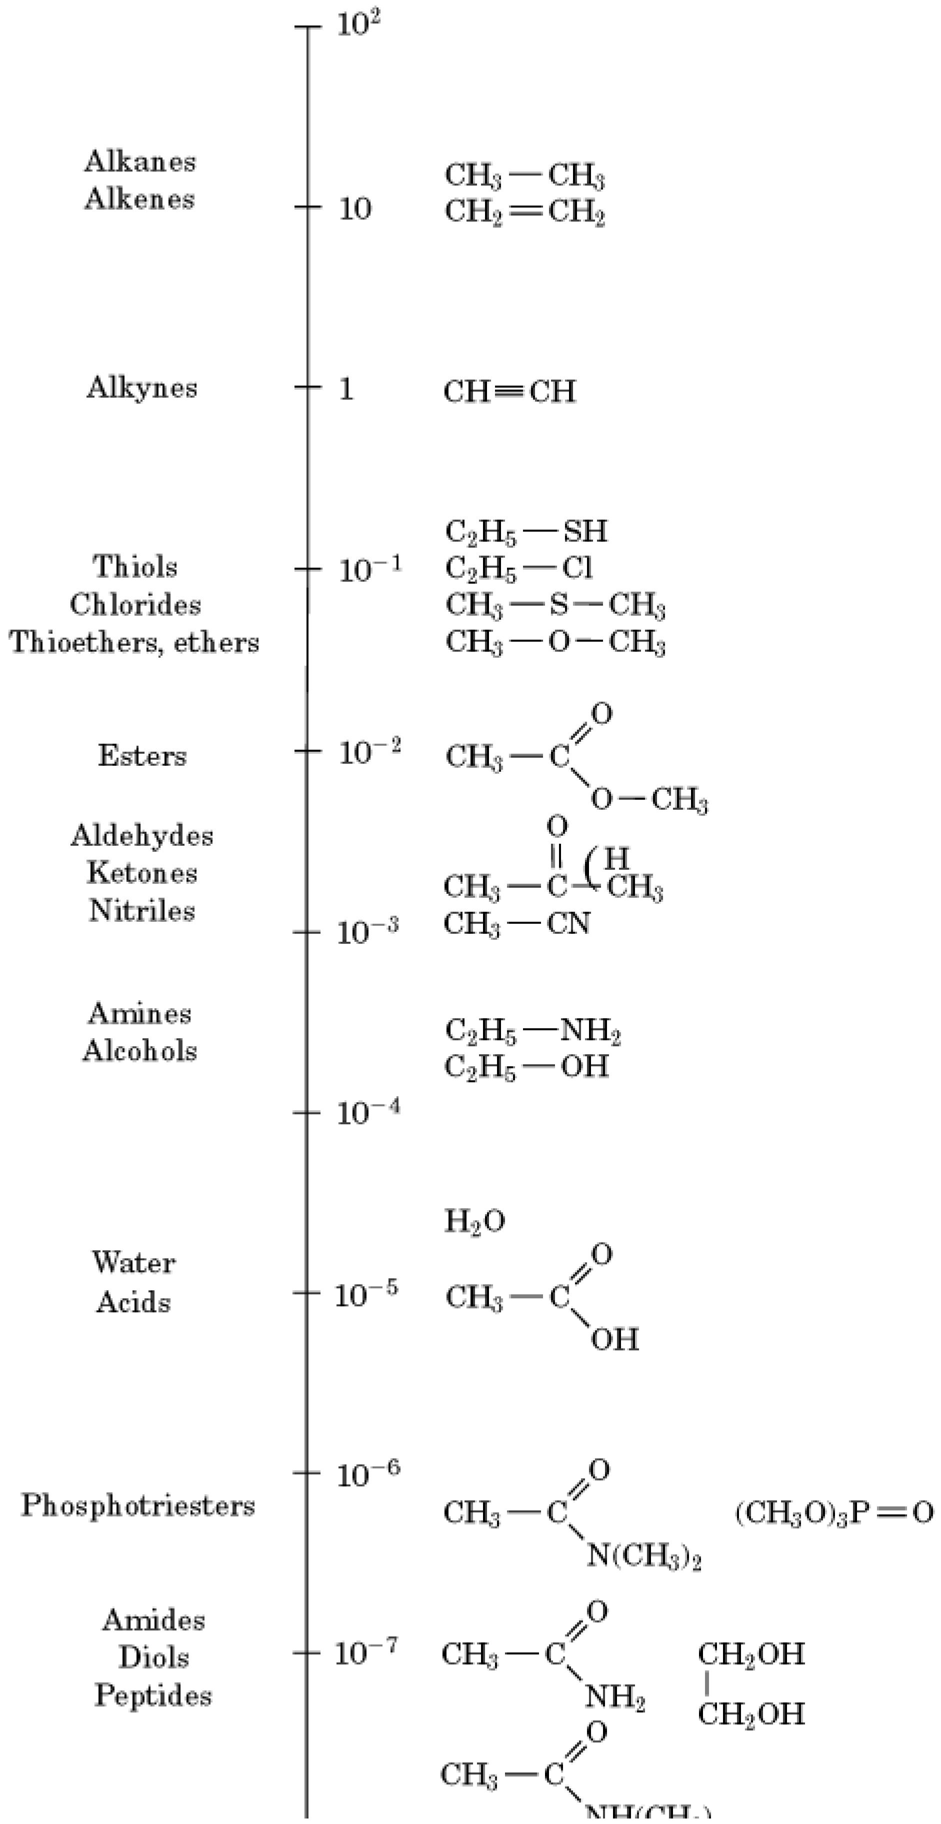
$$Keq = \frac{\text{Moles/liter (vapor)}}{\text{Moles/liter (aqueous)}}$$



These methods have revealed that the hydrophilicities of the protein amino acid side-chains, expressed in terms of their equilibria of transfer from the vapor phase to neutral aqueous solution at 25°C, span a range of approximately 10^{16}-fold(3, 5). These values are as follows:

	$\log_{10} K_{v \to w,pH7}$
Glycine	–1.75
Leucine	–1.68
Isoleucine	–1.58
Valine	–1.46
Alanine	–1.43
Proline	–1.10
Methionine	–1.09
Phenylalanine	–0.56
Cysteine	0.91
Threonine	3.59
Serine	3.72
Tryptophan	4.32
Tyrosine	4.49
Glutamine	6.90
Lysine	7.00
Asparagine	7.12
Histidine	7.55
Glutamate	7.50
Aspartate	8.05
Arginine	14.65

These values were found to be closely related to the tendencies of the corresponding amino acids found at the surfaces of proteins, as revealed by their structures determined by X-ray crystallography. Figure 3 shows the relationship between hydrophilicity and the nominal transfer free energy of each side-chain from the interior to the surface of a protein, as indicated by the relative populations of surface and buried residues for each amino acid. In addition, a remarkable bias in the genetic code was noted, such that purines (usually A) serve as the second code letter for all the more hydrophilic amino acids (3, 4). Figure 4 shows the amino acid side-chains in order of increasing hydrophilicity, alongside the code letters at the second position for each of the amino acids, but the significance of this correlation is not understood.

Figure 3. Tendencies of the 20 amino-acid residues to appear at the surfaces of globular proteins, compared with their free energies of transfer from the vapor phase to neutral aqueous solution (3, 4).

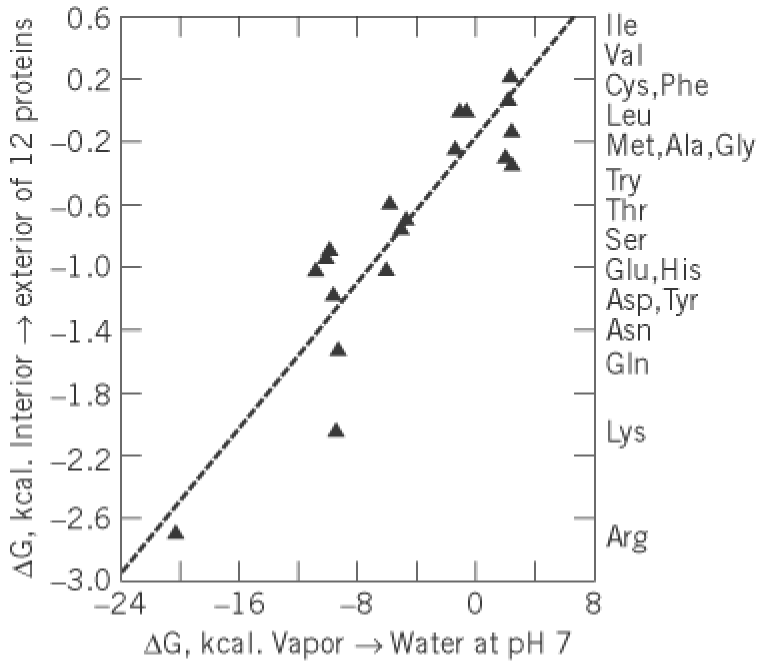


Figure 4. Code letters and anticode letters at the second position for each of the amino acids.

		2nd codeletter (mRNA)	2nd anticodeletter (DNA)
	Gly	G	C
	Leu	U	A
	Ile	U	A
	Val	U	A
	Ala	C	G
	Phe	U	A
	Cys	G	C
	Met	U	A
	Thr	C	G
	Ser	C(G)	G(C)
	Trp	G	C
	Tyr	A	T
	Gln	A	T
	Lys	A	T
	Asn	A	T
	Glu	A	T
	His	A	T
	Asp	A	T
Most hydrophilic	Arg	G	C

The close relationship observed between hydrophilicity and protein structure (Fig. 3) suggested that this scale might have some value in predicting **protein folding**. It was also used to propose a scale of hydropathy values for predicting the relative tendencies of different parts of a protein sequence to be found in membranes (6). More recently, this scale of hydrophilicities has been compared and contrasted with scales of hydrophobicity, obtained by reference to condensed phases including 1- *n*-octanol and to cyclohexane (7). Completion of a three-sided cycle allows estimation of equilibria of transfer between the vapor phase and cyclohexane, a pure measure of **van der Waals** forces. As expected, these are found to be roughly proportional to the accessible surface area. Since the interiors of protein molecules represent condensed phases, scales of hydrophobicity can be considered more directly related to folding equilibria than are scales of hydrophilicity using the vapor phase as a reference. Hydrophilicity, on the other hand, is more amenable to theoretical study because it does not entail the involvement of a second condensed phase in addition to water.

Hydrophobic Chromatography

1. The Basic Principle

Hydrophobic chromatography (HC) is a chromatographic method for the characterization, separation, and isolation of proteins and cells (1). It is based on **hydrophobic** (water-repelling) interactions between (a) hydrocarbon chains of different lengths and shapes that are anchored on inert beads and (b) the hydrophobic "pockets" or "patches" that are found on the accessible surface of proteins. Such hydrocarbon chains interact with the protein molecules submerged in water and bind them to minimize the surface of the hydrophobic area that is exposed to the water. This binding brings about the release of "ordered" water molecules, which forms the basis for the hydrophobic interactions. It turns out that proteins can be distinguished and resolved from one another by HC, because they differ in the size, number, and water repellence of their hydrophobic "patches" or "pockets." This basic principle in chromatography (2, 3) is also known as hydrophobic interaction chromatography and **reversed-phase** high-performance liquid chromatography (HPLC). It has now become a very powerful method of separation and has been used for research in biochemistry, molecular biology, and biotechnology—for example, in the preparation and characterization of drugs such as enzymes, hormones, antibodies, and receptors.

2. The Development of HC

HC was developed as a result of an unexpected observation made while attempting to make use of affinity chromatography (AC) (4). The basic concept in AC is based on the use of the specific affinity between the biorecognition site of a protein (an enzyme, an antibody, a receptor, etc.) and one of its biospecific ligands (a substrate, an inhibitor, a hormone, or a regulatory metabolite) that is covalently linked to an inert matrix backbone and can be regarded as an immobilized “bait” for the protein. The column with the immobilized bait is then used to “fish out” the desired protein from a mixture. While developing the basic principles of AC, it was observed that the purification of a desired protein is often improved by interposing a hydrocarbon chain (an “arm”) between the ligand and the matrix backbone (4, 5). It was presumed that such an arm relieves the steric restrictions imposed by the backbone on the ligand, thereby increasing its flexibility as well as its availability to the protein (5, 6). It was also implied that the hydrocarbon arms do not alter the inert nature of the matrix, a condition that obviously has to be ensured to preserve a strictly biospecific (active-site mediated) adsorption of the extracted protein. This assumption seemed reasonable at the time (at least with water-soluble proteins), because it had been shown in the case of lysozyme that “most of the markedly nonpolar and hydrophobic side chains ¼ are shielded from the surrounding liquid by more polar parts of the molecule” and that, as predicted by Sir Eric Rideal and Irving Langmuir, “lysozyme is quite well described as an oil drop with a polar coat” (7).

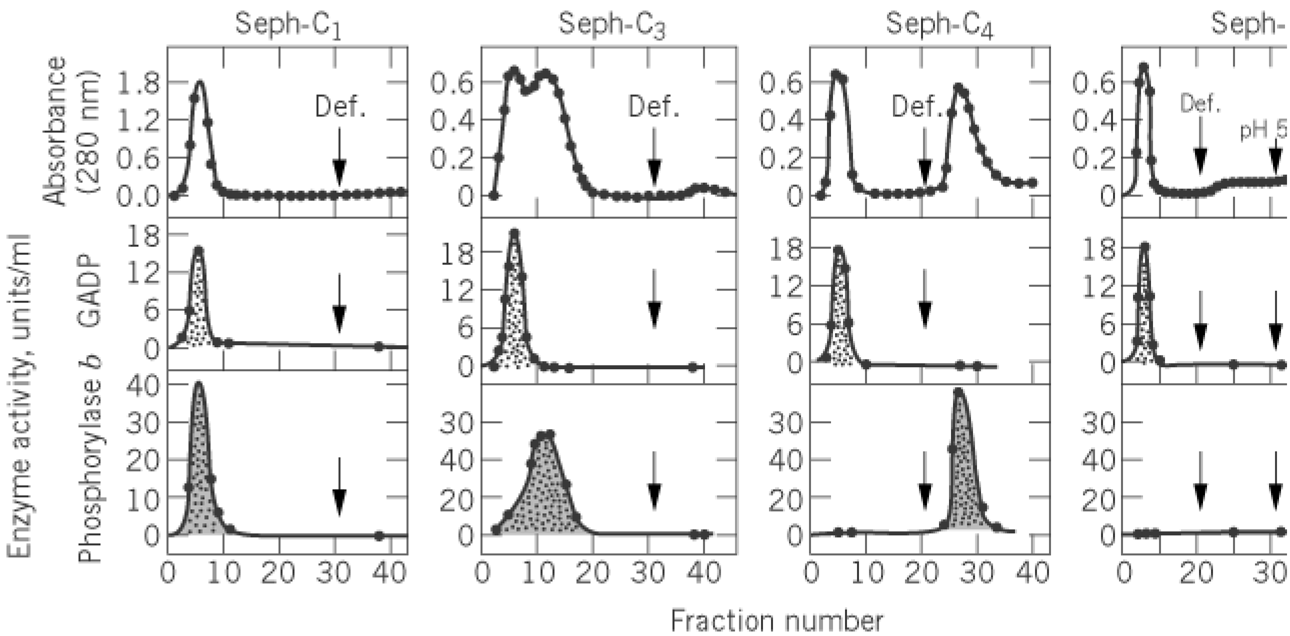
For the purification of enzymes involved in glycogen metabolism, glycogen (the “bait”) was anchored onto beaded agarose . Unexpectedly, two glycogen-coated agarose preparations that differed only in the length of the hydrocarbon chains bridging the ligand and the agarose bead (Seph-C_8-glycogen and Seph-C_4-glycogen) exhibited different behaviors: Whereas the column material with eight-carbon-atom bridges adsorbed glycogen phosphorylase *b*, that with four-carbon-atom bridges did not even retard it (2). Control experiments revealed that both the adsorption of the enzyme by Seph-C_8-glycogen and its exclusion by Seph-C_4-glycogen could be reproduced with columns that contained no glycogen whatsoever (Seph-C_8-NH_2 and Seph-C_4-NH_2), indicating that free w-aminooctyl chains (which had not reacted with glycogen) were mainly responsible for the retention of phosphorylase on Seph-C_8-glycogen and also raising the possibility that the very length of the hydrocarbon chain determines the retention power of these columns.

3. Homologous Series of Alkylagarose Columns

To challenge this working hypothesis, a homologous series of alkylagarose columns was synthesized, and their retention power was tested with two enzymes, glycogen phosphorylase *b* and glyceraldehyde-3-phosphate dehydrogenase (Fig. 1). This “homologous series of alkylagarose columns” (Seph-C_n) refers to a set of columns that are identical in their ligand density, net charge, and ultrastructure. Such a set of columns can be considered as a series of consecutive controls in which each column differs from the preceding one in the series only in having hydrocarbon chains one carbon atom longer. In general, under the same experimental conditions, different proteins display different adsorption profiles on the Seph-C_n columns (1-3). For example, under the conditions used to retain phosphorylase *b* ($n \geq 4$), D-glyceraldehyde-3-phosphate dehydrogenase was not even retarded on any of the columns tested ($n = 14$). Thus, while Seph-C_1 and Seph-C_2 would not distinguish between the two enzymes and would exclude both of them, Seph-C_3 would begin to resolve them, and Seph-C_4 would separate them efficiently, indicating that the ability to bind and to discriminate between two proteins (ie, to resolve and separate them) is a function of the number of carbon atoms in the hydrocarbon chains of the columns (Fig. 1). In addition, the above results showed that it is possible to adjust the tightness of adsorption of a given protein and avoid an overly strong retention, which would then require drastic conditions for elution that might **denature** the eluted protein. Finally, these studies illustrated the use of “deforming agents” (local, fully reversible **denaturants** that loosen the structure of the proteins) as efficient and delicate eluents in detaching adsorbed proteins from HC columns.

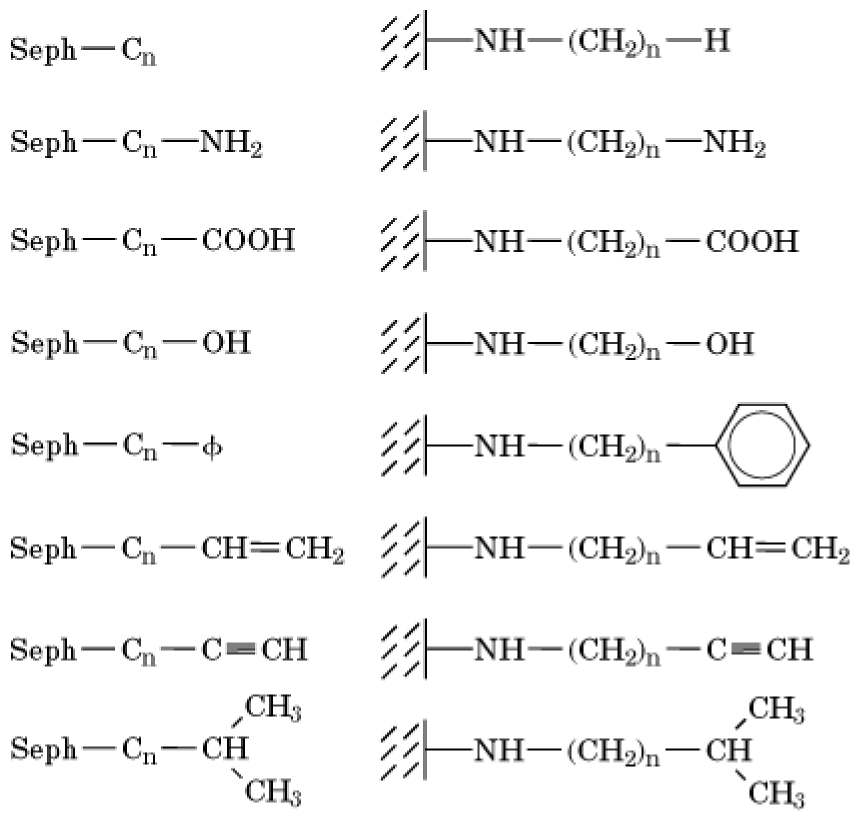
Figure 1. Preferential adsorption of glycogen phosphorylase *b* on alkylagarose columns varying in the length of their alk

chains. Samples containing D-glyceradehyde-3-phosphate dehydrogenase (GAPD) and glycogen phosphorylase *b* were a onto the columns. Nonadsorbed proteins were washed off, then (*arrow*) a deforming buffer (Def.) was applied, which el phosphorylase from Seph-C_4 but not from Seph-C_6. Acetic acid (0.2 M) was needed to detach glycogen phosphorylase *b* Seph-C_6, which in this case came out in an inactive (denatured) form.



HC provides now a general, systematic approach to the purification of water-soluble, as well as lipophilic, proteins. This approach makes use of homologous series of alkylagaroses and their derivatives (Seph-C_n-X where X = H, NH_2, COOH, OH, C_6H_5, etc.; Fig. 2) to achieve resolution and purification of proteins and cells. Each member in these series offers flexible hydrophobic arms or “yardsticks” that interact with accessible hydrophobic “patches” or “pockets” in the various proteins, retaining only some proteins out of a mixture. Further resolution is then achieved by gradually changing the nature of the eluent. The wide applicability of this type of chromatography in protein purification and in separating cells is now well accepted. Procedures for the synthesis and the characterization of Seph-C_n (n = 112) are described in Ref. 1.

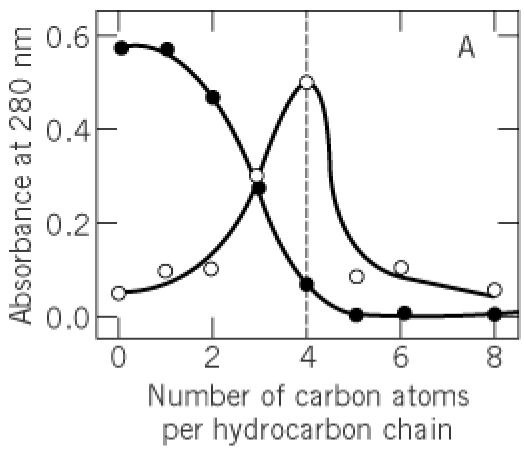
Figure 2. Examples of homologous series of alkylagarose derivatives (Seph-C_n-X) that can be used for HC (1).

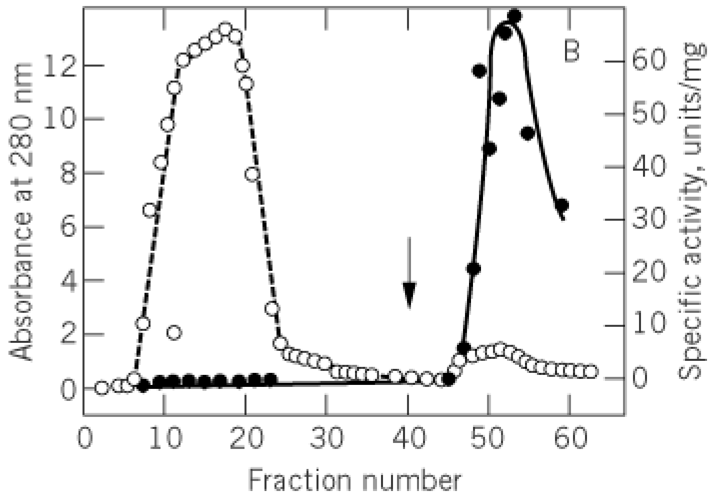


4. Selecting a Column for a Given Purification—the Exploratory Kit

The selection of a suitable substituted agarose within a given homologous series (eg, Seph-C_n) is achieved by means of an exploratory group of column materials designed for this purpose (1). Each column in the kit contains one member of the series. If, under certain conditions, a specific protein is adsorbed onto hydrocarbon chains X carbon atoms long, and if a change in the eluent promotes exclusion from Seph-C_x, then this is the column of choice. An example of an adsorption-elution profile of glycogen phosphorylase, *b*, on the Seph-C_n series, is given in Figure 3a. As seen in this figure, as the length of the hydrocarbon chains increases, less protein is excluded from the column. While Seph-C_0 and Seph-C_1 exclude all the protein, Seph-C_2 and Seph-C_3 retard it, whereas Seph-C_4 and higher members of the series retain the protein. By passage of a 0.4 M imidazolium-citrate buffer, a “deformer” for glycogen phosphorylase *b* (8, 9), it is possible to elute the enzyme quantitatively from the Seph-C_4 column, but not from higher members in the series. In fact, recovery of the enzyme from Seph-C_6 was achieved only with a drastic eluent, 0.2 M CH_3COOH, which displaces the enzyme but also denatures it. On the basis of such results, Seph-C_4 should be chosen for the preparative purification of this enzyme; and indeed this column allowed a 60- to 100-fold purification in one step, with >95% recovery of enzyme activity (Fig. 3b).

Figure 3. Hydrophobic chromatography (**a**) Adsorption profile of glycogen phosphorylase *b* on a Seph-C_n kit. The filled circles indicate the amount of protein passing straight through the column. Empty circles indicate the amount of protein eluted by a “deforming buffer.” (**b**) Preparative purification of the enzyme from a muscle extract. Absorbance (empty circles) and specific activity (filled circles) were monitored. Nonadsorbed protein was removed by washing, and elution with the “deforming buffer” was initiated at the fraction indicated by the arrow (1, 2).





5. Means of Elution

Studies aimed at the optimization of elution from alkylagaroses have shown that proteins can be desorbed from such columns by a variety of means: polarity-reducing agents, specific deformers, mild detergents, low concentration of denaturants, alteration in pH or temperature, and changes in ionic strength and ionic composition. Because the availability of hydrophobic crevices or patches on the surface of a protein appears to depend on its conformation, and because the retention of proteins by alkylagaroses depends largely on the lipophilicity, size, shape, and number of these crevices and patches, the above-mentioned means of elution may function either by directly disrupting the hydrophobic interactions between the column material and the protein or by changing the conformation of the protein. In fact, both mechanisms may often operate simultaneously. High selectivity in elution may also be achieved by using biospecific ligands, such as coenzymes, substrates, specific metal ions, and allosteric effectors, which often bring about ligand-induced conformational changes in proteins.

6. Useful Features of Hydrophobic Chromatography

The important features of hydrophobic chromatography are as follows: (i) It provides an independent criterion for the resolution of macromolecules. (ii) It provides means for gradually adjusting the adsorption forces and thereby avoiding an overly strong retention. (iii) It can be used for the detection of conformational changes in proteins when these are reflected in the size or distribution of hydrophobic crevices or patches. A potential use of these column materials may be in the purification and study of lipophilic membrane-bound proteins that have accessible hydrophobic regions used for their localization within the membrane. (iv) It provides a basis for the development of automatic consecutive fractionators (1) for the purification of proteins.

7. On the Mechanism of Action of Alkylagaroses

In their functional conformation, water-soluble proteins are folded so as to "bury" as many as possible of their hydrophobic side chains in the interior of the molecule and to expose as many as possible of their polar, charged side chains to interaction with water. It is now clear, however, that complete burying of all hydrophobic groups is generally not achieved, leaving some hydrophobic groups exposed at the surface of the protein. Together with hydrophobic components of charged amino acids, such as the ($-CH_2-$), stretches of lysine and glutamic acid residues, or the phenyl ring of tyrosine residues, these form hydrophobic "patches" or "pockets" at the surface of the molecule (Fig. 4). A sufficiently large hydrophobic patch may constitute a binding site for the hydrocarbon chains implanted on the hydrophilic agarose matrix and form "hydrophobic bonds," freeing "ordered" water molecules and allowing them to interact with each other (10-12). The available hydrophobic patches and pockets of different proteins vary in number, size, shape, and lipophilicity, and these variations are reflected in the relative affinities of different proteins for a specific alkylagarose. It is the properties of such patches, and perhaps their distribution on the surface of different proteins, that play a major role in the resolution of proteins on alkylagaroses.

Figure 4. Schematic representation of the surface of a protein molecule with an exposed hydrophobic amino acid residue (tryptophan) and hydrophobic "pockets" or "patches" (*hatched*). The scheme also illustrates how hydrophobic constituents of several nonhydrophobic amino acids bearing hydrophobic functional groups can together form a site capable of accommodating a hydrophobic hydrocarbon chain (1).

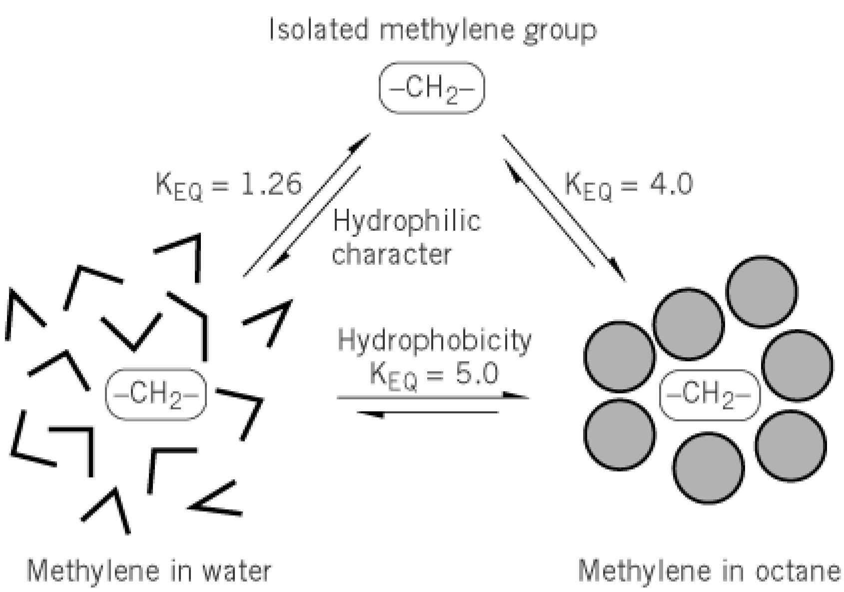
Hydrophobic Effect

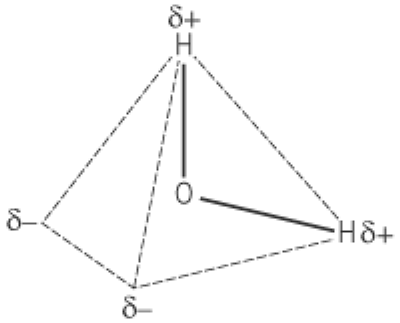
Cooks and physicists are aware of the tendency of oil to separate from water, a solvent that is very self-cohesive. In biology, this effect is expressed in the tendency of uncharged (or nonpolar) molecules to escape from water by entering less polar surroundings, or by adhering to each other (Fig. 1). This phenomenon, termed the *hydrophobic effect* (1, 2), is believed to play a decisive role in maintaining the stability of biological membranes, in the proper folding of protein molecules (see Protein Stability), and in determining the relative affinities of hormones, antibodies, and substrates for proteins that bind them. The tendency of any particular nonpolar molecule or chemical group at equilibrium to favor transfer from water to a nonpolar phase, such as a hydrocarbon solvent, is termed its hydrophobicity.

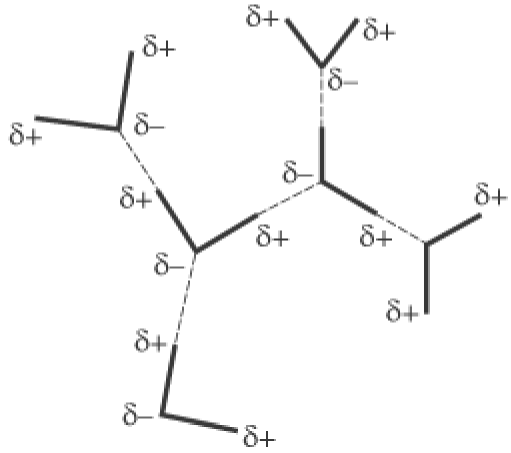
Figure 1. A partial view of the origins of the hydrophobic effect.

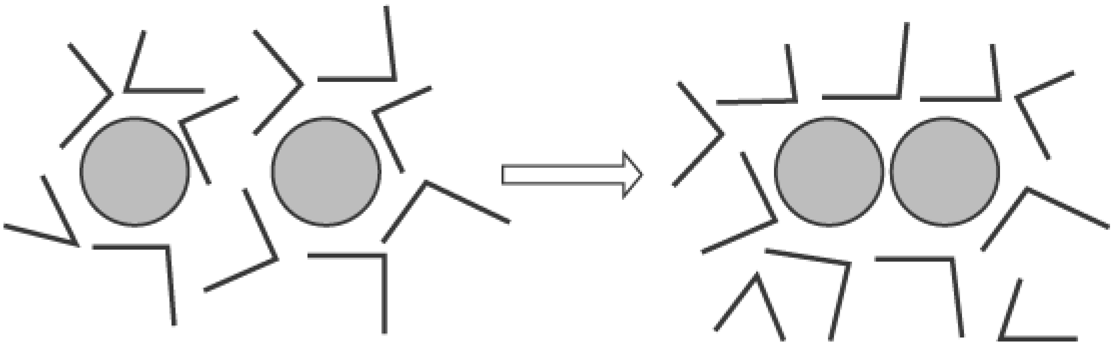


The physical origins of the hydrophobic effect remain controversial, because the properties of water as a solvent are not yet fully understood. It is of interest to ask whether nonpolar molecules, such as methane or ethane with no polar groups, tend to leave water and enter less polar solvents (octane is a familiar example) mainly because they are repelled by water; or whether they do so because they are attracted to the less polar solvent (or to each other). That question can be addressed by referring to an absolute standard, the vapor phase, that neither attracts nor repels solutes, and in which "solute" molecules exist in isolation most of the time. Using the vapor phase as a reference, single molecules of methane are found to exhibit an appreciable tendency to leave water, as indicated by their equilibria of transfer from water to the vapor phase. For methane, this equilibrium constant is 27 in favor of the vapor phase at 25°C. This tendency increases gradually with the size of a normal alkane, as can be seen in the series $CH_4$27, $C_2H_6$20, $C_3H_8$29, C_4H_{10}38, C_5H_{12}51, C_6H_{14}74, C_7H_{16}83. For each CH_2 increment, transfer to the vapor phase is enhanced by an average factor of 1.26. In contrast, each CH_2 increment enhances the equilibrium of transfer from the vapor phase to a nonpolar solvent by a factor of 4.0. As a result, each CH_2 increment increases the distribution coefficient for transfer from water to a nonpolar solvent by a factor of 5.0 (Fig. 2). Similar behavior has been observed in the normal series of hydrocarbons, esters of acetic acid, amines, and alcohols (3). In summary, single molecules of hydrocarbons have an appreciable tendency to leave water and enter the vapor phase, where they exist in isolation. These molecules are thus truly "hydrophobic" in the sense that they have an absolute tendency to escape from water. That is hardly surprising, since water is among the most self-cohesive molecules known, with an extremely high surface tension. However, this tendency to leave water is only slightly enhanced by increasing the size of the hydrocarbon (addition of a $-CH_2$ increment), whereas increasing size greatly enhances the tendency of a nonpolar solute to leave water and enter a nonpolar solvent. One is led to conclude that attraction to the nonpolar solvent also plays a major role in the hydrophobic effect, and this is believed to be due to van der Waals interactions, or London dispersion forces.

Figure 2. Analysis of the hydrophobic effect in terms of the equilibrium affinity of a solute for water and for a nonpolar liquid. (**a**) Electrons are more strongly attracted by the oxygen atom of the water molecule, leaving partial negative charges near the corners of a tetrahedron, and partial positive charges at the other two corners. (**b**) Water molecules are strongly attracted to each other by their partial charges, forming H-bonds between H and O atoms. As a result, liquid water is very self-cohesive. (**c**) Nonpolar molecules, like oil drops, break up the structure of water in which they are dissolved. The self-cohesiveness of water encourages these molecules or groups to coalesce, so that the part of the solvent can return to its preferred structure. This is called the hydrophilic effect.







The hydrophobic effect is unique, among the noncovalent forces involved in maintaining biological structures, in that it grows stronger with increasing temperature (1, 4), ie, **enthalpy** is released (D *H* is positive) when the force takes effect. If there is a net free energy of attraction (ie, D*G* is negative), then **entropy** must be released (*T*D*S* must be positive and greater in magnitude than D*H*), since D*G* = D*H*–*T*D*S*. If a protein's stability were dependent entirely on the hydrophobic effect, then the protein would be expected to lose its structure at low temperatures, and some proteins do in fact undergo "cold denaturation" (see **Protein denaturation**). There has been continuing interest in the probable structural origins of the entropy (and enthalpy) increases that accompany the formation of hydrophobic interactions. Changes in the properties of water in the immediate neighborhood of the solute almost certainly account, at least in part, for the loss of entropy that accompanies the introduction of a nonpolar molecule or methylene increment into water from the vapor phase or a nonpolar solvent. Frank and Evans (5) suggested that this might imply formation around solutes of a kind of *clathrate* or *iceberg* structure, in which water molecules were more ordered than in the bulk solute. These authors did not suggest that water surrounding a solute resembled Ice I in any literal sense, nor does current experimental evidence seem to support such a possibility. Entropy losses associated with introducing nonpolar solutes into water might also arise, at least in part, from restrictions on the mobility of solutes when they are introduced into a structured aqueous environment. In normal aliphatic compounds of increasing size, solubility might (according to this view) be reduced by progressive restrictions on internal rotation, and compounds with internal rotations already restricted would not be affected to the same extent. In apparent accord with this view, steroids and cycloalkanes display lower activity coefficients in water than nonrigid compounds of similar size, with reference to both nonpolar solvents and to the vapor phase (6), and the alicyclic amino acid proline is more hydrophilic than would be expected for an amino acid with an aliphatic side-chain of the same size (7). These effects could alternatively be due, at least in part, to the reduced surface area of cyclic as compared with open-chain compounds, resulting in the imposition of less severe restrictions on the solvent. These uncertainties illustrate the general difficulty of deconvoluting thermodynamic functions, which describe equations of state, without making assumptions that are themselves open to question. A clearer view of the origins of the structural origins of the hydrophobic effect awaits a more complete understanding of the properties of water and aqueous solutions.

All molecules, even those that are truly nonpolar, are attracted to each other by London dispersion forces. These forces are responsible for the fact that octane, and the lipid molecules present in biological membranes, are liquids at room temperature. They also make a major contribution to the hydrophobic effect discussed above, and to the resulting tendencies of protein molecules to adopt the specific structures needed for their activities. Anyone who has observed the wheels of a locomotive, or two cyclists riding a tandem bicycle, has a rough mental image of the London dispersion force. If we picture two atoms of argon near each other, it is easy to imagine that temporary fluctuations in the distribution of electrons around one of these atoms may, at any given instant, place a partial negative charge toward the other atom. In response to this fluctuation, electrons in the orbitals of the neighboring atom tend to adjust slightly, placing a partial positive charge in the vicinity of the first atom and creating a small electrostatic attraction between them. A moment later, the roles may be reversed, but a net attraction remains. Because of the small charges involved, and their fluctuating character, London dispersion forces are individually weak and intensely dependent on the distances separating the atoms. These forces reach a maximum at an optimal distance equivalent to the sum of the **van der Waals** radii of the two atoms (typical van der Waals radii are 0.10 nm for H, 0.16 nm for C, 0.135 nm for O, 0.145 nm for N, and 0.17 nm for S). Beyond that distance, their mutual attraction falls off with the 6th power of the distance separating the two atoms. At distances closer than optimal, repulsion between the electron clouds of the two atoms builds up rapidly (unless they are able to share their electrons in a covalent bond), with the 12th power of the distance separating the atoms. The number and aggregate strength of the attractions between nonpolar molecules can be considerable, even though they are individually weak. They account for a substantial part of the hydrophobic effect discussed above and are thus largely responsible for maintaining the integrity of biological membranes and the proper folding of protein molecules.

Hydrophobic Electrophoresis

Although aqueous buffers are the appropriate solvents for gel electrophoresis of native hydrophilic macromolecules, separations of **hydrophobic** species require the presence of detergents or miscible organic solvents. Uncharged or amphoteric detergents are compatible with the formation of a gel and electrophoresis. Alternatively, charged detergents can be added to the buffer and have a negligible effect on electrophoresis, so long as conductance is not greatly elevated. The most widely used detergent for that purpose is the strongly dissociating and denaturing detergent, **SDS**. However, the **molecular sieving** of charged detergent micelles in electrophoresis as a function of gel concentration needs to be considered, as well as the generation of moving boundaries in discontinuous buffer systems, with the detergent as a leading or trailing ion (see Disc Electrophoresis). Miscible organic solvents are particularly suitable for relatively hydrophobic gels, such as some of the "Hydrolink" gels (1) or the new spongelike copolymer gel media(2).

When it is desirable to preserve native or relatively undissociated structures and their biological activities, gel electrophoresis must be conducted in "nondenaturing detergents," ie, under conditions that render the particular detergent relatively innocuous with regard to the disruption and inactivation of active structures and complexes. For that purpose, seven groups of amphoteric or uncharged detergents are particularly useful(3). Their effectiveness in solubilization depends sharply on their concentration, critical micelle concentration (cmc) and micellar weights, and the protein/detergent ratio.

Hydrophobic-Interaction Chromatography

Hydrophobic (literally meaning "water hating") describes nonpolar compounds that have little affinity for polar molecules, such as water, and self-associate in a polar environment because of the hydrophobic effect . Hydrophobic interactions are energetically favorable because of an increase in **entropy** ($\Delta S > 0$) that originates when the solvent water molecules leave the more ordered structure around the nonassociated nonpolar compounds for the more unstructured, bulk polar environment. If matrices in a chromatography column provide hydrophobic surfaces to interact with analytes and one can separate mixtures of molecules with hydrophobic moieties, we are dealing with hydrophobic-interaction chromatography.

The principle of hydrophobic-interaction chromatography was originally known (1) by the name "**salting-out** chromatography," but it acquired its current name only after the synthesis of specific stationary phases in the early 1970s (2-4). In hydrophobic-interaction chromatography, retention is promoted by high concentrations of an appropriate salt, and elution is achieved with low salt concentrations. The matrices in the column are very hydrophilic and have only a very mild hydrophobicity. The increase in concentration of a salting-out salt drives the analytes out of the mobile phase and onto the stationary phase, much like the precipitation of highly water-soluble proteins or hydrophilic polymers that occurs under conditions of high ionic strength (see Salting In, Salting Out and Preferential Hydration).

Although many view hydrophobic-interaction chromatography as an extension of reversed-phase chromatography to an aqueous mobile phase without organic modifiers, there are a number of basic differences between these two separation techniques. In hydrophobic-interaction chromatography, the matrix is hydrophilic and is substituted with short-chain groups, such as phenyl, butyl, or octyl (see Ref. 5 for a list of different matrices), and the mobile phase is usually an aqueous salt solution. In reversed-phase chromatography, the matrix is an octyl (C8) or octadecyl (C18)-derived silica, and the mobile phase is usually a mixture of water and a less polar organic modifier (eg, methanol or acetonitrile). These two techniques exploit the different sources of the hydrophobicity of proteins. Hydrophobic-interaction chromatography depends on surface hydrophobic groups, which arise from the protein's **tertiary** and quaternary structures, and is carried out under conditions that maintain the integrity of the protein conformation. Reversed-phase chromatography is carried out on the unfolded protein, in which nearly all the hydrophobic groups are exposed to the matrix, and depends on the protein's primary structure. Proteins frequently **denature** under conditions of reversed-phase chromatography because organic solvents are needed for elution and/or because of the strength of the interaction with the stationary phase, whereas the mild elution conditions and mild hydrophobic interaction of hydrophobic-interaction chromatography matrices allow the elution and recovery of native proteins.

The most interesting aspect of hydrophobic-interaction chromatography is the frequent increase of retention with increasing temperature because this chromatographic method is an entropy-driven process. This is the opposite of any other type of retention chromatography. It should also be pointed out that the proteins are loaded onto the hydrophobic-interaction chromatography column using a buffer with a high salt concentration as the starting mobile phase and are then eluted by a gradient with decreasing ionic strength. This is the opposite of the procedure employed in ion-exchange chromatography .

Hydrophobic-interaction chromatography is extremely useful for purifying proteins and peptides. The principle of this chromatographic method is orthogonal to those of ion-exchange and size-exclusion chromatography methods. Therefore it is used effectively in schemes that combine all three chromatographic methods to separate proteins from complex mixtures. However, the solubilities of proteins in high-salt buffers are limited by the salting-out effect. This constrains the applications of hydrophobic-interaction chromatography for preparative purposes. A detailed operational protocol is beyond the scope of this article, so interested readers are directed to excellent reviews [5, 6, and chapter 13 (pp. 250–259) of Ref. 7].

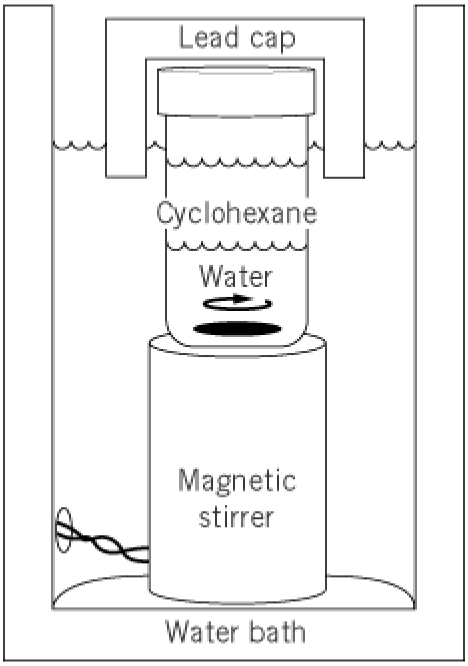
Hydrophobicity

A molecule is said to be *hydrophobic* if it has a tendency to move from the polar solvent water to a nonpolar, oily surrounding. The tendency of a molecule or chemical group to undergo transfer at equilibrium from water to a nonpolar phase, such as a hydrocarbon solvent, is termed its *hydrophobicity*. The inverse properties are hydrophilic and hydrophilicity. Hydrophobicity is important in allowing drugs to cross membranes, and its analysis has therefore been important in the development of the pharmaceutical industry (1, 2). The relative hydrophobicities of the amino acids are of particular interest to biochemists and molecular biologists, because of their role in **protein folding**. Thus, the least hydrophobic amino acids are found almost exclusively at the accessible surfaces of proteins in which they occur, exposed to solvent water, whereas the interiors of proteins are almost uniformly composed of hydrophobic amino acids (3). For reasons that are not yet fully understood, but may be related to protein folding, the hydrophobicities of amino acids are also associated with a pronounced bias in the composition of the genetic code (4) (see also Hydrophilicity).

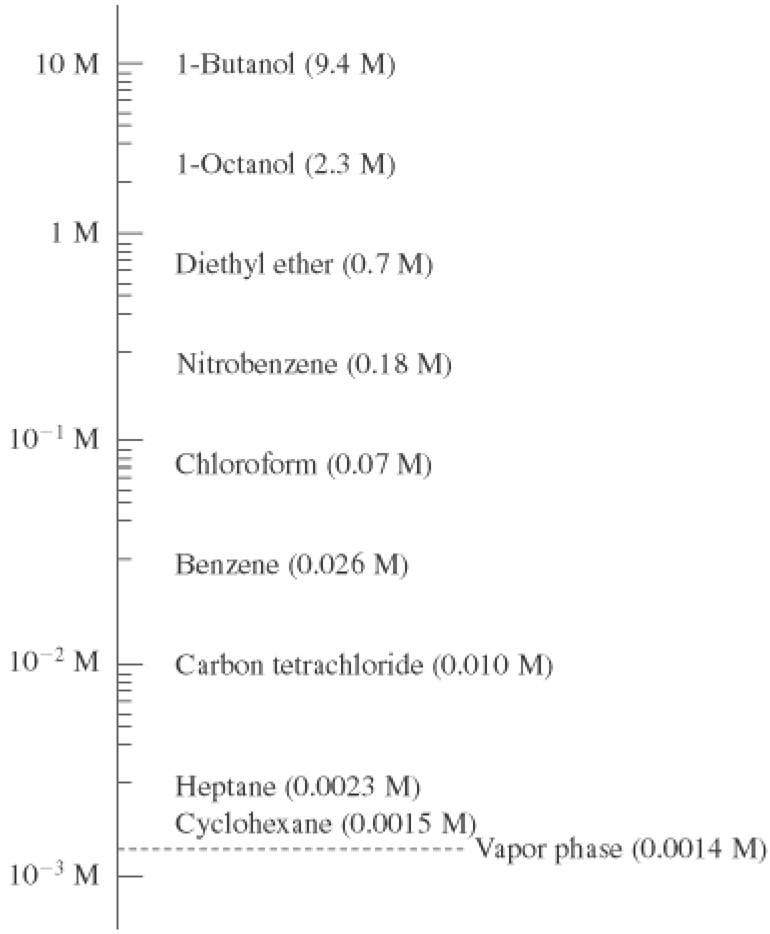
Hydrophobicity is usually expressed quantitatively as either the equilibrium constant or as the negative Gibbs **free energy** (-RT ln K_{eq}) for transfer of a solute from dilute aqueous solution to the nonpolar phase. This dimensionless equilibrium constant, the partition coefficient, is determined experimentally by measuring the concentration of the solute that is dissolved in each phase after thorough mixing, at equilibrium. After mixing equilibrium is achieved, a separatory funnel or similar device is used to separate the phases before measuring their solute content. A simple device for performing these experiments rapidly, with small volumes of material, is illustrated in Figure 1. Some solutes show a pronounced tendency to self-associate, either in water or in the nonpolar solvent. Self-association is indicated by an increasing tendency to favor one phase, that in which aggregation occurs more readily, as the solute concentration is increased. When such behavior is encountered, partition coefficients must be extended to sufficient dilution to avoid self-association in both phases. The results can then be used as a basis for calculating the concentration-independent distribution coefficient between phases, the hydrophobicity.

Figure 1. A simple apparatus for measuring hydrophobicity, consisting of a submersible magnetic stirrer, 20-mL scintillation vial, and lead cap to hold the vial in place. Measurements are made using aqueous solutions buffered in a pH range in which the solute is uncharged, using the solute at high dilution to avoid self-association, and a sensitive method of detection (typically NMR or radioisotopic assay). To estimate effective K_{dist} at pH 7, the observed K_{dist} is corrected for the fraction of solute that is ionized.



Certain immiscible solvents, such as 1-*n*-butanol and 1-*n*-octanol, are much more polar than others and are miscible with water to a considerable extent. Figure 2 shows that when a distribution measurement has been performed using octanol, the nonpolar phase contains 2.3 *M* water; in contrast, water-saturated cyclohexane contains only $1.6 \times 10^{-3} M$ water. Solutes experience relatively little change in surroundings in passing between wet octanol and water, so there is a “leveling” effect that tends to result in distribution coefficients that approach unity. To provide a more sensitive measure of differences in solute polarity, the nonpolar solvent that is used as a reference in these experiments should be as nonpolar as possible, ideally a liquid hydrocarbon such as cyclohexane. Adopting a scale of this kind, the side-chains of the amino acids that occur in proteins vary in their distribution coefficients between cyclohexane and neutral aqueous solution over a range of 4×10^{14}, from arginine (the most polar) to leucine and isoleucine (the least polar). For octanol-to-water distribution, the range is only 3×10^{2}. There is also evidence of specific interactions between solutes and octanol, as might be expected from the **hydrogen-bonding** potential of octanol's hydroxyl groups (2).

Figure 2. Solvents compared with respect to their water content at saturation, at 25°C.



For a highly polar compound, such as a carboxylic acid or an amine, the solute may partition so strongly in favor of water that the concentration in cyclohexane is difficult to detect. Sensitivity can be improved by using a very large volume (eg, 1000 mL) of the nonpolar phase to extract the solute from a small amount (1 mL) of water, separating the phases, then "back-extracting" the solute into a small volume (1 mL) of water. After appropriate correction, distribution coefficients as large as 10^7 can be measured in this way using NMR, UV spectroscopy or radioisotope methods as a means of detection. Ionization tends to render a solute extremely polar, and its hydrophobicity is then more easily determined at pH values where the compound is uncharged. Its hydrophobicity at pH 7 can then be calculated by multiplying the value for the uncharged compound by the fraction that is actually uncharged at pH 7.

Many molecules are found to exhibit behavior consistent with the view that a molecule's hydrophobicity, expressed as free energy, is a roughly additive function of the hydrophobicities of its constituent chemical groups. A comprehensive collection of early data from the literature, with correlations and exceptions noted, has been published by Hansch and Leo (2). More recently, data have been collected for the amino acid side-chains (3), **nucleic acid** bases (5), phosphoric acid esters and amides (6), *cis*- and *trans*- peptide bonds (7) and carbohydrates (8). The hydrophobicities of the reactants and products of hydrolysis of ATP have been shown to differ to such an extent that ATP hydrolysis, which is highly exergonic in water (see Adenylate Charge), becomes endergonic in its absence, ie, changing the solvation can be considered to provide the entire driving force for ATP hydrolysis (8).

Hydrophobicities of the amino acid side chains occurring in proteins, expressed as $\log_{10}$ of the equilibrium constant at 25°C, for transfer from neutral aqueous solution to cyclohexane (3), are

Leucine	3.62
Isoleucine	3.62
Valine	2.97
Proline	2.51
Phenylalanine	2.19
Methionine	1.73
Tryptophan	1.71
Alanine	1.33
Cysteine	0.93
Glycine	0.69
Tyrosine	–0.10
Threonine	–1.89
Serine	–2.49
Histidine	–3.42
Glutamine	–4.07
Lysine	–4.08
Aparagine	–4.88
Glutamate	–5.00
Aspartate	–6.41
Arginine	–10.97

Proline differs from the other amino acids in that its nitrogen atom is involved in a secondary amide linkage. From a family of related compounds, it can be inferred that proline is 2.9-fold less hydrophobic than valine (9), placing its value at 2.51 on the above scale.

It is of interest to compare the hydrophobicities of the amino acids that occur in proteins with their tendencies to appear in buried positions or at the surfaces of proteins. Such a comparison, shown in Figure 3, suggests that there is a close correlation. It should be noted that the slope of the line is very shallow, consistent with the view that the environment of buried amino acid residues is much less nonpolar than cyclohexane, especially in the case of the more polar amino acids.

Figure 3. Distributions of amino-acid side-chains, from surface to buried positions in proteins (10), treated as an equilibrium constant ($K_{exposed>buried}$), compared with distribution coefficients for the corresponding side-chains from neutral aqueous solution to cyclohexane (3).

Hydroxyapatite Chromatography

Hydroxyapatite, also known as hydroxylapatite and abbreviated as HA, is a modified form of crystalline calcium phosphate, $Ca_{10}(PO_4)_6(OH)_2$, that has proven to be a very useful inorganic matrix for purifying and fractionating diverse macromolecules. Hydroxyapatite chromatography was introduced by Tiselius et al. in 1956 (1). Bernardi (2, 3) undertook extensive studies of **protein** behavior on hydroxyapatite, worked out standard procedures for the operation of HA columns, and discussed the mechanisms of adsorption and elution. Gorbunoff (4-6) extended Bernardi's work and deduced a mechanism of protein–HA interaction based on three fundamental conclusions:

1. Adsorption and elution cannot be regarded as simple reversals of a single process.
2. **Amino** and carboxyl groups act differently in the adsorption of proteins to HA.
3. Elution of basic and acidic proteins by different salts occurs by different mechanisms.

Briefly, in the adsorption of proteins to HA columns equilibrated with phosphate buffer, amino groups act through nonspecific electrostatic interactions between their positive charges and the general negative charges on the HA column, whereas carboxyl groups are repelled electrostatically from the negative charge of the column and by binding specifically to calcium sites on the column. Basic proteins are eluted as a result of normal Debye–Hückel charge screening by F^-,Cl^-,ClO_4^-,SCN^- and phosphate anions, or by specific displacement by Ca^{2+} and Mg^{2+} ions. Acidic proteins are eluted by displacement of their carboxyl groups from HA calcium sites by ions, such as fluoride or phosphate, that form stronger complexes with calcium than carboxyl groups.

Hydroxyapatite chromatography provides a unique fractionation method that has properties distinct from other separation techniques, such as preparative electrophoresis, ion-exchange chromatography and **size-exclusion chromatography** . Therefore HA chromatography has been used to advantage in purification schemes, frequently as a final purification step, and is used widely in biochemical research (see Ref. 7, a booklet provided by Calbiochem). The reader requiring more detailed and practical information is directed to the excellent review by Gorbunoff (8).

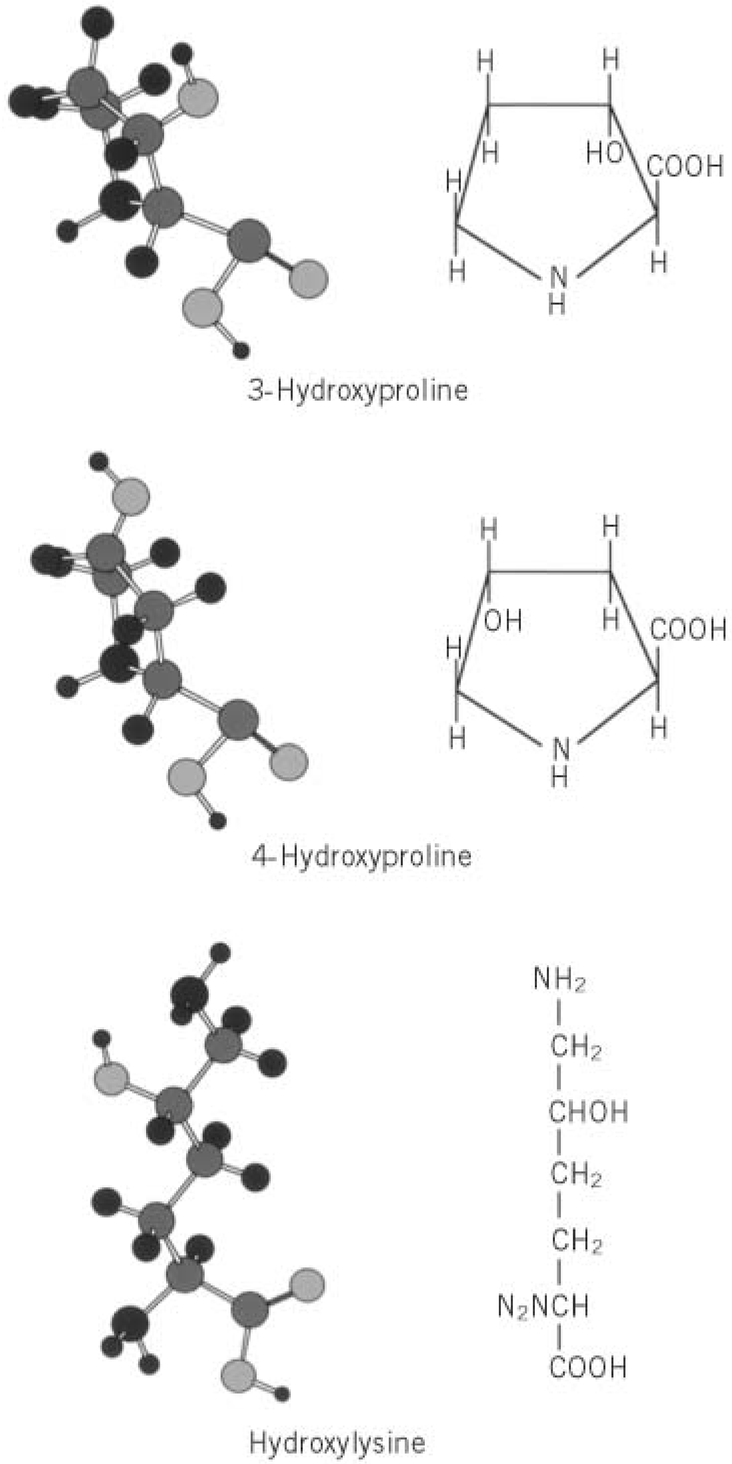
Hydroxylation (Lysine, Proline)

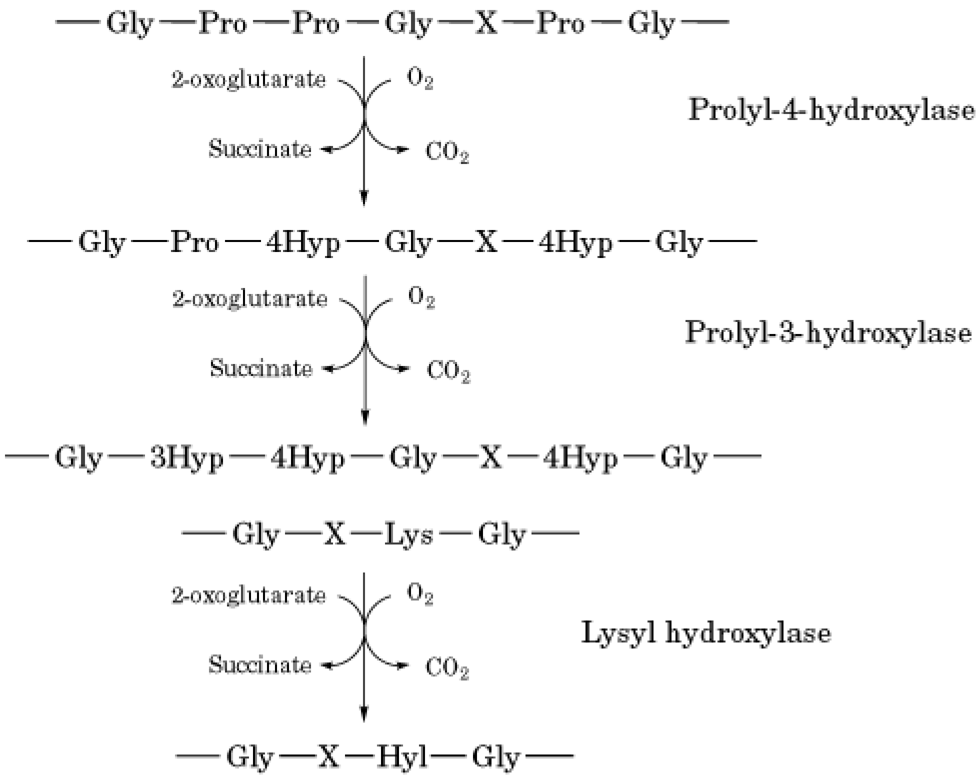
The principal posttranslational modifications of the polypeptides of collagen are the hydroxylation of proline and lysine residues to yield 4-hydroxyproline, 3-hydroxyproline (Hyp) and hydroxylysine (Hyl), plus glycosylation of the hydroxylysyl residues (Fig. 1). These modifications are catalyzed by three hydroxylases and two glycosyl transferases. The reactions occur until the polypeptides form the triple-helical collagen structure, which prevents any further modification reactions.

Figure 1. Structures of 4-hydroxyproline, 3-hydroxyproline, and hydroxylysine, as the free amino acids.



The hydroxylation of prolyl and lysyl residues in polypeptides is catalyzed by three separate glycoprotein members of the 2-oxoglutarate dioxygenase family of enzymes: prolyl 4-hydroxylase, prolyl 3-hydroxylase, and lysyl hydroxylase (Fig. 2). All three enzymes require a nonhelical polypeptide substrate. The minimum substrate structures for these enzymes are the triplets –X–Pro–Gly–,–Pro–Hyp–Gly–, and –X–Lys–Gly–, respectively. The activities of both prolyl 4-hydroxylase and lysyl hydroxylase are influenced by the adjacent amino acids and by peptide chain length.

Figure 2. Hydroxylation reactions on proline and lysine residues of collagen.



The reaction mechanisms of all three hydroxylase enzymes are similar, and each requires as cosubstrates Fe^{2+} , 2-oxoglutarate, and molecular O_2. The 2-oxoglutarate is stoichiometrically decarboxylated during hydroxylation; one atom of the O_2 molecule is incorporated into succinate and the other, into the hydroxyl group formed on the proline or lysine residue. The main function of ascorbate in the collagen hydroxylase reaction may well be to act as an antioxidant for the oxidation of Fe^{2+} to Fe^{3+} . Ascorbate is not consumed, and the hydroxylation reaction may proceed in its absence. The iron chelator, a,a′-dipyridyl, is a potent inhibitor of these hydroxylase reactions. In its presence, nonhydroxylated collagen is synthesized (in the case of type I collagen) or nonhelical chains may be secreted (in the case of type IV collagen).

1. Prolyl 4-Hydroxylase

The active prolyl 4-hydroxylase in vertebrates is a tetramer of molecular weight 240,000, and consists of two copies of each of two different types of subunits (a subunits, 64 kDa; b subunits, 60 kDa). It has two catalytic sites, one per pair of dissimilar subunits. The peptide- and 2-oxoglutarate-binding sites are located on the a subunit, while the ascorbate-binding sites may be composed of both a and b subunits. The principal contribution to the catalytic sites is from the a subunits, but some parts of the large catalytic sites may come from both the a and b subunits. The avian and mammalian a subunit sequences are highly conserved. The b subunit has proved to be a highly unusual multifunctional polypeptide that in isolation is protein disulfide isomerase (PDI).

2. Prolyl 3-Hydroxylase

Prolyl 3-hydroxylase (procollagen proline, 2-oxoglutarate 3-dioxygenase) requires a specific substrate sequence, catalyzing hydroxylation of prolyl residues only in the sequence –Pro–Hyp–Gly–. Prolyl 3-hydroxylase requires the same specific cofactors as does prolyl 4-hydroxylase. The reason for this modification is unknown, and the relative abundance of 3-hydroxyproline varies markedly in the different collagens. The individual chains of type I collagen each contain a single 3-hydroxyproline residue, while type IV collagen can contain up to 20 residues per 1000 amino acids.

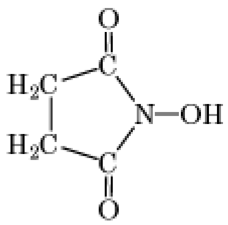
3. Lysyl Hydroxylase

The enzyme lysyl hydroxylase (procollagen-lysine, 2-oxoglutarate 5-dioxygenase) catalyzes the hydroxylation of lysyl residues at the d carbon atom (Fig. 1) in –X–Lys–Gly–triplet sequences by a mechanism similar to that described for prolyl 4-hydroxylase. The hydroxyl groups of the hydroxylysyl residues have two important functions—they act as attachment sites for carbohydrate residues (either galactose or glucosyl-galactose), and they play a role in the formation of intra- and intermolecular collagen crosslinks (see Collagen). The hydroxylysine content of the a chains of the different collagen types varies from 5 to 70 residues per 1000 amino acids.

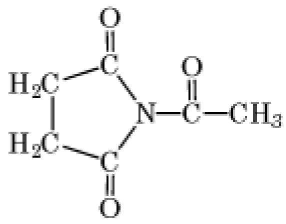
The enzyme lysyl hydroxylase in vertebrates is a **glycoprotein** containing asparagine-linked carbohydrate moieties. The enzyme is a dimer of 190,000 Da, composed of two monomers with different carbohydrate contents. The polypeptide chain of chick lysyl hydroxylase consists of 710 amino acids, with a 20-residue signal sequence. It is not very similar in sequence to the homologous, catalytically important a subunit of prolyl 4-hydroxylase, even though the enzymes share the same cofactor and substrate specificities.

N-Hydroxysuccinimide

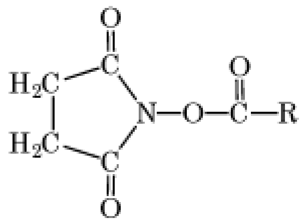
N-Hydroxysuccinimide [I] is employed as an **acetylating** or acylating agent in its acetylated [II] or ester [III] forms. The activated ester is prepared by reacting *N*-hydroxysuccinimide with **carbodiimide**-activated carboxyl groups. Acetylation of amino groups in proteins is conducted under milder conditions with *N*-acetylsuccinimide [II] or *N*-hydroxysuccinimide acetate than with acetic anhydride.



[I] *N*-Hydroxy-succinimide



[II] *N*-Acetyl-succinimide



[III] *N*-Hydroxysuccinimide ester

Various *N*-hydroxysuccinimide esters are prepared and employed to acylate proteins. These reactions are used for chemical modification and labeling of proteins (1). *N*-Hydroxysuccinimide esters are often employed as one part of the reactive groups in **bifunctional reagents** for cross-linking proteins (2). *N*-Hydroxysuccinimide esters are also employed to prepare activated column resins for affinity chromatography. *N*-Hydroxysuccinimide esters of amino acids are obtained by condensing of N-protected amino acids and *N*-hydroxysuccinimide with carbodiimide, and they are widely employed for peptide synthesis.

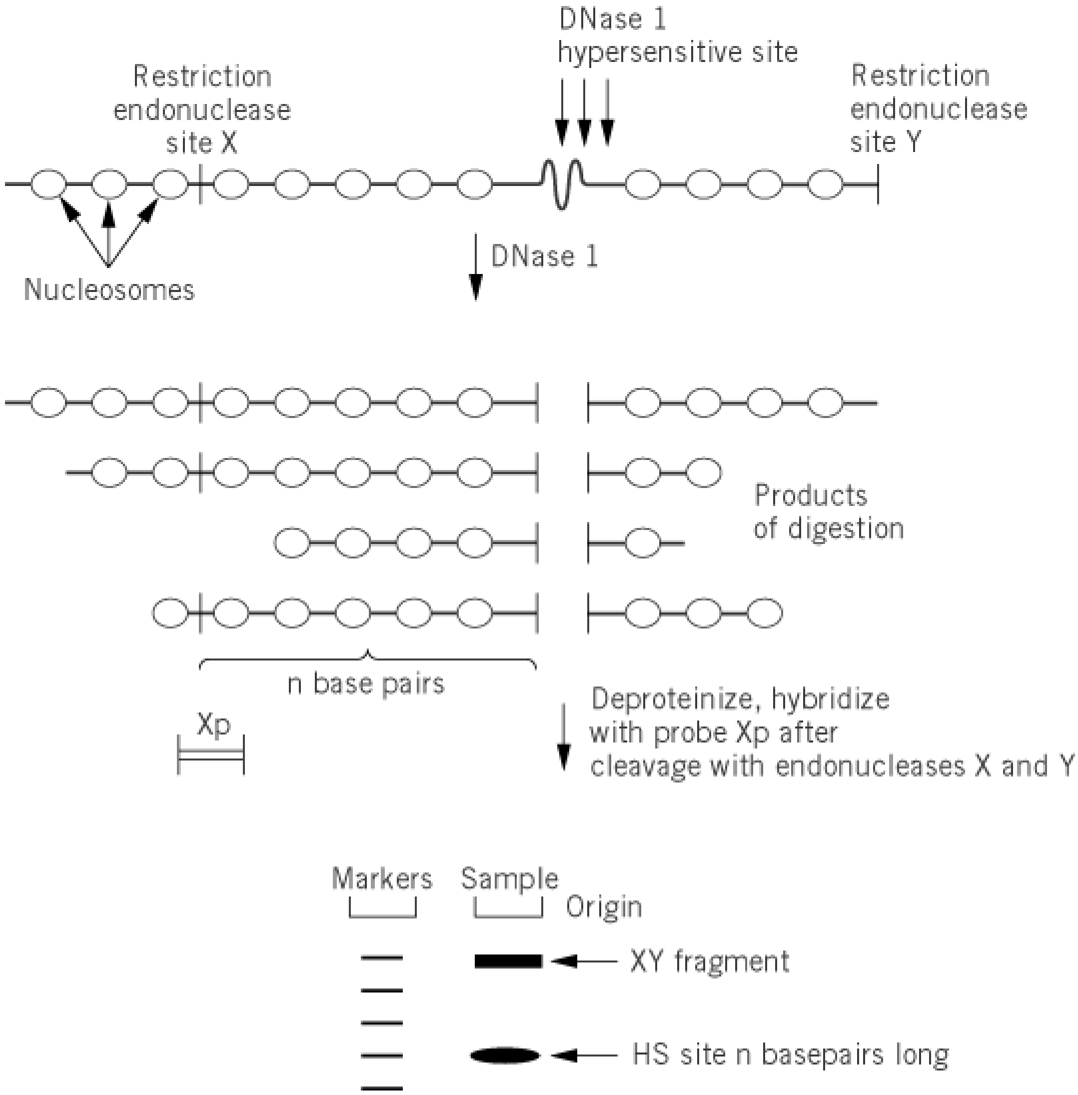
Hypersensitive Site

DNase 1 hypersensitive sites are the first place this **nuclease** introduces a double-strand break in chromatin (see DNase 1 Sensitivity). These sites usually involve small segments of DNA sequences (100 to 200 bp) and are two or more orders of magnitude more accessible to DNase 1 cleavage than inactive chromatin (1, 2). DNase 1 hypersensitive sites result from the assembly of specific nucleoprotein complexes that generally contain transcription factors flanked by positioned nucleosomes. DNase I hypersensitive sites also reflect the stable association of a transcription factor on the surface of a nucleosome (3). DNase I hypersensitive sites and nucleosome arrays are usually detected by DNase 1 or **micrococcal nuclease** digestion, followed by indirect end-labeling methodologies to map the hypersensitive site relative to a site of restriction enzyme cleavage (Fig. 1). As the most accessible regions of chromatin to non-histone DNA-binding proteins, DNase I hypersensitive sites generally denote DNA sequences with important functions in the nucleus.

Figure 1. A scheme for mapping the position of DNase I hypersensitive sites in chromatin relative to restriction endonuclease cleavage sites.

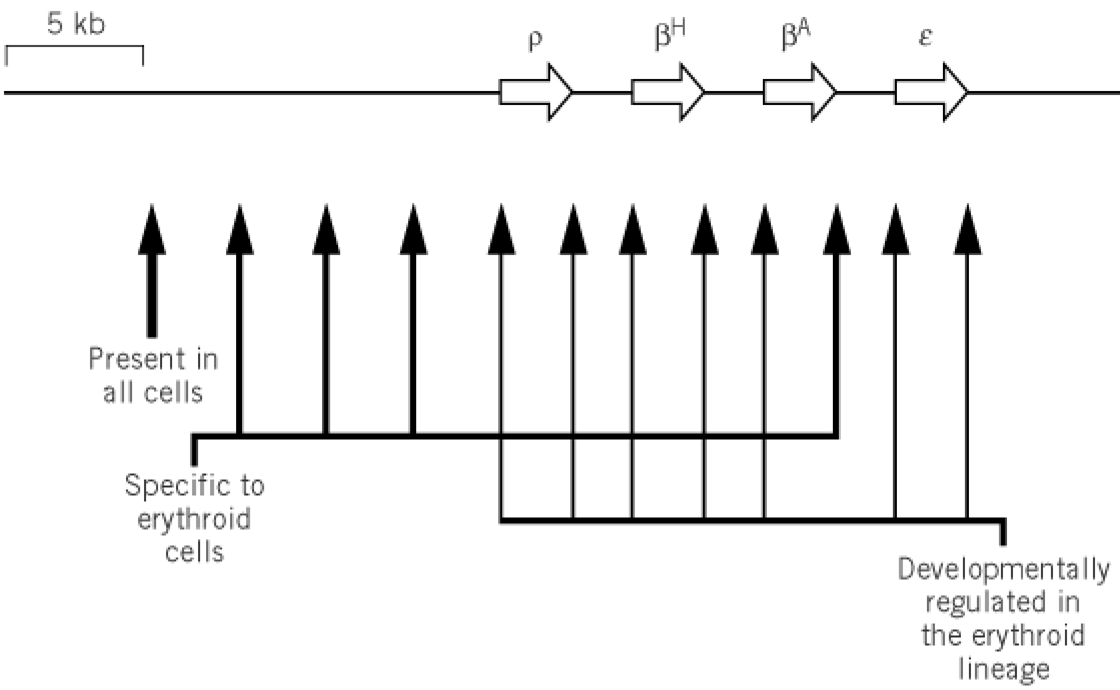


DNase 1 hypersensitive sites were first detected in the SV40 minichromosome, at the region that functions as an **origin of replication**, and in *Drosophila* chromatin (4). In general, these sites are accessible to all enzymes or reagents that cut duplex DNA. These sites have been mapped to a large number of functional segments of DNA, including **promoters**, enhancers, **locus control regions**, transcriptional **silencers**, origins of replication, recombination elements, and structural sites within or around telomeres (5).

These sites often fall into a hierarchy of patterns around regulated genes. Twelve DNase I hypersensitive sites are found in the chicken b-**globin** locus that contains four globin genes (5′-s-b^H-b^A-e-3′) and covers more than 65 kbp of DNA (Fig. 2). One site is present in all cells, independent of whether the genes are transcriptionally active or not. Three sites, upstream of the s-globin gene, were present only in erythroid cells destined to express the globin genes. These sites were initially without clear functional significance. However, a similar site was found between the b^A and e genes that corresponds to an enhancer element. Four sites were found over the promoters of each gene, depending on whether the gene was transcriptionally active, and three sites were found downstream of the genes, corresponding to transcription termination elements (the b ^{A} gene excluded). It is important to note that the formation of DNase I hypersensitive sites at the promoters of the globin genes is a relatively late step in the commitment of these genes to become transcriptionally active. However, it is clear that the formation of such sites precedes the actual initiation of transcription by

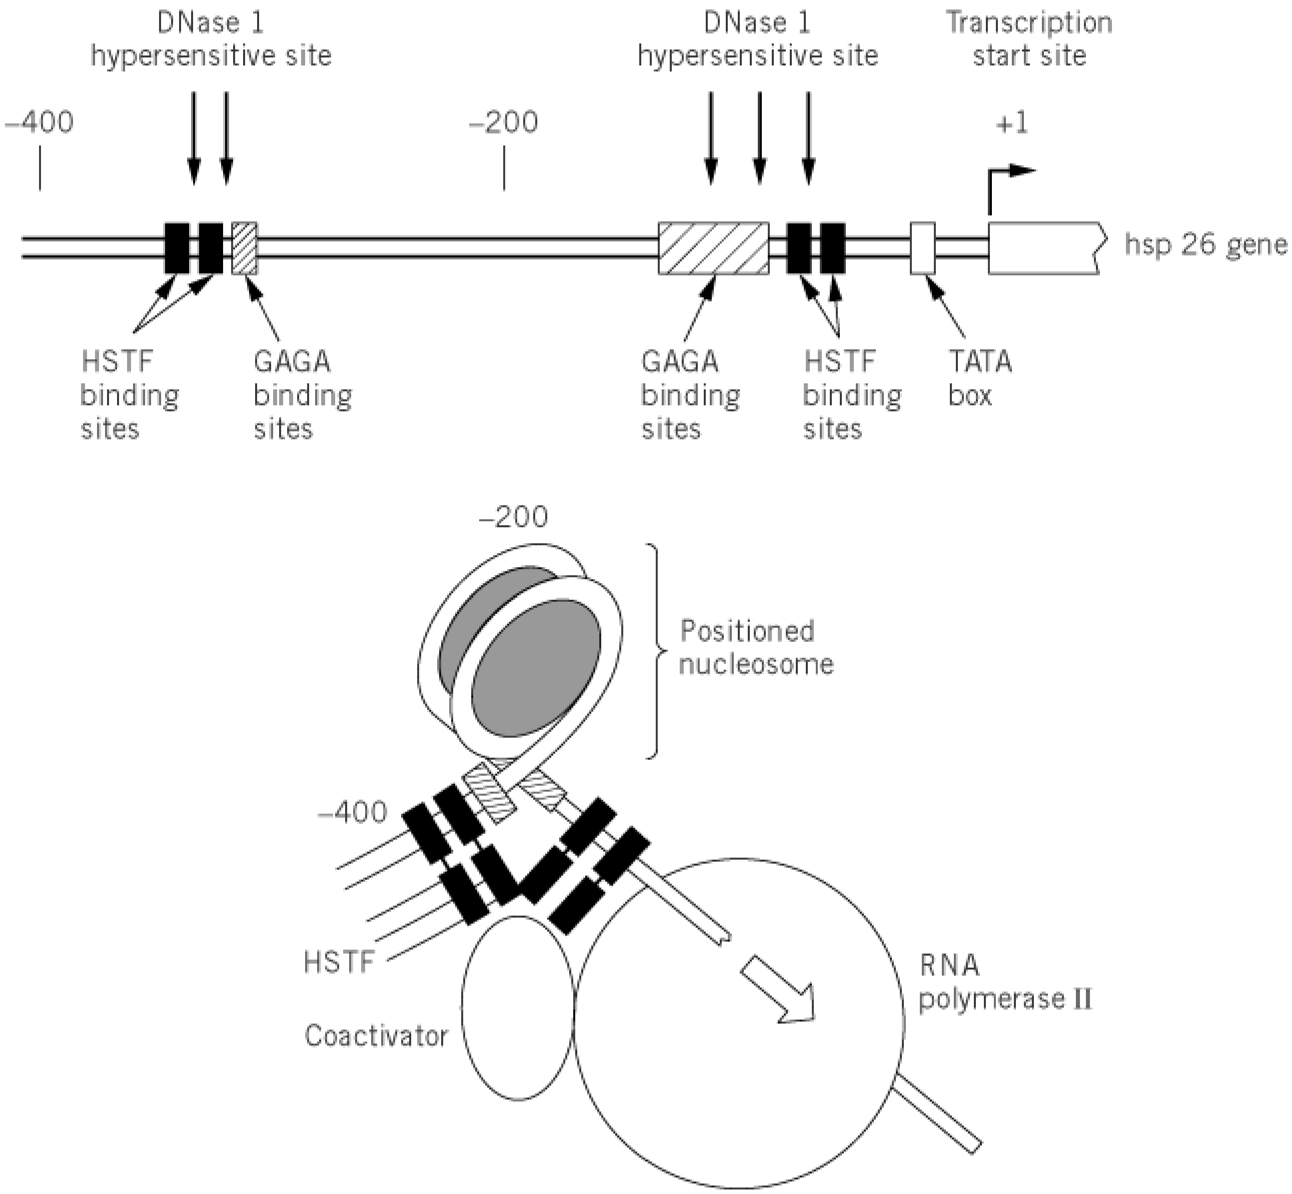
RNA polymerase. Indeed, the generation of these sites may account for a component of the general nuclease sensitivity of a gene (see DNase 1 Sensitivity) (6).

Figure 2. DNase I hypersensitive sites of the chicken b-globin locus. Contiguous genes are indicated as open arrows, the three distinct types of DNase I hypersensitive sites present in all cells specific to erythroid cells, and those that are developmentally regulated within the erythroid lineage are indicated.



One of the most thorough dissections of a DNase I hypersensitive site was carried out by Elgin and colleagues (4). The *Drosophila* **heat-shock** protein *hsp26* gene is very rapidly activated transcriptionally by raising the temperature of a fly to a stressful level (a heat shock of 34°C). Two DNase I hypersensitive sites exist at the promoter of the *hsp26* gene, including recognition sequences for the promoter-specific, heat-shock transcription factor (HSTF, a leucine zipper protein) (Fig. 3). Following heat shock, HSTF binds to these sites. In contrast, transcription factor TFIID is bound to the TATA box before and after heat shock. TFIID alone is insufficient to cause the *hsp26* gene to be transcribed, and the specific association of the HSTF protein is also required. High-resolution analysis revealed that a nucleosome is positioned between the proximal and distal binding sites for HSTF, i.e. between the two DNase I hypersensitive sites. In this case, the exact position of histone-DNA contacts within this nucleosome depends on the DNA sequence to which the histones bind (from –300 to –140 relative to the start site of transcription at +1), and also on adjacent DNA sequences. These are repeats of the type $(CT)_n.(GA)_n$, which bind a specific *transacting* factor, the GAGA protein (7). The $(CT)_n.(GA)_n$ repeat regions are located to either side of the positioned nucleosome at –347 to –341 and at –135 to –85. The GAGA factor bound to these repeats may function as a "bookend" to determine exactly where the nucleosome will be positioned. Recent evidence suggests that the GAGA factor might function through ATP-dependent mechanisms to direct the assembly of a particular chromatin architecture actively. Transcription of the gene is regulated through the association of the HSTF with recognition elements at –51,–170,–269, and –340. The sites at –170 and –269 will be wrapped around the core histones in rotational frames that prevent HSTF association. However, the wrapping of DNA around the nucleosome will also bring the HSTF molecules bound to the sites at –340 and –51 into juxtaposition, and the histones may potentially facilitate transcription by causing a clustering of HSTF activation domains. Direct evidence for transcriptional activation mediated by this nucleosome is yet to be established. It is clear, however, that the positioning of a nucleosome in this particular way allows key transcription factors to obtain access to essential regulatory elements in spite of the assembly of the gene into chromatin.

Figure 3. The specific chromatin organization of the *Drosophila* hsp26 promoter. Key cis-acting elements are indicated relative to the start site of transcription (hooked arrow). The organization of these sites on a specific nucleosomal scaffold is indicated together with the interactions necessary to prevent or activate transcription. A tethered RNA polymerase II molecule is released through events initiated by the binding of HSTF.



For a DNase I hypersensitive site on the vitellogenin genes, nucleosome positioning directed by the DNA sequence occurs between –300 and –140 relative to the start site of transcription at +1. The binding sites for the stimulatory transcription factors, the estrogen receptor and nuclear factor *1*, lie outside the region of DNA that is wrapped around the histones, at –300 to –330 and at –120 to –110, respectively (8). When these sites are brought together either by positioning a nucleosome in between them (or artificially by deleting the intervening DNA), transcription is enhanced about 5- to 10-fold. This moderate stimulatory effect is much more significant than it might appear because assembling a nonspecific chromatin structure would normally lead to a >20–fold repression of transcription as the binding sites for transcription factors are occluded by the histones. Thus in the vitellogenin gene example, nucleosome positioning has two roles: (1) to provide a scaffold that allows transcription factors to communicate more effectively; and (2) to prevent the formation of repressive histone-DNA interactions that may prevent any transcription factor from gaining access to a chromatin template.

DNase I hypersensitive sites have proven very useful in defining important DNA sequences. Among these are the four strongly nuclease-sensitive sites located 10 to 20 kbp upstream of the cluster of human b-globin genes. These sites, known as locus control regions (LCRs), represent ***cis*-acting** elements that allow genes integrated into a chromosome to be expressed independently of chromosomal position, i.e. position effects are abolished. A consequence of this is that LCRs allow each copy of a gene integrated in multiple copies to be expressed equivalently, so that gene expression is **copy-number** dependent. Therefore the LCR functions to control gene activity over an entire chromatin **domain**.

Hypervariable Locus

In general terms, a "hypervariable locus " is a genetic locus that shows a great degree of variability, or **polymorphism**, in the genomes of a population. High degrees of polymorphism occur at hot spots of mutation or recombination, or they can be the consequence of a continuously varying strong natural selection pressure on a locus, such as that exerted on the **major histocompatibility locus**. The term "hypervariability" is normally used, however, to indicate the instability of minisatellites, which is related to their sequence of 15 to 60 bp being tandemly repeated. The mutation frequency for changes in the number of tandem repeats has been estimated to vary between 10^2 and 10^4 per kbp per generation, which is one to three orders of magnitude higher than the rate of point mutation (1). **Unequal crossing over** within such a tandem repeat is likely to be an important generator of asymmetrical new alleles (2). Jeffreys noted that the core of his first hypervariable minisatellite shared some sequence characteristics with the **Chi sequence** of lambda phage, a signal for homologous recombination, which is probably achieved by binding a **Rec** protein that locally unwinds and nicks DNA (3). The hypothesis that minisatellites are recombination hotspots has been partially confirmed by the observation that most highly variable human minisatellites tend to be located in the subtelomeric regions of chromosomes (see Telomere), precisely those that exhibit high recombination rates (4).

Changes in the lengths of minisatellite repeats occur both in the **germline** and in **somatic cells**, possibly by sister chromatid exchanges. Somatic length mutations may represent markers of tumor cell progression and variation (5). With some hypervariable minisatellites, no difference has been found between the frequency of germline mutations in **oocytes** or **spermatocytes**. Given the large difference in the number of **mitosis** events that follow **meiosis** in the female and male germlines, it would seem that the cause of mutation is not always mitosis-dependent (6). Also, for some minisatellites, closely related **alleles** show the same flanking DNA sequences, whereas for other minisatellites flanking **haplotype** switching is observed. It should be concluded that recombinational events within minisatellites are not always the cause of length mutation.

Another mechanism possibly responsible for length mutation is slippage of the **DNA polymerase** during replication of the minisatellite, with the consequence of variation in one or very few units (7). A computer simulation to estimate the expected number and size range of alleles under a stepwise, replication slippage mutation model explained the available data better with the shorter microsatellites than with minisatellites (8).

Recently, methods have been devised for analyzing mutant alleles of single minisatellites by the polymerase chain reaction (**PCR**). Several features of the variability observed, such as its polarity, the addition of elements without evidence of **crossing over**, and rearrangement of elements with respect to their sequence in the homologous chromosome, suggest the involvement of complex **gene-conversion**-like events in the generation of mutant alleles (9).

I-Motif

The complementary DNA strand of the telomere TTGGGG sequence, CCCCAA, adopts an unusual DNA structure at low pH. The structure was first proposed by a NMR analysis (1) and later confirmed by X-ray crystallography (2) of cytosine-rich sequences under low pH conditions. It contains a highly unusual, mutually intercalated, four-stranded structure. This structure has been dubbed the i-motif, where two parallel duplexes intercalate with one another in an antiparallel orientation (Fig. 1). Each parallel duplex consists of hemiprotonated $C:C^+$ base pairs. It is unclear whether such a structural motif is associated with any biological function at present.

Ideogram

An ideogram is a diagrammatic representation of the karyotype that shows all of the pairs of homologous chromosomes in the nucleus. The pairs of chromosomes are lined up in order of size, so that the centromeres are aligned and the short arm is uppermost. An ideogram is a useful point of reference for analyzing mutations.

Idiotypes

The concept of the idiotype of **immunoglobulins** emerged in the early 1960s from two different approaches, one by Oudin with rabbit **antibodies**, the other by Kunkel and analysis of the immunochemical characteristics of human myeloma proteins. At the time, Oudin had described the allotypic specificities as defining **antigenic** characteristics of a group of individuals within a given animal species. This was observed for rabbit immunoglobulins and was the consequence of **allelic** variants of both the heavy and light chains. It was then found that when rabbit antibodies prepared against *Salmonella typhi* were injected into another rabbit expressing the same (known) allotypes, they induced the synthesis of antibodies that specifically recognized the anti-*Salmonella* antibodies raised in the first rabbit. It was also shown that they did not react with normal rabbit serum taken before the *Salmonella* injection, thereby excluding that they identified a new allotypic specificity. Idiotypic specificities were thus defined as antigenic specificities characteristic of one antibody (the idiotype) produced by one animal and specific for one given antigen. Antibodies produced by the second animal were termed **anti-idiotypic antibodies**. Idiotypes are also referred to as Ab1 while anti-idiotypes are referred to as Ab2, in a simplified nomenclature.

At the same time, Kunkel was comparing the immunochemical characteristics of human myeloma proteins with those of normal immunoglobulins. He found that antibodies raised against one given myeloma protein, which cross-reacted against normal immunoglobulins, became specific for the immunizing protein once extensively adsorbed on normal immunoglobulins. This was taken as indicative of determinants specific for any given monoclonal product, although it was not entirely clear whether it was also linked to the pathological “abnormal” nature of the myeloma protein.

Structural analysis confirmed, as anticipated, that idiotypic determinants, or idiotopes, were present on the Fab fragments and, more precisely, on the variable regions of H and/or L chains (see Immunoglobulin Structure), depending on the idiotype. Extensive analysis of idiotype structure performed by a combination of immunochemical and structural analysis of anti-**hapten** antibodies revealed several types of idiotopes. Some Ab1–Ab2 interactions could be inhibited by a hapten of Ab1, indicating that the corresponding idiotopes were part of the antibody combining site, whereas other were not. Genetic analysis also revealed that some idiotypic specificities were common to several idiotypes, whereas others were strictly specific for one given Ab1, leading to the distinction of public and private idiotypes, a notion that was directly related to the dual origin of antibody diversity, germline encoded and somatically generated. Idiotypy was studied extensively when it was discovered that the cascade Ag(X) → Ab1 → Ab2 could be continued and amplified in a large idiotypic network of interactions, providing a basis for autoregulation of the immune system. An especially interesting observation was that Ab2 could induce certain Ab3 molecules that resembled Ab1 in that they could bind the original Ag(X) antigen. This led to the definition of the “internal image” of the antigen, proposed by Jerne, containing the idea that the collection of normal immunoglobulins of an individual could represent a huge population of internal images of the outside antigen world. It also stimulated approaches of idiotypic vaccines that could have been used in place of classical antigens, an interesting idea whenever antigens were either difficult to identify or poorly immunogenic.

IgA

Immunoglobulin A (IgA), accounts for about 10% to 15% of the circulating **immunoglobulins**. The main feature of IgA is its presence in high concentrations in all mucosal secretions (intestine, lung, colostrum, tears, etc.), and for this reason it is generally considered of prime importance in fighting pathogens, against which it constitutes a first line of defense. The presence of elevated amounts of IgA in secretions correlates with their special structural features, namely their ability to dimerize and to have an extra Ig secretory component added upon passage through epithelial cells.

The basic Ig structure of IgA is a classical H_2 L_2 monomer in which the heavy chains are a chains, composed of the usual V_H region and three C_H domains. In humans there are two **isotypes**, IgA1 and IgA2, encoded by distinct C_H genes. As a result, the two isotypes differ from each other by small amino acid sequence differences and by the length of their hinge regions. In addition, the IgA2 isotype has two **allelic** variants, recognized by specific antisera as two distinct allotypes, IgA2 m(1) and IgA2 m(2). The IgA2 m(1) has a special structural feature, because its heavy chain lacks the cysteine residue that is covalently **disulfide-bonded** to the light chains in other isotypes; consequently, the H–L interactions are exclusively noncovalent, whereas the light chains are covalently dimerized. Carbohydrate moieties account for about 10% of the molecule and are mostly attached in the vicinity of the hinge region. In the serum, the IgA are essentially monomeric, whereas they polymerize in the vicinity of epithelial cells, with the formation of dimers (major), but also trimers and tetramers. When polymerized, the IgA gains an extra chain, termed the J chain [which as not the same as the **J (joining) region**], which is disulfide-bonded to part of the IgA heavy chains. Once dimerized, the IgA molecule is covalently bound to the poly-Ig receptor, expressed at the basal pole of the epizthelial cell. This complex is internalized, and the polymerized IgA is released at the apical pole of the cell in the lumen of the corresponding organ upon **proteolytic** cleavage between two **domains** of the poly-Ig receptor, so that one subunit remains covalently linked to the IgA polymer, forming the so-called secretory component. Besides allowing the IgA to migrate through the epithelial cell, the secretory component is thought to protect the immunoglobulin from cleavage by proteinases. The local concentration of IgA may be very high and, due to its polymerized state, this Ig has an increased avidity for antigen. Because of its abundance in colostrum, it is of crucial importance for passive antibody transfer to the newborn and thus ensures a temporary protection against pathogens, because the immune system will remain immature for some time. It should be recalled, however, that the protective effect of colostrum and/or milk greatly varies from one species to the other. Whenever the placental barrier is easily passed by an active transfer of IgG, the importance of colostral IgA is minimized. In humans, protection is ensured by transplacental transfer. An example of the reverse situation is seen in cattle.

Mucosal immunity, as immunologists like to refer to it whenever IgA is involved, is presently a rapidly expanding field. It has not been studied sufficiently, considering that it appears to be of prime importance in fighting against pathogenic microorganisms.

IgD

IgD is an immunoglobulin that is present on the surface of mature B cells. Its circulating concentration is in the range of 40–400 µg/mL, which does not contribute significantly to the overall amount of secreted Ig (compare with the 10 mg/mL range for IgG). IgD exists as only one isotype and is exclusively a d_2k_2 or d_2l_2 monomer. The d chain in humans has three **constant domains**, whereas there are only two in murine species, in which Cd_2 is replaced by an unusually long hinge region. The main characteristic of IgD is to be essentially coexpressed at the surface of the same B cell with IgM. This does not contradict the clonal selection theory, because the two B-cell receptors express the same variable regions and hence have the same antibody specificity. This is because the switch region that is located at the 5′ position of all C gene isotypes is absent from the Cd locus. Coexpression of m and d chains results from alternative splicing, thus leading to both IgM and IgD that are associated to same k or l chains within a given B cell. Occasionally, clones expressing solely IgD without IgM can be encountered. This is most apparent in rare myeloma cells that are IgD producers. In that case, the absence of IgM probably results from a deletion of the Cm genes at the genomic level. This seems also to be the case of a recent observation of B cells detected in human tonsils that express exclusively IgD and have surprisingly accumulated an unusually large number of somatic mutations. Despite their very peculiar specialization as surface Ig, the role of IgD is still very poorly understood, although some arguments point to their possible role in B-cell induction of **tolerance**.

IgE

IgE is the immunoglobulin most commonly known as the main cause of anaphylaxis or, more generally speaking, of the immediate hypersensitivity states, such as asthma, hay fever, atopic dermatitis, and other well-known manifestations of atopic patients. IgE is present in normal individuals at very low concentrations, normally somewhat less than 1 µg/mL. This concentration may be considerably elevated in patients suffering from one or another form of immediate hypersensitivity, and also in patients with internal parasite infections. This points to a major role as support of anaphylactoid states and suggests a possible role in the defense against parasites, a view that has been seriously reinforced of late.

IgE is a monomer of molecular formula $\epsilon_2 k_2$ or $\epsilon_2 l_2$. It may, as all the other Ig subclasses, be expressed as cell-surface or circulating Ig, and it has an elevated carbohydrate content (>10% by weight). The ε chains have four constant Cd **domains**, and the molecular weight of IgE averages 180 kDa. IgE does not fix **complement** and is heat-labile. Its role in driving the immediate hypersensitivity reactions is due to the fixation of circulating IgE antibodies on **Fc receptors** of very high affinity; FcRεI is located on several cell types, mostly basophils and mast cells. These large cells contain granules that contain a high concentration of pharmacologically active substances, like histamine, neutral proteinases, proteoglycans, and **tumor necrosis factor a**; (TNFa). Contact of an antigen (here denominated an allergen) with specific IgE fixed to such cells of an atopic patient who has already been sensitized will activate the target cell and release the pharmacologically active substances, thus initiating a large cascade of secondary reactions. Histamine will bind selectively to H1-type receptors and exert various deleterious effects, such as vasodilatation, local exudation, and spasmogenic activity of intestinal, uterine, or bronchial muscles, depending on the localization of the target. TNFa liberated upon mast-cell activation may have a beneficial effect in antimicrobial defense. Other mediators are synthesized as a response to IgE triggering. Those include prostaglandins, PGD2, leukotrienes, and so on, and a large number of **cytokines** that considerably amplify the response and especially initiate a strong inflammatory reaction. Fixation of IgE on other cell types, like eosinophils, **macrophages**, or platelets, can also occur through the FcεRII, which is of lower affinity than FcεRI, and trigger liberation of many mediators, including free radicals that may be beneficial by helping to fight against pathogens, although most of the effects are quite aggressive for the host tissues.

Discovery of the two main populations of helper T cells, Th1 and Th2, which drive a fine regulation of the immune response through a complex network of cytokines, has opened the way to a reinvestigation of the possibility of modulation of the expression of IgE, which is of prime importance for atopic patients, but also to fight more effectively against parasites, which remain quite elusive pathogens to date. IgE production is essentially driven by cytokines of the Th2 group, particularly interleukin 4, which was shown to favor the **class switch** to this Ig class.

IgG

IgG is the major class of immunoglobulin (Ig) and has long been taken as the basic Ig model. IgG are found either as free circulating molecules in the bloodstream, where they account for about 70% of total Ig, or anchored at the B-cell surface, constituting the B-cell receptor in association with the IgaIgb heterodimer signaling module. They contain two g and two light chains, either k or l, and about 2% by weight of carbohydrate, located on the CH $_2$ **domains**. IgG is expressed as four distinct subclasses, termed IgG1, IgG2, IgG3, and IgG4 in humans, resulting from the presence of the corresponding g1 to g4 heavy chains encoded by separate germline Cg genes. The four **isotypes** have minor structural differences, both in the length of their hinge region and in primary structure, which remain 95% identical; this suggests that the amplification of g isotypes is a rather recent event. IgG subclasses also exist in other species. In the mouse there are also four discrete isotypes called IgG1, IgG2a, IgG2b, and IgG3. That there is no correspondence between the various human and mouse isotypes confirms that the subclass expansion is characteristic of each animal species and occurred after they diverged. The different isotypes are endowed with somewhat different biological properties. All except for IgG4 bind **complement**. The first component of the complement cascade, C1q, has a binding site on the C $_H$2 domain. This site becomes accessible once the antibody molecule has interacted with antigen, presumably as the result of an opening of the Fab–Fc angle, which is made possible because of the flexibility of the hinge region (see Immunoglobulin Structure). The IgG subclasses bind to different **Fc receptors**. The major subclass is IgG1, followed by IgG2. Expression of the various subclasses during development follows different kinetics, with IgG2 and IgG4 being synthesized only slowly after birth. Allotypic markers termed Gm factors have long been identified on IgG and have provided an interesting basis for studying human population genetics.

IgG can be cleaved, in the native state, by a variety of **proteolytic** enzymes, due to the flexibility of the hinge region and to the somewhat accessible short regions that separate the various domains. Porter (1) reported the isolation of Fab and Fc fragments upon cleavage with papain; IgG may also be cleaved with **pepsin**, which largely destroys the C_H2 domain, leaving a $(Fab')_2$ fragment, which has two pieces slightly larger than an Fab **disulfide-bonded** through the inter-heavy-chain bridges that have remained untouched, and the Fd′ fragment, which covers roughly the C_H3 COOH-terminal domain. Cleavage with **plasmin** cleaves off the last C_H3 domain, leaving a major Facb fragment (for antibody and complement binding). Finally, it is possible in a limited number of cases to release the variable V_H-V_L domains noncovalently bound as the Fv fragment, which contains one intact antibody combining site. The three-dimensional protein structures of the isolated domains are quite independent of their interactions with other parts of the IgG molecule. Extensive protein engineering has been made on this structure, by introducing the corresponding complementary DNAs into vectors that are expressed in bacteria or other systems, such as the baculovirus. Extensive phage display libraries have been constructed that provide a huge combination of V_H–V_L pairs having an almost infinite set of discrete recognition Ig-like molecules.

During the early phases of the primary immunization, IgM is rapidly replaced by IgG upon class switching, a molecular mechanism that operates at the genomic level, leading to the replacement of one isotype by the other, without changing the variable regions and thus conserving the antibody specificity. Somatic hypermutations occur primarily in IgG molecules, so they become increasingly adapted to the exquisite recognition of **epitopes** of the immunizing antigen. This implies both an enzymatic mechanism for mutations and a strong selection exerted by the antigen itself on IgG-producing B cells. Some of the selected clones with high affinity will ultimately differentiate into plasma cells and produce circulating IgG, whereas others will become memory cells, expressing membrane IgG of high affinity that will rapidly react in a subsequent reexposure to the antigen, initiating a secondary response.

IgM

Immunoglobulin M (IgM) is the first immunoglobulin to appear after immunization, the first to occur in ontogeny and in phylogeny, and the first to be expressed at the surface of B cells during their differentiation. Most of these properties are a result of the fact that the genes encoding their C_H regions are the closest to the V_H locus. IgM is built on the classical H_2L_2 model as either m_2k_2 or m_2l_2 monomers (see Immunoglobulin Structure). As such, these monomers are expressed at the B-cell surface, where they represent, associated with the Iga–Igb heterodimer signaling module, the B-cell receptor that interacts with the immunogen upon primary immunization. In the serum, most of the circulating IgM is a pentamer, $(m_2k_2)_5$ or $(m_2l_2)_5$, in which monomers are covalently **disulfide-bonded**, a linkage that involves the addition of theJ chain, similar to that present in the IgA dimer. The constant region of the m chain does not contain a hinge region, but instead has an additional C domain, as compared with IgG. IgM has a high content of carbohydrate (10% to 12% by weight) which is bound at ***N*-glycosylation** sites of the first three Cm domains.

The basic monomer has a molecular weight of 180 kDa, and the pentamer has a molecular weight of about 970 kDa. Because of their size, circulating IgM subclasses were originally designated as macroglobulins. They are found in a lymphoproliferative disease, the Waldenstrom macroglobulinemia, where they are overexpressed as the result of the malignant amplification of an IgM-producing B-cell clone. In normal serum, IgM accounts for 10% to 15% of the total circulating immunoglobulins. IgM behaves as expected as decavalent antibodies for binding to **epitopes**, provided that they are located on a small antigen, such as a hapten. On larger antigens, as a result of steric hindrance, IgM pentamers will interact with at most five molecules of antigen. Individual antibody-combining sites are most often of low affinity but the pentamerization potentiates the binding efficiency, demonstrated by the “avidity” of the antibody, a typical immunologist parameter not really defined in mathematical terms. IgM is very efficient in **complement** binding and thus is highly lytic for cellular targets, which may be bacteria or eukaryotic cells like red blood cells; in this case one uses the term *hemolysins*, rather than *hemagglutinins*, when the complement component is not participating in the final reaction.

The so-called natural antibodies are most often of the IgM type. This is the case of natural anti-A and anti-B hemagglutinins, described as the classical **alloantibodies** responsible for major transfusion incompatibilities. More generally speaking, natural antibodies are frequently endowed with **autoimmune** recognition properties and thus may bind a large variety of molecules, such as tubulin, actin, double-stranded DNA, and so on. These natural antibodies are harmless and most likely represent the basic repertoire of germline-encoded immunoglobulins, which therefore have nearly no somatic mutations. As a result, their specificity is very low, which makes them bind many antigens, although usually only weakly. Why these antibodies are not aggressive to the organism is still subject to debate, although the combination of two parameters, low affinity and low concentration, is possibly the answer.

As already mentioned, IgM is the first group of isotypes to be produced upon primary immunization. Whenever the antigen is T-dependent, which is the most frequent situation, IgM is rapidly replaced by IgG, which will warrant a better affinity because of the acquisition and selection of somatic hypermutations. Immunization with polysaccharides, which are essentially T-independent antigens, will thus be limited to the production of IgM antibodies. In phylogeny, IgM is also the first group of immunoglobulin classes that have been identified in primitive fishes. It should be mentioned that the classical immune response, with the existence of circulating antibodies, seems to have occurred with the lower vertebrates. Invertebrates have, however, other types of responses to fight very efficiently against pathogens.

Illegitimate Recombination

Illegitimate recombination includes those events that do not fall into any of the more clearly defined categories of recombination (homologous recombination, **site-specific recombination**, and transposition). Illegitimate recombination may itself include an assortment of types of events. Parental DNA molecules or DNA segments in illegitimate recombination often share a few homologous base pairs. Some of these events result from DNA replication errors and others from joining broken DNA ends. Illegitimate recombination generates deletions and translocations and therefore can have profound genetic consequences.

One type of illegitimate recombination widely studied in bacteria results from slippage between the template and newly replicated DNA strands. The prototype for this mechanism is that suggested by Streisenger et al. (1) for generating frameshift mutations at points of repeated nucleotides. For example, DNA containing on one strand A_5 can generate A_4 or A_6 by loss or gain of a base pair by the following proposed mechanism. Replication pauses within the repeat. The newly synthesized strand unwinds and anneals with the template, but out of register, leaving one or more nucleotides as a single-stranded loop on either the template or the newly synthesized strand. Replication resumes, and this newly synthesized strand has fewer or more nucleotides than the parent. In the absence of repair synthesis, another round of faithful replication fixes the mutation.

A similar event can occur between direct repeats of any sequence that may or may not be separated by intervening base pairs. If the repeats do not themselves have internal repeats, interaction between them produces a deletion or duplication of one copy of the repeat plus the intervening sequence. One could imagine that these events occur by homologous recombination where the repeats are out of register (unequal crossing over), but in *Escherichia coli* these events are independent of known homologous recombination functions. The events are not reciprocal, that is, a deletion is not formed concurrently with a duplication. Deletions can occur between repeats separated by thousands of base pairs, although the frequency decreases as this separation becomes larger (2).

Linear DNA introduced into mammalian cells by transfection often undergoes illegitimate recombination by integration into the genome or by end-joining. End-joining has been extensively studied and occurs by ligation of the ends without any apparent requirement for homology. If excision of nucleotides from one or both ends occurs before or after transfection, a few homologous base pairs may be exposed, and annealing may occur between them. Filling of gaps and ligation can generate a novel joint. These events may be paradigms for integration of exogenous linear DNA and for chromosomal translocations. These events typically occur between DNA molecules sharing little or no homology and may occur between broken chromosome ends that swap partners and rejoin.

The DNA ends that provoke illegitimate recombination may be generated by a variety of mechanisms. Linear DNA may be introduced into cells, as in transfection. Restriction Enzymes may be induced to cut DNA at special sites in cells. DNA **topoisomerases** make transient double-strand breaks that may be illegitimately rejoined. This process is stimulated by topoisomerase inhibitors. Pausing or termination of DNA replication generates single-strand gaps whose ends may provoke illegitimate recombination, perhaps after conversion of the gap into a double-strand break. The variety of mechanisms that generate breaks may account for the variety of types of illegitimate recombination observed in cells.

Illegitimate recombination is not entirely a haphazard process. Regulated forms of this process occur in generating functional immunoglobulin genes by gene rearrangements and in eliminating micronuclear DNA in *Tetrahymena* **macronucleus** development. Other types of recombination previously considered illegitimate are recognized now as site-specific recombination and transposition. Further studies of illegitimate recombination may reveal unappreciated mechanisms and the biological roles of these events.

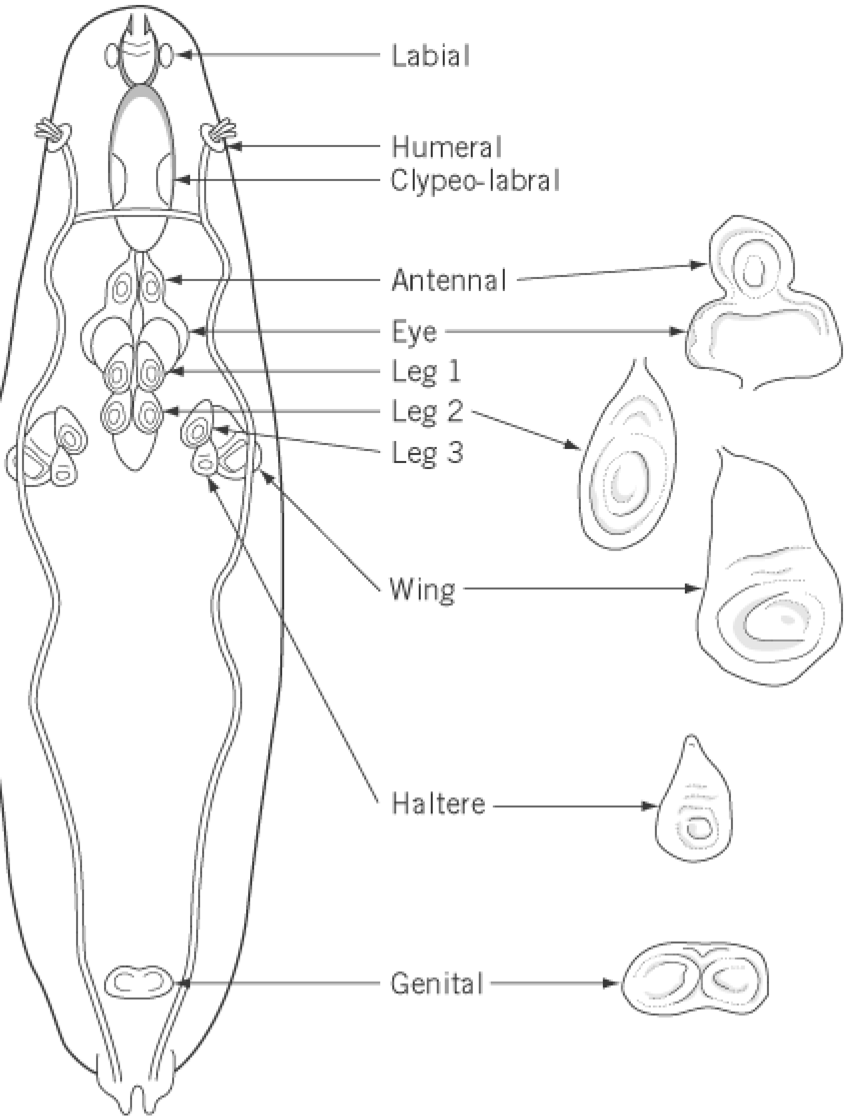
Imaginal Disc

The past decade has witnessed enormous progress in understanding the molecular mechanisms that control the development of imaginal discs in insects. Lessons obtained from the studies of imaginal discs are being used to unravel mechanisms underlying vertebrate development, because many **genes** and developmental pathways are conserved throughout evolution.

The development of imaginal discs is a feature unique to the holometabolous insects (beetles, moths, flies, and butterflies). The life cycles of holometabolous insects include four stages: embryo, larva, pupa, and adult (also known as *imago*). Development through these stages does not occur simply by increasing the sizes of exiting structures; instead, it involves a dramatic transformation from larva to adult. The transformation is achieved by the replacement of larval tissues with a special population of cells, known as *imaginal discs*, which form sac-like structures residing inside the larva. Imaginal discs have been studied most extensively in the fruit fly *Drosophila melanogaster* (1-4). There are 10 major pairs of imaginal discs, which give rise to adult cuticular structures of the head and the thorax, and a single genital disc, which forms the adult genitalia. The location of the imaginal discs in the mature larva (third instar stage) is illustrated in Figure 1. Studies in *Drosophila* have shown that imaginal discs are initially set aside during embryogenesis, apart from most embryonic cells that will contribute to the larva. In the embryo, the imaginal disc precursor cells can be visualized by the expression of molecular markers or by their particular sizes, shapes, and movement. The imaginal discs appear in the newly hatched larva as local thickenings of the epidermis and, in the case of the wing disc, contain around 40 cells (5). Subsequently, the imaginal disc cells proliferate rapidly during larval stages. By the end of the larval stage, the largest imaginal disc, that of the wing, contains approximately 50,000 cells (6). During pupation, the imaginal disc cells go through morphogenetic movements, in response to a pulse of the molting hormone ecdysone, to give rise to specific adult structures, accompanied by the breaking-down of the larval tissues.

Figure 1. Locations of imaginal discs in a third instar larva, and the morphology of several major imaginal discs. There are 10 major pairs of imaginal discs, which give rise to adult cuticular structures of the head and the thorax, and a single genital disc, which forms the adult genitalia. (After Ref. 86)



The molecular studies of imaginal discs in *Drosophila* have been addressing the following major questions. First, how are the imaginal disc precursor cells set aside (or established) during embryogenesis? Second, how is the growth of imaginal discs in the larva regulated? Third, how do developmental patterns form in the mature imaginal disc along its anterior–posterior, dorsal–ventral, and proximal–distal axes? And fourth, how is the identity of a given imaginal disc specified? The following is a brief summary of our current understanding on these topics.

1. Establishment of the Imaginal Disc Precursor Cells in the Embryo

The fate of imaginal disc precursor cells is determined by intersecting anterior–posterior and dorsal–ventral signals in the embryo. These signals are provided by two sets of patterning genes along the embryonic anterior–posterior and dorsal–ventral axes. Along the anterior–posterior axis, a regulatory hierarchy involving gap genes, pair-rule genes, and segment polarity genes determines the different cell fates. In particular, the activities of several segment polarity genes, including ***wingless*** (*wg*), ***engrailed*** (*en*), *patched* (*ptc*), and ***hedgehog*** (*hh*), are required for the consolidation of the parasegment boundaries, which appear during early development of the embryo (7, 8). Among these genes, *wg*, encoding a secreted molecule of the Wnt family of proteins (9), is required for the establishment of the thoracic wing and leg discs, which originate from primordia spanning the parasegment boundaries (10, 11). Like the anterior–posterior axis, the embryonic dorsal–ventral axis is also patterned by a hierarchy of maternal and zygotic genes. In particular, the decapentaplegic (dpp) protein, a member of the **transforming growth** factor b (TGF-b) gene family of signaling molecules (12), and other molecules in the dpp signaling pathway function to specify dorsal cell fates (13, 14). In contrast, the DER protein, the *Drosophila* **EGF receptor** homologue, and other genes in the DER signaling pathway are required to specify ventral cell fates (15, 16). The positions of the thoracic disc precursor cells along the dorsal–ventral axis are determined by the combined repressing activities of the dpp and the DER proteins, which limit the thoracic disc precursor cells to lateral positions of the embryo (17). Therefore, the thoracic disc precursor cells are established by the intersecting signals of Wg along the anterior–posterior axis, and dpp and DER along the dorsal–ventral axis.

2. Regulation of the Imaginal Disc Growth in the Larva

As mentioned above, imaginal discs increase their number of cells by thousands of fold during larval development. Misregulation of disc growth can result in imaginal discs with abnormal sizes and morphology. Genetic studies have identified a large number of mutants that are either defective or excessive in disc growth. The disc overgrowth mutants are of particular interest, because they may provide genetic models for tumor suppressor genes in humans. Recessive mutations in several dozens of genes have been identified that cause two types of disc overgrowth phenotypes: hyperplasia and neoplasia (18-20). Hyperplastic discs retain the normal epithelial organization and the capacity to differentiate, whereas the neoplastic discs do not. These several dozens of genes are known as tumor suppressor genes in *Drosophila*, and over 10 of them have been characterized molecularly. For example, one of these genes, *lethal(1)discs large* (*dlg*), is the first identified member of a evolutionary conserved family of proteins, called membrane-associated guanylate kinase homologues (MAGUKs) (21). In *Drosophila*, *dlg* is localized at and required for the formation of septate junctions in epithelial cells, and loss of *dlg* function causes epithelia to lose their organization and overgrow (22). Further studies of these *Drosophila* tumor suppressor genes are likely to shed light on general mechanisms in the regulation of cell proliferation.

3. Pattern Formation in the Imaginal Discs

3.1. Anterior–Posterior Patterning

Previous studies have shown that imaginal discs are subdivided into distinct cell populations, called compartments (23, 24). The compartmental boundary serves as a line of lineage restriction, and cells in one compartment do not intermingle with cells in the other. The anterior and posterior compartments of the thoracic discs can be traced back to the embryonic stage when the disc precursor cells are specified initially along the anterior–posterior axis of the embryos (25). In these discs, the posterior compartment is defined by the expression of the transcription factor *engrailed* (*en*) (26), which activates the expression of *hedgehog* (*hh*) in the same compartment (27, 28). In the wing disc, the hedgehog protein synthesized in the posterior compartment diffuses a short distance into the anterior compartment to induce the expression of *dpp* in a stripe of cells just anterior to the anterior–posterior boundary (27, 29). The decapentaplegic protein in turn acts as a long-range morphogen to organize the growth and patterning of the whole wing (30, 31) (Figure 2). The leg disc is very similar to the wing disc, except that in the leg disc the induction of *dpp* by the hedgehog protein is limited to the adjacent dorsal anterior cells, whereas the adjacent ventral anterior cells are induced by the hedgehog protein to express *wg* (32, 53). In addition, *dpp* and *wg* mutually repress the transcription of each other (Figure 3) (34, 35). The unpaired genital disc consists of three primordia, the female genital, the male genital, and the anal primordia. Each primordium of the genital disc is divided into anterior and posterior compartments. Here, *hh*, *dpp*, and *wg* are used to pattern each primordium in a manner similar to how they function in the leg disc (36, 37). In contrast to the wing, leg, and genital discs, the eye disc is not divided into any lineage-restricted compartments. Pattern formation in the eye disc is accompanied by movement of the morphogenetic furrow (MF), a morphological distinguishable indentation, which sweeps across the eye disc from posterior to anterior. Cells anterior to the MF are undifferentiated, whereas cells posterior to the MF undergo cellular differentiation (37). The initiation of eye disc differentiation is regulated by interactions between the positive regulator *dpp* and the negative regulator *wg*. Subsequently, the progression of differentiation requires *hh*. Despite the lack of the anterior and posterior compartments, the regulatory relationships between *hh*, *dpp*, and *wg* are retained in the eye disc. It has been shown that *dpp* and *wg* suppress the expression of each other, and the hedgehog protein produced by cells posterior to the MF induces *dpp* expression within the MF (39, 40).

Figure 2. Axis formation and gene expression in the developing wing. In the first instar larva, the wing disc has already posterior compartment is identified by the expression of *engrailed* (26). In the second instar larva, the dorsal–ventral axi identified by the expression of *apterous* (33). The dorsal-specific expression of *apterous* is maintained during third larva begins to be expressed in a region slightly anterior to the anterior–posterior boundary (87). The dorsal and ventral surfac of the late third instar disc: the perspective ventral surface folds under the dorsal one, while the wing blade unfolds and l wing blade region (X) is placed at the tip of the wing.(After Ref. 54.)

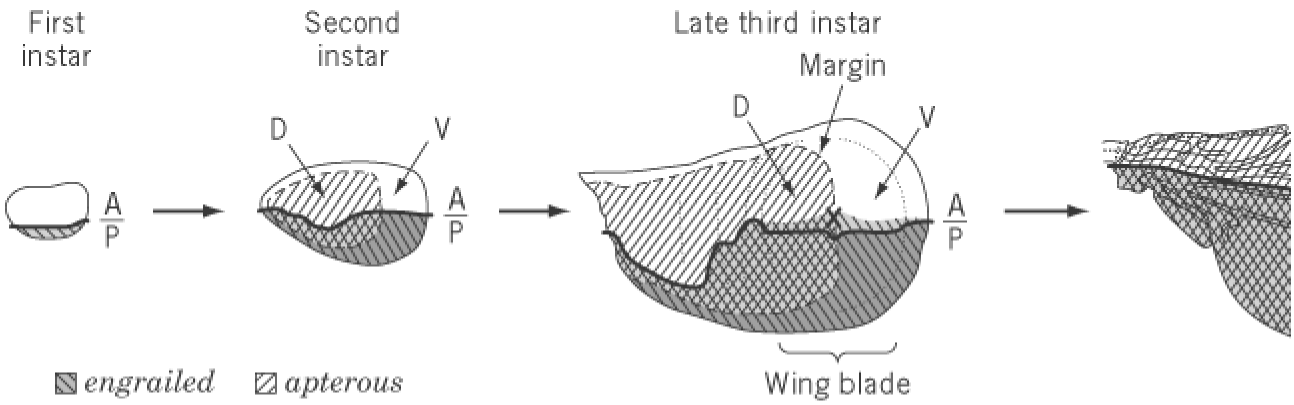


Figure 3. Spatial expression and regulatory interaction between *hedgehog* and other genes in the leg imaginal disc. The l cells diffuses across the anterior–posterior compartment boundary; it induces the adjacent dorsal anterior cells to express anterior cells to express *wingless* (32, 55). The central region of the disc, where *decapentaplegic* and *wingless* are coexpr and *aristaless* and defines the distal tip of the leg (68-70).(After Ref. 32.)

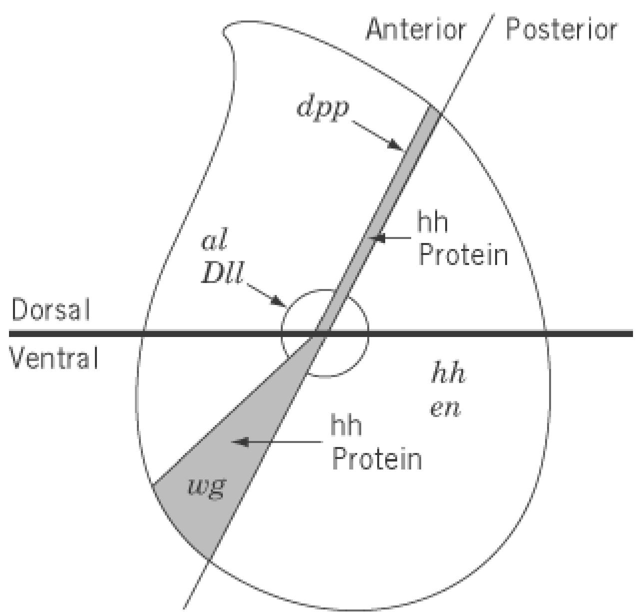

Several other components of the hedgehog signal transduction pathway have been identified. Positively-acting components of the pathway include the seven transmembrane protein smoothened

(41), the kinase fused (42), and the transcription factor **cubitus interruptus** (43); negatively-acting components of the pathway include the transmembrane protein patched (44, 45), protein kinase A (46-49), and the **kinesin**-related protein costal2 (50). The current model suggests that the patched and smoothened proteins constitute the receptor for the hedgehog signal (51). The cubitus interruptus protein, which is expressed only in the anterior cells due to the repression by the engrailed protein in the posterior compartment, forms a protein complex with the fused and costal2 proteins (50, 52). In some anterior cells, the cubitus interruptus protein is cleaved to generate a truncated form that translocates to the nucleus and represses *dpp* transcription. The hedgehog protein inhibits the proteolysis of the cubitus interruptus protein, leading to the expression of *dpp* in a stripe of anterior cells adjacent to the anterior–posterior boundary (53).

3.2. Dorsal–Ventral Patterning

During the second instar larval stage, the wing disc is also divided into dorsal and ventral compartments (23). The dorsal–ventral compartmental boundary lies at the future wing margin, which separates the upper surface of the wing from the lower one. Wing formation depends on the interactions between the dorsal and ventral cells (54). The dorsal selector gene *apterous* (*ap*), which encodes a LIM **homeodomain** protein, is expressed and required in the dorsal cells (33, 55-57), and it activates the expression of *fringe* (*fng*) in these cells (58). The fringe protein acts through two ligands of the **Notch** receptor, *Serrate* and *Delta* (59-63), to restrict the expression of downstream genes *wg* and *vestigal* (*vg*) along the dorsal–ventral boundary, which in turn coordinate wing growth and patterning (64-66).

3.3. Proximal–Distal Patterning

Besides the anterior–posterior and dorsal–ventral axes, appendages (wing and leg) also possess a proximal–distal axis. It appears that interactions between the anterior–posterior and dorsal–ventral axes of the disc are critical for patterning along the proximal–distal axis (67). In the leg, the hedgehog protein secreted from the posterior compartment induces the adjacent dorsal anterior cells to express *dpp* and ventral anterior cells to express *wg*. The region where *wg* and *dpp* are coexpressed expresses *Distal-less* and *aristaless*, which defines the most distal part of the leg (68-71). Accordingly, a secondary proximal–distal axis can be induced when a new intersection point of *wg* and *dpp* expression is generated in the leg disc. Similarly in the wing disc, the intersection of *dpp* expression along the anterior–posterior boundary and *wg*–*vg* expression along the dorsal–ventral boundary corresponds to the distal tip of the wing.

4. Specification of the Imaginal Disc Identity

Although patterning of all imaginal discs share some common features, the identity of an individual imaginal disc is specified by the **homeotic** and other selector genes. Homeotic genes in the **Bithorax** and **Antennapedia** complexes are involved in the specification of head and thoracic discs (72). For example, ***Ultrabithorax*** (*Ubx*) is expressed in the haltere, but not in the wing disc, and specifies the haltere fate (73-75). Loss of *Ubx* function in the haltere results in a haltere-to-wing transformation, generating the famous four-winged fly (76). The homeotic gene *Antennapedia* (*Antp*) specifies the leg disc, and ectopic expression of *Antp* in the eye–antenna disc results in antenna-to-leg transformation (77, 78). However, homeotic genes are not the only genes that are used to specify disc identity. The *Drosophila* ***Pax*** family gene *eyeless* (*ey*), which encodes a protein containing a paired domain and a homeodomain, is required for the determination of the eye disc fate (79). Ectopic expression of *ey* can induce ectopic eye development in other imaginal discs (80). Several genes have been shown to act downstream of *ey* in this process, including *eyes absent*, *sine oculis*, and *dachshund* (81, 82).

Studies of imaginal disc development in *Drosophila* have shed new light on various aspects of vertebrate development. For example, gene expression and functional studies suggest a striking similarity between fly appendages and vertebrate limbs (32, 67, 83, 84). The dorsal–ventral boundary of the wing disc is analogous to the apical ectoderm ridge (AER), which is a major signaling center for the developing vertebrate limb. The posterior compartment of the wing disc is analogous to the zone of polarizing activity (ZPA), the source of the morphogen, sonic hedgehog, that patterns the anterior–posterior axis of the vertebrate limb bud. In addition, several key regulatory genes in patterning imaginal discs have been implicated in human diseases. For example, mutations in the human *patched* gene are responsible for basal cell carcinoma, a common form of human cancer (85).

Immortalization

Cell lines isolated from normal tissue continue to proliferate for a fixed number of cell population doublings, after which the culture undergoes senescence; that is, it will undergo a culture age-dependent cessation of growth (1). Such cell lines are called *finite cell lines*, in contrast to *continuous cell lines* (see Cell Line). Several potential explanations have been proposed for their limited lifespan *in vitro*: nutritional deficiency, cumulative genetic damage, delayed interaction with an infectious agent, or genetically programmed aging. Although there are, undoubtedly, cell lines that die out soon after isolation, due to nutritional deficiency or infectious agents such as mycoplasma, there is now overwhelming evidence that the replicative lifespan is programmed into cells (2-4). This has been established by **somatic cell** hybridization and microcell fusion experiments, which have shown that there are at least ten dominant **genes** that will re-establish a finite lifespan in continuous cell lines after fusion with cells from a finite cell line (5, 6). The identity of these genes is not clear, but their interaction with cell cycle regulators has been suggested (7). As finite cells show progressive shortening of their telomeres with successive generations in culture, until replication is no longer possible, regulation of telomerase (8-10) or an alternative mechanism for maintenance of telomere length (11), is now the most likely regulator of replicative lifespan. The vast majority of continuous cell lines from tumors (11, 12) re-express telomerase, which is capable of regenerating the truncated telomere at each cycle, thereby preventing cessation of cell division. Reintroduction of the telomerase gene extends the lifespan (13, 14) and may, ultimately, prove to be the most satisfactory means of immortalizing cells, particularly if under the control of a regulatable promoter.

Agents used to immortalize cell lines, such as irradiation, mutagens, **oncogenes**, or viral genes such as **SV40 virus** large T Antigen, adenovirus E1a, or HPV E7, interact with cell-cycle regulatory proteins, such as p53 and **retinoblastoma** proteins and the cyclin/Cdk complexes, either directly or via mutation (15). Mutations may be induced directly by irradiation; alternatively, interactions with p53 and other genome guardian proteins may allow spontaneous mutations to be propagated and not repaired or eliminated from the cell population. While these mutational events may lead directly to inactivation of senescence genes, it is also possible that reduced cell cycle control and DNA surveillance allows cells to proceed beyond their normal lifespan, allowing time for small minority populations of cells expressing telomerase to appear, particularly if one of the mutations was in a telomerase repressor (16).

Senescence was first described with human diploid fibroblasts but has been shown to occur for other cell types (10) and other species (17). There is a general relationship between the proliferative lifespan *in vitro*, the age of the donor individual, and the average lifespan of the species. Cell lines derived from embryos and young individuals will generally survive longer than cell lines from older donors; moreover, cell lines from long-lived species generally survive longer than those from short-lived species, although this correlation is less well established than that with donor age. Not all cell lines will senesce; notable exceptions are cell lines derived from mice or from tumors of many species. In these cases, evidence of senescence can still be seen, but transformed cells appear within the population and eventually overgrow, producing continuous cell lines. Such immortalized cell lines have been generated spontaneously from many species, such as Syrian (18) and Chinese hamsters (19), cows (20), and monkeys (21, 22), but rarely from normal human or chick cells. Because spontaneous immortalization is such a rare event in normal human cell lines, when it does occur, it begs the question as to whether the cell lines from which immortal lines do arise are really normal, or whether they were already genetically predisposed by one or more initiating mutations in a positively acting **oncogene** by or deletion or inactivation of a negatively acting tumor suppressor gene.

Transformation is a term with many different meanings, depending on the context in which it is used (see Neoplastic Transformation). Transformation of cultured cells implies a heritable **phenotypic** change resulting from a spontaneous or experimentally induced genomic alteration. It is usually associated with an increased life-span and alterations in growth control, and it may, but does not always, give rise to a tumorigenic cell line. There are at least three discernible processes: immortalization, development of aberrant growth control, and neoplastic transformation. A cell line may become immortal without becoming neoplastic or losing many aspects of normal growth control, such as contact inhibition, density limitation of cell proliferation, or anchorage dependence. Examples of this are NIH-3T3 primitive mouse embryo mesodermal cells and BHK21 baby hamster kidney fibroblasts. However, both of these may progress to fully transformed lines: 3T3 cells spontaneously (23) (by maintenance at high cell density) and BHK21 by infection with a transforming virus, such as **polyoma** (10). It is not clear whether immortalization is a prerequisite for neoplastic transformation or aberrant growth control, although life-threatening progressive neoplasia almost certainly requires immortalization of one or more stem lines of the tumor.

Immortalization can be defined as the acquisition of an infinite lifespan, usually taken as in excess of 100 population doublings, while, in this context, transformation implies loss of growth control mechanisms, such as growth factor or serum dependence, G1 cell cycle arrest, contact inhibition of cell motility, density limitation of cell proliferation, dependence of cell proliferation on anchorage to, and spreading on, a substrate, and increased production of secreted proteinases such as plasminogen activator. Neoplastic transformation implies that the cells will grow as an invasive tumor *in vivo* and usually incorporates all, or most of, the growth control aberrations listed above. It is possible, therefore, that there are only two stages, immortalization and transformation, which need not have a fixed temporal relationship to one another.

Immortalization can also be induced by agents that interfere with growth regulatory genes, or senescence genes (5, 6). These may be physicochemical agents, such as high energy irradiation (24), oncogenes (25) or viral genes, such as SV40 large T antigen (26), E1a from adenovirus, E6 and E7 from papilloma viruses (27), and Epstein–Barr virus genes (28). Viral immortalization can be achieved by transfection of the appropriate viral genes or infection with whole virus. The second has biohazard safety implications and requires, for safe handling, demonstration that the immortalized cells do not produce infectious virus. For this reason, transfection of cloned genes, most commonly SV40 large T antigen, is generally preferred. Typically, transfected cultures arrest at the M1 stage of the cell cycle, but a few morphologically altered clones will continue to proliferate. These can be picked or selected as resistant if cotransfected with a selectable marker, such as resistance to G418 or hygromycin B (29). These clones are usually pooled and subsequently undergo crisis (M2), a cessation of growth, from which a small fraction of cells may grow through to form a continuous cell line. The frequency of occurrence of immortalization within a cell population may be as low as 1×10^9, or as high as 1×10^5.

Continuous cell lines have many advantages for routine culture (Table 1), mostly due to their higher growth rate and saturation density, their ability to proliferate in suspension, and their high plating efficiencies. These properties are associated with transformation, however, and continuous cell lines, which are immortalized but not transformed, will not give such high yields or plating efficiencies. As some interference with normal growth control mechanisms is implied in both immortalized and transformed cells, no continuous cell line can be said to be normal. However, cell lines that are immortalized, but not neoplastically transformed, may be said to be closer to the normal phenotype. In both cases, regrettably, there is a tendency to lose lineage markers and the capacity to differentiate (30, 31). However, there are a number of cases where differentiation and lineage markers are retained (24, 32) and there are good prospects for normal **gene expression**, post-transcriptional and post-translational modification, and phenotypic expression. Such cell lines may be useful for the production of proteins by protein engineering, such as factor VIII (33), or as vectors for further transfection studies. The advent of telomerase-induced immortalization, particularly if the gene is introduced with a promoter that is temperature- or hormone-sensitive, may prove to be the best way forward for generating immortalized cell lines capable of both indefinite replication and expression of differentiation under appropriate conditions.

Table 1. Properties of Transformed Cells[a]

Growth Characteristics	Genetic Properties	Structural Alterations	Neoplastic Properties
Immortal	High spontaneous mutation rate	Modified actin cytoskeleton	Tumorigenic

Anchorage independent: clone in agar, may grow in stirred suspension	Aneuploid	Loss of cell-surface-associated fibronectin	Angiogenic
Loss of contact inhibition	Heteroploid	Increased lectin agglutination.	Enhanced proteinase secretion, eg, plasminogen activator
Growth on confluent monolayers of homologous cells "focus" formation	Overexpressed or mutated oncogenes	Modified extracellular matrix	Invasive
Reduced density limitation of growth: high saturation density, high growth fraction at saturation density	Deleted or mutated suppressor genes	Altered expression of cell adhesion molecules (cadherins, integrins)	
Low serum requirement	Stable or elongated telomeres	Disruption in cell polarity	
Growth-factor-independent	Overexpressed telomerase or ALT genes		
High plating efficiency			
Shorter population doubling time

Immune Response

The immune response is a complex sequence of events initiated by the introduction of an immunogen in an organism. In vertebrates, it is the consequence of the stimulation of B and/or T lymphocytes, leading either to the production of specific **antibodies** from B cells or to the occurrence of effector **T cells**—for example, cytotoxic T lymphocytes. Immunologists classically make a clear distinction between immune responses that are characterized by antibody production and those that result primarily in the emergence of cytotoxic T cells or delayed-type hypersensitivity, which are depicted as humoral and cellular immunity, respectively. In fact, penetration of complex

antigens, such as most bacteria and **viruses**, trigger both types of immune responses. Furthermore, antibody responses directed against T-dependent antigens, the most common case, require cellular cooperation between B and T cells, and the humoral and cellular responses are quite intricate.

It must be realized that both the nature and the intensity of the immune response is largely dependent on the nature, dose, and mode of penetration of the antigen. For example, when given subcutaneously or intravenously, proteins stimulate a good circulating antibody response, provided that they are given in an immunogenic range of doses. If given orally, mucosal antibody production will occur preferentially. By contrast, intradermal injection will induce delayed hypersensitivity, mediated by T lymphocytes. The level of response may be substantially increased by admixing antigen with adjuvants that ensure a long-lasting liberation of antigen, in addition to providing nonspecific stimulation of the immune system.

Whatever the nature of the response, it always follows basic principles that are most simply quantified in a classical humoral response. Following antigen administration, two parameters may be followed: One is the disappearance of antigen from the body fluid, and the other is the occurrence of circulating antibodies. After a first immunization, the blood concentration of antigen decreases rapidly within a few hours, remains somewhat steady for a few days, and then rapidly decreases again, until it is no longer detectable. This occurs after 5 to 7 days, when antibodies start to be produced. As they circulate in the bloodstream, they bind to the remaining antigens, and the immune complexes are eliminated (which may be a major problem for individuals suffering renal failure). The antibodies that first appear are IgM. Their yield increases for a few days, until they are replaced by IgG antibodies that result from class switching of the isotype. The antibody titer slowly diminishes and becomes barely detectable. This is a typical primary response. As B cells start making IgG antibodies in germinal centers of peripheral lymph nodes, they rapidly accumulate somatic hypermutations so that antibodies with higher affinity will occur and be positively selected by antigen. A fraction of these B cells will constitute the long-lived memory cells that will react immediately upon a second administration of antigen. The secondary response then takes place, characterized by a rapid elevation of the IgG antibody titer, which will remain high for a much longer period of time. If a different antigen were used instead of the first one, a typical primary response would have been observed, and this is illustrative of the high specificity of the immune response. Antigen may be given several times, ensuring a successive boost of responses, leading to a hyperimmunized state.

The general kinetics described above are typical of T-dependent soluble antigens. With polysaccharides, there is no secondary response, and the antibodies remain essentially of the IgM type (with some IgG2a and IgA2 in humans). The immune response to particulate antigens, such as bacteria, is generally more complex, due to antigenic diversity. The respective contribution of humoral and cellular responses is largely dependent on the microorganism.

Immunity

Immunity may be defined as a resistant state conferred on a living organism by a wide variety of cells and molecules that tend to eliminate pathogens or aggressive agents, thus ensuring the individual's integrity. Immunologists often make a distinction between natural, or innate, and adaptive immunity, although the latter is also quite “natural” when understood as a basic physiological phenomenon. It might be advisable to use instead the concept of nonspecific versus specific, but even this is not entirely satisfactory, because the limits are not so clear. This is well illustrated by the opposed views that were expressed at the end of the nineteenth century by those, like Metchnikoff, who supported the cellular basis for immunity, centered on the phagocytic properties of the macrophage and those, like Ehrlich, who gave a major role to circulating **antibodies**, thus supporting humoral immunity. In fact, both mechanisms are part of the organism defenses; and the macrophage, which was initially considered to have nonspecific phagocytic potentialities, turned out to be able to acquire some specificity by opsonisation—that is, the binding of antibodies of the various isotypes to its **Fc receptors**. Much more recently, the ability of macrophages to process and present protein antigens proved definitively that all these partners could be linked and that a clear-cut distinction was primarily a scholastic dispute. Defense mechanisms are quite diversified in the living world, although vertebrates have developed a highly complex immune system endowed with an adaptive response that can face a huge potential antigenic repertoire because of a sophisticated genetic organization that may express at any given time millions of different and specific **immunoglobulins** or **T cell receptors** (TCRs) produced by B cells and T cells, respectively. Invertebrates have also developed immune defenses against pathogens that involve, in addition to phagocytic cells or soluble enzymes, mechanisms like those described in insects, which have a limited repertoire of genetically encoded peptides endowed with diverse bacteriolytic, antiviral, or antiparasite activities.

One may consider that the defense mechanisms that operate in vertebrates are organized on successive levels. The first one involves cutaneous and mucosal barriers that ensure a physical protection, as well as a chemical one, including enzymes such as lysozyme that can have a bactericidal effect. The second level is used whenever pathogens have entered the bloodstream. Examples of efficient but nonspecific mechanisms that can be mobilized quickly are (a) phagocytosis by monocytes and macrophages, (b) inflammatory reaction that produces many cytolytic factors, (c) lytic activity initiated by components of the **complement** cascade, (d) natural killer (NK) cells, and (e) various **cytokines**, with special reference to interferons that block viral replication, and so on. Simultaneously, the adaptive immune response is initiated, leading to the occurrence of the first wave of IgM antibodies, which are soon replaced by more efficient IgG, and/or to the emergence of cytotoxic T lymphocytes, which are of prime importance in destroying virus-infected cells. Vaccination will reinforce immunity by stimulating a specific immune response to major dangerous pathogens, allowing the organism to react quickly with the appropriate B- and T-cell responses when a natural infection takes place.

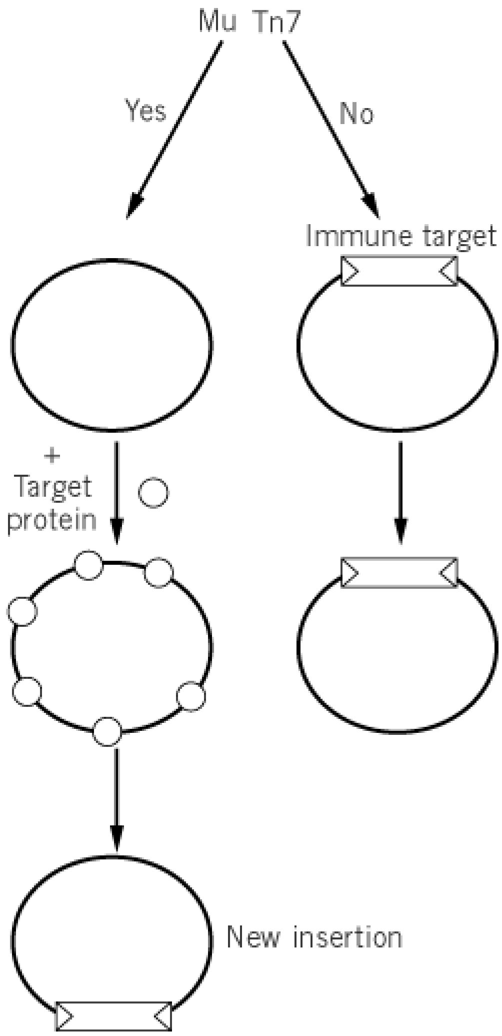
Immunity, Transposon

For some transposable elements, the frequency at which they insert into a target DNA that already contains a copy of the element is much reduced from their frequency of insertion into that same DNA lacking a copy of the transposable element (Fig. 1). This inhibition does not represent a global inhibition of transposition within the cell: The inhibition is specifically cis-acting on the DNA that contains the transposable element. This inhibition is called *transposition immunity* or *target immunity*. Although target immunity is usually evaluated in intermolecular transposition reactions, it is likely that a principal function of this phenomenon is to discourage intramolecular transposition—that is, to prevent the insertion of a mobile element into itself or into adjacent donor backbone. Target immunity has the effect of discouraging insertions locally and promoting insertion at a distance from the donor site of the mobile element .

Figure 1. Target immunity. For some elements such as Mu and Tn7, the frequency with which they insert into a target DNA already containing a copy of the element is much reduced. A target DNA already containing a copy of the transposon is a poor target because the target binding protein (small circle) is not effectively bound to the immune target. Binding of the target protein is discouraged by transposition proteins that bind specifically to the transposon ends in the immune target DNA.



Target immunity has been observed for a number of bacterial elements. The phenomenon was first observed with Tn3-like transposons and subsequently with bacteriophage **Mu** (1), and Tn7 (2, 3), a **drug-resistance** element. Phage Mu uses multiple rounds of transposition to set up replication forks that promote phage replication during lytic growth. Through transposition immunity, Mu ensures that new insertions made during the replication process will not be into extant copies of Mu, destroying these copies; thus transposition immunity facilitates Mu replication.

The mechanism of immunity has been dissected *in vitro* with Mu (4, 5), and Tn7 (6, 7). Common features of these elements are that the activity of the transposase is controlled by an ATP-dependent regulatory protein that interacts with the transposase and the target DNA via an ATP-dependent **DNA-binding** activity. Transposition occurs when the transposase interacts with this regulatory protein in an ATP-bound state on the target DNA. The ATP state of the regulatory protein is key to its activity, promoting transposition when it exists in an ATP-bound state on the target DNA and being inactive in a non-ATP state removed from the target DNA. As described below, the state of the ATP regulatory protein appears to be the key to immunity. A reasonable model is that the establishment of immunity involves discouraging the interaction of the ATP-dependent regulatory protein with the target DNA (Fig. 1).

In all systems examined, target immunity is imposed on a potential target DNA by the DNA sequence ends of the transposon—that is, the *cis*-acting recombination sequences at the ends of the transposon that are the transposase recognition sites. An attractive model for immunity is that when the transposase interacts with transposon end sequences on the potential target DNA, it exists on the target DNA in high local concentration and actively discourages the interaction of the ATP-dependent regulatory protein with the target DNA, thus effectively clearing the target DNA of targeting protein and discouraging transposition into that DNA. The ends of the transposon with bound transposase appear to interact with the target protein by simple protein–protein interactions facilitated by DNA looping (5, 7).

It seems likely that different forms of the transposase will interact with the target protein to execute transposition and transposition immunity. In Tn7, for example, immunity can be imposed by one of the protein components of the transposase, while actual transposition requires collaboration between both protein subunits of the transposase (7). In other cases, such as Mu, different forms of transposase, for example in different oligomeric states, may signal these different reactions.

Retroviruses also show a form of immunity in that intramolecular insertion is discouraged, although they show no inhibition for insertion into DNAs containing retroviral ends (8). The ability to block intramolecular insertion has been correlated with a requirement for a particular human protein (9), but the role of this protein and the mechanism of retroviral immunity remain to be established.

Immunization

Immunization occurs as the result of the penetration of an immunogen in an organism, leading to the stimulation of the immune system and the production of **antibodies** and/or T-cell effectors that specifically recognize the initiating antigen. Immunization may occur naturally, upon penetration of a pathogen, bacteria, virus, or parasite, and requires several days before becoming fully effective fighting the invader. This may be too slow to ensure efficient protection, and this led to the development of systematic vaccinations against major pathogens. The word *vaccination* originates from the first vaccine that was directed against smallpox, using the cross-reactive vaccinia virus. Used on a worldwide basis, it led to the complete eradication of this severe disease, and thus is no longer in use. Major vaccines used in humans include tetanus, **diphtheria**, measles, **polio**, mumps, rubella, **influenza**, rabies, **hepatitis B**, and a few others. Vaccines are most frequently administered by injection, but sometimes orally, as in the case of the live attenuated poliovirus vaccine. A vaccine may be used as the full pathogen after it has been inactivated, or as an attenuated genetic variant. One also can use a purified molecule that has been isolated from the pathogen or genetically engineered.

For laboratory purposes, immunization generally aims at producing antibodies for immunochemical analysis. Conventional polyspecific antibodies are generally prepared in mice, guinea pigs, rabbits, or goats. There is no standard immunization procedure, but only some general guide lines that define basic conditions for good immunogenicity. Besides using an appropriate dose, the antigen might have to be conjugated to a carrier protein. Use of adjuvant, most frequently the complete Freund's adjuvant, is admixed with the immunogen. Finally, repeated injections will increase both the affinity and the titer of the antibodies generated.

Immunoaffinity Chromatography

Immunoaffinity chromatography (IAC) is a widely used method for the selective extraction of **antibodies** or other biomolecules on the basis of the biospecific affinity between an antibody (Ab) and its antigen (Ag) (1). The antigen may be a small molecule (a hapten) or a macromolecule (M) such as an enzyme, a hormone, a growth factor, and so on. IAC has been used for many years for the purification of antibodies by immobilized antigens and also for the purification of antigens (enzymes, receptors, hormones, growth factors, etc.) by antibodies anchored to inert carriers. The antibodies used can be polyclonal, provided that a pure antigen is injected to obtain the antibodies and that strict specificity is ascertained. It is often advisable to use anti-peptide (sequence-oriented) polyclonal antibodies to reduce the danger of heterogeneity in the specificity of the antibody population. Monoclonal antibodies are usually a very good choice because they are homogeneous and directed against a distinct epitope. Under ideal conditions, antibody columns allow separation of specific peptides or proteins from crude mixtures in one step. The procedure for an IAC purification involves the same steps described for affinity chromatography.

A major difficulty in the use of immobilized antibodies is the high affinity of some antibodies for their antigens. This sometimes makes the recovery of active enzymes difficult, because the harsh conditions that are required in the elution step bring about either an inactivation of the enzyme or the loss of an important regulatory function. Among the eluents that have (and are) being used in IAC are buffers with a low pH (2.2) or a high pH (11.5), **chaotropes** (5 M KSCN), or mild **denaturants** such as urea (3.5 to 8 M) or **guanidinium** salts (2–6 M). Therefore, attempts are sometimes made to purify by exclusion (also known as "reverse immunoadsorption"). In this procedure, the contaminating proteins are the ones to be adsorbed and removed, while the desired protein is excluded (2).

With the introduction of monoclonal antibodies in IAC, it became possible to use homogeneous immunoglobulins not only directed against a distinct antigenic determinant (3, 4) and to tailor their affinity. A lowered affinity permits milder conditions for elution and reduces the possibility of irreversible denaturation during the elution step. As expected, the use of monoclonal antibodies has had a significant impact in biochemistry, in molecular biology, and in medicine.

Immunoassays

Immunoassays are a collection of techniques for measuring biological or synthetic materials, using **antibodies** specific for those materials. Immunoassays are also applied in reverse, in which a purified antigen or hapten is used to quantify an uncharacterized antibody preparation. The common element in all immunoassays is the interaction of an antibody with a ligand. The assay methods differ in the accessory chemical reactions that take place prior to, or as a consequence of, ligand binding, and in the instrumentation used to detect the binding event or subsidiary reaction. Radioimmunoassays and enzyme-linked immunosorbent assays (ELISA) are especially widely used types of immunoassay. Others are complement fixation, agglutination, Farr Assay, and Ouchterlony Double Diffusion. They are listed as separate entries and not discussed here. Below, we sketch the principles underlying the most common immunoassay methods relevant to molecular biology.

1. Fluorescence Quench

The emission of a photon as a molecule returns to its electronic ground state from an excited state produces **fluorescence**. "Quenching of fluorescence" refers to chemical interactions that allow an excited state to dissipate its energy through a nonradiative mechanism (see Fluorescence Quenching). Common mechanisms that can cause quenching include collisions with solvent, protonation or deprotonation reactions, resonance energy transfer, and collisions or static contact with quenchers. Quenchers encompass a huge variety of substances, from molecular oxygen to heme proteins, and the binding of a quencher to an antibody can easily be measured. Quenchers most relevant to immunoassays are aromatic organic molecules, which are frequently used as haptens. These molecules are thought to cause nonradiative deexcitation by transiently accepting electrons from the excited state of a fluorophore.

Tryptophan is the only strongly fluorescent naturally occurring amino acid, and antibody sequences usually show an abundance of exposed Trp residues in the antigen-combining site (1). Consequently, binding of a quenching antigen or hapten to an antibody nearly always causes decrease of Trp fluorescence from the antibody. Furthermore, the fluorescence decrease is generally linear with the number of combining sites filled; hence it is a direct measure of the degree of saturation of the antibody (2). Bound and free Ab as a function of added ligand can be calculated and displayed as a Scatchard Plot or used for direct fitting to a binding equation to determine the antibody valency and the association equilibrium constant for binding the ligand. Fluorescence quench on antigen binding is a very desirable technique for immunoassay, because it allows direct measurement of antibodies and antigens interacting in solution and can be performed without chemical labeling of the molecules under study with reporter groups.

2. Fluorescence Anisotropy or Fluorescence Polarization

This method relies on the change in molecular tumbling rate that occurs when an antibody–antigen complex forms. Fluorescence anisotropy is most appropriate for antibody-antigen pairs that are of different molecular size (3), and may be applicable even if no overt change in fluorescence signal results from complex formation.

Plane-polarized light absorbed by a fluorophore will (to a first approximation) be emitted with the same plane of polarization, unless the fluorophore molecule reorients during the lifetime of its excited state. Since the tumbling rate is a function of molecular size, polarization of emitted light is very sensitive to complex formation. A small molecule will tumble rapidly, hence the orientation of an excited state fluorophore will randomize, and fluorescence emission will be isotropic. In contrast, a large molecule will tumble slowly; hence emission from a fluorophore will remain polarized. A small molecule that binds to a large molecule will take on the tumbling characteristics of the large molecule. For example, anisotropic emission from a fluorescent tag on a small antigen will sharply increase on complexation with a large antibody. To use this principle for a quantitative immunoassay, fluorescence anisotropy is measured separately for the free antigen and fully complexed antigen. Between these two limiting values, anisotropy will be linear with the extent of antigen complexation; hence the degree of complex formation in a test sample may be inferred from the observed anisotropy.

Fluorescence anisotropy is measured by exciting a fluorophore with polarized light and observing fluorescence intensity through a polarizing filter oriented parallel ($I_{\parallel}$;) or perpendicular ($I_{\perp}$;) to the excitation plane. The relative intensities from the parallel and perpendicular emissions are used to calculate anisotropy or polarization from the equations:

$$\text{Anisotropy} = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + 2I_{\perp}} \quad (1)$$

$$\text{Polarization} = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + I_{\perp}} \quad (2)$$

Although polarization and anisotropy are very closely related, equations relating observed intensities to ligand binding and other phenomena are generally simpler when expressed in terms of anisotropy; hence this is the preferred parameter. Fluorophores used for anisotropy measurements of proteins, such as fluorescein and **dansyl**, typically have excited-state lifetimes of 5 ns. This lifetime is on the same order as the tumbling times of protein antigens. The small, globular protein lysozyme, for example, also has a rotational correlation time of 5 ns (4); hence a fluorescein label on lysozyme would show considerable depolarization of fluorescence. Intact IgG has a rotational correlation time of 220 ns; hence its complex with the labeled lysozyme would show strong fluorescence anisotropy.

One complication to the fluorescence anisotropy technique is the occurrence of local motions affecting the fluorophore, often referred to as "segmental flexibility." The timescale for these local motions can be sufficiently fast to reorient the fluorophore and depolarize emission, even if the fluorophore is attached to a large, slowly tumbling macromolecule (5).

3. Phosphorescence or Time-Resolved Fluorescence

Phosphorescence is a fluorescence phenomenon in which, for quantum-mechanical reasons, the excited state of a fluorophore cannot easily return to the ground state by emission of a photon. Emission does occur, but on a much longer timescale than is normal for fluorescence. Because of this long lifetime, the presence of even small amounts of quenching agents such as O_2 is sufficient to suppress observation of any signal from naturally phosphorescent biological compounds. Phosphorescence is measured by exciting a sample with a pulsed light source, waiting an interval for short-lived fluorescence states to decay, then integrating photon counts during the remaining dark period before the next pulse. This ability to resolve short-lived from long-lived fluorescence is the chief advantage of a phosphorescent probe, as background phosphorescence of biological samples is almost nil. By contrast, the steady-state fluorescence background is often quite high, and the signal-to-background ratio in short-lived fluorescence-based assays is a more common limitation of sensitivity of an assay than the absolute magnitude of the signal.

Europium is the most common phosphorescent probe in time-resolved fluorescence immunoassays (6). This metal ion is attached to antibodies or antigens through bifunctional linker molecules containing a chelate moiety at one end and a group reactive with protein residues at the other. In a typical assay, a trapping antibody is immobilized on a solid support, antigen in a test sample is allowed to bind, and then the Eu^{3+}-labelled antibody is allowed to bind the trapped antigen. After washing away unbound reagents, Eu^{3+} is extracted from the antibody in low pH buffer containing phosphorescence enhancing agents (7). These agents act both by sequestering the Eu^{3+} ion from quenchers and transferring absorbed light to the Eu^{3+} ion. The fluorescence emission is integrated repetitively over several hundred microseconds, using a stroboscopic fluorimeter. Comparison of the response from the test sample to a standard curve constructed with known concentrations of analyte allows determination of the concentration of analyte in the test sample.

4. Chemiluminescence

Chemiluminescence is a phenomenon related to fluorescence, in which an electronic excited state of a molecule is reached through a chemical reaction. Emission of a photon, which is optically detected, returns the molecule to the ground state. A chemiluminescent immunoassay involves an antibody or antigen that has been covalently tagged with a molecule capable of participating in a chemiluminescent reaction. The tag remains inert through immunologic steps such as antigen or secondary antibody binding. Subsequent mixing with a trigger solution initiates the luminescent reaction.

A chemiluminescent immunoassay to detect an antigen typically begins with immobilization of a capture antibody on a solid support. The test sample is added, followed by the tagged detection antibody. Luminol was the first luminogenic tag to be used for an immunoassay (8), but derivatized acridinium esters are now more common (9, 10). Unbound reagents are washed away, and luminescence is determined in a luminometer. This device combines two automated functions (11). First, trigger solutions (alkaline H_2O_2 in the case of acridinium labels) are added to the sample to initiate the luminescence reaction. Mixing is usually complete in less than 1 s. Next, a detector, usually with photon-counting electronics, measures light emission from the sample over a defined time interval, typically 10 s. As with other immunoassays, the response of a test sample is compared to the responses from a set of standards to determine the analyte concentration in the test sample.

Because photon emission from luminescent tags can be induced to occur quantitatively over the span of a minute, as compared to radioactive decay of isotopic isotopes, which continues over months in the case of ^{125}I, chemiluminescent assays are inherently very sensitive. ELISA assays that use a luminogenic substrate, which are sometimes referred to as “chemiluminescent immunoassays,” are perhaps the most sensitive of all assays. Combination of an enzyme tag on the antibody and a luminogenic enzymatic reaction yields a degree of amplification that can detect as little as 1000 molecules of analyte (12).

Immunoelectron Microscopy

In molecular biology, the location of specific molecules in organelles and cells at the microscopic level has gained prominence in recent years through the development of a wide range of cytochemical techniques. These techniques are based upon the property that specific markers can be chemically coupled to a wide variety of molecules. Examples are fluorescent markers for light microscopy and electron-dense markers, such as ferritin or colloidal gold, for electron microscopy. The use of poly- and monoclonal antibodies has widened the possibility of localization to essentially every particle that can invoke an immunogenic response. The antibodies produced can be bound to markers used in microscopy and the distribution of the molecules of interest visualized directly by 1-, 2-, or 3-step labeling procedures (1).

Immunocytochemistry is the application of antibodies in labeling protocols and must be performed in an aqueous environment to ensure that the antigen detectability is accurate and reproducible. Hence, cryotechniques are much preferred over the classical technique of chemical fixation, dehydration, and plastic embedment, which usually results in a loss of antigenicity. Along with cryofixation and cryosectioning, the use of colloidal gold is now commonplace. Colloidal gold has numerous advantages, among which are (i) it is electron dense and easily visualized in electron microscope images; (ii) various sizes of gold particles can be obtained, allowing double-labeling experiments; (iii) it can be easily complexed with a wide variety of ligands; and (iv) the maintenance of bioactivity of complexed molecules is excellent. Typically, the primary antibody binds to the antigen of interest and is visualized by labeling with a secondary antibody to which colloidal gold is conjugated in analogy to the use of fluorescent antibodies in immunofluorescence. With immunogold labeling, certain considerations should be addressed before starting (2). (i) Where is the antigen located? Additional preparative steps may be necessary to make the antigen accessible to the gold antibody. (ii) What is the nature of the antibody? A monoclonal antibody may not bind the antigenic site if the site is modified during electron microscope preparation; this problem is generally much less severe with cryotechniques. Polyclonal antiserum, which contains a number of different antibodies directed against more than one epitope on the antigen, is less susceptible to conformational changes or modification of the antigen. (iii) From which species were the antibodies derived? Care should be exercised to ensure that antibodies are raised to pure undenatured antigens in a species compatible with the labeling system.

A recent advance in photooxidation has allowed for precise correlative immunolocalization on the same specimen using fluorescent light and immunoelectron microscopies (3). With use of this technique, proteins can first be localized to individual cells or tissue types at the light microscope level with an antibody containing a suitable fluorescent label such as eosin. Subsequently, the protein can be further localized at the electron microscope level by illuminating the fluorophore in the presence of oxygen and diaminobenzidine. Fluorophores with a relatively poor quantum yield, such as eosin, produce reactive oxygen intermediates that oxidize the diaminobenzidine, producing a brown osmophilic polymer. Preparation of these specimens for electron microscopy by osmium fixation yields a highly localized osmium stain at the antigen. Fluorescence photooxidation can also be used with nucleic acid sequences by using biotinylated probes and an eosin–streptavidin conjugate (see Streptomycin).

Immunoelectrophoresis

If an antibody specific for the protein of interest is available, immunological detection and immunoelectrophoresis are the preferred methods for identification of that protein. Specifically, since the immuno-reactive site on a protein need not be affected by any post-translational modifications of a protein, immunological identification is the principal method for the recognition of a particular gene product in an electrophoretic pattern. Blotting of protein gel electrophoresis patterns to a membrane, with subsequent exposure of the blot to antibody, is the primary tool of immunological identification. More than any other factor, it is responsible for the possibility to construct protein databases from the hundreds to thousands of spots separable by two-dimensional gel electrophoresis .

Immunoelectrophoresis is the electrophoresis of one or more macromolecule in gels containing specific antibodies against them. Depending on the relative concentrations of the antibody and macromolecule, plus their affinity for each other, they interact to form complexes, which can then **immunoprecipitate** within the gel. The precipitates are visible within the gel. In this way, it is possible to quantify the amount of macromolecule present, by measurement of the size of the “rocket” produced and comparison with a known standard concentration (1). The antigenic relationships between proteins can be inferred from the precipitation patterns generated when the two are subjected to immunoelectrophoresis in adjacent wells of the gel, so that their precipitation patterns overlap (Fig. 1). If the overlapping rockets behave independently, the two molecules responsible are not immunologically related. If, however, they generate “fused rockets,” at least some of the same antibody molecules recognize both macromolecules. Crossed immunoelectrophoresis (Fig. 1) consists of an initial gel electrophoresis separation of the macromolecules of interest, followed by their electrophoresis at a right angle to the initial separation into a gel containing the antibody; this technique can yield particularly high resolution (3).

Figure 1. Crossed immunoelectropherogram of human serum. First dimension: Electrophoresis occurred in 1% (w/v) agarose, sodium barbital buffer, pH 8.6, 0.02 *M* ionic strength, at 10 V/cm and 15°C, for 70 min, with the anode to the left. The circular well where the sample of human serum was applied is visible at the right. Second dimension: Electrophoresis occurred in the same gel and gel buffer, but containing 12.5 μl rabbit antibody against human serum/cm^2 of gel, at 2 V/cm, for 20 h, with the anode at the top. The antibody is isoelectric at pH 8.6 and therefore stationary during electrophoresis. (Fig. 3 of (1)).

Immunogen

Immunologists make the distinction between antigen and immunogen. This came from the observation that small molecules termed haptens could interact with **antibodies**, even though they were unable by themselves to stimulate an immune response. Raising anti-hapten antibodies therefore necessitates preparing a conjugate of the hapten with a carrier protein. On this basis, it was proposed to distinguish antigenicity from immunogenicity and, consequently, an antigen from an immunogen. Antigenicity describes the chemical structures that contribute to interaction with an antibody, whereas immunogenicity defines the properties of a molecule for inducing an immune response. Natural immunogens, as opposed to chemically derived hapten conjugates, possess the dual properties of inducing the immune response and interacting with the resulting antibodies. Thus one must consider that a protein molecule, which is recognized by the antibodies through its epitopes, also behaves as its own carrier. This simply results from the antigen processing/presentation mechanisms that take place in the antigen-presenting cells.

Because immunogenicity is linked to the presentation phenomenon, which is genetically regulated because it involves the active participation of molecules of the Major histocompatibility complex (MHC), it is largely dependent upon the genetic constitution of the animal that receives the antigen. It has long been noticed that one strain of mice will not respond to a given antigen, whereas another one would develop an excellent response. This was strictly correlated with the presence of certain **alleles** of the MHC genes and provided a clear demonstration that the immune response was under strict (dominant) genetic control. This is why two outbred individuals, chosen at random, will respond differently to the same antigen. See Antigen Processing, Presentation for a more comprehensive explanation of immunogenicity.

Finally it should be remembered that, depending on the conditions used for immunization, the same antigen may reveal itself as immunogenic or not. One important parameter is the dose of antigen given. Either too low or too high a dose may prevent immunization and even induce a **tolerant** state, so the correct dose must be carefully defined before deciding whether a molecule is immunogenic or not. Another parameter is the route of injection, which conditions the secondary lymphoid organs that will be encountered by the antigen. Also, immunogenicity may be greatly enhanced by the addition of adjuvants to the antigen solution. Immunogenicity therefore results from a large variety of causes and is far from depending solely on the nature of the immunogen.

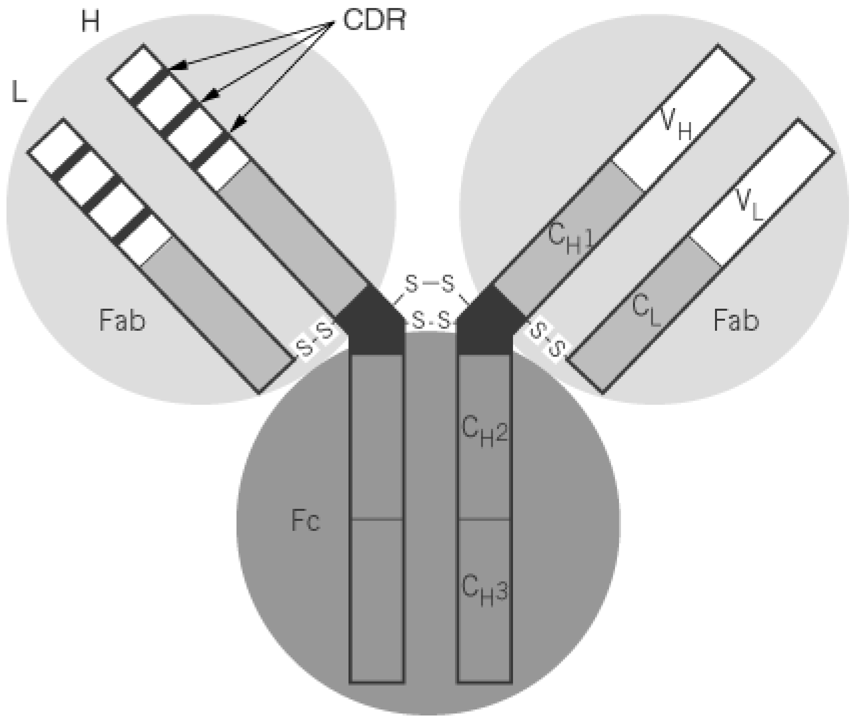
Immunoglobulin

Immunoglobulins (Igs) are **glycoproteins** synthesized by B lymphocytes that are the agents for B-cell recognition in the immune system. They are expressed either at the surface of B lymphocytes, where they represent the B-cell receptor (BCR), or in a soluble form in the body fluids, especially in the bloodstream, where they are also designated as **antibodies**. Immunoglobulins exert a dual function: (a) They recognize native **epitopes** on the antigen surface and (b) they are endowed with biological or effector functions such as **complement** fixation, **active transport** through the placental barrier in mammals, fixation to a variety of cells that express specific receptors for the various Ig isotypes [**Fc receptors** (FcRs)], and so on. The number of potential epitopes that immunoglobulins may recognize is enormous. This is the repertoire problem. By contrast, the number of effector functions is very limited, which immediately raises a major problem for the organization of the Ig molecules, which must accommodate a high diversity of antibody combining sites at one end and rather conserved structures at the other end. This difficulty has been solved by a very special structural organization of Ig, which is the consequence of a very sophisticated organization of the **genes** that encode the Ig polypeptide chains.

1. The Basic IgG Topological Model

Immunoglobulins have a multichain structure characterized by the basic pattern of IgG, the major Ig class or isotype, which contains two identical heavy (H) **polypeptide chains** and two identical light (L) chains (Fig. 1). This basic pattern was defined in the 1960s as the result of many independent workers, but predominantly by Porter and Edelman, who received the Nobel Prize in 1972, and by Hilschmann, who reported the first amino acid sequences of human light chains. The H chains have a molecular weight of about 52 kDa, and the L chains have a molecular weight of 23 kDa. The IgG molecule is symmetrical and contains two identical antibody-combining (or antigen-binding) sites. It contains about 2% by weight carbohydrates, which are located on the COOH-terminal half of the heavy chains. B cells are clonally organized, so that each one makes an Ig of one particular specificity; the entire population of Ig of one individual is extremely heterogeneous. Hence, structural studies had to be performed primarily on monoclonal materials, either derived from the product of malignant cells (myeloma proteins) or from monoclonal antibodies. Until the beginning of the 1980s, most structural data were derived from amino acid sequencing, thereafter by DNA sequencing of complementary DNA or **genomic** DNA.

Figure 1. Topological model of the IgG molecule. The symmetrical molecule contains two identical H and two identical L chains, each having a variable (VH and VL) and a constant (CL, CH) region. The constant region of the heavy chain contains three homology regions (CH1, CH2, CH3) and a flexible hinge between CH1 and CH2, which makes the molecule accessible to proteolytic enzymes that will release the Fab (antigen binding) and Fc (crystallizable) fragments. Homology regions provide the structural basis to the domain organization of Ig molecules.



Structural analysis revealed that Igs were built in a very peculiar way, with a general organization centered on a pseudo-unit or homology region of about 110 amino acid residues containing an intrachain disulfide bond. The light chain contains two such regions: one NH_2-terminal, which is highly variable from one L chain to another, the so-called **variable region** or V_L, and one COOH-terminal, which is highly conserved between the various chains, termed C_L. There are two types of light chains, **kappa** (k) **and lambda** (l), built on the same model, but encoded by genes at different loci, K and L, respectively. The relative proportion of either type varies extensively from one animal species to another. In the mouse, k chain Ig account for 95% of the total, whereas the proportion is inverted in cattle or horses. In humans, the k/l ratio is approximately 60/40. Heavy chains are built on the same principle: They contain a V_H region of somewhat similar size and contain a C_H region that contains three homology regions, termed C_H1, C_H2, and C_H3. The NH_2-terminal half of the heavy chain, composed of V_H-C_H1 and designated the Fd fragment, is covalently bound by a disulfide bond to the light chain. The ensemble Fd-L is the Fab (for antigen binding fragment), whereas the COOH-terminal halves of the two heavy chains form the Fc (for crystallizable fragment) because they were initially obtained by Porter upon cleavage with papain. The complete IgG therefore contains two Fab fragments, each having one identical antigen binding site, because the molecule is a symmetrical one, and one Fc; each of these fragments has roughly the same molecular weight of 150 kDa. The short section of the heavy chains located between the Fab and the Fc fragments is flexible and, for that reason, accessible to **proteolytic** cleavage, and it is called the *hinge region*. Within both the V_H and V_L, cumulative sequence data have revealed the presence of **hypervariable** regions that have been shown to interact directly with epitopes and that were for this reason called *complementarity determining regions*, or CDR (see Immunoglobulin Structure).

2. Domain Organization and the Basic Ig Fold

The special general architecture of Ig, characterized by the existence of the homology regions, is of particular interest for several reasons. First, it strongly suggests that this is the result of a long series of gene duplications from an ancestral gene that might have encoded a basic 110-residue polypeptide chain from which constant and variable regions would have evolved, making possible the dual functions of Ig. Second, the gene duplication phenomenon has allowed effector functions to be amplified by the emergence of other immunoglobulin **isotypes**, which fall into five classes in higher vertebrates, termed IgG, IgM, IgA, IgD, and IgE. These molecules differ from each other structurally by the nature of the constant region of their heavy chains, which are g, m, a, d, and ε, respectively, whereas their light chains are the same. In the course of immunization, antibodies are the first of the IgM class, and there is a **class switch** later on to the production of another isotype, usually IgG, which represents 70% of circulating Ig. Because the V_H region is conserved during this switch and because the light chain remains unchanged, the antibody specificity is maintained, whereas new specialized biological functions have occurred, as described separately under specific headings.

The existence of homology regions has not only provided a basis for understanding the molecular evolution of immunoglobulins, but has also raised the point that, if these regions had diverged and been selected for the emergence of new biological functions, they had to be endowed with thermodynamic autonomy, so that each may acquire a three-dimensional (3-D) structure independently of the others; this is a prerequisite to achieve separate and specialized functions. This was the essence of the **domain** hypothesis, proposed in 1970 by Edelman, which was later fully verified when X-ray crystallography studies of antibodies and antibody–antigen complexes were reported. In fact, because of the presence of a floppy hinge region in the IgG molecule, it was not possible to get crystals of a complete molecule but, instead, of the separated Fab and Fc fragments, which turned out to have the same general multiglobular structure, precisely centered on each homology region or domain. This led to the definition of the domain "immunoglobulin fold", depicted in Fig. 2 and well-defined from the 3-D structure of a light chain. Both the V and the C domains are similarly organized as a b-barrel, characterized by two planes containing antiparallel **b-sheets** stabilized by the intrachain disulfide bond. The various **b-strands** are connected by loops of variable length, and the V domain has extra loops that contribute the antigen binding site. There are other some minor differences between the V and the C domains, because nine b-strands are present in the V_H and V_L domains, whereas only seven are in C_L and C_H1 and eight are in C_H2 and C_H3. All CDRs are located in loops, and the 3-D analysis of an antibody–antigen complex confirms that all participate in antigen binding. The immunoglobulin fold was subsequently identified in many other proteins, including many molecules of immunological interest, providing a basis for the definition of the immunoglobulin superfamily.

Figure 2. Schematic organization of light-chain V and C domains, indicating the basic immunoglobulin fold. Arrows indicate the antiparallel b-strands as arranged in each domain as two distinct b-pleated sheets tightly anchored by an intrachain disulfide bond.(From Ref. 1959, with permission.)

Immunoglobulin Biosynthesis

The biosynthesis of immunoglobulins (Igs) is a particularly complex process, because it necessitates a long sequence of events: (a) Ig gene rearrangements that take place during early B-cell differentiation in bone marrow; (b) assembly of heavy (H) and light (L) **polypeptide chains** to form the basic H_2L_2 monomer; (c) transport to the cell surface, through the various intracellular compartments that permit the protein core to be sequentially glycosylated; (d) pentamerization for the IgM isotype, dimerization for IgA, with binding of the J chain; and (e) shedding of the final Ig as a circulating antibody. In addition to these steps, one must also include **classing**, **switching** of isotype, and the alternative splicing that allows the heavy chain to be synthesized in either membrane or secreted forms (see Membrane Proteins and Protein Secretion).

The phenomenon of Ig gene rearrangement is described in other entries (see Gene Rearrangement, Allelic Exclusion, B Cell, V Genes, and Recombinase). In brief, before transcription, any Ig gene must first rearrange the various elements that will encode the **variable regions** of both the H and L chains. This takes place in bone marrow, where the **antigen-independent** early steps of B-cell differentiation, which are mostly devoted to Ig gene rearrangement, a highly controlled sequential succession of events ($D \rightarrow J_H$, $V_H \rightarrow D - J_H$and $V_L \rightarrow D - J_L$), occur. As a result of these rearrangements, a membrane-bound IgM is expressed at the surface of the immature B cell. Finally, as the cell leaves the marrow to enter the periphery, coexpression of IgD and IgM occurs in mature B cells. Further differentiation to plasma cells is **antigen**-driven. At this terminal stage, Igs are secreted as circulating antibodies. Expression of other isotypes implies that the switch mechanism has been operative, leading the way to all remaining steps of Ig biosynthesis mentioned above.

Each heavy and light chain is translated separately on discrete **polysomes** of the endoplasmic reticulum. This is a rapid process, as for most polypeptides (about 1 min for H, and 30 s for L). The heavy chain is retained by BiP, a **heat-shock** protein, Hsp70, until it binds a light chain. Two pathways have long been known, depending on the isotype and the animal species. In the first, most frequent one, half-molecules (HL) are formed that rapidly dimerize. In the other, heavy chains dimerize, and then H_2L and finally H_2L_2 are formed. All these events take place in the ergastoplasm cisternae where the first carbohydrate, an *N*-acetylglucosamine, is added. Monomers are transported to the Golgi apparatus after formation of an ergastoplasmic vesicle. Subsequent carbohydrates are added, and the glycosylated monomer is included in Golgi vesicles that will fuse at the plasma membrane of the cell. After addition of a fucose residue, the molecule is either shed or anchored at the cell surface, depending upon whether this heavy chain is of the membrane or secreted type.

All surface isotypes are expressed as H_2L_2 monomers. Pentamerization of secreted IgM takes place just before leaving the cell, in the immediate vicinity of the plasma membrane, simultaneously with formation of a disulfide bond to the J chain. Dimerization of the IgA isotype occurs in mucosal plasma cells, where disulfide bonding to the J chain takes place. This causes covalent binding to the poly-Ig receptor, expressed at the basal pole of the epithelial cell. After internalization, the complex is transported through the epithelial cell, and the polymerized IgA is released at the apical pole of the cell in the lumen of the corresponding organ, along with **proteolytic** cleavage between two **domains** of the poly-Ig receptor, so that one subunit remains covalently linked to the IgA polymer, forming the so-called secretory component. Besides allowing the IgA to migrate through the epithelial cell, the secretory component is thought to protect the immunoglobulin from cleavage by proteolytic enzymes.

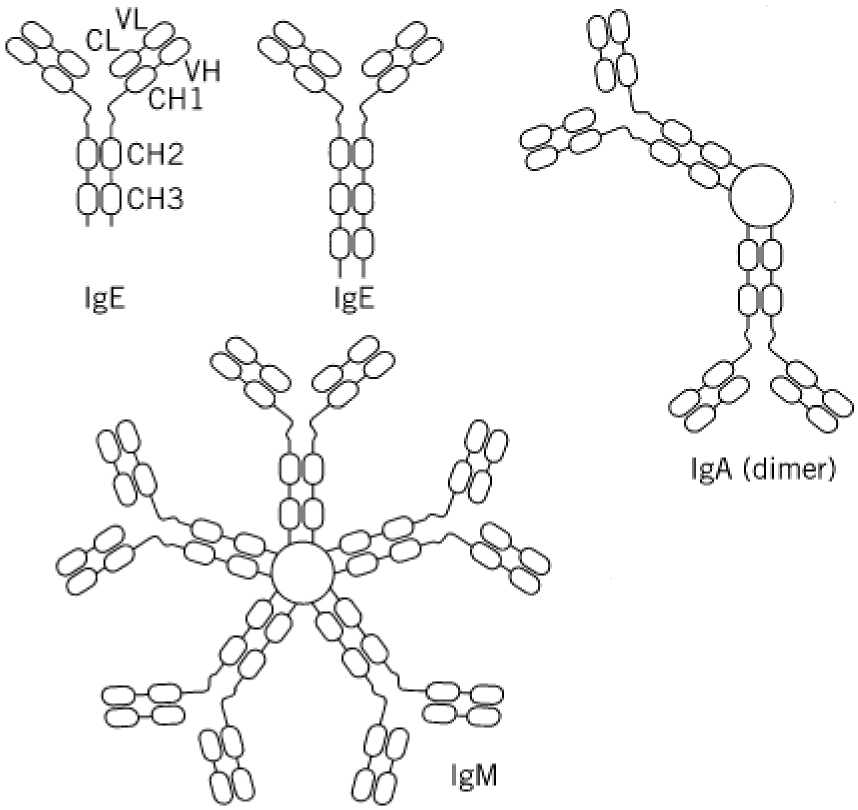
Immunoglobulin Structure

The **immune** system has evolved to recognize the entire organic world by producing complementary **immunoglobulins**, or **antibodies**, to identify and defend the vertebrate body against foreign substances (for a general reference, see (1)); an entry point to the many web sites containing information about antibodies is `http://www.antibodyresource.com`). Antibody molecules, like enzymes and many other proteins, have specific binding sites that interact with **ligands**, often in a true lock-and-key manner (see Antibody–Antigen Interactions). They also interact with other molecules involved in intercellular signaling, for example, the **Fc receptor**. Antibodies are part of a superfamily of proteins, some but not all of which participate in the immune response. Molecules related to antibodies that appear on cell surfaces mediate cell–cell recognition and signaling processes to trigger proliferation of particular cells in response to antigenic challenge.

The mechanism by which antibody diversity is created is now understood in considerable detail at the genetic (or sequence) level and at the protein structural level (see Immunoglobulin Biosynthesis). Common features of immunoglobulins were first recognized physicochemically and serologically, then described in terms of their amino acid sequences, and only much later revealed in atomic detail by X-ray crystallography . Limited **proteolytic** digestion and cleavage of disulfide bonds shows that antibodies contain multiple **polypeptide chains** (Fig. 1). The chains are classified by size into light (L) chains (about 23 kDa) and heavy (H) chains (about 60 kDa). Systematic internal **homologies** in the amino acid sequences suggest that immunoglobulins are composed of multiple copies of related units, each forming an individual, quasi-independent, three-dimensional structure, or **domain**, that has a common folding pattern. Light chains contain two domains, and heavy chains contain four or five. Heavy chains were distinguished originally on the basis of their amino acid sequences into k and l classes or **isotypes**. In humans, k and l light chains are present in comparable proportions. In the mouse, k light chains predominate.

Figure 1. Domain structures of the most common immunoglobulins. Most immunoglobulins contain both light and heavy chains, each of which comprises one variable domain and varying numbers of constant domains. The combination of two light plus two heavy chains is a higher order building block, of which immunoglobulins of different classes (IgG, IgA, IgM, IgD and IgE) show different states of oligomerization. Additional chains are linkers where necessary.



Different types of antibody molecules show variations on a general structural theme. They are multichain proteins built from domains about 100 amino acid residues long known as the immunoglobulin fold. Before the first crystal structure determinations of immunoglobulins, Kabat and co-workers identified the regions involved in antigen binding by analyzing the distribution of variability in aligned immunoglobulin sequences (2). Two types of domains were recognized on the basis of the variability of their sequences: variable (V) and constant (C) domains. Within the variable domains, they noticed regions of still greater variability called the hypervariable regions or complementarity determining regions (CDR), which they correctly and presciently predicted would be responsible for antibody specificity for different antigens. The regions of the variable domain outside the CDRs are called the **framework regions**. The framework provides a scaffolding of nearly constant structure to which the antigen-binding loops are affixed.

Indeed, when the first structures of immunoglobulin domains were determined by X-ray crystallography, it appeared that both constant and variable domains had a similar, double beta-sheet structure in the framework region, that the hypervariable regions corresponded to surface loops in the variable domains, and that these loops did indeed interact with bound antigens. In almost all immunoglobulin domains, a conserved disulfide bond links the two sheets, and a **tryptophan residue** packs against it. Chothia and Lesk subsequently carried out the three-dimensional analog of the sequence comparisons of Kabat and coworkers by using the crystal structures (3). This led to some revision of the boundaries between the framework and CDR regions.

Different classes of immunoglobulins–IgG, IgA, IgM, IgD, and IgE–differ in their assembly from chains and domains. Figure 1 shows the domain structures of the different classes of immunoglobulins. Molecules in the class best known structurally, the IgGs, usually have two heavy chains that contains four domains and two light chains that contain two domains. The antigen-combining site in most IgGs is formed from three loops from the light chain and three from the heavy chain. Each IgG has two copies of the binding site, one from each light chain–heavy chain pair, which permits multiple interactions with antigens to form aggregates.

The IgG molecule contains four polypeptide chains, two identical light chains, each containing one variable and one constant domain, denoted V_L and C_L, and two identical heavy chains, containing one variable and three constant domains, denoted V_H, C_{H1}, C_{H2}, and C_{H3} (see Fig. 2). The C_{H1} and C_2 domains are linked by a segment of polypeptide chain called the hinge region. The angle between the V_L–V_H domain pair and the C_L–C_{H1} domain pair is called the elbow angle. These joints are usually flexible in solution. Immunoglobulins also contain carbohydrate moieties introduced by ***N*-glycosylation** that are not shown.

Figure 2. A schematic diagram of the structure of an IgG molecule (**a**), showing the distribution of domains in the heavy and light chains and (**b**) the interchain disulfide bridges, and the definitions of the fragments - Fab, Fab′ and Fc - produced by limited proteolytic cleavage.

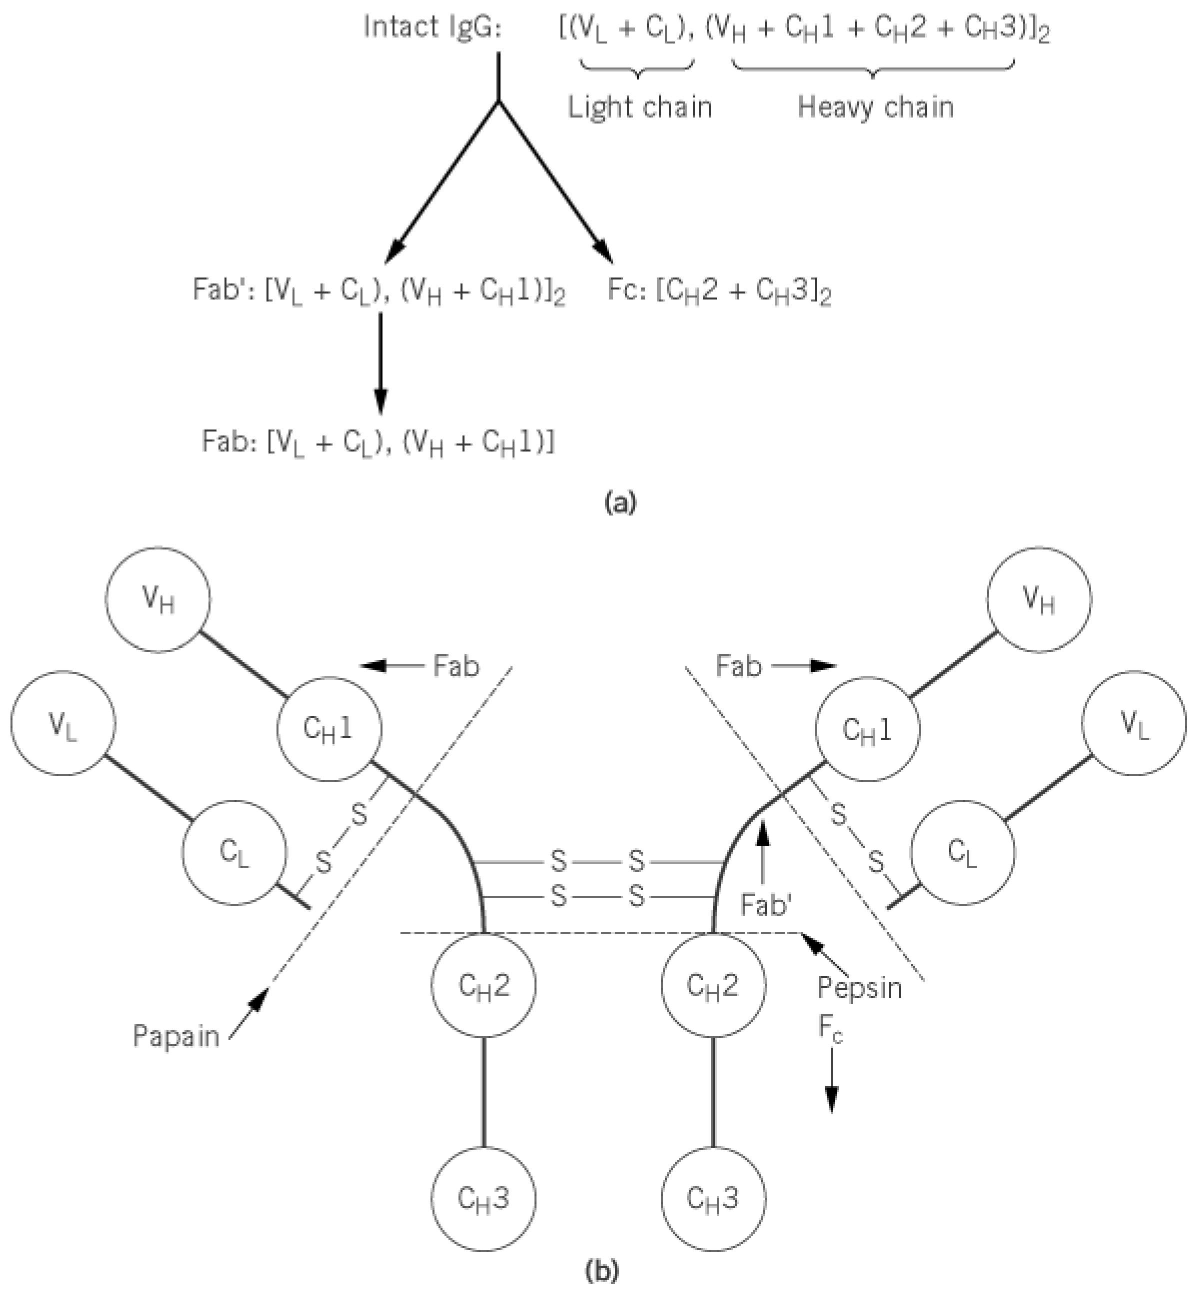


Figure 2 defines the fragments produced by limited proteolytic cleavage. Most of the structural analysis has been carried out on Fab fragments (4). Single-chain Fv fragments, in which the C-terminus of the V_H domain is linked by a flexible peptide to the N-terminus of the V_L domain, or vice versa, are important in protein engineering (5).

The interactions between the different polypeptide chains in an IgG include the disulfide bonds (see Fig. 2) and the interfaces between corresponding domains–V_L–V_H, C_L–C_{H1}, and C_{H3}–C_{H3}, but not C_{H2}–C_{H2}–that pack together to form extensive **van der Waals** contacts. It is characteristic of proteins that interior interfaces are formed by the packing of complementary surfaces. This complementarity of fit fixes the relative spatial disposition of the pieces that interact. A tendency to conserve the residues involved in these interfaces explains why different light and heavy chains pair fairly freely to form complete immunoglobulins. In the V_L –V_H interaction, conservation of the relative geometry has the additional important consequence that, to a reasonable first approximation, the double b-sheet frameworks of V_L and V_H domains form a scaffolding of nearly constant structure on which the antigen-binding site is erected.

Figures 3 and 4 show the **secondary structures** and tertiary structures, respectively, of the V and C domains. Each has the form of a double b-sheet “sandwich.” In immunoglobulin domains, the two sheets are oriented so that their strands approximately parallel. Figure 5 shows the interface between V_L and V_H domains (6).

Figure 3. The folding patterns of (**a**) variable domains and (**b**) constant domains. The domains shown are the V_L and C_H Strands of b-sheet are shown as polygonal ribbons, and the loops joining them as lines that join the C_{alpha} atoms of succ domain contains two b-sheets. One domain is shown in solid lines and the other in broken lines.

0.1. The Antigen-Binding Site
The study of antibody antigen-binding sites lies at the intersection of two topics of interest. One is th immune response: What is the relationship among the sequences of immunoglobulins generated by t genetic combination and somatic mutation and the three-dimensional conformations of the resulting sites? The second is the question of how the recognition and binding of an antigen by antibodies rela understanding of protein–ligand interactions, and the extent to which we can quantitatively explain a specificity at the level of interatomic interactions.

Most antibody antigen-binding sites are formed primarily from six loops–three from the V_L domain V_H domain. The three loops from the V_L domain are called L1, L2, and L3, in order of their appeara acid sequence. Alternatively, they are called CDR1, CDR2, and CDR3. V_H domains contain three cc loops H1, H2, and H3. In contrast, the antibodies of the camel and related animals contain only heav V_H CDRs suffice to create the antigen-binding site. This observation has obvious applications to sele artificial antibodies for therapy. Four of the loops, L2, H2, L3, and H3, are "**hairpins**," in that they li antiparallel strands of a single b-sheet, connecting strands of sheet that are hydrogen-bonded to each L1 and H1 bridge a strand from one of the two b-sheets to a strand in the other (Fig. 6).

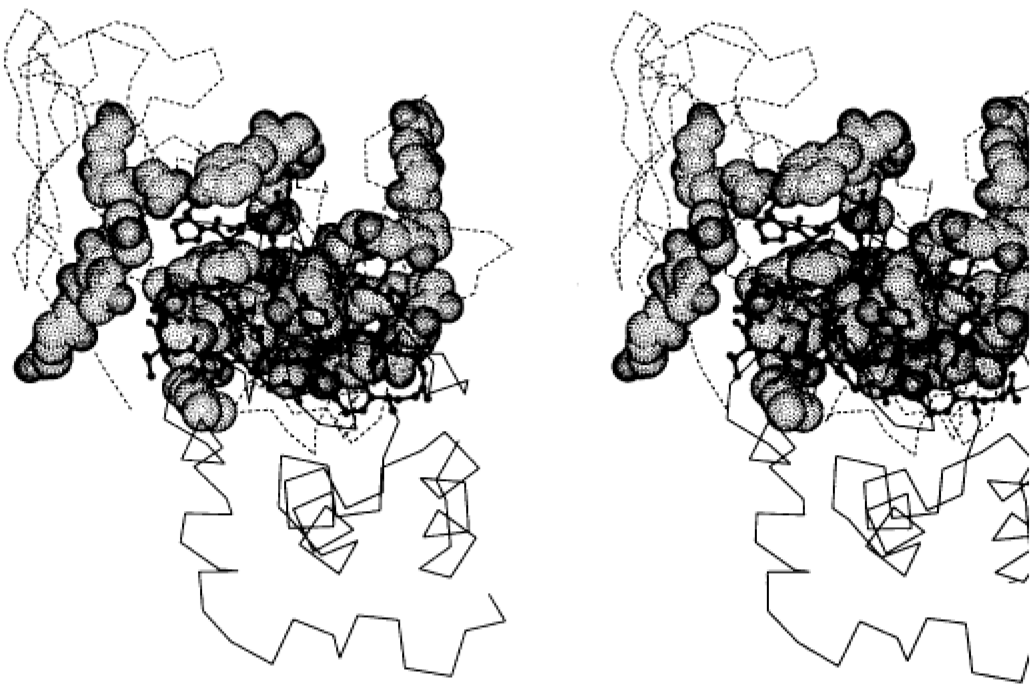
Broken lines indicate hydrogen bonds between antigen and antibody.



In many cases, antigen-antibody interactions involve the rigid association of the two structures. In
mechanism analogous to “induced fit” takes place, in which the structures of the free and ligated ai
significant structural changes. The structures of complexes between antibodies and protein antigen
antibodies specific for different **epitopes** of lysozyme and one specific for **neuraminidase**, demon
general features of the interactions are similar to those seen when other proteins associate without
conformational changes (7) (see Protein–Protein Interactions). The number of residues in contact g

from 27 to 39, distributed approximately equally between antibody and antigen. The accessible sur the antibody–antigen interface varies between 1250 and 1940 Å^2, and the interfaces are densely pa many cases several buried water molecules occupy sites within the interface. There are typically 1(bonds across the interface.

In the complex between Fab D1.3 and hen egg white lysozyme, for example, the interface is a relat dimensions $20\ \text{Å} \times 30$, although one glutamine side chain from the lysozyme inserts into a pocke (8). A total of 17 residues from the antibody make contact with a total of 17 residues from the lyso pairs of residues are in contact. Of the 17 residues from the antibody, three are framework residues adjacent to CDRs.

In the lysozyme–antibody complexes of known structure, there is rather little change in structure o relative to their unliganded states. Therefore, these complexes fit the picture of recognition by fairl have preformed complementarity. This is not observed, however, in complexes of antibodies and o clipped out of protein structures, because the latter are flexible in solution. In the complex between nine-residue region from influenza virus hemagglutinin (9), the peptide in the complex has the con type I b-turn, somewhat different from its conformation in the native hemagglutinin structure. Con structure of the Fab fragment of the antibody in free and liganded forms shows that there has also b rearrangement of the structure of loop H3. The relative orientations of V_L and V_H domains change antigen by a rotation, typically of about 3°, but up to 11° in known structures.

Another peptide–Fab complex, B13I2 (10), contains the seven-residue epitope of a 19-residue anti; to the C-helix of myohemerythrin. The residues of the peptide in the complex have the conformatio turn, not helical as in the native protein. What is most significant is that the antibody cross-reacts v protein, which it could not do while retaining its native structure. It is interesting that apomyoheme more strongly to the antibody. Apomyohemerythrin lacks the iron atoms, one of which binds to res C-helix in the native state. This implies that myohemerythrin changes conformation to bind the ant removal of a stabilizing interaction–a barrier to conformational change–enhances binding. (The str B13I2–myohemerythrin complex has not been determined.)

0.3. The Sequence Repertoire of the Immune System

Analysis of sequences of the loci on human chromosomes that carry the genes for antibodies and c these results with the amino acid sequences of expressed antibodies reveal what genetic resources t system possesses and how it uses them. The following discussion is restricted to human sequences

The gene for the variable region of the light chain is formed during B-cell development by combin segment. The k locus contains more than 40 functional V_k; segments and 5 J_k segments. The l locu functional V_l segments and 4 J_l segments. The gene for the variable region of the heavy chain is fo combinatorial joining of three segments: V_H (variable), D (diversity) and J (joining). Each individu approximately 51 functional V_H segments (11), 25 D segments, and six functional J segments. Des number of possibilities implied by these various combination, they apparently are not used with eq Comparing a database of expressed antibodies with the set of V_k germ-line sequences, of a total of germ-line V_k segments, only about 11 are used frequently, and others appear in only a minority of $_l$ sequences, 10% of the functional V_l gene segments produce 50% of the expressed V_l repertoire (

The nonuniform appearance of sequences is also reflected in a bias in the structures of the hyperva the associated primary antibodies. As discussed later, antigen-binding loops of antibodies usually h conformations chosen from a small repertoire of discrete canonical structures. The antibodies studi show strong preferences for particular main-chain conformations in their light-chain hypervariable

corresponding analysis of the V_H segments–which code for a region containing the first two hyper
the V_H domain–revealed similar nonuniform structural preferences (14). For example, sequences c
segments, which code for the part of the V_H domain that includes loops H1 and H2, suggest that th
different canonical structures of H1 and six of H2, potentially producing 18 different structures. H
sequences contain only seven different combinations of canonical structures of H1 and H2 (14).

0.4. Somatic Mutation and the Maturation of the Antibody Response

The distribution of residues that differ from their germ-line identities in expressed antibodies has b
Tomlinson and co-workers (15) by comparing sequence diversity on a residue-by-residue basis bet
antibodies and mature ones. Whereas the diversity in the germ-line antibodies is greatest in H3 anc
center of the antigen-binding site (because of junctional diversity in gene assembly; see Immunogl
Biosynthesis), somatic mutations spread the diversity to its periphery. In almost all cases, somatic
isolated single-residue substitutions, not insertions or deletions. The total change is less than the ty
between germ-line segments, that is, if one thinks of the germ-line segments as "islands in a seque
somatic mutations extend the domains of the individual germ-line segments, rather than filling in t
them. Thus, there was no ambiguity in identifying the germ-line segment from which each mature
Somatic mutation is a perturbation of a germ-line segment rather than a major reconfiguration of th
site.

Wedemeyer et al. (16) studied the maturation of an anti-nitrophenyl phosphonate catalytic antibod
crystallography. They solved the structures of the germ-line and somatically mutated Fab fragment
without ligand. Their results reveal both the sites of mutation and the structural effects. There are n
sequence changes between germ-line and mature antibody, three in the light chain and six in the he
the light chain mutants is in the L1 loop. The other two are at positions near in the sequence to L1
heavy-chain mutants appears in H2, three are in regions adjacent to or in contact with the antigen-b
two are surface residues at the opposite ends of the domains, which presumably have little effect o
binding site. No mutation is at a position directly in contact with the antigen. No mutation appears
although there are extensive contacts between H3 and the hapten. The conformations of two of the
loops (H1 and H2) differ between germ-line and mature antibody.

The antigen-binding site of the mature antibody has a similar conformation with and without boun
conformation that is complementary to the hapten. This structure is shared by the ligated state of th
antibody, but the unligated state of the germ-line antibody differs in conformation, that is, the gern
adopt the hapten-binding conformation, but this is induced by the ligand. In contrast, the mature an
conformation even in the absence of ligand.

Wedemeyer et al. (16) suggest that conformational flexibility in the primary antibody response rep
mechanism for generating antibody diversity. Indeed, it is possible that still other conformations o
antibody might be induced by alternative, related ligands. In this way the same primary antibody c
starting point for alternative maturation pathways to produce secondary antibodies to different liga
there is no direct structural evidence that this happens, nor how different the induced conformation

0.5. Structures of Loops in Proteins

The many known protein structures demonstrate that generally loops connecting strands of a b-she
characteristic sets of conformations, which depend on their lengths, sequences, and interactions wi
surroundings. For short hairpins in proteins, the conformation is usually determined primarily by t
sequence of the loop itself (17). For a polypeptide chain to reverse direction in a "tight" turn, it usu
advantage of a special residue, such as Gly or Pro, that allows a nonstandard main-chain conforma
Conformations of many short hairpins depend on the length and position of such a special residue.
also applies to many of the shorter CDR hairpins, L2, L3, and H3. H2 is exceptional, however, in t
residue strongly influences its conformation (18).

Medium-sized loops fall into two classes (19). The conformations of those that have ends close tog usually determined by hydrogen-bonding interactions of polar atoms that point into the interior of t typical V_k L3 loop, illustrated in Figure 9, exemplifies this case.) The conformations of more exte as H1, depend on the packing of bulky side chains against or into the core of the protein. In H1, for 29 of the heavy chain is usually a Phe, which is packed into the framework (see Fig. 10).

Figure 9. The most common canonical structure of V_k; L3, that from REI. This shows the characteristic *cis*-proline p C-terminus and the polar side-chain at the residue just before the loop that forms hydrogen bonds to stabilize the conf region.

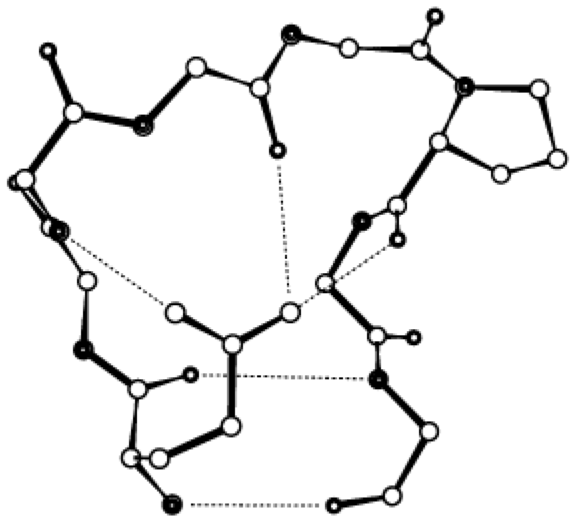


Figure 10. The H1 loop of Fab J539. An important contribution to stabilizing the conformation of this loop is the pac Phe29 into the region between the two sheets.

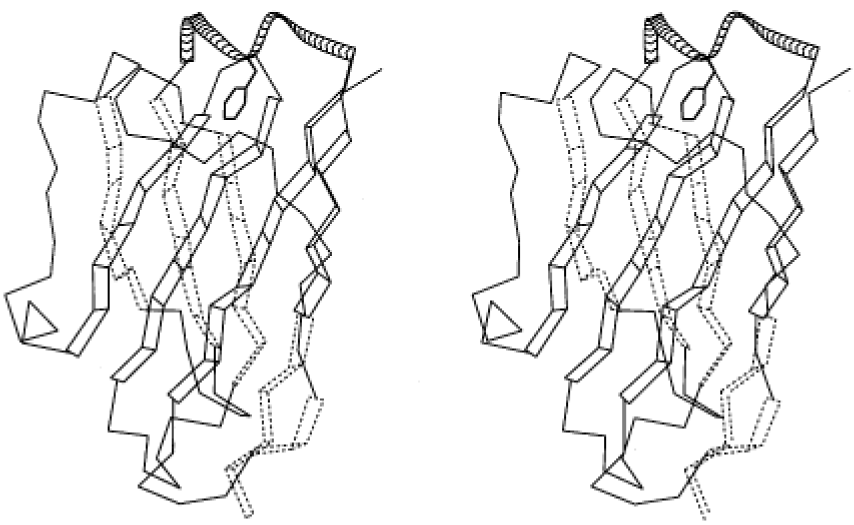


The Canonical Structure of Antigen-Binding Loops of Antibodies

Studies of immunoglobulin structures have shown that their antigen-binding loops have only a sm discrete main-chain conformations. These conformations are determined by a few particular resid outside the loop but interacting with it. Among corresponding loops of the same length, only these be conserved that maintain the conformation of the loop (20). The conserved residues may be thos special main-chain conformations or that form special hydrogen-bonding or packing interactions. residues in the sequences of the loops are left free to vary to modulate the surface topography and distribution of the antigen-binding site.

The biological significance of this robustness of the main-chain conformation of the antigen-bindi play a role in tuning antibodies by somatic mutation. In the system as it has evolved, a change in a antigen-combining site in most cases produces only a conservative structural change. This is what in a system that already shows affinity and requires only "fine-tuning." Consider the alternative. I completely altered the main-chain conformation of the loops, the effect would produce a successi primary responses, rather than a secondary response whose structures are perturbed in only minor important) ways from a set of already selected primary antibodies. One should not underestimate tiny structural changes to produce very large effects on binding affinity.

The ability to isolate the determinants of loop conformation in a few particular residues in the seq it possible to analyze the distribution of loop conformations in the many known immunoglobulin out of the six hypervariable regions of antibodies–L1, L2, L3, H1, and H2–have only a few main- conformations or "canonical structures" H3 is discussed separately later. Most sequence variation surface by altering the side chains on the same canonical main-chain structure. Sequence changes sets of positions switch the main chain to a different canonical conformation.

As an example, Figure 9 shows the L3 loop from V $_k$ REI. There is a proline residue at position 9 peptide bond. Hydrogen bonds between the side chain of the residue at position 90, just N-termina main-chain atoms of residues in the loop stabilize the conformation. The side chain is a Gln in RE other V_k chains. The combination of this loop length, one of these polar side chains at position 90 constitute the "signature" of this conformation in this loop, from which it can be recognized in a s immunoglobulin for which the structure has not been experimentally determined. The conformati 10) illustrates a nonhairpin loop, which joins strands in separate sheets. Its conformation is stabili inward-pointing side chains against the framework. General support for the canonical structural d antigen-binding loops has come from analysis of known sequences and structures of immunoglob conformations observed in the relatively few known immunoglobulin structures account for the lo proportion of all immunoglobulins.

When the canonical structural model was proposed, analysis of the large compilation of immunog sequences of Kabat and co-workers (21) showed that over 90% of the hypervariable regions in V the same length and contain the "signature" residues of a known canonical structure and therefore have conformations close to those found in the currently known immunoglobulin structures. Indee was conservative in that it includes only those hypervariable regions that matched the sequence re exactly. Of course one was dealing then with a limited number of known structures, and the mode overturned if subsequent structural determinations produced an unbounded proliferation of main-c conformations. However, the conclusion that the repertoire is limited and discrete is justified, alth canonical structures have appeared. Recently, 244 hypervariable regions in 49 immunoglobulin Fa structures determined at resolutions of between 1.7 and 3.1 Å were analyzed according to their str (22). Some 85%, and even more in subsequent work, were clustered into groups identified as kno structures and had very similar conformations. The structures on which the canonical structure an primarily human and mouse antibody fragments. However, analysis of the sequences of shark and suggest that the basic pattern of canonical structures goes back to the very early stages in the evol immune system (23). These observations suggest that the main-chain conformations of five of the regions–L1, L2, L3, H1, and H2–are described by a small repertoire of canonical structures. Most present among the immunoglobulin structures already known, and the main-chain conformations o an immunoglobulin of unknown structure can very often be predicted from the sequence by the pr specific residues (24).

A roster of current canonical structures is available (20). Its accuracy and completeness depend o
determination of the sets of residues responsible for the observed conformations and (2) the assun
changes in the identities of residues at other sites do not significantly affect the conformation of tl
results have been tested and refined by using them to predict the atomic structures of binding sites
immunoglobulin structures before determining them by X-ray crystallography (24).

0.6.1. Precision of the Canonical Structural Model

Qualitatively, the canonical structure model states that the main-chain conformations of five of th
binding loops fall into small, discrete clusters. It is important to know quantitatively how similar a
exemplars of the same canonical structure in different antibodies, for a proper understanding of th
mechanism of immune recognition and for the designing or modeling antibody structures. The tw
addressed are, what is the spread in the main-chain conformations of the canonical structures and
spread in their positions and orientations with respect to the framework? When the canonical struc
initially proposed, this question was difficult to answer, partly because the differences in observec
were comparable with the experimental error. Some of the structures had been determined only at
resolution and, even more seriously, some contained qualitative errors.

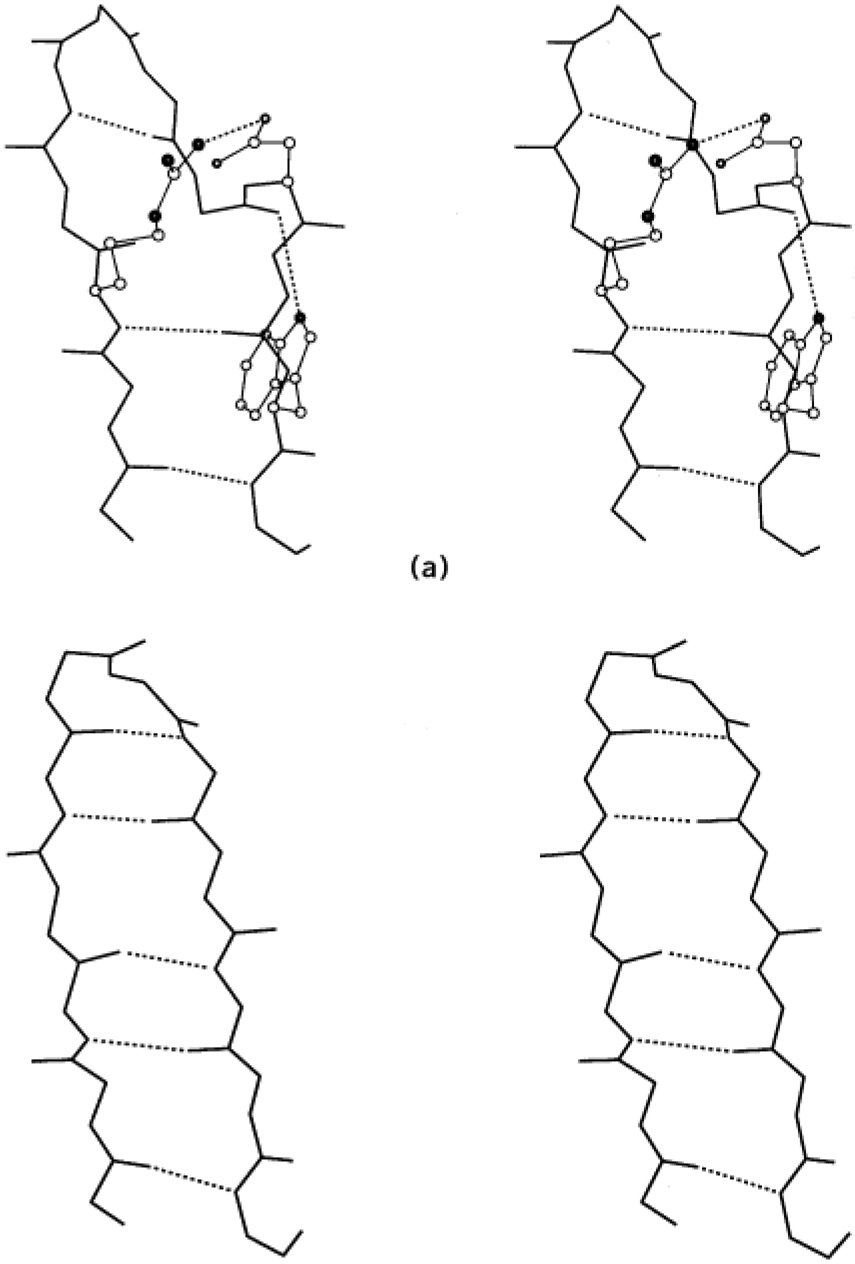
Now, the precision of canonical structures has been examined by analyzing and comparing of the
the antigen-binding loops in 17 immunoglobulins for which accurate structures have been determi
resolution (20). The structures used were determined to a resolution of 1.6 to 2.3 Å and refined to
greater than 21%. These contain 7 V_l, 10 V_k, and 15 V_H chains. Although the hypervariable regio
particular immunoglobulins do not cover all of the known canonical structures, they do include al
ones. The results indicate that the main-chain conformations of different examples of the same ca
in different antibodies are usually conserved to within about 0.3 to 0.4 Å rms deviation, which is a
degree of similarity.

0.6.2. The H3 Loop is Even More Variable

H3, the third hypervariable region of the heavy chain, is far more variable in length, sequence, an
the other antigen-binding loops (21). Therefore, it cannot be included in the canonical structural d
conformational repertoire that applies to the three hypervariable regions of V_L chains and the first
chains. Because the H3 loop falls in the region of the V-D-J join in the assembly of the immunogl
chain gene (Fig. 11), several mechanisms contribute to generating its diversity, including combina
V_H, D, and J gene segments and alternative splicing patterns at the junctions.

Figure 11. The roles of the V, D, and J gene segments in determining the immunoglobulin fold. Loop H3 arises fro
the V-D-J join in the assembly of the heavy chain gene. In the V_H domain of McPC603 shown here, the region enco
segment coincides almost exactly with the H3 loop region.

Figure 12. Two H3 loops with alternative torso conformations: (**a**) McPC603 - the bulged torso conformation, (**b**) 4 nonbulged torso conformation.



(a)

(b)

In expressed antibodies, H3 is prominently at the center of the antigen-binding site (see figs. 7,8) central position, H3 makes significant interactions with other loops with the framework, with the partner, and with ligands, which influence its conformation. Thus H3, in contrast to the other five binding loops, has a conformation that depends strongly on its molecular environment. Indeed, a containing the V_H domain of antibody B1-8 combined with two different V_L domains has two ve conformations of H3 (25). This important observation implies that general rules governing the cc H3 (unlike the other five antigen-binding loops) must involve interactions outside the local regio

To include all residues that contribute to determinants of the conformation of the H3 region and l conserved residues Cys92 and Gly104 provide useful landmarks to identify the H3 region in a ne H3 region is defined as the residues from Cys92 to Gly104. Analysis of the conformations of H3 divided the H3 region into a torso section comprising a head, the apex of the loop, and residues p framework–four residues starting from the conserved Cys92 and from the N-terminus and six res

C-terminus. For H3 structures that contain more than 10 residues, there are two main classes of t conformations (see Fig. 11). In the major class, the conformation of the torso has a **b_{12}-bulge** at a few H3 regions, the torso does not contain a bulge, but continues the regular hydrogen-bonding b-sheet.

The choice of bulged or nonbulged torso conformation is dictated primarily by the sequence. A b formed whenever residues are present that permit formation of a salt bridge between the side cha Lys residue at position 94 and Asp101, unless a residue at position 93 forms the salt bridge. Inde the torso region were chosen as the largest set of residues proximal to the framework that have a repertoire of conformations, as in the canonical structure model of other antigen-binding loops. I heads or apices of the H3 loops have a very wide variety of conformations. In shorter H3 regions containing the nonbulged torso conformation, the heads follow the rules relating sequence to stru hairpins. For longer H3 regions containing the bulged torso conformation, there are many very d conformations of the head, which can be catalogued but are difficult to classify.

Accurately predicting the conformation of the torso of the H3 region from amino acid sequence i most cases. Predicting the conformation of the head is possible in some cases. However, our und sequence–structure relationships has reduced the uncertainty to no more than a few residues at th region, but these residues appear in a crucial position within the antigen-binding site!

0.7. Prediction of Antigen-Binding Sites

The possibility of accurately predicting the three-dimensional structures of immunoglobulins at t is centrally important for engineering antibodies with prescribed specificity. Several methods for structures of antigen-binding sites have been proposed. Some apply information from known stru are based on *a priori* methods.

The canonical structural analysis of the conformations of the hypervariable loops suggests a mod all but the apex of the H3 loop: Construct the frameworks by standard **homology modeling** techn Then identify, if possible, canonical structures of the loops and graft them onto the modeled fram

Another procedure for predicting the structures of antigen-binding loops relies on conformationa calculations. The main-chain conformation of an antigen-binding loop attached to a given frame constraint that the chain must connect two fixed end points with a specified number of residues. fewer than about six residues, it is possible to enumerate a fairly complete set of feasible main-ch chain conformations, which bridge the given end points and do not make steric collisions within between the loop and the rest of the molecule. The search procedure can be fine enough to incluc the correct one in the many possibilities enumerated. To choose one of them as the predicted con possible to estimate conformational energies and to evaluate the accessible surface areas of each context of the remainder of the protein and set criteria for selecting the most favorable one. Typi conformational energy calculations include terms representing hydrogen bond, van der Waals, ar interactions. Accessible surface area calculations estimate the interaction between the protein anc Note that these procedures are completely general, independent of the current state of the structu

Procedures for conformation generation and evaluation have been implemented in a number of c programs. An application to predict all six antigen-binding loops of McPC603 and HyHEL-5 has (29). The resulting models of the antigen-binding loops of McPC603 and HyHEL-5 have rms de range 0.3 to 2.6 Å (backbone) and 1.4 to 4.1 Å (all atoms).

Jones and Thirup (30) developed an alternative approach to modeling loops, based on selecting l proteins in the database of known structures that span the given end points and overlap with pept termini. For this procedure to be useful, it is required (1) that the loops in immunoglobulin antige appear in other proteins in the database; (2) that the geometrical relationship between the loop an that flank it are the same in immunoglobulin antigen-binding sites and proteins in the database co of the same conformation; and (3) if several loops are found in the database that properly join the flanking an antigen-binding loop, it must be possible to select the correct one. This problem is th faced in methods in which loop conformations are generated *a priori*. If the selection from candi identified from homologous regions of other immunoglobulins by database searching is based on patterns in the sequences, the procedure reduces in effect to the canonical structural method.

The main-chain conformations of most antigen-binding loops recur in other antibody structures (course, one of the elements of the canonical structural model) and also in unrelated proteins (18, exceptions are unusually long loops, such as L1 of McPC603 or H3 of KOL. In other words, the loops whose structures commonly appear in antibodies are not unique to antibody structures. Ho geometrical relationship between the loop and its flanking peptides usually differs when compari binding loop with a loop of similar conformation in an unrelated protein (except for short hairpin conformation). In these cases it would not be possible to build a correct model of an unknown im A protocol that combines these approaches, by using a CONGEN procedure alone for short loops supplements it with database search techniques for longer loops, has been described (32).

1. Conclusions: How Does the Immune System Generate and Then Refine Molecules of Genera

Based on the studies of sequences and structures, we can provide some fairly detailed answers to about what the immune system is doing at the structural level. Here we are concerned with the ge diversity in structure and thereby in affinity and specificity but do not treat the cellular mechanis which challenge by antigens elicits the proliferation of those cells that produce antibodies that bi Immunoglobulin Biosynthesis).

The antigen-combining site has a main-chain conformation determined by the canonical structure L2, L3, H1, and H2, plus the more variable H3. The number of potential main-chain structures in binding site is equal to the product of the number of possible canonical structures for loops L1, L H2, and of the number of possible structures of H3. Although putting numbers into these stateme large numbers of potential antibody sequences, there are preferences for structure at the level of canonical structures. Because only a relatively few residues are required to fix the canonical stru chain, most of the antigen-binding loop residues can be freely decorated with side chains to vary topography and charge distribution of the binding site.

The immune system is one of many biological examples of molecular recognition. Individual ant complexes fit the classical ideas of lock-and-key complementarity and induced fit, but the system more complex than, for example, enzymes, in which the lock and key are in most cases fixed and within the lifetime of the organism. In the primary immune response, the immune system achieve many keys by providing many locks, but to achieve the spectacular affinity of the secondary resp mechanism to perturb the locks for better fit. The integration of the immune response over the sy involving both sequence and structural dimensions together with the clinical and biotechnologica makes it a fascinating topic to study.

Immunophilin

Cytosolic receptor proteins for immunosuppressant drugs in mammals of the cyclosporin and peptidomacrolide type have been named immunophilins because of their putative involvement in the signaling mechanism of the cellular immune response (1). It was further pointed out that the immunophilin/immunosuppressant complex is active, not the individual free drug or receptor. A composite surface formed by the bound drug and by the surrounding immunophilin residues functions by binding other cellular proteins involved in signal transduction. Initially, because of the limited knowledge about the diversity of these enzymes, the groups of immunophilic receptor proteins coincided with the enzyme classes of peptidyl prolyl cis/trans isomerases (PPIase), cyclophilins, and FK506-binding proteins (FKBP). Now, cyclophilins and FKBP have been isolated that display only modest affinity for these drugs or cannot form active enzyme/drug complexes. Furthermore, the new PPIase families of trigger factors and parvulins do not bind the immunosuppressive drugs at all. On the other hand, there are now also many other proteins that have considerable affinity for the immunosuppressants and are not PPIase (2). To avoid confusion with nomenclature, the term immunophilin should be limited to PPIases with proven involvement in immunosuppression.

Imprinting

1. Mammalian Imprinting: From Genomes to Genes

Sexual reproduction, which involves the fusion of two gametes produced by two distinct individuals, is the most common form of reproduction encountered among higher eukaryotes. Although sexual reproduction has obvious long-term benefits, such as being a powerful source of genetic variability and in triggering evolution, many short-term disadvantages, including what is called the “cost of meiosis” (1), could have acted against its maintenance during evolution. In this regard, one can view imprinting as a way to “maintain” sexual reproduction, by providing an absolute short-term advantage. Parental imprinting, also known as genomic or gametic imprinting, is a genetic effect in which the expression (behavior) of **genomes, chromosomes**, or chromosomal regions differs according to their parental origin. As a result, individuals from species in which imprinting occurs require a contribution of both parental genomes to develop properly. This phenomenon is observed in many biological systems, from bugs, where sexual determination involves the inactivation and sometimes even the loss of the whole paternal genome (2), to mammals, which will be the main subject of this review.

In mammals, evidence that maternal and paternal genomes are imprinted to function differentially during development initially came from the study of parthenogenetic and androgenetic mouse embryos generated by pronuclear transplantations (3-5). In general, parthenogenetic embryos (two maternal genomes) fail to develop normal extraembryonic components, whereas androgenetic embryos (two paternal genomes) have a very poorly developed embryo proper. Mouse genetic studies involving the analysis of maternal and paternal disomies and/or duplications of defined chromosome regions have subsequently demonstrated that this phenomenon does not affect the whole genome *per se*, but rather only specific regions (6). Ten regions on six mouse autosomes have been shown to be subject to imprinting [chr 2, 6, 7, 11, 12, and 17, (6)]. The maternal and paternal duplications for five of the imprinted regions have distinct consequences, indicating that there are in total 15 known imprinting effects. One cannot exclude the possibility, however, that there are additional imprinted regions with phenotypic effects too subtle to be detected.

Further investigations have revealed that the genetic basis for these imprinting effects is likely to be the genes themselves, because some of the genes lying within these regions are subject to imprinting, which means that they are monoallelically expressed, either from the paternal or the maternal chromosome, depending on the gene. In the same way, monoallelic expression can occur in most tissues of the individual or can be restricted to a very specific developmental stage and/or cell lineage. Now, more than 25 imprinted genes have been identified in mouse, and most of these are conserved in human (Table 1). Despite the growing list of imprinted genes and their more detailed characterization, the function of imprinting remains a mystery. The abnormalities displayed by parthogenetic and androgenetic mouse embryos underscore, however, that imprinting plays a pivotal role in development.

Table 1. List of Imprinted Genes in Human and Mouse and Some of Their Characteristics[a]

				Human		
Gene	**Function**	**Chr**	**Exp**	**Specificity**	**Methylation**	**Ch**
Human Chromosome11/Mouse Chromosome 7						
IGF2/Igf2	Growth factor		pat	Mostly monoallelic except in choroid plexus,leptomeninges and adult liver		
INS2/Ins2	Insulin		pat + mat			
H19	Noncoding RNA		mat	Mostly monoallelic except in early placentae	Hypermethylation of the paternal allele	
HASH2/Mash2	Transcription		mat	Mostly monoallelic		

	factor					
KVLQT1/Kvlqt1	Potassium channel		mat	Mostly monoallelic except heart		
$p57^{KIP2}$	Cyclin-cdk inhibitor		mat	Mostly monoallelic with weak expression of thepaternal allele in most tissues; biallelic in fetal brain		
IPL/Ipl	Role in apoptosis?		mat	Mostly monoallelic with some mosaicism		
IMPT1/Impt1	Metabolite transporter?		mat	Allelic bias		
Human Chromosome15/Mouse Chromosome 7						
ZNF127/Zfp127	Zinc-finger protein		pat	Mostly monoallelic	Hypermethylation of the maternal allele	
ZNF127A S/Zfp127as						pat
NECDIN/Necdin			pat	Mostly monoallelic		Hypermet of the mat allele
SNRPN/Snrpn	Splicing		pat	Mostly monoallelic	5′ Region methylated on the maternal allele 3′ region methylated on the paternal allele	
PAR-SN	No ORF		pat	Monoallelic (lymphoblast)		
PAR-5			pat	Monoallelic (fibroblast)		
IPW	No ORF		pat	Mostly monoallelic		
PAR-1			pat	Monoallelic (fibroblast)		
UBE3A/Ube3A	Ubiquitin protein ligase		mat	Moallelic only in brain	No allelic methylation identified	
DST			mat	Moallelic only in brain		
UBE3A/DST-antisense	Regulation of UBE3A imprinting?		pat	Expressed and monoallelic only in brain		
Miscellaneous Genes						
p73	Tumor	1p36	mat	Mostly monoallelic	NT	

	suppressor					
IGF2R/Igf2r	IGF2 receptor	6q25-26	mat + pat	Mostly biallelic.	Region 2 hypermethylated on the maternal allele	17
				Some cases of monoallelic expression		
Igf2r−antisense	Regulation of Igf2r imprinting?					17
MAS/Mas	Cell surface receptor	6q25-26		Monoallelic only in adult breast	17	
PEG1-MET/Peg1-Mest	a/b Hydrolase fold family	7q32	pat	Monoallelic in fetus, biallelic in blood	Maternal methylation	6
HTR2	Serotonin receptor	13q14	mat	Monoallelic (fibroblast)	Maternal methylation	14
U2af1-rs1	Splicing	NC				11
Peg3/Pw1	?					7
Grf1	Regulates synthesis and release of growth hormone					9
Peg5/neuronatin						2

[a] The first part of the table corresponds to the human chromosome 11/mouse chromosome 7 cluster; the second part of the table corresponds to the human chromosome 15/mouse chromosome 7 cluster; and the third part of the table corresponds to miscellaneous genes. Chr, chromosomal localization; Exp, allele expressing the gene; pat, paternal; mat, maternal. Specificity: specificity of the monoallelic expression. Methylation: allelic methylation. Noted as G when inherited from the gametes, S (somatic) when not. NC (in the case of U2af1-rs1 in man) indicates not conserved at the location homologous to that in mouse. Blank cells indicate not tested or not published results.

This is also true in humans, because the presence of two paternal genomes without a maternal one results in the formation of hydatidiform moles (7), which is essentially equivalent to that found with the androgenetic embryos in the mouse. In addition, the deregulation of imprinting causes disease, and the expression of several inherited diseases is strongly influenced by the sex of the transmitted parent. The best-known examples are the Beckwith–Wiedemann syndrome (BWS) and the Prader–Willi and Angelman syndromes (PWS and AS) (8). BWS is often associated with lack of a biparental inheritance of chromosome 11p15 and is characterized by pre- and postnatal overgrowth, including hemihypertrophy, visceromegaly, and macroglossia (enlarged tongue), and an increased probability of developing childhood cancers, the most frequent ones being Wilm's tumor and adenocortical carcinoma. The involvement of imprinting in this syndrome was suggested by the preferential maternal transmission of mutations in BWS (9, 10) as well as the occurrence of paternal uniparental disomies (UPDs) of chromosome 11p in several sporadic cases of BWS (11).

PWS and AS are two clinically distinct syndromes that share a chromosomal location (15q11-q13) but display opposite parental origins of transmission. PWS is characterized by hypotonia, hypogonadism, variable mental retardation and obesity (12), while the AS clinical features include hyperactivity, ataxic gait, "puppet-like" arm movements, bouts of inappropriate laughter, seizures, EEG abnormalities and severe mental retardation with absence of speech (13, 14). Most (60% to 70%) PWS and AS cases are associated with *de novo* cytogenetic deletions of the 15q11-q13 region. In PWS, the deletion occurs exclusively on paternal chromosome 15 (15), whereas AS chromosome 15q11-q13 deletions are of maternal origin (16). Maternal and paternal uniparental disomy (UPD) also occur in some PWS (17) and AS (18) cases, respectively. Roughly 25% of PWS patients display UPD with both chromosomes 15 being inherited from the mother and no chromosome 15 being derived from the father. Only about 5% of AS cases result from paternal UPD and maternal nullisomy for chromosome 15. These observations indicate that the gene(s) responsible for PWS are expressed only from the paternal chromosome, whereas the AS gene(s) are transcribed from the maternal chromosome.

The list of human diseases resulting from abnormal imprinting will no doubt expand as the catalogue of imprinted genes (see Table 1) becomes more complete. The identification of other loci subject to genomic imprinting requires some knowledge of the properties specific to such regions.

2. Characteristics of Imprinted Regions and Genes

The occurrence of imprinting and its consequent monoallelic expression implies that both alleles of the same gene can be recognized and differentially regulated within the same nucleus. The fact that imprinting occurs in laboratory inbred mouse strains, which are genetically identical at all loci, indicates that the basis of imprinting must be epigenetic. Imprinting is a two-step process that must fulfill two conditions. The first step is the apposition of the mark, the imprint, which will allow one allele of a gene (or a chromosomal region) to be distinguished from its homologue. This "labeling" must occur during gametogenesis, which is the only stage where both alleles are physically separated. The question remains as to which allele, the repressed or the expressed one, carries the imprint, although recent evidence suggests that it is the silent allele that is modified in the gamete (see text below). The second step of the process is the reading of the imprint in the appropriate developmental stage and/or tissue, which implies that the imprint has not been erased during development and is stably maintained. Stability is one of the required characteristics of imprinting. Once established, the imprint must indeed be clonaly inherited and maintained through cell divisions. Reversibility is the other necessary property of impritinting, because the imprint must be erased and properly reestablished at each generation. Both stability and reversibility are features of, and can be explained by, epigenetic modification of the chromatin.

Differential **methylation** of the cytosine residue in **CpG** dinucleotides is an attractive candidate as the "label" of imprinted genes and regions, because it is an epigenetic modification that is reversible and heritable, and it can play a role in the regulation of gene (19, 20). The association of DNA methylation with transcriptional activity and chromatin conformation is most evident in the case of the mammalian X chromosome, where the **promoters** of several **housekeeping genes** on the inactive X chromosome are enriched for 5-methylcytosine. These results suggest that repression of gene activity can be mediated through methylation of 5′ regulatory elements. This association is less clear for tissue-specific autosomal genes where, despite a significant body of suggestive evidence, there is no direct proof that DNA methylation modulates transcriptional activity.

A significant difference in the degree of methylation between the paternal and maternal genomes has been elegantly demonstrated by Rougier et al. (21). These authors used **antibodies** to 5-methylcytosine to label metaphase chromosomes in mouse preimplantation embryos, and they observed distinct differences in the labeling patterns at the one-cell stage. The **euchromatic** arms of the maternal chromosomes were intensely stained and demonstrated an R-like banding pattern. In contrast, the antibody staining of the paternal set of chromosomes was quite faint (21). While these data demonstrate the marked difference in global DNA methylation between the two parental chromosome complements in preimplantation development, more direct evidence of a role for DNA methylation in the process of epigenetic marking has been derived by the analysis of sites of allelic methylation within imprinted genes. Most imprinted genes indeed display parent-specific methylation (Table 1). For some of them, including *H19* and *SNRPN* (22-25), methylation is associated with the repressed allele, whereas for others, like *Igf2*, it is the expressed allele that is methylated (26). Strong evidence for the pivotal role of DNA methylation in the regulation of imprinted gene expression comes from studies in mice bearing a disruption of the DNA methyltransferase gene (Dnmt), the enzyme responsible for the maintenance of cytosine methylation (27). Such mice display embryonic lethality and a content of 5-methylcytosine that is reduced to about 30% of wild-type levels (27). Moreover, the expression of several imprinted genes in Dnmt -/- mice is abnormal with, for example, activation of the normally repressed paternal *H19* allele and silencing of the normally active paternal *Igf2* allele (28). While these results clearly indicate the functional role of allelic DNA methylation in imprinted gene expression, the imprinting of some genes, such as *Mash2*, appears normal in Dnmt-/- mice, suggesting the possibility of different mechanisms of imprinting in terms of its association with methylation (29).

Another property of imprinted regions is asynchronous DNA replication. Chromosome replication banding studies generally indicate that homologous regions on both autosomes of a pair replicate at the same time in the S phase of the cell cycle (30). Using this approach, Izumikawa et al. first observed that this was not the case for the imprinted chromosomal region 15q11-q13 (31). That imprinted chromosomal regions replicate asynchronously has been confirmed in other replication banding studies (32, 33) and by using a different assay of DNA replication involving the technique of fluorescence in situ hybridization (FISH) (34). The use of the FISH assay has revealed that DNA replication asynchrony is a feature of other imprinted regions (34-36). The parental origin of the earlier replicating allele was investigated for several probes from different imprinted regions, and it was generally found that DNA replication occurs earlier on the paternal homologue (34, 37-39). The patterns of allele-specific replication have also been investigated in the cells of PWS and AS patients (34, 37-40), with one important finding being that the DNA replication of various probes from the PWS/AS region is synchronous in the cells of PWS and AS UPD individuals (37-40), suggesting the requirement of a biparental contribution for the regulation of replication asynchrony (38). These findings led to the suggestion that allelic cross-talk might be involved in the normal pattern of imprinting. As several such cross-talk models of transcriptional regulation involve pairing of homologous chromosomes, the possibility that the maternal and paternal chromosome 15 homologues physically associate during somatic cell division was investigated.

Three-dimensional analysis of FISH in spatially intact nuclei was performed by laser scanning confocal microscopy to determine the distance between homologous chromosomes in cell cycle-fractionated human lymphocytes (41). The results demonstrated that in normal cells the chromosome 15 homologues pair during the late S phase. The most tightly paired region was observed to be 15q11-q13, consistent with the hypothesis that allelic cross-talk could be involved in the normal pattern of imprinting in chromosome 15q11-q13 (41). Homologous association was also observed at the imprinted IGF2 locus on chromosome 11p15 (41), suggesting that the physical association of chromosome homologues is another manifestation of imprinting in normal human somatic cells and that regulation in *trans* could play an important role in the establishment and/or maintenance of imprinting.

The hypothesis that *trans*-sensing effects may play some role in the regulation of imprinting has been confirmed to some extent at the molecular level using mouse models, where imprinted genes have been modified or deleted by **gene-targeting** mutagenesis (42, 43). Crosses between mouse strains bearing different *H19* deletions revealed that transmission through the maternal germline affects the DNA methylation pattern of the paternal *Igf2* allele. In these crosses, where the maternal (active) *H19* allele is deleted, the paternal copy of *Igf2* is hypomethylated relative to that in wild-type animals (42). It has also been shown that imprinted expression of another gene, *Ins2*, which is tightly linked to *Igf2*, can be affected by the *trans* allele (43). In the latter experiments, the level of transcription of the maternal copy of a reporter gene (Lac Z) construct inserted at the *Ins2* locus depended on what was present on the paternal copy. Expression of the maternal copy of LacZ was repressed in the case where the paternal copy was an insertion of a different reporter (Neo), but not in mice where the paternal homologue is wild type. These results suggest that interaction between two alleles in *trans* can modulate both allele-specific transcription and DNA methylation and thus play a fundamental role in the establishment and/or maintenance of imprinting.

The properties of imprinted regions summarized above underscore the fundamental role of epigenetic modification of chromatin in the establishment and the maintenance of the imprint. There is, in addition, some molecular evidence for allele-specific changes in chromatin structure at imprinted loci. For the imprinted gene *U2af1-rs1* (see Table 1), there is a correlation between imprinted expression and an “open” or “active” chromatin expression, because the gene shows both expression and the presence of nuclease-hypersensitivity at sites in the promoter region of the paternal, but not the maternal, allele (44). No such allele-specific differences in nuclease sensitivity has been identified for the imprinted *Igf2* gene (45), however, suggesting that differential chromatin structure, at least as assayed by these approaches, is not a general feature of imprinted genes. Alternatively, these discrepant findings may reflect different mechanisms of imprinting for *U2af1-rs1* and *Igf2*. Further evidence for an association between imprinting and chromatin structure at the global level comes from the observation of sex-specific meiotic recombination frequencies in imprinted regions (46, 47).

3. A Catalog of Imprinted Genes and Their Characteristics

Although the occurrence of imprinting in mammals was demonstrated in 1984 (3, 4), one had to wait several years for the first imprinted genes to be described. As it is often the case in biological research, several papers, published at approximately the same time, reported imprinting of three genes, *Igf2r, Igf2*, and *H19* (48-50). These are the most studied of the imprinted genes in terms of understanding imprinting mechanisms (see text below). Since these initial reports, the number of genes identified as imprinted has continuously increased. There were eight reported by 1994 (51), and four years later more than 25 genes are identified as being monoallelically expressed in a parental-dependent way, at least at some point during development (Table 1). Due to limited space, these cannot be described in detail here, and only a few have been chosen as examples.

Igf2r was mapped to mouse chromosome 17, in a region known to contain the Tme locus, a **maternal-effect** mutation that results in the death of embryos at day 15 of gestation (52). **Northern blot** hybridizations of RNA from embryos having inherited a deletion of Tme from their mother or their father showed that only the maternal allele of *Igf2r* is expressed (48). Methylation analysis of a 130-kbp region spanning the *Igf2r* locus has identified two CpG island regions that display allelic methylation (26). Region 1, which corresponds to the 5′ end of the transcription unit, is hypermethylated on the transcriptionally silenced, paternal allele. Region 2, localized in the second **intron** of the gene, shows the opposite pattern, with hypermethylation of the expressed, maternal allele. Only the region 2 hypermethylation profile is inherited from the gametes and remains constant in all developmental stages and must therefore represent the imprint for the *Igf2r* gene. The functional role of this region in the imprinted expression of *Igf2r* was demonstrated by generating transgenic mice carrying a yeast artificial chromosome (YAC) from that region, which successfully reproduced methylation and expression of the endogenous *Igf2r* (53). Deletion of region 2 from these transgenes results in loss of imprinting and biallelic expression of *Igf2r*. Moreover, the region 2 CpG island was shown to be responsible for the expression of an **antisense** RNA (AS) whose expression profile is opposite to that of *Igf2r*. Only the paternal allele is normally transcribed and, in the case where *Igf2r* biallelic expression is associated with deletion of region 2, both alleles are repressed. It has been suggested that the antisense is the “imprintor” gene that regulates in *cis* the imprinted expression of *Igf2r* (54) (see text below).

Evidence for the imprinting of *Igf2* came initially from genetic studies of knockout mice generated to investigate the potential role of this gene during development. Heterozygotes having inherited the deletion from the father are smaller in size than normal animals and are indistinguishable in appearance from homozygotes (55). In contrast, when the mutation is transmitted through the mother, the heterozygotes are phenotypically normal. Molecular analysis of *Igf2* expression in genotyped embryos using ribonuclease protection assay subsequently confirmed that the paternal *Igf2* gene is transcriptionally active, whereas the maternal transcript is not detectable, except in choroid plexus and leptomeninges (49).

H19 is an abundant RNA in the developing mouse embryo. Despite the absence of coding potential of *H19*, it is conserved significantly between human and mouse (56). Overexpression of *H19* in transgenic mice results in late prenatal lethality, suggesting that its dosage must be strictly controlled during development (57). In addition, *H19*, like *Igf2*, was mapped to mouse chromosome 7, in a region known to display an imprinting effect. Imprinted expression of *H19* was assessed using a ribonuclease protection assay that could distinguish between **polymorphic** alleles from different mouse subspecies. Only the maternal allele was shown to be expressed in liver and skeletal muscle of neonates and adults (50). Fine mapping subsequently localized *H19* less than 90 kbp from *Igf2*, with both genes having the same transcriptional orientation (58). Thus, both genes are physically clustered and imprinted, although in the opposite direction. In addition, *Igf2* and *H19* display a very similar, if not identical, pattern of expression during development (59). These findings led to the hypothesis that *H19* and *Igf2* operate from a common set of regulatory elements (60). Indeed, two endoderm-specific **enhancers**, located distal to *H19*, were shown to be responsible for the maternal expression of *H19* and the paternal expression of *Igf2* (61). The choice of the gene (*H19* or *Igf2*) to be activated by these enhancers is dictated by their methylation status. Both *H19* and *Igf2* have a region of hypermethylation on the paternal chromosome (23, 62). Only in the case of *H19*, however, is the methylation inherited from the gamete, suggesting a role as the imprint to distinguish the two alleles of *H19* (63). This paternal-specific *H19* methylation is thought to result in the strong preference for *Igf2* expression on the paternal chromosome. Methylation of *H19* on the paternal allele thus indirectly triggers the expression of *Igf2*. On the maternal chromosome, the preference for *H19* expression could well result from its closer proximity to the enhancers, a possibility that has been demonstrated by creating transgenic mice with duplicated and mislocated enhancers (64). *H19* can therefore be classified as a gene that is directly imprinted, whereas *Igf2* is imprinted indirectly, leading to the suggestion that the role of *H19* is to regulate the expression of *Igf2* and other flanking genes. This role for *H19* is analogous to that of an imprintor as mentioned above (54).

As shown above, initial reports of imprinted genes were based on genetic evidence: either the observation of a parental effect associated with a mutation (*Igf2*), or the mapping of a gene to a region known to display an imprinting effect (*Igf2r* and *H19*). This latter “strategy” has led to the identification of other clusters of imprinted genes, including that of mouse chr. 7/human chr. 11 *H19/Igf2* cluster and the mouse chr. 7/human chr. 15 cluster (Table 1).

The human 11p15 region, which contains *H19* and *IGF2*, is associated with the Beckwith–Wiedemann syndrome (BWS). *IGF2* has long been a strong candidate for this syndrome, since it is highly expressed in the tissues that are the most affected in BWS. Moreover, *IGF2* imprinting is lost in 80% of BWS cases, resulting in biallelic expression of the gene (65), a finding that could explain the overgrowth characteristic associated with this syndrome. However, no chromosome rearrangment or mutation affecting the expression of *IGF2* alone has been identified in BWS patients, and the search for additional candidate gene(s) has led to a detailed transcription and imprinting map of the region. *p57* ^{KIP2}, an imprinted gene (66) that encodes a cyclin-dependant kinase (CDK) inhibitor, is the first gene shown to be mutated in BWS patients (67). *KVLQT1* was identified by positional cloning and mapped between *p57* ^{KIP2} and *IGF2*. *KVLQT1* is disrupted by chromosomal rearrangements in BWS patients (68) and is imprinted, with predominant maternal expression in most tissues. One exception is heart, where biallelic expression is observed. In several specimens, including different fetal tissues, however, monoallelic expression is not complete and, although the maternal allele is predominately expressed, residual expression from the paternal gene is detected. This "weak" or "leaky" imprinting is even more pronounced in the case of the mouse homologue *Kvlqt1*. While early expression of the gene is maternal in origin, this strong maternal bias is gradually lost in a tissue-specific manner as embryogenesis proceeds. Adult animals show complete biallelism (69). *IMPT1*, an other imprinted gene lying in the human 11p15.5/mouse distal 7 regions, also shows an allelic bias ("unequal allelic expression") toward the maternal allele (70).

Incomplete imprinting has also been reported for *UBE3A*, the gene involved in Angelman syndrome. This gene displays highly tissue-specific imprinting, with predominant maternal expression in brain, but the paternal allele still expresses [TEXnical Error] of the total (71). In that case, this is likely to be due to the presence of different cell populations in the brain samples studied, one displaying complete monoallelic expression and a second, less abundant one, showing normal, biallelic expression; in mouse, *Ube3A* imprinting was shown to be restricted not only to brain but, more specifically, to certain types of neurons (72). Whether similar explanations are valid for most cases of incomplete imprinting remains to be determined. Most techniques used so far to study the imprinting status of genes, such as Northern blot, reverse transcriptase–polymerase chain reaction (**RT-PCR**), or ribonuclease protection, are performed on tissue samples or even whole individuals (embryos), which implies a mixture of several cell types. Analysis at the cellular level will require the use of more sophisticated technologies, like single-cell PCR or RNA-FISH. As suggested by the recent description of "weakly" imprinted genes, more detailed analyses of the expression pattern of genes may prompt us to reconsider our definition of imprinting. Will any gene showing monoallelic expression in a reasonable number of cells at any developmental stage or in any tissue be considered as imprinted? One important point to keep in mind, however, is that if imprinting implies monoallelic expression at some point during development or in some cell types, monoallelic expression doesn't necessarily indicate imprinting. This is evident from the observation that genes such as those encoding the olfactory receptors (73) and the lymphokine IL-2 (74) are monoallelically expressed but cannot, however, be considered as imprinted, because their expression can be from either the maternal or the paternal allele (random allelic expression).

It may also be very difficult to exclude that any gene is imprinted, because of the difficulty in analyzing the status of allelic expression in all cell populations within any tissue at any developmental stage. In other words, if the demonstration of nonrandom allelic expression is the molecular proof of imprinting, the "failure" to detect such an expression pattern is not proof of the absence of imprinting. One example that illustrates this problem is the Angelman syndrome gene, *UBE3A*. This gene was shown to be responsible for Angelman syndrome based on its chromosomal localization and the presence of point mutations in several patients. However, *UBE3A* displayed biallelic expression in fibroblasts and lymphocytes since the only cell types that had initially been tested, this gene was considered as not imprinted. It was shown only later that *UBE3A* is indeed imprinted, but that this is restricted to brain (71, 75) or, even more specifically, to certain types of neurons (72).

4. Mechanisms of Imprinting

Imprinted genes appear to be preferentially organized into clusters, rather than dispersed throughout the genome, although this may be biased by the fact that the search for imprinted genes has been mostly based on their localization within a region displaying an imprinting effect. This organization into clusters, along with additional molecular evidence, suggests that each imprinted gene is not regulated independently from the other member of the cluster and that cis-acting elements are crucial for their concerted regulation. Two main types of *cis*-elements will be described here, imprinting centers and imprintors, and their relation to each other will be discussed.

4.1. Imprinting Center

As mentioned above, PWS and AS are two distinct syndromes that map to the chromosome 15q11-q13 region. Analysis of several patients carrying distinct rearrangements has allowed definition of two nonoverlapping regions responsible for these syndromes, with the AS region being smaller and lying distal to the PWS region (76). However, small deletions of less than 50 kbp within the PWS interval, in the 5′ region of the paternally expressed *SNRPN* gene (Table 1), were shown to be associated not only with PWS upon paternal transmission, but also with AS when transmitted maternally (77). These deletions affect the methylation profile and the gene expression pattern of the entire PWS region and, probably, although this has not yet been proven, the AS region. In such PWS patients, both chromosomes carry a maternal-specific methylation profile, and the paternally expressed genes of the region, such as *SNRPN, PAR-1*, and *PAR-5*, are transcriptionally silent (78). In AS patients, these genes are expressed biallelically (79) and the paternal methylation pattern is found on both chromosomes. The expression profile of the maternally expressed, AS gene *UBE3A* has not been tested, but it is expected to be silenced on both alleles. Because of these long-range effects, the deletions are thought to affect an imprinting control region, the imprinting center (IC), and are called “imprinting mutations.” Fine mapping of the IC has led to the identification of alternative *SNRPN* 5′ exons, the BD exons, which are spliced to exon 2 of *SNRPN*, skipping the first exon and giving rise to another transcript, different from the *SNRPN* transcript but also paternally expressed (80).

In general, AS imprinting mutations result from the deletion of the BD exons, while PWS imprinting mutations are associated with deletion of at least *SNRPN* exon 1 (80), indicating that the IC has a bipartite structure. One model presented to explain how the IC regulates the imprinting process in PWS and AS invokes a mechanism of imprint switching (77, 80). In this model, the *SNRPN* exon 1 acts as an initiation site, functioning in the paternal germline to switch the chromosome epigenetic state from maternal to paternal. Mutation or deletion of this region causes a failure in the imprint switch during paternal gametogenesis, leading to PWS, because the paternally inherited chromosome has a maternal imprint. The other *cis* element of the bipartite IC would function via an interaction in *trans* with a female-specific factor in the maternal-to-paternal switch of epigenetic states. Mutation or deletion of this structure results in a failure of switching in the maternal germline and a chromosome 15 abnormality where the maternally transmitted chromosome carries a paternal imprint. An individual inheriting this chromosome would have AS due to the lack of a normal maternal contribution of the 15q11-q13 region. While the elements that control the imprint switching process remain to be identified, it has been proposed that the BD exons regulate imprint switching in the maternal germline (80).

It would appear that imprinting mutations may also be involved in the molecular pathogenesis of BWS (36). The evidence for this comes from a translocation family where *IGF2* is expressed biallelically, rather than paternally, although monoallelic DNA methylation of sites in the 3′-end of the gene is observed in most individuals and tissues. Such an uncoupling of allelic DNA methylation from transcription suggests that the disease results from an imprint mutation.

4.2. Imprintors

The findings that only a subset of imprinted genes display a site(s) of allelic methylation that are inherited from the gametes has led to the concept of imprintor genes (54). Such genes inherit the allelic methylation signal from the gametes and thereby act in *cis* to control the expression of the other imprinted “target” genes in the domain by a mechanism of promoter/enhancer competition, as discussed above for the coordinate regulation of *H19* and *Igf2* (60), with *H19* acting as the imprintor in this domain. This concept has also been invoked to explain the regulation of *Igf2r* and its antisense (53). In the latter case, the maternal allele-specific methylation of a CpG island within region 2 (see above) is inherited from the mother and persists in embryonic and adult tissues (26). This region 2 corresponds to a promoter for an antisense that is specifically transcribed from the paternal allele, but repressed on the maternal, strongly suggesting involvement of the antisense in the regulation of *Igf2r* imprinting (53). In the context of the model of Barlow (54), the antisense acts as the imprintor in the *IGF2r* domain.

There is also evidence to indicate that antisense may also play a role in imprinting at the AS locus due to the recent observation of a *UBE3A* antisense transcript (81). This antisense, which also encompasses another sense transcript that is downstream of *UBE3A*, displays the opposite pattern of allelic expression (paternal), and this only in brain. In other tissues where *UBE3A* is biallelically expressed, such as lymphocyte and fibroblast, the antisense is silenced, suggesting that expression of the two transcripts is mutually exclusive (81). These findings once again implicate a role for antisense in regulation of imprinted gene expression and suggest, in two cases, that the putative imprintor is an antisense, although this does not hold true for *H19*. One property shared by the *Igf2r* and *UBE3A* antisense transcripts and *H19* is that these do not have protein coding potential, which does not contradict their acting as imprintors, given that the sole function of an imprintor is to regulate the imprinted expression of other genes.

4.3. Relation Between Imprinting Centers and Imprintors

There are two difficulties with the imprint switch model as it relates to the mechanism of action of the IC in the AS/PWS region. The first is that the BD exons display paternal allele-specific expression, making it difficult to understand how these might function to initiate switching in the maternal germline. Because of this puzzling observation and because these alternative *SNRPN* exons are not conserved in mouse, an alternative model involving competition for a common set of regulatory elements has been proposed to explain the mechanism of the IC (82).

The latter model was proposed initially to explain the opposite imprinting of *H19* and *Igf2* (60) (see above). In the case of the bipartite IC in the AS/PWS region, the element that overlaps the region spanning the BD exons elements is a *cis*-acting maternal epigenetic mark. This *cis*-acting site is extensively methylated in the female germline and represses the paternal genes via spreading of DNA methylation (82). Deletion of this *cis*-acting element would cause AS by transmission of an unmethylated maternal chromosome which thus carries a paternal epigenotype. The *SNRPN* promoter would somehow maintain the PWS region in an unmethylated state in the soma, and its deletion would result in a failure of the maintenance of this state and cause PWS. A neuronal enhancer would also be located in the PWS/AS region to explain the repression of maternally expressed genes, including *UBE3A*, on the maternal chromosome. *SNRPN* and *UBE3A* would compete for this enhancer, with access of *UBE3A* to this enhancer being regulated by the methylation status of the *SNRPN* promoter, which is normally paternally methylated (82). There is, however, evidence to suggest that the region spanning the BD exons is biallelically methylated (83) and that some sites in the PWS region are more methylated on the paternal chromosome (24, 77). Both these findings contradict the enhancer-competition model to explain imprinting in chromosome 15q11-q13 (83).

A different concept of the imprintor, which includes aspects of both models, has been presented to explain the action of the PWS/AS IC (54). On the one hand, the paternally expressed *SNRPN* transcripts encoded that contain the alternative BD exons could function as the imprintor expression competition with *UBE3A*. Alternatively, an imprintor gene encoded from within the AS critical region, but not from the IC, would compete for expression with *UBE3A* (54). The finding of a *UBE3A* antisense provides some support for this latter version of the imprintor model.

The arguments summarized above indicate that, despite much progress, the function and mechanism of action of imprinting centers is not yet understood. Neither the imprint switch, the imprintor, nor the original enhancer-competition model explain an important property of the IC—that is, how these centers act over extensive (1–2 Mb) genomic regions. A mouse model, in which the region syntenic to the PWS-IC has been deleted, not only has some features of PWS, but also displays lack of expression of several paternally expressed genes, including *Ndn*, a gene that is about 1 Mb proximal of the IC (84). Further characterization of these mutant mice should be quite useful in further studies of the function of the IC during development. Finally, the observation that a fragment spanning the *SNRPN* exon 1 can function as a **silencer** element in transgenic *Drosophila* suggests that elements within the IC may regulate imprinting via a silencing mechanism that is evolutionarily conserved (85). It remains to be determined, however, if the silencing element identified by this approach can act over genomic distances in the Mbp size range, as would be predicted for the functional element of an IC.

5. Evolution and Function

Although evidence is accumulating that clearly implicates parental imprinting in developmental and pathological processes, its function in normal development raises more questions than provides answers. Several theories have been developed to explain the acquisition and, more importantly, the maintenance (fixation) of imprinting in mammals. One of these is the subtle and precise control on gene expression that imprinting allows during development. Imprinting has also been described as having evolved from a host defense mechanism (86) and, alternatively, as a surveillance mechanism for chromosome loss (87). However, these hypotheses are often dismissed, because there is no explanation for the fact that imprinting, as described here, is restricted to mammals. In contrast, the parental conflict theory is based on the hallmark manifestation of mammalian evolution—that is, the acquisition of a placenta, which mediates the interaction between the embryo and the mother during intrauterine growth (88). Following the latter theory, the evolutionary interest of the father is to promote growth of its own progeny by maximizing the amount of resource extracted from the mother. On the other hand, it is in the interest of the mother to maximize her total number of surviving offspring without showing favoritism toward the offspring of particular males. This is particularly true for offspring within litters from several fathers. This theory predicts that paternally controlled genes would favor fetal growth, whereas maternally controlled genes would tend to reduce offspring size. This is in agreement with the global observation that androgenetic embryos display abnormal extraembryonic tissues and that parthenogenetic embryos have a poorly developed embryonic portion. At the molecular level, the case of *Igf2/Igf2r* also favors this theory; *Igf2*, a paternally expressed gene, is involved in fetal growth, whereas *Igf2r*, which is maternally transcribed, is supposed to facilitate the degradation of *IL2*. A systematic analysis of the effects of UPDs on fetal growth has, however, shown several contradictions to the predictions of the conflict model (89).

As the number of imprinted genes identified will increase, theories proposed for the evolution of imprinting will probably multiply. The general picture emerging presently is that more genes than initially suspected are imprinted. Whether the imprinted status is “necessary” for their function remains, however, to be determined. Some can be imprinted as “bystanders” because of their location in an imprinted region. It also becomes more and more evident that imprinting is not an “all or nothing” phenomenon. It can affect genes with a high cellular specificity and/or only partially, with the “silent” allele still expressed, albeit at a low level. As a result, we might then consider imprinted expression to be the rule rather than an exception.

In Situ Hybridization

The spatial distribution of a target nucleic acid in a tissue, cell, or chromosome can be visualized by in situ hybridization techniques. As with other hybridization techniques, there are many variations. Each procedure shares a set of common steps: (*1*) fixing the sample to preserve its structure, (*2*) limited proteinase digestion that provides access to the hybridization probe, (*3*) addition of the hybridizing probe, (*4*) washing to remove unhybridized probe, and (*5*) detection of hybrids.

Small probes are usually preferred over larger probes for *in situ* hybridization. The probe must **diffuse** efficiently into the sample so that the hybridization reaction can occur. The advantage imparted by faster diffusion of small probes is partially countered by their tendency to be lost in the washing step. Because the stability of the hybridized duplex depends on concentration for short oligonucleotides, the dilution that accompanies the washing step can result in release of some of the probe from the hybrid duplexes.

Visualization is difficult when a small number of target molecules are present. This limited most of the applications of the method to hybridization of messenger RNA. Low copy-number DNA and RNA are, however, physiologically important. Viral DNA also may be present in cells in low copy number. The need to increase the sensitivity of the technique to permit visualization of low copy-number targets has led to incorporation of amplification techniques into *in situ* hybridization techniques. Several amplification techniques have been employed, with polymerase chain reaction (**PCR**) being the most widely applied.

Radioisotope or **fluorescence** detection of the hybrid duplex can be employed, but the current method of choice is bioluminescence or chemiluminescence . A biotin label is detected by streptavidin coupled to alkaline phosphatase or horseradish peroxidase. These enzymes catalyse several reactions that can begin a cascade of reactions leading to production of light. Because biotin is a natural metabolite, high background signals may be observed in some tissues. One of the many alternatives is a digoxigenin label that is recognized and bound by a specific antibody linked to alkaline phosphatase or horseradish peroxidase. Counter staining permits identification of cellular structures and, in turn, observation of the distribution of hybrid duplexes within the cell or tissue.

Inborn Errors of Metabolism

Inborn errors of metabolism is the term applied to genetic disorders caused by loss of function of an enzyme. Enzyme activity may be low or lacking for a variety of reasons, such as lack of transcription and translation of the corresponding gene, improper folding of the polypeptide, unstable tertiary structure, a defective active site, failure to bind the corresponding coenzyme under physiological conditions, or failure to enter into complexes with other proteins. A single good copy of the gene is often sufficient, and many inborn errors are therefore recessive traits. The severity of the phenotype is highly variable among inborn errors, depending on the role of the biochemical pathway in metabolism. A few inborn errors can be treated by diet. Most cannot. Inborn errors were the first genetic disorders to be considered for gene therapy.

1. Early Recognition of Inborn Errors

The phrase *inborn errors of metabolism* appears to have been first used by A.E. Garrod in the Croonian Lectures of 1908, published as a monograph with that title in 1909. In 1902, Garrod published an account of a patient with alkaptonuria and speculated that it was due to an inherited derangement of metabolism. Subsequently, he encountered other rare patients who suffered from apparent metabolic defects. The fact that the parents of such patients were often related to each other suggested that the metabolic defects might be inherited as recessive traits. In his 1909 publication, he suggested four candidate disorders as examples of inborn errors: alkaptonuria, albinism, pentosuria, and cystinuria. Although the sciences of genetics and biochemistry were in their infancies at the time, Garrod was remarkably perceptive in recognizing the possibility of inherited variations in metabolism.

Garrod's prescient observations were largely ignored except as a footnote in the biochemical literature. The geneticists were not ready for biochemistry, nor were biochemists quite ready to deal with genetics. Enzymes were just being identified as the important agents in metabolism, and little was known about the enzymes themselves or other protein functions. Nothing was known about the chemical nature of genes or how they act. It was not until the late 1930s that geneticists began to employ biochemical approaches to study what genes do. Soon thereafter, G.W. Beadle, E.L. Tatum, and others, based primarily on studies of *Neurospora*, observed that each mutant form studied appeared to be defective in a specific enzymatic conversion. Their work led to the *one gene-one enzyme* hypothesis, which equates the action of each genetic locus with the activity of a single enzyme.

We know now that many proteins are not enzymes. Also, many enzymes are complexes of different proteins. (Some RNA molecules have enzyme activity—the ribozymes—but these will not be considered here and are not active in metabolic pathways as that term is usually defined.) We also know now that genes are composed of DNA and their function is to code for the primary structure of proteins. The inborn errors of metabolism envisioned by Garrod are readily explained by the role of genes in coding for specific enzymes or enzyme subunits. Errors in metabolism reflect loss of activity of a particular enzyme due to an error in a gene that codes for that enzyme. The terms *metabolic block* and *metabolic error* are used as synonyms for inborn errors of metabolism.

2. Some Properties of Enzymes

It is helpful to consider how enzymes function if one is to understand the many variations that lead to malfunction. First, the polypeptide chain that is coded by a gene must be folded into the correct three-dimensional structure. Protein folding is a consequence of the amino acid sequence and the interaction of the side chains with each other and with water. Many detrimental mutations act by substituting one amino acid for another, interfering with the electrostatic and hydrophobic interactions of the functional enzyme. In the case of glucose 6-phosphate dehydrogenase deficiency, hundreds of mutant forms have been identified. A common feature of many is decreased stability of the folded enzyme.

To function, enzymes must have an active site that determines substrate access and binding. They often require coenzymes, small organic molecules that bind and help carry out the chemical transformations at the active site of the enzyme. Some coenzymes are made by the host organism. Others, of which the B vitamins are examples, must be supplied in the diet in higher animals. The coenzymes must bind at specific sites on the apoenzymes to form active holoenzyme. Mutation at those sites can reduce or abolish the affinity of the enzyme for the coenzyme. In some instances when the affinity is reduced, increase in the coenzyme level can compensate. For example, homocystinuria results from a defect in cystathionine synthase, which catalyzes the conversion of homocysteine to cystathionine. The homocysteine substrate accumulates and is excreted in urine as homocysteine. Some cases are treatable with large doses of vitamin B_6, which is converted to the coenzyme pyridoxal phosphate and increases the level of active enzyme. In other patients, the molecular defect is in another part of the enzyme, or the enzyme may be missing. Vitamin B_6 is of no value in those cases. The two types of cases are not distinguishable clinically apart from the response to therapy.

Coenzymes that are synthesized in the body may also be absent due to defects in their synthesis. This causes loss of activity of the enzymes of which they are a normal part. An example is found in phenylketonuria (PKU). PKU is a classic inborn error of metabolism usually caused by mutation of the phenylalanine hydroxylase gene. This enzyme uses tetrahydrobiopterin as a coenzyme. In a small proportion of cases, the genetic defect is in synthesis of tetrahydrobiopterin. The end result is the same. Phenylalanine cannot be broken down by the normal pathway and accumulates, causing the classic features of PKU.

Many enzymes and other proteins function as dimers, higher multimers, or part of a multisubunit complex. This imposes a requirement that the monomeric form have a configuration that permits complex formation. Changes in the amino acid sequence can alter the ability of a monomeric enzyme to enter into complexes, either with itself to form an active dimer or with other subunits to form a complex. The mutant subunit might still have activity under some circumstances, but the conditions under which the substrate is encountered inside a cell may be very different.

This list of protein functions is not exhaustive. Many properties of an enzyme can be affected by structural changes. Any change that substantially or completely blocks the activity so that a metabolic conversion does not occur can be the cause of an inborn error of metabolism.

3. Metabolic Errors and Phenotypes

Although some inborn errors are relatively benign, many are quite detrimental, often fatal. The impact of a metabolic error depends greatly on the metabolic pathway and on the ability of other metabolic and physiological systems to compensate for the error. Alkaptonuria is relatively benign. The pathway that is blocked is in the catabolic breakdown of homogentisic acid, and no essential products are missing because of this block. Homogentisic acid is not reabsorbed by the kidneys and is excreted in the urine, preventing accumulation of high levels in the body. Over time, oxidation products of homogentisate are deposited in joints, causing a form of arthritis. In contrast, the block in phenylketonuria is in the conversion of phenylalanine to tyrosine. Phenylalanine is efficiently reabsorbed by the kidneys and accumulates to high levels in the blood, generating by-products that interfere with development of the central nervous system.

Several blocks in the breakdown of gangliosides are responsible for degenerative diseases of the central nervous system (e.g., Tay-Sachs disease). In these instances, breakdown occurs in the lysosomes. The large gangliosides accumulate in the lysosomes, which become very large, eventually interfering with cell function and ultimately causing death. Such disorders are examples of lysosomal storage diseases. A characteristic of these disorders is an initially normal phenotype, followed by degeneration as the lysosomes store increasing amounts of material.

Another group of metabolic blocks depends on environmental agents for expression. Galactosemia is one of the earliest known examples. Affected persons cannot metabolize galactose, which comes from lactose in milk. The galactose 1-phosphate that accumulates interferes with other metabolic processes and can lead to death unless milk is avoided. Other rare individuals are homozygous for absence of functional plasma cholinesterase. If succinyldicholine is administered as a muscle relaxant during electroshock or other treatment, they have very prolonged recovery of muscle function.

4. Inborn Errors and Genetics

In most cases, if a locus that codes for an enzyme has one normal allele, a normal phenotype results; it is haplosufficient. Two nonfunctional alleles are required for the metabolic error to occur. This means that the condition is inherited as a recessive trait. If q is the frequency of the mutant allele, the frequency of homozygotes would be q^2, and the frequency of heterozygous "carriers" would be $2pq$. For $q = 0.01$, the frequency of homozygotes therefore is $q^2 = 0.0001$ and $2pq = 0.0198$. The bulk of the recessive alleles in the population are in heterozygous combination and not subject to elimination by selection. Some genes that code for enzymes are haploinsufficient. The mutant allele is associated with a modified phenotype and is transmitted therefore in pedigrees as a dominant trait. The phenotype of the heterozygote need not be identical to the homozygous mutant phenotype, which might be more severe.

With the advent of prenatal diagnosis for nearly all metabolic errors, once the gene is identified, the frequency of affected children born can be substantially reduced if a mating is known to be at risk. Identification of such matings usually occurs because of a prior pregnancy that involved an affected offspring. Without massive population screening of normal persons, however, the frequency of matings at risk will not change.

5. Treatment of Inborn Errors

Reference has been made to treatment of phenylketonuria and galactosemia by elimination of components of diet. Some forms of homocystinuria respond to high levels of dietary vitamin B_6. The number of inborn errors that are managed by diet is small. Because inborn errors are usually associated with loss of activity of a single enzyme, the idea of enzyme replacement has been an enticing goal for many years. How to do this technically is a major challenge. The principle has been demonstrated in a sense in a boy with phenylketonuria who received a liver transplant for reasons unrelated to the PKU. The condition was cured. Because PKU is effectively treated by diet, liver transplants are not considered an appropriate therapy.

There are a number of inborn errors of great severity that are candidates for gene therapy. The first attempts at gene therapy involved a patient with adenosine deaminase deficiency, which causes severe immunodeficiency. The gene is well characterized and can be incorporated into viral vectors. The results were very promising, but a satisfactory protocol has yet to be achieved. Another candidate disorder is Lesch-Nyhan syndrome, which is due to loss of activity of hypoxanthine phosphoribosyl transferase (hprt). Patients are mentally retarded and engage in self-mutilation. A very low level of hprt activity is sufficient to prevent the disorder. Gene therapy need not be very efficient in order to be effective. Success has been elusive, however.

Despite the disappointments in early attempts at gene therapy, it remains the most promising approach for metabolic errors as well as for certain other genetic disorders.

Inclusion Bodies

Inclusion bodies are insoluble, biologically inactive aggregates of partially folded **protein**, which are often produced when a heterologous or recombinant protein is overexpressed, especially in the popular and frequently used *Escherichia coli* bacteria (see Expression Systems). Inclusion body formation is frequently seen in both **Gram-negative** and Gram-positive bacteria, but less often in yeast, insect, or mammalian cells. Inclusion bodies are also called *refractile bodies* because they refract light and are visible in the phase-contrast **microscope**. Usually, there is only one inclusion body per cell, which can span the whole diameter of the cell, depending on the expression level of the protein. Inclusion bodies can occur in both the cytosolic and **periplasmic** location in bacteria. If the initial expression level is sufficiently high, the inclusion bodies tend to be a rather homogeneous aggregate of the overexpressed protein. However, several other proteins are also found as coprecipitants, such as elongation factor EF-Tu, outer membrane proteins, and small **heat-shock** proteins.

Systematic analysis of inclusion body formation shows no correlation with the size, relative hydrophobicity, or number of proline residues (see Cis/Trans Isomerization) in the protein. However, the relative charge and the number of amino acid residues that prefer the turn conformation correlate reasonably well with the tendency for inclusion body formation. Also, there is an excellent correlation between inclusion body formation and high expression level of the protein. Even native, cytosolic proteins can form inclusion bodies at a sufficiently high expression level. A kinetic model has been suggested that takes these observations into account. It states that inclusion body formation is dependent on the relative rates of **protein biosynthesis**, **protein folding**, and aggregation.

Overexpression of a particular protein can be deleterious to cell viability (1). The protein may have a biochemical activity that is directly toxic, or the overexpression state itself is toxic. This is marked by an inability of the cell to recover after a period of overexpression. One major contributing factor is the observed destruction of ribosomes (2). Finally, a word of caution. The most abundant *E. coli* protein is elongation factor EF-Tu, reaching 5% to 10% of the total cellular protein. Any protein that is expressed at higher levels challenges the biosynthetic capacity of the cell, especially if it is made from a gene with a high portion of rare **codons**. The most negative consequences are less growth capacity and high error levels in translation.

1. How Can the Formation of Inclusion Bodies Be Avoided?

In most cases, the native, soluble form of a protein is desired in high quantity and purity. It is therefore important to avoid inclusion body formation, which requires that the protein be solubilized, generally in a **denatured** state, and then folded. Furthermore, the quality of protein folded from inclusion bodies can be inferior (3).

There are several ways to avoid inclusion body formation. First, fermentation parameters can be varied, such as the richness of the medium, its pH, and the level of aeration or micronutrients. A major improvement is often seen when the growth temperature is lowered. Second, the expression level of the protein can be varied. This can be done by selecting an appropriate expression **vector** with sufficiently weak **promoter** and/or translation initiation elements. Also, an expression vector that allows regulated but variable steady-state levels of gene expression can be used (4). However, most overexpression systems are inducible, so that varying the level of **inducer** may suffice. Third, coexpression of protein folding modulators, such as the **molecular chaperones** GroES/EL can help. Coexpression of the **DnaK/DnaJ** chaperones may help when GroES/EL is ineffective. Also, coexpression of *E. coli* thioredoxin can counteract inclusion body formation (3). Other folding modulators of potential use are peptidyl-prolyl ***cis/trans*** **isomerases** and thiol/disulfide oxidoreductases. Fourth, genetic engineering can improve soluble expression. The simplest solution is to fuse the protein of interest to other proteins that are known to improve the yield of soluble protein, such as the bacterial thioredoxin and IgG binding domains of *S. aureus* protein A (see Fusion Gene, Fusion Protein). A more sophisticated approach involves the rational design of higher solubility by the introduction of specific point mutations by site-directed mutagenesis, and elimination of amino acid sequences involved in aggregation. Finally, a **signal sequence** can cause the transport of the protein of interest to the **periplasm** or to the extracellular medium, where the environment favors the folding of some proteins.

2. How Can Inclusion Bodies Be Used?

Even inclusion body formation can be turned into an advantage so long as the protein can be refolded. The primary advantage is the ease of purification of inclusion bodies; those with a recombinant protein fraction of more than 60% can be isolated by centrifugation of crude cell lysate at moderate rotor speeds (5000 to 12,000 g). The purity of an inclusion body protein can be improved further by resuspension and centrifugation in a buffer containing 2% sodium deoxycholate (5). Inclusion bodies are often the only way to obtain a protein that is highly toxic in its native form. Any protein can usually be isolated via inclusion bodies if it is fused to an amphiphilic extension (6) or if it is expressed at a sufficiently high level (eg, using T7 promoter vectors). Also, host strains with a defective **heat-shock** response or with a mutation in an important molecular chaperone system may be useful. Inclusion bodies are often an advantage when the yield of the native protein is low because of extensive **proteolysis**.

The key to efficient use of inclusion bodies is to know how to solubilize and refold the protein in high yield. The strong denaturants 4 to 6 M **guanidinium chloride** or 6 to 10 M urea are the most common solubilizing reagents. Another method uses detergents, such as cetylmethylammonium chloride or sarkosyl, or alkaline solution (7). Often, it is necessary to use **thiol** reagents along with the **chaotropes** to facilitate reduction of nonnative disulfide bonds.

All methods for folding the solubilized and denatured protein are based on the removal or dilution of the denaturant and reducing agent. This can be done by one-step dilution, by dialysis or, as when sarkosyl is used, by the addition of a micelle-forming detergent (eg, **Triton X-100**) that sequesters the protein-bound sarkosyl (8).

A major drawback to most *in vitro* folding approaches is the presence of aggregation side reactions, which compete with the proper folding reaction. It is therefore often necessary to refold at low protein concentration or to use pulse renaturation techniques (9). Furthermore, low temperatures or the composition of the refolding buffer may affect the yield of native protein. A major improvement can be observed when the denatured protein is refolded on a solid support, which effectively prevents aggregation by protein-protein contacts (10, 11).

Molecular chaperones, such as GroES/EL, have also been used for *in vitro* refolding of denatured proteins. A promising new development is the advent of refolding chromatography, where immobilized chaperones or fragments thereof are used for refolding of protein. Elaborate "artificial" chaperone systems have also been constructed, applying nonprotein refolding agents or changes in the physical environment (6). A combination of detergents and cyclodextrins has been used to mimic the two-step action of GroES/EL in protein folding. Systems have also been made that are based on temperature-jump techniques or refolding on a solid support.

Indel

An "indel" is a site of insertion or deletion in aligned, homologous protein or nucleotide sequences (1). Mutational events in nucleic acid sequences include insertions and deletions, as well as base substitutions. Often, it is not possible to distinguish between insertional or deletional events, because this would require either access to the (presumably dead) common ancestor of the aligned sequences or else a sufficient number of related sequences to reveal the nature of a particular event in a recently derived lineage. In globular proteins, indels are largely restricted to sites (usually loops) at the protein surface (2). A gapped region of a sequence alignment may actually have a history of multiple insertions and deletions, and it is then a fruitless exercise to try to retrace the actual events. Indel is therefore a useful term as it avoids the need to make an error-prone assignment of the actual mutational event(s). The most sensitive algorithms for aligning sequences allow for the possibility of indels being placed at any position in any sequence, using gap penalties to apply a cost to indel insertion, to limit their frequency (3, 4).

Induced Fit

The specificity of enzymes is of importance for their function and involves the fit of a substrate into the active site of the enzyme. The concept of enzyme specificity, which implies that there is a close steric relationship between an enzyme and its substrate, was proposed in 1894 by Emil Fischer, who developed the lock and key hypothesis of enzyme action. He explored the idea that the active site of an enzyme was simply a rigid template for the substrate and this would account for the ability of an enzyme to act on only one or a limited number of substrates.

The lock and key hypothesis was accepted for several decades. But it was questioned in 1958 by Koshland (1), who recognized that it did not account for the low activity of many enzymes with water, which is always present at a concentration of 55 *M*, as a substrate or for the failure of enzymes to act on compounds whose structure was similar to that of the normal substrate. He proposed that:

- The active site of an enzyme is not necessarily a template for the substrate.
- The binding of the substrate at the active site produces a structural, or conformational, change.
- Conformational change brings about the correct alignment of the catalytic groups of the enzyme with those of the substrate so that a reaction occurs.

The induced fit concept can explain why molecules of a structure similar to that of the normal substrate can combine at the active site, but not undergo reaction, because they lack the structural features required for catalysis.

An early, and now classical, demonstration of substrate-induced conformational change is the binding of glucose to hexokinase (2). This enzyme has two lobes, and between them is a cleft in which the active site is located. The binding of glucose induces the rotation of the two lobes and closure of the cleft; these movements have the effect of excluding water and facilitating transfer of the phosphoryl group from ATP to glucose, rather than to water. Kinetic evidence for conformational changes with hexokinase comes from studies on the ATPase activity of the enzyme that occurs in the absence of glucose. This activity is low relative to the rate of phosphorylation of glucose, but is stimulated by lyxose. This sugar does not undergo phosphorylation, but interacts at the binding site for glucose to increase the maximum velocity of the reaction and lower the Km for $MgATP^{2-}$(3). The ability of substrates to cause conformational changes at the active site of enzymes has now been demonstrated by a variety of techniques, including X-ray crystallography. These changes are also a characteristic feature of the catalytic function of **allosteric** enzymes.

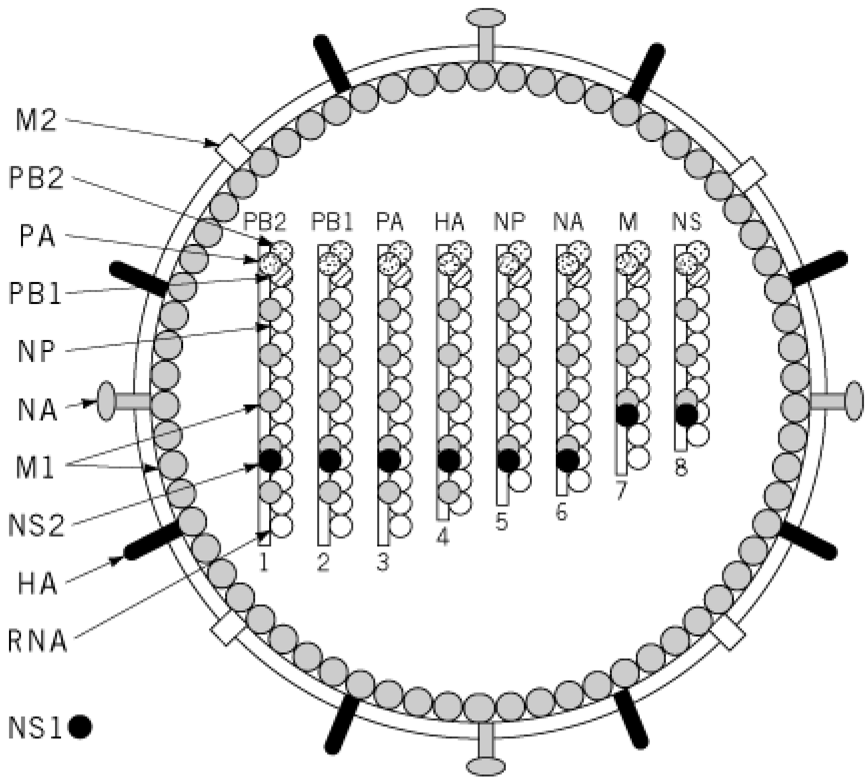
Influenza Virus

Influenza viruses, which belong to the family of *Orthomyxoviridae*, are enveloped **viruses** with single-stranded, negative-sense RNA as the genome. The lipid envelope of influenza viruses is derived from the plasma membrane of the host cell in which the virus was grown. Influenza A and B viruses each contain eight species of RNA segments (Fig. 1), whereas influenza C virus contains seven segments. Influenza A, B, and C viruses are divided on the basis of antigenic differences between their nucleoprotein (NP) and matrix (M) proteins. Influenza A viruses are further subdivided into subtypes based on the antigenic differences of the hemagglutinin (HA) and neuraminidase (NA) glycoproteins (currently into 15 HA and 9 NA subtypes). Influenza A and B viruses grown in eggs or tissue-culture cells have a spherical structure, are 80 to 120 nm in diameter with some pleomorphism, and exhibit variation throughout the life cycle. Viruses freshly isolated from humans or animals exhibit greater heterogeneity and pleomorphism, including the presence of greatly elongated forms.

Figure 1. Schematic diagram of influenza A virus particle.



Influenza A and B virus envelopes each contain two kinds of 10- to 14-nm spikes radiating outward (the HA and the NA) (Fig. 1). The HA has a trimeric rod-shaped structure, while the NA has a tetrameric mushroom-shaped structure. The HA has the receptor (sialic acid)-binding and fusion activities. The NA has a neuraminidase activity that cleaves the virus receptor. Influenza A virus envelope also contains a tetrameric M2 **ion channel**, while influenza B virus contains a NB ion channel. The influenza C virus envelope contains only single spikes (HE), organized into orderly hexagonal arrays, that have both hemagglutinin and esterase activities.

The first isolation of the Influenza A virus from swine was reported in 1931, and that from humans was reported in 1933. The complete **nucleotide sequence** of the influenza virus was first reported for the A/PR/8/34 (PR8) strain in 1982, and it contains 13,588 nucleotides. The PR8 virus RNA segment 1 (2341 nucleotides) codes for PB2 (759 residues, 30 to 60 molecules/virion), 2 (2341 nucleotides) for PB1 (757 residues, 30 to 60 molecules/virion), 3 (2233 nucleotides) for PA (716 residues, 30 to

60 molecules/virion), 4 (1778 nucleotides) for HA (566 residues, 500 molecules/virion), 5 (1565 nucleotides) for NP (498 residues, 1000 molecules/virion), 6 (1413 nucleotides) for NA (454 residues, 100 molecules/virion), 7 (1027 nucleotides) for M1 (252 residues, 3000 molecules/virion), and M2 (97 residues, 20 to 60 molecules/virion) via splicing, 8 (890 nucleotides) for NS1 (230 residues, nonstructural) and NS2 (121 residues, 130 to 200 molecules/virion) via splicing (Fig. 1).

The viral transcription and replication takes place in the nucleus of the infected cell. The PB1, PB2, and PA proteins form a tetramer that has RNA-dependent **RNA polymerase** (replicase and transcriptase) activity. The PB2 protein has **endonuclease** activity and cuts the host mRNA to generate 10- to 13-nucleotide-long capped-RNA primer for the viral transcription (known as “cap snatching”). The viral RNA genomes and the NP protein form helical ribonucleoprotein (RNP) complexes. Twelve nucleotides at the 3′ end and 13 at the 5′ end of the RNA genomes are well-conserved among all influenza viruses, and they comprise the **promoter** where the virus polymerase binds and starts transcription and replication. The genomes also form a “panhandle structure,” in which the ends of an otherwise single-stranded RNA are held together by base pairing. The M1 is thought to underlie and probably integrate into the inner layer of the lipid bilayer. The M1 also interacts with the RNP, as well as with the HA and the NA. The NS1 protein is not incorporated into the virion. It interferes with the splicing and nuclear export of the cellular mRNAs. It also regulates the viral translation. The NS2 (it is currently known as NEP) has a nuclear export signal (NES, see Nuclear Import, Export).

Influenza virus is a major causative agent of the acute respiratory influenza illness, which is sometimes lethal for the elderly. In the pandemic of 1918 to 1919, called Spanish influenza, 20 to 40 million people were killed by infection with influenza A virus (H1N1). Influenza A viruses naturally infect humans, swine, horses, seals, a wide variety of birds, and some other mammalian species. Wild aquatic birds are probably the primordial reservoir of all influenza A viruses. On the other hand, influenza B viruses infect only humans. Influenza C virus infects humans and swine.

Immunity to influenza is long-lived and is subtype-specific. The HA contains the major neutralizing antigenic **epitopes**. The accumulation of point mutations (antigenic drift) alters the antigenicity of the HA. The appearance of new subtypes occurs by the reassortment of the HA or the NA gene among influenza A viruses (antigenic shift). Inactivated influenza vaccines are currently used widely worldwide, but live attenuated vaccines are being developed. Amantadine hydrochloride is a licensed antiviral agent for prophylactic and therapeutic use against all influenza A virus subtypes in humans.

Genetic manipulation of influenza A and B viruses has been successful, and some influenza A virus vector systems also have been developed.

Initiation Codon

Protein biosynthesis starts using the specific genetic code, named the initiation codon or start codon. In general, the AUG codon is used universally in both prokaryotes and eukaryotes. Occasionally, GUG is used as an alternate initiation codon in about 10% of bacterial genes, and very rarely is UUG also used. In eukaryotes, UUG is never used, but CUG, ACG, and GUG are occasionally or rarely used as an alternate initiation codon. There is only one known case in bacteria in which AUU functions as an initiation codon. The initiation codon is recognized by the specific transfer RNA referred to as initiator tRNA, $tRNA^{iMet}$ (eukaryotes) or $tRNA^{fMet}$ (prokaryotes) and is decoded as *N*-formyl methionine (fMet) (see fMET (N-Formyl Methionine)).

In prokaryotes, polycistronic genes are often regulated cooperatively at the translational level. This phenomenon, referred to as translational coupling, is observed when the downstream initiation codon overlaps the upstream stop codon in the sequence AUGA, or the downstream initiation codon is sequestered by the RNA stem structure. Ribosomes can enhance translation initiation of these downstream genes by slippage of the 30S ribosomal subunit or by unwinding the inhibitory RNA stem structure.

Initiation Complex

Initiation of protein synthesis is believed to be a rate-limiting step, because it requires multiple initiation factors and specific signals on messenger RNA that coordinately interact and function to form initiation complexes. The obvious difference between prokaryotic and eukaryotic mechanisms is based on the difference of where the ribosome enters the mRNA. Prokaryotic mRNAs are often polycistronic, and ribosomes can gain entry to the mRNA directly at the translation start site within the mRNA sequence to form initiation complexes, while eukaryotic mRNAs are monocistronic and ribosomes must gain entry to mRNA at its Cap and move downstream to the translation start site to form initiation complexes (see Scanning Hypothesis). Correct recognition of the site for initiation complex formation by prokaryotic ribosomes is mediated by complementary base-pairing between the **Shine–Dalgarno** sequence on mRNA and the anti-Shine–Dalgarno sequence on the 3′ terminus of 16S rRNA. The eukaryotic initiation process is in sharp contrast to the prokaryotic process, because it involves numerous initiation factors. This reflects the fact that specific protein factors are required for 5′ Cap recognition by the ribosome and for scanning of the ribosome to the downstream initiation site (1).

An initiation complex is first formed as a preinitiation complex composed of the small ribosomal particle (30S for prokaryotes, 40S for eukaryotes), **fMet-**transfer RNA, initiation factors, and GTP at the start site of mRNA. Upon formation of proper preinitiation complexes, the large ribosomal particle (50S for prokaryotes or 60S for eukaryotes) joins the preinitiation complex, to form the initiation complex (2). During this step, GTP is hydrolyzed to GDP while the fMet-tRNA-carrier factors, IF-2 (prokaryotes) and eIF-2 (eukaryotes), dissociate from the ribosome, leaving fMet-tRNA at the P site of the ribosome.

Although the translation of virtually all eukaryotic cellular mRNAs and the majority of viral RNAs is initiated via the scanning ribosome mechanism, there is a small, yet not insignificant, number of RNAs (particularly viral RNAs) that are translated by an internal initiation mechanism [see Internal Ribosome Entry Site (IRES)(3)].

Initiation of protein synthesis is a good target for regulating gene expression. Most of the bacterial ribosomal proteins are negatively autoregulated at the initiation step of their synthesis. When present in excess over rRNA, a set of ribosomal proteins (**translational repressors**) bind to their own mRNA and stop its translation. The ribosomal protein-binding site on its mRNA (or **operator**) overlaps the ribosome binding site, thereby blocking the formation of initiation complexes. The operator consists of a specific RNA structure that mimics the rRNA structure where the ribosomal protein (repressor) binds. Like the ribosomal protein repressor, *E. coli* threonyl-tRNA synthetase (ThrRS) is negatively autoregulated at the translation level when in excess of its substrate $tRNA^{thr}$. ThrRS binds to the leader region of its own mRNA at the translational initiation site and represses its translation by preventing ribosome binding. The ThrRS operator mimics the structure $tRNA^{thr}$.

Initiation of protein synthesis in eukaryotes can be regulated by **phosphorylation** of eIF-2a by mammalian protein kinase PKR (4). The PKR activity was originally detected as the enzyme responsible for double-stranded (ds) RNA-dependent protein synthesis inhibition in **poliovirus**-infected HeLa Cells, and in cell-free translation systems made from rabbit reticulocytes. The target of dsRNA's mysterious ability to inhibit protein synthesis initiation was eventually shown to be the protein kinase PKR, which blocks protein synthesis by phosphorylating initiation factor eIF-2a. Higher eukaryotic cells possess an intrinsic defense system that is mediated by interferon. Interferon release by virus-infected cells sensitizes neighboring cells by inducing the transcription of genes that encode anti-viral products. Some of these, notably the protein kinase PKR and 2,5A synthase, act at the level of protein synthesis. (2,5A synthase makes an oligonucleotide that activates a latent ribonuclease.) Viruses, in turn, have elaborated products (e.g., the VA RNA produced by adenovirus) that neutralize these cellular defenses, thereby enabling the production of viral proteins and progeny virions.

Recruitment of the 40S small ribosomal subunit to eukaryotic mRNA is mediated by interactions between a limited set of translation initiation factors (2). One of these factors, eIF-3, is a 40S subunit-associated factor comprised of at least eight subunits in mammalian cells that interacts with the mRNA-associated initiation factor eIF-4F (Fig. 1). eIF-4F consists of two core subunits. These are the mRNA **5′-Cap**-binding protein eIF-4E and the large subunit eIF-4G. Recent studies on eIF-4G have revealed that it binds to eIF-4E and eIF-3, as well as to the **poly(A)**-binding protein (Pab1p in yeast) (5). The multipurpose adapter nature of eIF-4G allows it to recruit the 40S ribosome to mRNA via the simultaneous association of eIF-4G with both eIF-4E and eIF-3 (Fig. 1). Knowledge of eIF-4E's interaction with the 5′-Cap permits an understanding of cellular and viral strategies to control Cap-stimulated translation. For example, cells express a small family of inhibitory proteins that regulate eIF-4E assembly. These are called the 4E-binding proteins [4E-BPs (6)]. The 4E-BPs share an amino acid motif with the *N*-terminal domain of eIF-4G that is known to be required for eIF-4G's interaction with eIF-4E. In their nonphosphorylated form, the 4E-BPs act as competitive inhibitors of the eIF-4G-eIF-5E interaction (Fig. 1).

Figure 1. Control of initiation complex formation via Cap binding in eukaryotes (7). (**a**) eIF-4E recruits the 40S subunit of mRNA by protein interaction with eIF-4G and eIF-3. (**b**) Regulation of initiation complex formation by phosphorylati eIF-4E binding proteins, 4E-BPs.

Initiation Factor (IF)

Formation of an initiation complex for translation of protein biosynthesis on 70 S ribosomes in bacteria involves, in addition to initiator fMet-$tRNA^{fMet}$, messenger RNA, and GTP, the cooperative interaction of three proteins, initiation factors IF-1, IF-2 and IF-3 (Table 1). Until now, no convincing data have indicated the existence of additional factors. Numerous *in vitro* experiments demonstrate that IF-1 and IF-3 shift the ribosome-dissociation equilibrium from 70 S ribosomes toward dissociation into 30 S and 50 S subunits. Under physiological conditions, the ribosomal subunit equilibrium is toward 70 S formation, and IF-1 serves to increase the rate constant for both the dissociation and association of 70 S ribosome, whereas IF-3 shifts the equilibrium strongly toward dissociation by binding to the 30 S particle. IF-3 also selects the initiator tRNA in the presence of the initiation codon triplet, as well as on a natural mRNA template. IF-3 action distinguishes the initiator transfer RNA from elongator tRNAs by specific domains in the tRNA and not by its formyl methionine (fMet). Part of the information is located in the anticodon stem and loop region. IF-3 has been shown to destabilize selectively polynucleotide-primed 30 S complexes formed with elongator tRNAs. The third initiation factor, IF-2, directs fMet-$tRNA^{fMet}$ binding to the 30 S subunit. This initiation factor might also exclude noninitiator tRNAs from the P site, while allowing formylated charged initiator tRNA to enter. This reaction is stimulated by IF-1 and GTP. In addition, IF-2 helps the association of the two subunits and has a GTPase activity in the presence of ribosomes. The process of initiation complex formation in prokaryotes is summarized in Fig. 1 (1).

Figure 1. The initiation pathway of protein synthesis in prokaryotes.

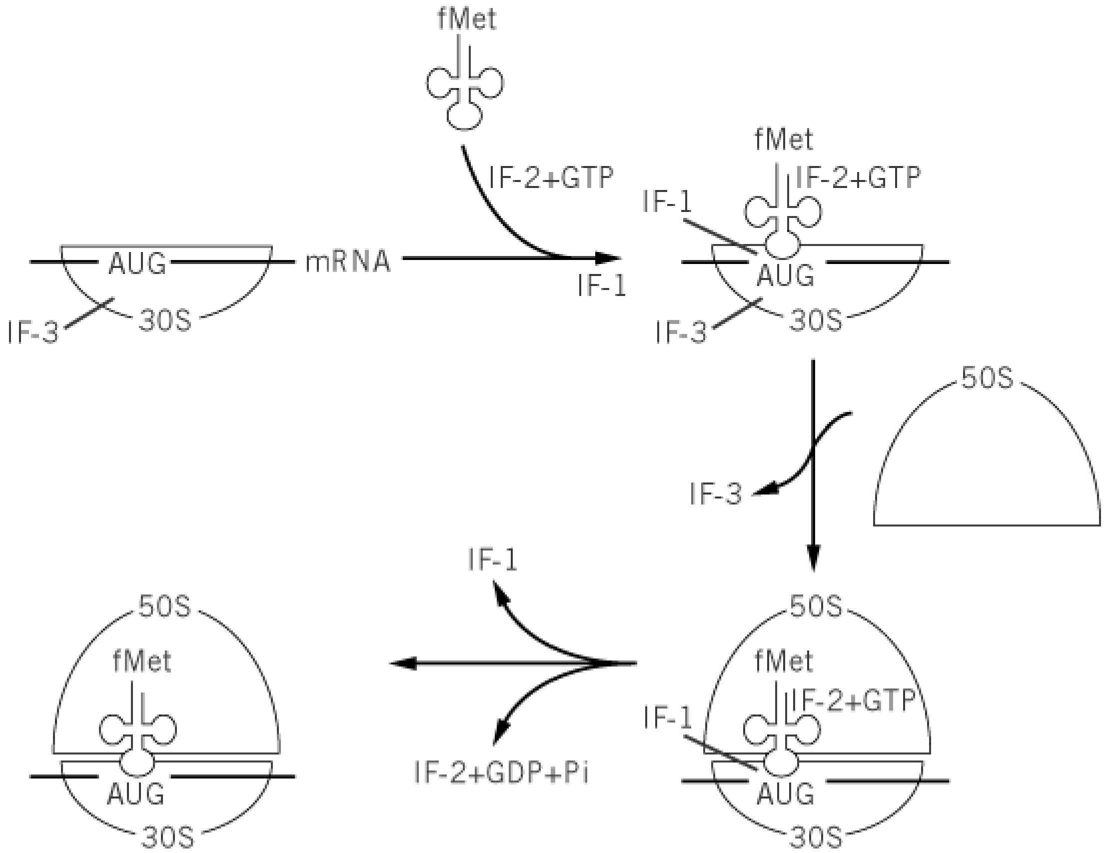

Table 1. ***Escherichia coli*** **Initiation Factors**

Factor	Molecular Mass	Number of Amino Acids	Gene	Function
IF-1	8,119	71	*infA*	Promotes IF-2 and IF-3 functions
IF-2a	97,300	889	*infB*	Binds fMet-tRNA and GTPase
IF-2b	79,700	732	*infB*	
IF-3	20,668	181	*infC*	Ribosome dissociation and mRNA binding; increasesthe specificity of the initiation complex for fMet-tRNA

In the absence of tRNA or initiation factors, the 30 S particle by itself binds to the proper initiation region on mRNAs. The sequence of events directed by initiation factors shows that IF-1 and IF-3 are released before or during the joining of the subunits, whereas IF-2 is released after their joining and requires GTP hydrolysis. The three factors are present in cells at sufficiently high concentration to saturate the free 30 S particle. The steady-state levels of initiation factors are coordinately regulated in exponentially growing bacteria relative to one another and relative to ribosome levels. All levels rise as a function of increasing growth rate, suggesting that the cellular levels of initiation factors are under metabolic control. Neither IF-2 and IF-3 synthesis is under stringent control *in vivo*.

All of the initiation factor genes have been cloned and mapped: *infA* for IF-1, *infB* for IF-2, and *infC* for IF-3. They are dispersed on the bacterial chromosome and, with the exception of *infA*, are associated with other components of the protein biosynthesis apparatus (threonyl and phenylalanyl-tRNA synthetase, and ribosomal protein L20 and L35 for IF-3; $tRNA^{fMet}$, NusA, and ribosomal protein S15 for IF-2). The *infB* gene produces two forms of IF-2, IF-2a (97.3 kDa), and IF-2b (79.7 kDa), using two in-frame initiator codons. Both forms are implicated in fMet-tRNA binding to 30 S ribosomes and possess a ribosome-dependent GTPase activity. The meaning of the existence of two forms of IF-2 in bacteria, as well as their functional difference, is not known.

The eukaryotic initiation steps are promoted by at least 10 different initiation factors, some of which are themselves complexes of numerous protein subunits. Figure 2 summarizes where the more important of the initiation factors function in the pathway (2). eIF-1A and eIF-3 are involved in the dissociation of ribosomes; eIF-2 and eIF-2B are primarily concerned with $tRNA^{iMet}$ binding to 40 S subunits; eIF-4A, eIF-4B, and eIF-4F promote mRNA binding and scanning; and eIF-5A is involved in the junction step. Essentially all the initiation factor polypeptide cDNAs have been **cloned** and sequenced (Table 2).

Table 2. Eukaryotic Initiation Factors (2)

Factor	Subunit	Molecular Mass (kDa)	Function
eIF-1		12.6	Enhances initiation complex formation
eIF-1A		16.5	Ribosomal dissociation; promotes Met-$tRNA^{iMet}$ binding

eIF-2		125	Binds Met-tRNA^{iMet}and GTP
	a	36.1	Phosphorylated subunit
	b	38.4	Binds Met-tRNA^{iMet}
	g	51.8	Binds GTP; Met-tRNA^{iMet}
eIF-2B		270	Guanine nucleotide exchange factor for eIF-2
	a	33.7	
	b	39.0	Binds GTP
	g	58	Binds ATP
	d	57.1	Binds ATP
	e	80.2	Phosphorylated subunit
eIF-2C		94	Stabilizes ternary complex in presence of RNA
eIF-3		650	Dissociates ribosomes; promotes Met-tRNA^{iMet} and mRNA binding
	p35	35	Highly phosphorylated
	p36	36.5	
	p40	39.9	
	p44	35.4	RNA binding motif
	p47	47	
	p48	52.5	Identical to Int-6 (oncogene) homologue
	p66	64.0	Binds RNA
	p110	105.3	
	p116	98.9	Major phosphorylated subunit
	p170	166.5	
eIF-4A		44.4	ATPase, helicase, binds RNA
eIF-4B		69.8	Binds RNA, promotes helicase activity
eIF-4F		250	Binds 5′ Cap, helicase
	eIF-4E	25.1	Cap-binding subunit
	eIF-4A	44.4	ATPase, helicase
	eIF-4G	153.4	Binds eIF-4A, eIF-4E, eIF-3, and Pab1p
eIF-5		48.9	Promotes GTPase with eIF-2 and ejection of eIFs
eIF-6		25	

eIF-2 forms a ternary complex with Met-tRNA^{iMet} and GTP that binds to the 40 S ribosome, where it is established by eIF-1A and eIF-3. The resulting 43 S preinitiation complex then interacts with mRNA prepared by eIF-4F, eIF-4A, and eIF-4B. eIF-4F is a heterodimeric complex that binds to the -Cap structure of mRNA. It is composed of one molecule each of eIF-4E, eIF-4A, and eIF-4G. eIF-4E is of lower abundance in the cell than the other subunits and initiation factors, thereby making the eIF-4F complex rate-limiting under most circumstances. eIF-4A is an RNA-dependent ATPaseand binds RNA only weakly. Its sequences contain ATP-binding elements found in the **DEAD box** family of RNA Helicases. eIF-4B is an RNA-binding protein that contains two **RNA-binding** motifs: the RNP consensus octamer and hexamer elements and an arginine-rich domain. eIF-4F (bound to the 5′ Cap) together with eIF-4B possess RNA helicase activity dependent on ATP hydrolysis. When mRNA secondary structure is melted, the 40 S ribosome is able to bind to the 5′ Cap region and begin scanning. Proper interaction of the Met-tRNA ^{iMet} anticodon with the AUG initiator codon is monitored by eIF-5, which promotes GTP hydrolysis, followed by the ejection of initiation factors and junction of the 40 S initiation complex with 60 S subunits. eIF-2 leaves as a complex with GDP and requires eIF-2B-catalyzed exchange of the GDP for GTP in order to promote another round of initiation.

Initiation Of DNA Replication

How replication of a chromosome is initiated has been a major subject of molecular genetics, because the regulation of chromosomal replication occurs primarily at the stage of initiation (see DNA Replication). Molecules that might be involved in the initiation of replication of the bacterial circular chromosome were proposed by Jacob et al. in 1963 (1). They assumed that each replicon consists of two elements participating in positive regulation of the initiation: (1) a *cis*-acting DNA signal (the replicator, which is now called the replication origin), and (2) a *trans*-acting protein factor (the initiator), which would interact directly with the replicator. The positive regulation for the initiation of chromosomal replication arose from the observation that **protein biosynthesis** is required for the initiation of each round of replication in *Escherichia coli*. Later, it was found that initiation occurs when each individual cell reaches a fixed amount of cell mass relative to the number of the replication origins, regardless of the growth rate (2). To explain these phenomena, the initiator accumulation theory was proposed (3). In this model, an initiator is synthesized and accumulates in the cell at the same rate as the cell mass increases, and initiation takes place every time a certain number of initiators accumulate for each replication origin. The model also proposed that the initiator should act as a repressor of its own **gene expression** to maintain the cellular content of the protein (autogenous regulation) as constant and so it is accumulated in concert with an increase in cell mass. Although Jacob and his colleagues merely stated that the model was a simplified one, their far-sighted hypothesis has now proven to be correct concerning the prokaryotic replicons, those of bacteria, **bacteriophage**, and **plasmids** (see DNA Replication).

1. Initiation of Bacterial Plasmid Replication

The replication of bacterial plasmids and phage has been shown to start from a unique site on the replicon (the origin, see Replication Origin), and most plasmids and phage encode a gene, often designated *rep*, for a replicon-specific protein required for the initiation of DNA replication. The replicon-specific Rep proteins have been shown to recognize specific sequences at the origin and to act positively to recruit host-encoded replication enzymes (4). The initiation frequency of the replication of plasmids is regulated so as to maintain a steady-state **copy number** characteristic of the particular plasmid in a given host bacterium (5). The majority of plasmids in **Gram-negative** bacteria contain direct repeats of the Rep binding sequence (iterons) within the origin. Many of these plasmids also contain indirect repeats of sequences related to the iterons within the **promoter** region of the *rep* gene, and the expression of the Rep protein is autoregulated, as proposed in the initiator accumulation theory. Direct repeats within the functional origin of an iteron-containing plasmid, when inserted into a plasmid normally compatible with the iteron-containing plasmid, show strong incompatibility with the plasmid. In addition, insertion of additional homologous iterons into an iteron-containing plasmid results in a reduction of the copy number of the plasmid. Based on these observations, it was proposed initially that replication begins when a sufficient amount of Rep protein is accumulated to cover the iterons at the origin, and additional Rep binding sequences reduce the effective amount of the initiator (6). However, extensive studies conducted on the regulation of initiation of the iteron-containing plasmids have revealed properties that argue against the simple titration model (5). For example, increasing the concentration of the Rep protein of several plasmids *in vivo* did not result in a proportional increase in the copy number. Several Rep proteins have been shown to exist as two forms; dimers that bind to the iterons in the origin and monomers that regulate its own expression. Although new models that modify the simple titration model to explain the regulation of the initiation of plasmid replication have been proposed, much remains to be learned to understand it completely (5).

2. Initiation of Replication of Bacterial Chromosome

A number of genes have been identified as being involved in the initiation of chromosomal replication in bacteria. The functions of these genes during the initiation process have now been well defined through genetic and biochemical studies in *E. coli* (4, 7). DnaA protein was found to function at the first step in the initiation process by binding to specific DNA repeats (the DnaA box) in the replication origin of the chromosome (*oriC*), and then opening the double strand for formation of the primosome, the machinery for the first primer synthesis (see DNA Replication). The combination of a DnaA box and DnaA protein functioning as *cis* and *trans* regulatory elements, respectively, in the initiation of chromosomal replication was subsequently found to be common in **eubacteria** (7, 8).

Expression of the *E. coli dnaA* gene is negatively regulated by the DnaA protein itself, by the protein binding to DnaA boxes located in the promoter region of the gene, and the concentration of the DnaA protein is kept proportional to the origin concentration. Overproduction of the DnaA protein stimulated the initiation of chromosomal replication up to two-fold, and that stimulation was proportional to the increase in the DnaA protein concentration within this limited range. DnaA overproduction also resulted in a two-fold increase in minichromosome (*oriC* plasmid) copy number. Thus, *E. coli* DnaA protein is considered to fulfill the qualifications required for an initiator that controls the timing of initiation of replication during the cell cycle, and the time of initiation is assumed to be set by the DnaA protein accumulating to a threshold level (9). However, it should be noted that other factors affecting initiation control have been identified. The characteristic of *oriC* of enterobacteria is the presence of many GATC sequences, which are sites for the Dam **restriction-modification** methylase. It was found that newly replicated *oriC* DNA strands are not methylated during up to one-third of the cell cycle after the replication. Such hemi-methylated DNA tends to bind to the cell membrane and does not act as a template for activation by DnaA protein. Furthermore, initiation of replication occurs more or less at random in relation to the cell cycle in a mutant lacking Dam methylase (7). The DnaA protein can be modified in different ways by binding ATP or ADP. Phospholipids were found to reactivate the inactive form (ADP–DnaA) *in vitro* by exchanging ADP for ATP. Initiation from *oriC* seemed to be inhibited *in vivo* in a mutant in which the synthesis of phospholipids was limited (10).

The *dnaA* gene is also autoregulated in *Bacillus subtilis*. However, expression of the *B. subtilis dnaA* gene is coupled to initiation of replication of the chromosome. It is assumed that the autorepression by interaction of DnaA protein with many DnaA boxes near the promoter is so strong in *B. subtilis* that the gene is expressed only when the chromosome undergoes vigorous conformational changes during the replication of the gene itself (11). In *B. subtilis*, fewer than one *oriC* plasmid/cell is allowed to coexist with the chromosome. Introduction of extra copies of DnaA boxes would be incompatible with chromosomal replication. This stringent control of the initiation observed may be ascribed to the strong negative control of *dnaA* expression. Accumulation of the DnaA protein to a threshold level was shown to be prerequisite for the initiation of replication in *B. subtilis*. However, control of the timing of the initiation may require other factors, because the DnaA protein seems to be synthesized only in the early stage of the replication cycle in this cell. Although the role of DnaA as a key factor for regulation of initiation is clear in both *E. coli* and *B. subtilis*, the overall view of the regulation of the timing of initiation is not still clear. And, different devices to control the timing seem to have been evolved in two bacteria.

3. Initiation in Eukaryotes

A unique initiator protein (T Antigen) has been identified to regulate the initiation of replication of the eukaryotic **SV40 virus**. However, no single initiator protein like bacterial DnaA has been found for eukaryotic chromosomes. Instead, multiprotein complexes have been identified to initiate replication of the multiple replicons of eukaryotes. Furthermore, a complex network of protein–protein interactions (complex formation) and protein modifications (**phosphorylation**) regulates the initiation (see DNA Replication).

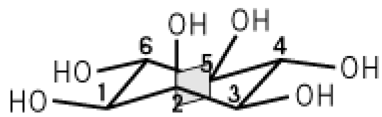
Inositol Lipids and Phosphates

*Myo*inositol, a carbohydrate first found in the mid-1800s in muscle, was defined in the 1930s as a growth factor for yeasts and mammals and then as a component of membrane phospholipids (phosphoinositides) (1, 2). In the 1950s, Hokin and Hokin found that secretory stimuli often accelerate phosphoinositide turnover in their target cells (2, 3). This initial observation led ultimately to recognition of inositol lipids and phosphates as crucially important regulatory molecules in eukaryote cells.

1. *Myo*inositol

*Myo*inositol is one of nine stereoisomeric hexahydroxycyclo-hexanes (the inositols). Several inositols occur in nature, but only *myo*inositol is used widely in the headgroups of membrane phospholipids and in water-soluble inositol polyphosphates. When in the preferred “chair” configuration, *myo*inositol has five equatorial hydroxyl groups (1-6): only the 2-OH is axial (Fig. 1) (1, 2, 4). IUPAC recommendations decree that D- *myo*inositol 1-phosphate (abbreviated as Ins1*P*; the same molecule as L-*myo*inositol 3-phosphate) is the reference molecule for the numbering of biological *myo*inositol derivatives (4). Inositol is made biosynthetically by cyclization of the central metabolite glucose 6-phosphate (by way of 5-ketoglucose 6-phosphate) to Ins3*P*, which is then dephosphorylated (1).

Figure 1. The configuration of, and carbon atom numbering (D-configuration) in, *myo*inositol. The mirror plane () identifies the plane of symmetry through the 2- and 5-carbons of the inositol ring.



It is not clear how evolution “selected” *myo*inositol (from here on simply termed *inositol*) to take on multiple biological roles. Maybe inositol's stereochemistry gives its derivatives some biologically desirable property. Alternatively, evolution may have “needed” a conveniently synthesized and stable polyol, and selected a molecule that comes, by a very short route, from a ubiquitous cell constituent.

The stereochemical versatility of inositol has allowed biology to put it to many uses. Because it has an axis of symmetry through its 2- and 5-carbons (Fig. 1), addition of one substituent to C-1, C-3, C-4, or C-5 immediately renders every carbon in the ring stereochemically unique. For example, Ins1*P* and Ins3 *P* are enantiomers, as are the inositol tetrakisphosphates Ins(1,3,4,5)P_4 and Ins(3,4,5,6)P_4 (L-Ins(1,3,4,5)P_4) (1, 4). Thus, the possible variety of stereochemically (and biologically) unique inositol derivatives can be almost endless.

2. Inositol lipids and phosphates: variety and evolution

Inositol seems to be essential to all eukaryotic cells, and some members of both bacterial kingdoms (Eubacteria and Archaebacteria) also contain inositol lipids and phosphates. Many of the functions of the inositol lipids are becoming understood in remarkable detail, but only a few functions have been definitively ascribed to particular inositol polyphosphates.

Before about 1950, cells were thought to contain a single inositol glycerophospholipid, namely phosphatidylinositol (PtdIns; *sn*-1,2-diacyl-glycero-3-phospho-D-1-*myo*inositol) (Fig. 2). This is generally the most abundant inositol glycerophospholipid, and it and its phosphorylated derivative often have a 1-arachidonyl, 2-stearoyl acyl fatty acyl pairing in mammalian cells. Seven other glycerophosphoinositides, all of which are phosphorylated derivatives of PtdIns, have been identified since 1949 (Fig. 2). Figure 3 summarizes the likely metabolic and functional interrelationships between these glycerolipids.

Figure 2. The “simple” inositol glycerolipids of eukaryotic cells.

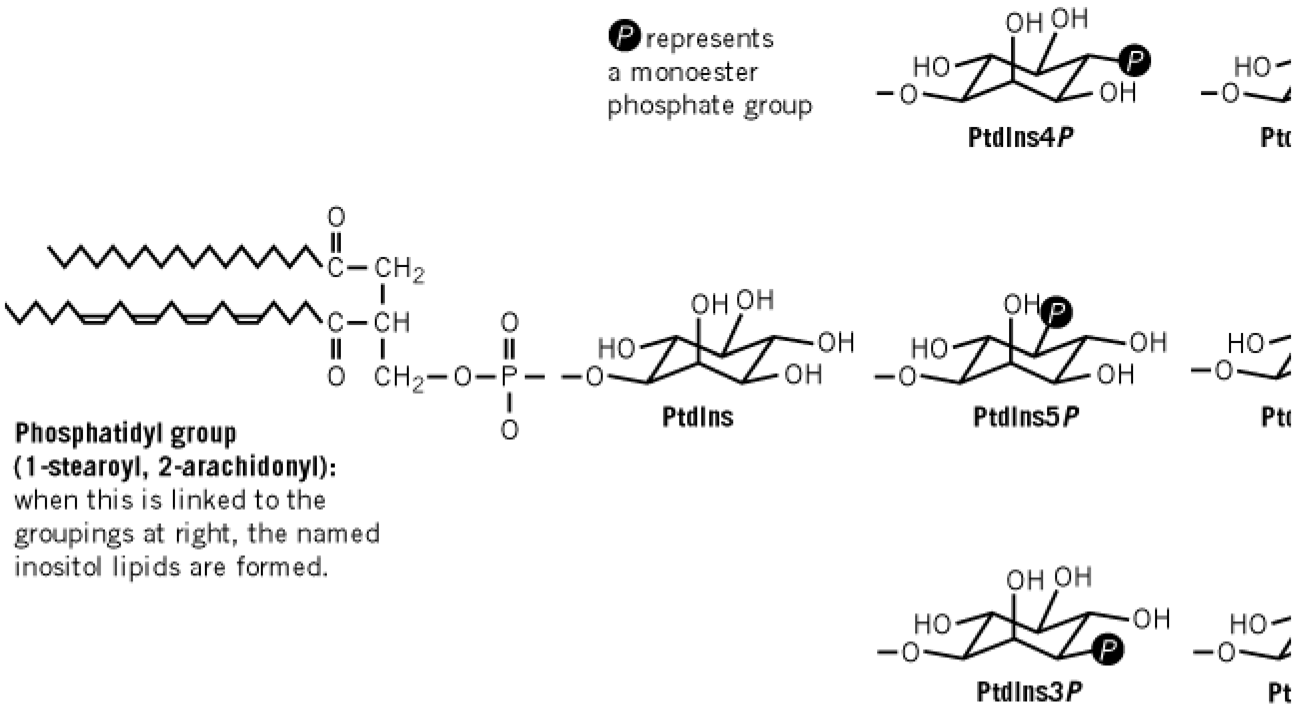


Figure 3. Likely pathways involved in eukaryotic glycerophosphoinositide-based signaling. Substrates of signaling path in shaded ovals, and proven or probable second messengers are in shaded boxes. Note that PtdIns serves as the common and that PtdIns(4,5)P_2 3-kinase signaling pathways and PtdIns(4,5)P_2-directed (Type I) and PtdIns-directed (Type III) in functions.

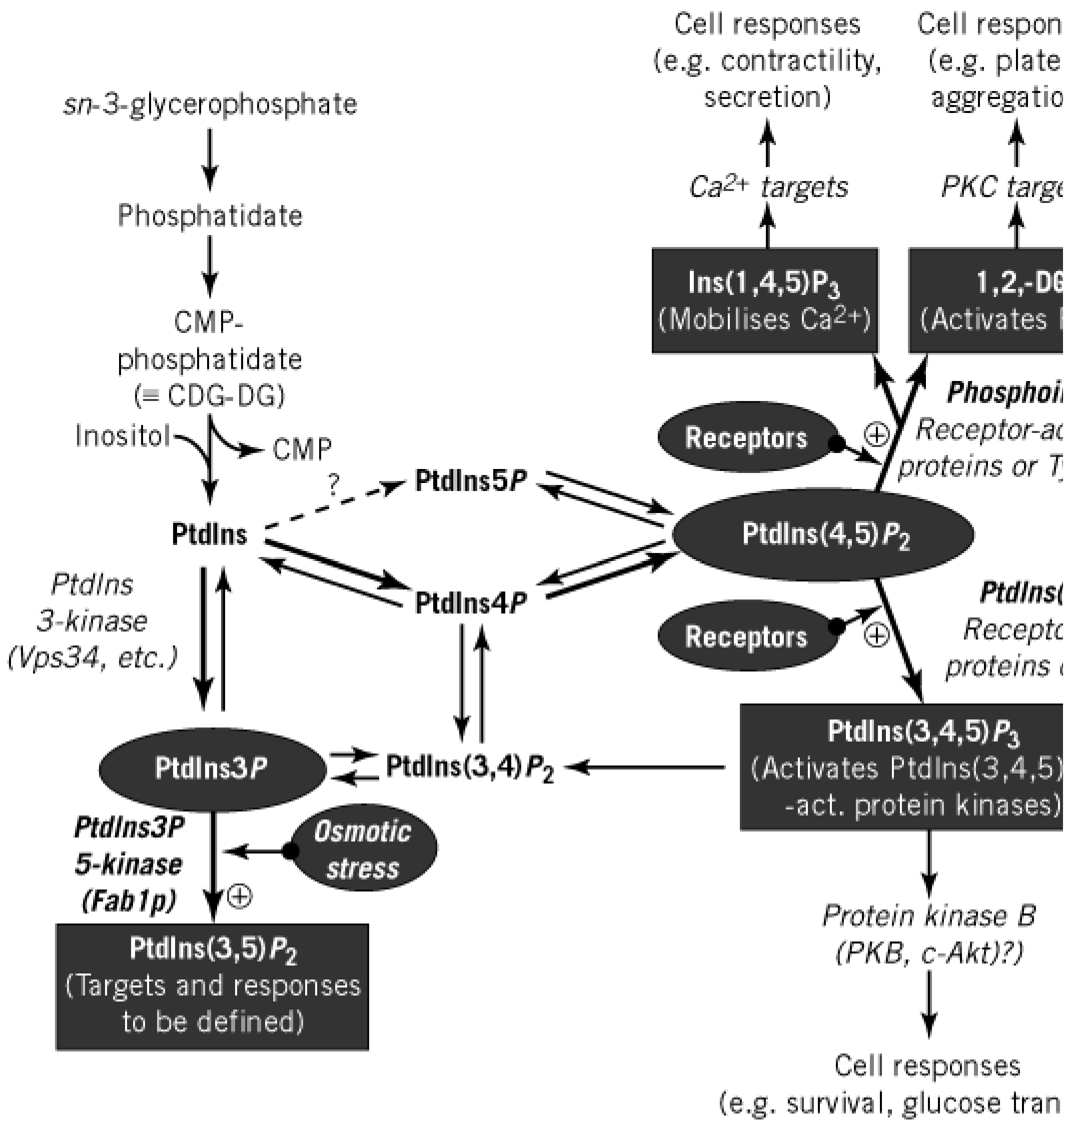
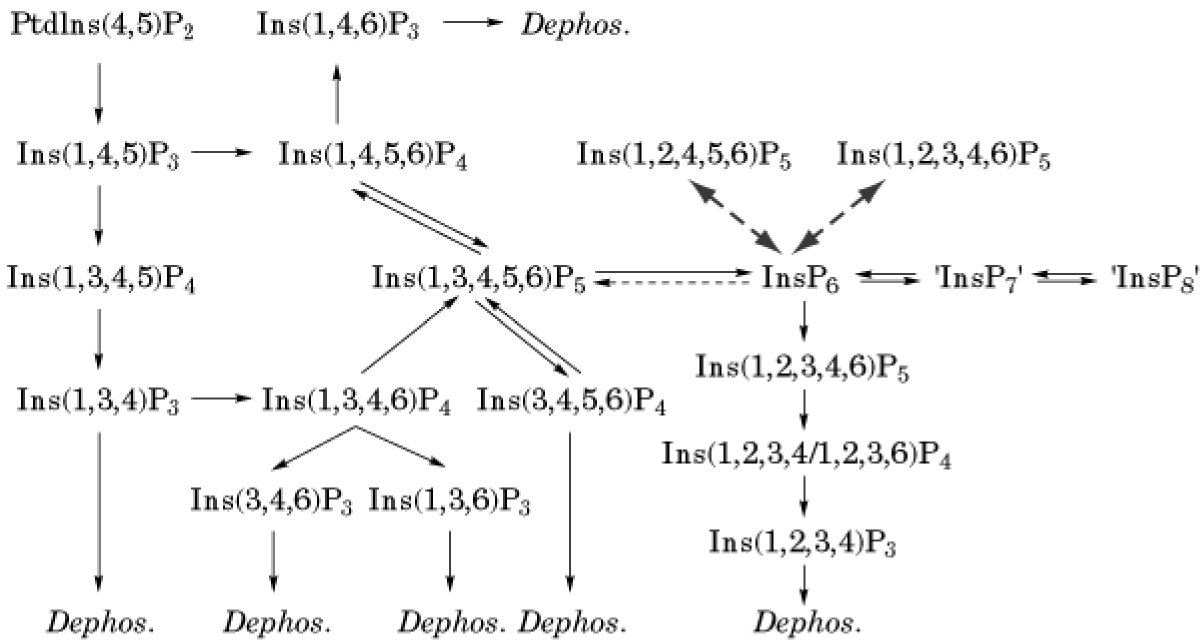


In addition to these relatively simple membrane lipids, the membrane-penetrating lipid anchors of many cell-surface (glyco)proteins and their precursors are PtdIns glycans of varying complexity (see GPI Anchor). Some eukaryotic cells, notably plants and yeasts, also contain complex sphingolipids with inositol-containing headgroups. Although these do not yet have proven functions, their metabolism in yeast is somehow linked to vesicle trafficking (5).

Cells also contain many water-soluble inositol (poly)phosphates. For example, Dictyostelium and mammalian cell lines, such as WRK1 (mammary tumor) and HL60 (myeloid), contain 25 or more different inositol phosphate species (eg, ref. 6). Figure 4 summarizes the metabolic links between many of these inositol phosphates, primarily as in mammalian cells. A variety of inositol phosphate interconversion pathways have been reported from plants and yeasts, including a remarkably direct conversion of Ins(1,4,5)P_3 to InsP_6, apparently by a single enzyme (7). Plant seeds store much of the phosphate essential to their successful germination and development as phytate (an insoluble bivalent cation complex of InsP_6), alleged to be the most abundant phosphate ester in nature.

Figure 4. Pathways of inositol polyphosphate interconversion in eukaryote cells. For simplicity, individual inositol monophosphates and bisphosphates on the dephosphorylation pathways have been omitted.



Some families of Eubacteria have additional inositol-containing phospholipids, the best characterized being the PtdIns mannosides of mycobacteria. Archaebacteria, which inhabit some of the most hostile environments on the planet, have glycerophospholipids that are very distinctive, both because the steric configuration of the diradylglycerol backbone of these lipids is opposite to that of the eukaryotic and eubacterial lipids and because they use very different, and chemically very stable, hydrocarbon side chains. Again, however, some of these have inositol headgroups (8). Moreover, hyperthermophilic archaebacteria use inositol in another remarkable way. When they are exposed to temperatures that are even more extreme than usual, they synthesize very high cytosolic concentrations (~0.5M) of the K^+ salts of water-soluble inositol phosphate derivatives, such as dimyoinositol 1,1′-(3,3′)-phosphate, as cytoprotective solutes (9).

When the primeval cells from which all later organisms evolved were emerging, a fairly early step was almost certainly enclosure of the newly evolving cellular metabolic machinery within a selectively permeable membrane envelope made of amphiphilic lipids. The fact that *myo*inositol, an unusually stable cyclic polyol, is a component both of the diether lipids of Archaebacteria and of the (mainly) diacyl-glycerolipids of Eubacteria (some) and eukaryotes suggests that it was recruited into membrane lipids very early. This probably happened before the two-billion-year-old evolutionary radiation that gave rise to the major biological kingdoms, making inositol a very ancient cell component.

Only since the early 1980s, however, has it been recognized how inositol's stereochemical versatility has let cells employ its derivatives for many different jobs. Throughout this recent period, frequent discoveries of “new” inositol-containing cell constituents have regularly been followed by the definition of “new” functions for inositol derivatives.

3. Inositol lipids and phosphates in signaling

One of the most essential characteristics of cells is their ability to respond with changes in their behavior to chemical changes in their environment. Many of these extracellular chemical signals cannot penetrate the plasma membrane, and so the cell surface receptors that respond to them couple to transmembrane signal transduction mechanisms that pass information to the cell interior. Inositol lipids play essential roles as the metabolic substrates and/or the output signals of at least two, and maybe three or more, widespread cell signaling systems.

3.1. Signaling through Phospholipase C Activation

The best characterized of these signaling pathways uses receptor activation of PtdIns(4,5) P_2 hydrolysis by phosphoinositidase C (phospholipase C, PLC) to make the second messengers inositol 1,4,5-trisphosphate (Ins(1,4,5) P_3) and 1,2-diacylglycerol, as outlined in Fig 3 (top right). Despite extensive early work by the Hokins (3), only in the 1970s was it realized that inositol lipid hydrolysis has the properties of a coupling reaction that links cell-surface receptors to the intracellular mobilization of Ca^{2+} (2) (see Calcium Signaling). PtdIns(4,5)P_2 hydrolysis was then identified as the primary stimulated reaction (10). Meanwhile, Nishizuka defined the polyunsaturated 1,2-diacylglyerol (1,2-DG) liberated from PtdIns(4,5)P_2 as a second messenger that activates many members of the protein kinase C family (11). Finally, Streb et al. showed that Ins(1,4,5) P_3 released Ca^{2+} from an intracellular store (12). We now know that Ins(1,4,5)P_3 triggers intracellular Ca^{2+} release through the intrinsic cation **channels** of at least four subtypes of Ins(1,4,5)P_3 “receptor” that are expressed primarily in various elements of the endoplasmic reticulum (13).

These revelations established two new principles. First, chemical species very different from nucleotide cyclic phosphates (see -cyclic AMP, cAMP); -Monophosphate, cGMP)) and the Ca^{2+} ion, the prototypic intracellular messenger molecules that were recognized between the mid-1950s and the mid-1970s, can function as “second messengers.” Second, receptor-generated intracellular messenger molecules need not be water-soluble and thus mobile within the cell. Instead, protein kinase C homes to the 1,2-DAG that is formed at the plasma membrane as a consequence of PtdIns (4,5)P_2 hydrolysis. There it is activated by simultaneous interactions with 1,2-DAG, anionic aminophospholipids, notably phosphatidylserine, in the inner leaflet of the plasma membrane, and the ambient concentration of cytoplasmic Ca^{2+}.

There are numerous excellent reviews of the PLC signaling pathway and the extraordinary variety of receptors that harness it (eg, refs. 11-15; and see Phospholipases C): some of the important receptors that harness this signaling pathway are listed in Table 1(see also Acetylcholine Receptor, Rhodopsin). There is a substantial family of PLCs that can hydrolyze PtdIns(4,5)P_2, and these are activated by two or more fundamentally different mechanisms (16). PLCs of the b-family are activated by some subfamilies of receptors in the 7-span or “serpentine” superfamily. Different serpentine receptors activate PLC-bs, either through the GTP-ligated a-subunits of heterotrimeric G proteins of the G_Q subfamily (**pertussis toxin**-insensitive) or bg-subunit dimers that are liberated following activation of G proteins in the G_i/G_o subfamily (**pertussis toxin**-sensitive). PLCs of the g-subfamily are attracted to the cytoplasmic face of the plasma membrane by certain phosphotyrosine-containing peptide motifs that are made by activated **tyrosine kinases**, and there they are tyrosine-phosphorylated: these two events cooperate to activate PtdIns(4,5)P_2 hydrolysis by the PLCgs (16). PLCds exist alongside PLCbs and PLCgs in animal cells, but only PLCds seem to be present in yeasts and plants. To some degree, the PLCds remain a puzzle, particularly because we still do not fully understand how they are activated. They can be activated by increases in cytosolic (Ca^{2+}) that are fairly large but physiologically plausible, but there may be other activating factors yet to be discovered.

Table 1. Stimuli that Transmit Signals into Target Cells at Least in Part Through Phosphoinositide-Based Signaling Pathways

PLC-Catalyzed PtdIns(4,5)P_2 Hydrolysis

Platelet-derived growth factor (PDGF)	Angiotensin I (AT$_1$receptor)
	Endothelins (3 receptors)
Adrenergic (a$_1$receptor)	Rhodopsin (invertebrates only)
Histamine (H$_1$ receptor)	
Acetylcholine (muscarinic, 2 subtypes)	Thromboxane A$_2$
	Interleukin 8
Vasopressin (V$_1$receptor)	Glutamate (metabotropic receptors)
Oxytocin	
Substance P and other tachykinins	Some taste receptors?
PtdIns(3,4,5)P_3 Synthesis Catalyzed by Type I Phosphoinositide3-Kinases	
Platelet-derived growth factor (PDGF)	The ab/CD3 antigen receptor complex of T lymphocytes
Insulin	
IGF-1	*f*MetLeuPhe
Colony-stimulating factor-1 (CSF-1)	
PtdIns3P 5-Kinase-Catalyzed PtdIns(3,5)P_2 Synthesis	
Hyperosmotic stress (yeast)	

A particularly clear illustration of the essential nature of the phospholipase C signaling pathway has emerged from genetic studies of the visual systems of insects (eg, *Drosophila*), which use rhodopsin-linked phospholipase C activation as their primary signaling pathway in response to the light activation of rhodopsin (17). Fly retinas show a striking set of genetic defects in this signaling pathway. They do not function properly if they lack: (1) a receptor-coupled phosphoinositidase C; (2) a diacylglycerol kinase and CDP-diacylglycerol synthase necessary for the resynthesis of PtdIns from the hydrolyzed PtdIns(4,5)P_2; or (3) a PtdIns transfer protein that is assumed somehow to maintain the PtdIns supply to the photoreceptor membranes (see Table 2and ref. 5).

Table 2. Biological Effects for Eye Function in *Drosophila* of Mutations in, or Changes in, the Expression Level of Proteins Involved in Phosphoinositide-Based Signaling (See Ref. 3 for References to Original Observations)

Gene or Protein	Target Protein	Phenotype
NorpA	PLC-b, coupled to light-activated rhodopsin	Eye elements fail to generate a light-triggered receptor potential
RdgA	Diacylglycerol kinase	Photoreceptors degenerate
RdgB	PtdIns transfer protein	Light-induced degeneration of photoreceptors
Cds	CDP-diacylglycerol	Reduced signal gain

	synthase (a step in PtdIns biosynthesis)	during photoreception; light-dependent degeneration of photoreceptors
Type-I PtdIns(4,5)P_2 3-kinase	Organ-targeted Type I PI3K	Eye size correlates positively with the concentration of expressed PI3K

3.2. Signaling through 3-Phosphorylation of PtdIns(4,5)P_2 to Phosphatidyl-inositol 3,4,5-Trisphosphate (PtdIns(3,4,5)P_3)

In the late 1980s, eukaryote cells yielded up both PtdIns3 *P* and phosphoinositide 3-kinases that can make PtdIns3 *P* from PtdIns (generically abbreviated below as PI3Ks). Soon, however, it was found that some PI3Ks can use PtdIns, PtdIns4*P*, and PtdIns(4,5)P_2 as substrates and so can also make two other novel lipids: PtdIns(3,4)P_2 and PtdIns(3,4,5)P_3. Moreover, neutrophils stimulated by the chemotactic attractant *f*MetLeuPhe (see Chemotaxis) were seen to make a lipid with the charge of a phosphatidylinositol trisphosphate (PtdIns P_3): this proved to be PtdIns(3,4,5)P_3.

Soon came recognition that many activated receptor tyrosine kinases (see Growth Factors; Platelet-Derived Growth Factor; Insulin) and a few G-protein-coupled serpentine receptors (especially those in hematopoietic cells) can very rapidly (within seconds) stimulate a subset of PI3Ks that phosphorylate PtdIns(4,5)P_2 to PtdIns(3,4,5)P_3 (see Table 1). These are now known as the Type I subfamily (18).

The PtdIns(3,4,5)P_3 generated in response to receptor stimulation, which is the most highly charged membrane phosphoinositide present in cells, is presumed to be located in the inner leaflet of the plasma membrane. This identified it as another potential receptor-generated signaling molecule. Several key observations soon combined to confirm this view (18-20). First, the PtdIns (4,5)P_2 3-kinase responsible for PtdIns(3,4,5) P_3 synthesis in response to activated tyrosine kinases is a heterodimer of a catalytic subunit (p110) and a **SH2 domain**-containing regulatory subunit (p85). Immediately after the activation of some growth factor receptors, this p110/p85 PI3K becomes physically complexed with the activated receptor tyrosine kinase. This binding is mediated by the SH2 domain of p85, which recognizes a particular phosphotyrosine-containing motif (typically *P*Tyr-Met-Asp/Pro-Met) in the cytoplasmic “tail” of the activated receptor tyrosine kinase. Interaction with this motif localizes the kinase to the inner surface of the plasma membrane, where it becomes tyrosine-phosphorylated and is activated. Second, mutations of the “kinase insert” sequence of the platelet-derived growth factor (PDGF) receptor abolish this *P*Tyr-containing motif and reduce the growth-stimulating and survival-promoting activity of PDGF. Third, the tyrosine kinase activities of the activated insulin and insulin-like growth factor I receptors phosphorylate insulin receptor protein 1 (IRS-1), generating multiple PI3K-activating motifs. This activation of PI3K activity is essential both for the survival-promoting activities of these hormones and for a number of their classical actions on carbohydrate metabolism (19, 20). Fourth, overexpressed or constitutively active PI3Ks are growth-promoting and can be oncogenic (18). Finally, neutrophils contain a different Type I PtdIns(4,5)P_2-directed PI3K, which is activated by the G protein bg–subunit complexes that are released following activation of some G protein–coupled receptors (eg, the *f*MetLeuPhe receptor) (21).

The fungal metabolite wortmannin A was a key reagent in many of these studies. Interest in this compound was aroused when it was found to inhibit multiple, and apparently unrelated, cell responses to external stimulation. These included:

1. The rapid oxidative burst characteristic of stimulated neutrophils;
2. Insulin-stimulated glucose uptake into target tissues, notably adipose and skeletal muscle, which is achieved primarily by fusion of vesicles enriched in glucose-permeable channels with the plasma membrane;
3. Maintenance of cell survival in response to “growth/survival factors” such as IGF1; and
4. Activation of the formation of lamellipodia at the leading edge of migrating cells (see Cytoskeleton).

Once it was realized that wortmannin is a very potent inhibitor of the Type-I PI3Ks that make PtdIns(3,4,5)P_3, this became an obvious candidate as the immediate activator of some or all of these responses. Although subsequent studies showed that wortmannin can be a less than scrupulously precise pharmacological reagent, other evidence has subsequently confirmed that many of the biological responses that are most sensitive to wortmannin inhibition are indeed consequences of PI3K activation. Used carefully, therefore, this compound has remained valuable for the initial identification of responses that might be consequences of receptor-stimulated PtdIns (3,4,5)P_3 synthesis.

Some details of how cells sense and respond to a PI3K-driven rise in PtdIns(3,4,5)P_3 concentration as a regulatory signal have been elucidated. Most notably, accumulation of PtdIns(3,4,5)P_3 very quickly leads to activation of protein kinase B (PKB, also known as c-Akt), a **serine-threonine protein kinase** and the product of a proto-oncogene (22). To become fully activated, cytosolic PKB must become firmly localized to the inner face of the plasma membrane and must be phosphorylated on two widely separated residues (Thr473 and Ser308). PKB physically associates with the plasma membrane, primarily through a direct interaction between its pleckstrin homology (PH) domain and the normal PtdIns(4,5)P_2 complement of that membrane, but this association may be strengthened by newly formed PtdIns(3,4,5)P_3.

Receptor-stimulated formation of PtdIns(3,4,5)P_3 triggers phosphorylation of the membrane-bound PKB. In this process, one PtdIns(3,4,5)P_3-activated protein kinase (phosphoinositide-dependent kinase 1; PDK1) phosphorylates PKB on Thr308, and another may phosphorylate it on Thr473 (Fig. 2; refs. 23, 24). The interaction that activates PDK1 seems to be between the newly formed PtdIns(3,4,5)P_3 and a PtdIns(3,4,5)P_3-selective PH domain in PDK1.

A substantial number of other candidate target proteins avidly and selectively bind PtdIns(3,4,5)P_3: these include the so-called centaurins (25, 26) and Bruton's tyrosine kinase, an enzyme essential for normal B lymphocyte development (27). Which, if any, of these serve as directly-controlled regulatory targets of this receptor-responsive polyphosphoinositide remains to be determined (20).

4. Phosphoinositides and membrane trafficking

The earliest work on receptor-stimulated phosphoinositide turnover, in the 1950s and 1960s, focused primarily on its possible relationship to the triggering of secretory processes (3). The emphasis then moved to unraveling the central roles of phosphoinositides in signaling. Recently, however, there has been a remarkable resurgence of interest in how phosphoinositides contribute to intracellular membrane and protein trafficking (28).

4.1. PtdIns(4,5)P_2 Synthesis and Exocytosis

It has long been known that **secretory vesicles** (eg, adrenal medullary chromaffin "granules") support rapid PtdIns4*P* biosynthesis, and recently it was recognized that **exocytotic** secretory processes in yeast and in mammalian cells fail in the absence of a functional cytosolic "PtdIns transfer protein" (PITP). In yeast, *Sec14*, one of many ***Sec*** genes implicated in secretory protein transit early in the pathway between the Golgi apparatus and the plasma membrane, encodes a PITP and, in permeabilized PC12 cells (which mimic catecholamine secretion by adrenal medulla), a PITP is among the proteins that are needed to reconstitute ATP-driven exocytotic secretion.

PtdIns is made at the endoplasmic reticulum but is involved in signaling at the plasma membrane. Soon after the discovery of PITPs in the 1970s, it was recognized that these molecules might serve as "ferries" that move PtdIns around cells (2), an idea that was recently validated (29, 30). PITPs bind PtdIns and/or phosphatidylcholine, one molecule at a time, and shuttle these lipids across the cytosol from membrane to membrane. Mammals have two very similar PITPs (a and b), either of which can support PtdIns(4,5)P_2-dependent signaling and exocytosis. Although the yeast protein encoded by *Sec14* is functionally quite similar, it has an unrelated amino acid sequence.

A second cytosolic protein that is essential for catecholamine secretion by PC12 cells is a PtdIns4*P* 5-kinase. Successful exocytosis, therefore, requires PtdIns to be delivered to the secretory vesicle membrane and phosphorylated to PtdIns(4,5)P_2 (31). Accumulation of a substantial amount of PtdIns(4,5)P_2 in the secretory vesicle membrane may somehow "prime" the vesicles, switching them to a state in which they can fuse with the plasma membrane in a subsequent Ca^{2+}-activated exocytosis step.

4.2. PtdIns3P and Membrane Trafficking

PtdIns3*P*, by contrast, is somehow implicated in vesicular protein sorting to the vacuole of yeast and the lysosomes of mammalian cells (which are functionally homologous organelles), and also in membrane fusion between elements of a membrane vesicle compartment (the "early" endosomes) that plays a central role in the import into eukaryotic cells of macromolecules such as the iron-carrier protein transferrin. This first became apparent when the protein encoded by *vps34*, one of many genes whose disruption interferes with vesicular protein sorting in cells, was identified as a PtdIns-specific PI3K: Vps34p and other Vps34p-like PI3Ks make up the Type III PI3K subfamily. It is not clear how PtdIns3*P* contributes to the membrane fusion and fission events in these membrane trafficking processes. However, detailed studies of EEA1, a protein characteristic of early endosomes, have shown that a **zinc finger**like protein domain known as a "FYVE finger" serves as a highly selective PtdIns3*P*-binding domain; similar FYVE finger domains are present in several other mammalian and yeast proteins involved in membrane trafficking processes (32, 33).

The importance of the 3-phosphorylation of PtdIns by Type III PI3Ks was further emphasized when it was discovered that the PtdIns3 *P* that Vps34p makes is the substrate for the synthesis of phosphatidylinositol 3,5-bisphosphate (PtdIns(3,5)P_2), the most recently discovered of the polyphosphoinositides (34, 35). Whereas PtdIns3*P* synthesis is a constitutive activity of unstressed cells—as it should be if it is involved in the continuous vesicle-mediated protein flows into cells from the exterior and from Golgi to lysosomes—PtdIns(3,5)P_2 synthesis is acutely regulated. In both fission and budding yeasts, hyperosmotic stress provokes a striking acceleration of PtdIns(3,5)P_2 synthesis (35). The exact function of this striking response is yet to be defined.

5. Inositol lipid-binding domains in proteins

One common theme that has emerged particularly strongly from many recent studies of the functions of inositol lipids and phosphates is the involvement of stereospecific, high-affinity interactions between particular polyphosphorylated inositol lipid or phosphate species and **protein**

domains whose primary function appears to be the selective recognition of these molecules. Many of these domains are members of a large family of so-called pleckstrin homology (or PH) domains (15, 36), but see also the mention above of 'FYVE fingers.'

PH domains have a characteristic cluster of basic amino acid residues that, in each protein, ligates a particular subset of polyphosphorylated inositol derivatives [eg, (37)]. For example, the PH domains of PKB/Akt and of Bruton's tyrosine kinase preferentially bind PtdIns(4,5)P_2 and PtdIns(3,4,5)P_3, respectively (23, 27). As the name suggests, the prototypic PH domain was found in pleckstrin: this is an abundant platelet cytosol protein that becomes heavily phosphorylated by protein kinase C downstream of receptors (eg, for thrombin) that activate phospholipase C but whose function is still not entirely clear. A major function of PH domains is to mediate noncovalent binding of proteins to the cytoplasmic surfaces of polyphosphoinositide-containing membranes—notably the plasma membrane, but also other structures such as exocytotic secretory vesicles—so as to localize them at their functional sites. Some such effects are likely to be constitutive, as when a PH domain-containing protein homes to the steady-state complement of plasma membrane PtdIns(4,5) P_2. In other circumstances, PH domains probably play a major regulatory role. For example, PtdIns(3,4,5) P_3-binding PH domains will relocate proteins to the plasma membrane, often for activation, only after cells have been exposed to a PtdIns(3,4,5)P_3-generating stimulus.

6. The Functions of inositol phosphates

Although the biological function of Ins(1,4,5)P_3 is clear, why cells contain so many other inositol polyphosphates remains uncertain. That eukaryotic cells commit substantial genetic resources and metabolic energy to complex inositol polyphosphate interconversion pathways (see Fig. 4) surely indicates that at least some of these molecules have important cellular functions, but few of these are established with any certainty. Some of these are summarized in Table 3, and discussion of others can be found in recent reviews (5, 6, 15, 36, 42, 43).

Insertion Sequence Elements

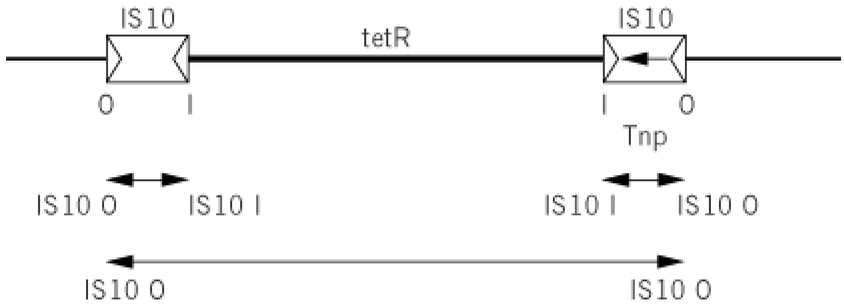
Insertion sequence (IS) elements are small (0.75 to 1.5 kbp) transposable elements found in bacteria (1). They usually encode only a transposase gene and special sequences at the tips of the element on which the recombinase acts to move the element from place to place. IS elements thus structurally resemble, for example, P elements from *Drosophila*, the widespread Tc1/mariner elements, and Ac elements from maize, although IS elements are generally much smaller. Like P, Tc1/mariner, and Ac elements, IS elements alter DNA in the host genome upon insertion and can cause gene inactivation.

IS elements were among the first nonmaize transposable elements discovered, being identified in bacteria in the late 1960s as the cause of highly polar mutations in bacterial operons and also as components of translocatable antibiotic-resistance segments. It was possible to manipulate bacterial

DNA molecules at this time because of their relatively small size, something that was not possible for other organisms such as maize, and the direct characterization of the DNA of these polar mutations revealed that they resulted from an insertion of a discrete piece of DNA.

Some IS elements also associate to form what are called *composite elements* in which two ISs flank a region of DNA that encodes a selectable trait, for example an antibiotic-resistance determinant (Fig. 1). The action of transposase at the two external edges of the IS elements can move the entire IS–drug resistance gene–IS element from place to place (Fig. 1). Each IS element can also move independently, although this does not result in movement of the antibiotic resistance determinant. IS elements are found as individuals at various positions in bacterial chromosome.

Figure 1. IS elements can associate to form composite transposons. IS elements encode information to promote their translocation, a transposase (arrow) and special sequences at their ends (triangles). Composite transposons are formed by two IS elements flanking a drug resistance determinant, here tetracycline. When the inside (I) and outside (O) ends of an individual IS element are the substrates for recombination, the IS element alone translocates. When the outside (O) ends of the two ISs flanking the antibiotic resistance determinant are the substrates for recombination, the entire IS–drug resistance–IS segment translocates.



Particularly well-studied IS sequences are IS10 (2) and IS50 (3). The composite transposon Tn10 consists of two IS10 elements flanking a DNA segment that encodes a tetracycline-resistance determinant. The composite transposon Tn5 is composed of two IS50 elements flanking a **kanamycin**-resistance encoding segment. Both of these elements translocate by a cut-and-paste mechanism, in which the element is excised from the donor DNA and then inserts into the target DNA. They and their derivatives have also been invaluable reagents in the genetic analysis of bacteria (4). The strategy of using transposon mutagenesis to tag genes physically to allow **gene** isolation has been a very valuable technique.

Another class of IS elements—members of the IS3 family that includes IS3 and IS911—have an interesting strategy for expressing transposase. The element contains two open reading frames, OrfA and OrfB. OrfA encodes the DNA-binding determinant that directs this protein to the ends of the transposon, but OrfA has no transposase activity. The actual transposase OrfAB results from a frameshifting event near the end of OrfA that joins OrfA and OrfB (5). The amount of transposase, and thus the frequency of transposition, is determined by the amount of frameshifting. These elements also appear to transpose by an unusual mechanism (6, 7). Transposition begins by cleavage at one end of the transposon, exposing a 3′OH end of the element, followed by an intramolecular attack of that 3′OH end to just outside the 5′ end of that same strand; note that this is the same chemistry as is involved in other transposition reactions, the only difference being that the joining reaction is intramolecular, rather than intermolecular. By either another such single-strand cleavage and intramolecular joining, or by replication, a double-stranded DNA circle results in which the IS ends are closely juxtaposed, with just a few nucleotides separating them. This “circle junction” version of the IS element then interacts with the target site and is inserted by breakage at 3′ ends of the transposon and joining the exposed ends to the target DNA.

It should be appreciated that although some of the well-studied elements and widely used bacterial elements such as Tn10 and Tn5 contain IS elements, certainly not all bacterial transposable elements contains IS sequences. Tn3, Mu phage, and Tn7 are all examples of bacterial elements that lack IS sequences, and these elements do not associate to form composite transposons.

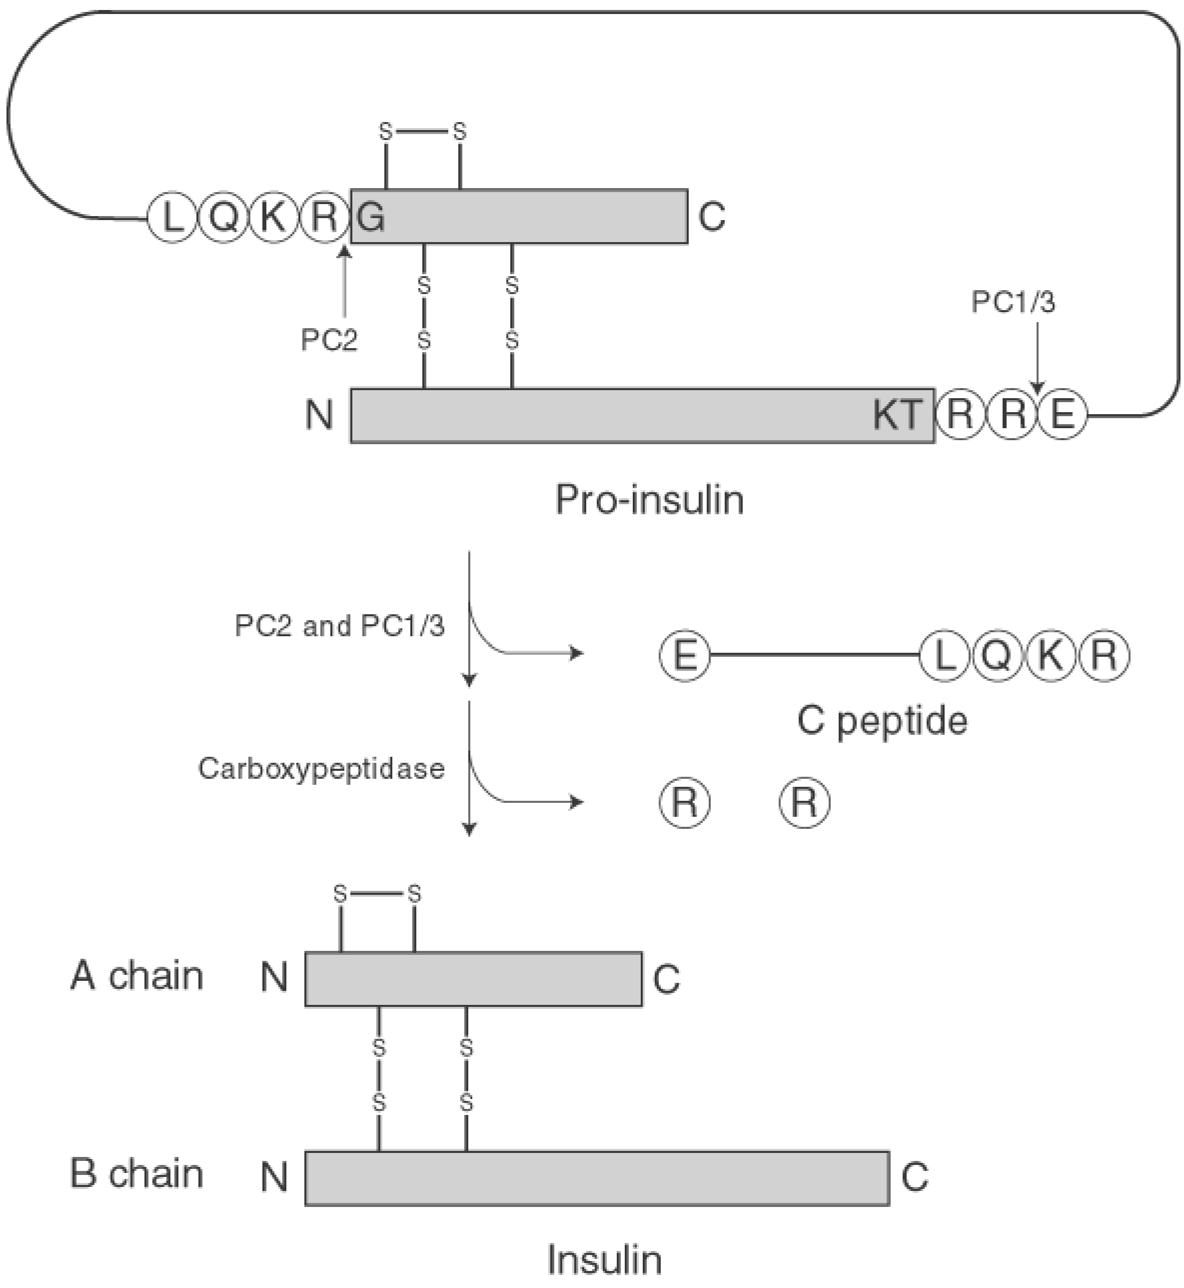
Insulin

Insulin is a peptide hormone that is secreted by the b-cells of the islets of Langerhans in the pancreas. The principal role of this hormone is the regulation of glucose metabolism and homeostasis by regulating the concentrations and activities of numerous enzymes involved with catabolism and anabolism. The molecule (MW 5808) consists of two polypeptide chains, A and B, linked by two disulfide bonds (Fig. 1). Reduction of these disulfide bonds results in the loss of biological activity.

Figure 1. The processing of pro-insulin (top) to the two polypeptide chains of insulin linked by disulfide bonds (bottom). The sequence of the pro-insulin polypeptide chain is shown, by one-letter abbreviations, only near the sites of cleavage by the convertases PC1 / 3 and PC2 and the carboxypeptidase; the remainder of the connecting C peptide that is removed proteolytically is shown as the solid line only.



In humans, the insulin **gene** is located on chromosome 11. Several **alleles** coding both normal and pathological forms of insulin have been identified. An individual's genes are co-dominantly expressed. Insulin is synthesized initially on **polyribosomes** of the rough endoplasmic reticulum (ER) as pre-pro-insulin (see Polyproteins), a single-chain precursor protein of molecular weight 11,500. The *N*-terminal signal peptide of 23 or 24 primarily **hydrophobic** residues is cleaved immediately by signal peptidase after penetration of the peptide into the ER lumen. The resulting pro-insulin (MW 9000) undergoes **protein folding** and disulfide bond formation. It is then transported to the Golgi apparatus and is sorted into **clathrin**-coated **secretory granules**. **Posttranslational modification** by **membrane**-bound endoproteinases, pro-hormone convertases PC-2 and PC-1 / 3, and a carboxypeptidase converts proinsulin into equimolar amounts of insulin and free C peptide (Fig. 1). Other than to facilitate proper folding, the C peptide has no known function. The insulin stored in the mature secretory granules assumes a hexameric quaternary structure with two bound zinc ions (1). In response to plasma glucose levels, the mature granule translocates to the cell membrane, fuses with the membrane, and discharges its contents. Other than glucose, several other substances (eg, mannose, ribose, arginine, and leucine) also stimulate release.

Upon secretion by the pancreas, insulin is directly infused into the portal vein and the liver, where it exerts its primary metabolic effects. Monomeric insulin generates intracellular effects by binding to its plasma-membrane receptor (see Peptide Hormones). The precise signal transduction mechanisms (see Signal Transduction) are still not completely known (2).

The principal target tissues of insulin are liver, muscle, and fat. In most tissues, insulin increases the number of plasma membrane glucose **transporters**, such as GLUT 4 (3, 4), but glucose uptake in the liver is also increased because of the increased activity of regulatory enzymes that play a role in glycolysis. Glycogenolysis is inhibited. Glucokinase, **phosphfructokinase** -1, pyruvate kinase, and insulin-dependent **phosphodiesterase** are all involved. In addition, specific **phosphatases** increase the activity of glycogen synthase and thus lead to increased glycolysis. Glucose-6-phosphatase is inhibited. Overall, hepatocyte glucose and its phosphorylated forms are increased, resulting in lower blood levels of glucose. The actions are complex, because all the metabolic pathways must be coordinated and maintained to effect homeostasis.

The insulin-receptor gene is located on chromosome 19. The insulin receptor (see Hormone Receptors Peptide Hormones) is a **tyrosine kinase** and comprised of two identical extracellular a-subunits (MW 135 kDa) and two identical transmembrane b-subunits (MW 95 kDa). The a-subunit contains the insulin-binding domain, and the membrane-spanning b-subunit transduces the signal. After the hormone-receptor complex is formed, it is internalized by endocytosis mechanisms. The receptor is recycled back to the membrane, while the insulin molecule is degraded (5).

Mutations occur in some forms of diabetes mellitus in both the genes for insulin and its receptor (6), as well as defects in ER and Golgi processing (7). The mutations may result in impaired binding, impaired transmembrane signaling, altered endocytosis and recycling, or impaired transport of the receptor to the cell membrane. Diabetes is thus a catabolic disease caused by an apparent insulin deficiency. There are genetic components to both type I (insulin dependent) and type II (insulin independent) diabetes. Moreover, type I diabetes can result from an **autoimmune** response that destroys the pancreatic b-cells and insulin production (8).

Therapy consists of the subcutaneous administration of insulin. Protein engineering of human insulin production in *Escherichia coli* now provides the therapeutic drug. Use of insulin-secreting cell lines as **gene therapy** is presently only in the early stages of development (9).

Insulin-Like Growth Factors

The insulin-like growth factors (IGFs) are among the most ubiquitous class of peptide growth factors in the body and are found in most tissues and in blood. Two types, IGF-I and -II, have been purified from serum, each with molecular masses of approximately 7.6 kDa. Liver is a major site of their expression, both in fetal and postnatal life, although almost all tissues have been shown to express these peptides in the human and animal fetus (1, 2); this suggests a predominantly autocrine or paracrine role, in which the IGF affects primarily the same cell or only nearby cells. In the fetus, the most abundant isomer is IGF-II, but in some species, such as rat, but not humans, IGF-II is absent from adult serum and is replaced by IGF-I. In humans, IGF-II persists throughout life, although the relative abundance of IGF-I increases postnatally. A high-affinity type 1 IGF receptor is ubiquitous in developing tissues and recognizes IGF-I with an order of magnitude greater binding affinity than it does IGF-II. Consequently, IGF-I is a more potent **mitogen** with a half-maximal response on most cell types at approximately 1 to 3 nM. The IGFs also have proven roles in the control of cell differentiation and are preventive of apoptosis in many cell types. In postnatal life, synergy between endogenous IGF-I and trophic endocrine hormones facilitates endocrine glandular function. For example, thyroid-stimulating hormone synergizes with IGF-I to support thyroxine synthesis, while a synergy of IGFs with follicle stimulating hormone allows sex steroid production in the ovary (3). The type 1 IGF receptor has an intracellular tyrosine kinase domain that is capable of **phosphorylating** the insulin receptor substrate proteins (IRS-1 and -2). IGFs are able to activate the proto- **oncogene** *ras* in many cell types, which subsequently signals gene transcription changes in cell nuclei, often by a mitogen-activated protein (MAP) kinase pathway, but also by the activation of phosphoinositol-3 kinase (see Inositol Lipids and Phosphates), culminating in the activation of the transcription factors *fos*, *jun*, and *myc*. An additional high-affinity receptor that specifically binds IGF-II, the type II or cation-independent **mannose-6-phosphate receptor**, is ubiquitous but has no consistent intracellular signaling pathway or biological endpoint.

The IGFs are seldom found in free form but are complexed to one of six distinct classes of specific binding protein, termed IGFBP-1 to -6. These are found both in serum and in extracellular fluids, and they serve not only as carrier proteins to extend the biological half-life of the ligands but also modulate their biological actions by either interacting or competing with the type 1 IGF receptors. While all six IGFBPs have a conserved core structure, differences in their *N*- and *C*-termini confer individual relative binding affinities for IGF-I and -II and an ability to interact with both the extracellular matrix and the cell surface (4). Two of these IGFBPs, IGFBP-1 and -2, contain an **integrin**-binding motif that allows binding to the cell surface a_5b_1 integrin, which is the fibronectin receptor. The ability of these IGFBPs to potentiate IGF action is related to their integrin-binding activity, which may facilitate an advantageous presentation of the ligand to its high-affinity receptor. All IGFs except IGFBP-1 also contain heparin-binding **domains**, allowing binding to sulfated glycosaminoglycans in the extracellular matrix and on the cell membrane. The majority of IGF-I and -II in blood is carried on IGFBP-3. From the second half of fetal development, IGFBP-3, together with an IGF molecule, is associated with an acid-labile subunit in the circulation to generate a tertiary complex of 150 kDa. In this form, IGFs cannot leave the circulation; the fraction accessible to extracellular fluids is carried by IGFBP-1, -2, -4, and -5.

A large proportion of the IGF:IGFBP complexes in extracellular fluids and stored within the extracellular matrix are probably inaccessible to the cell-surface receptors. Their availability depends on modification of the IGFBPs by specific proteinases, resulting in a reduced binding affinity for IGFs. Such proteinases have been identified for IGFBPs-2 to -5. An IGFBP-3-degrading proteinase appears in maternal serum from the second trimester of human pregnancy until term, which reduces the amount of IGF carried by IGFBP-3 and increases its transcapillary passage in association with other IGFBPs (5). A naturally occurring tissue proteinase can also remove the three *N*-terminal amino acid residues from IGF-I, resulting in a much reduced binding affinity for IGFs. Thus, while IGF-I and -II are present in the circulation, this serves predominantly as an extracellular store.

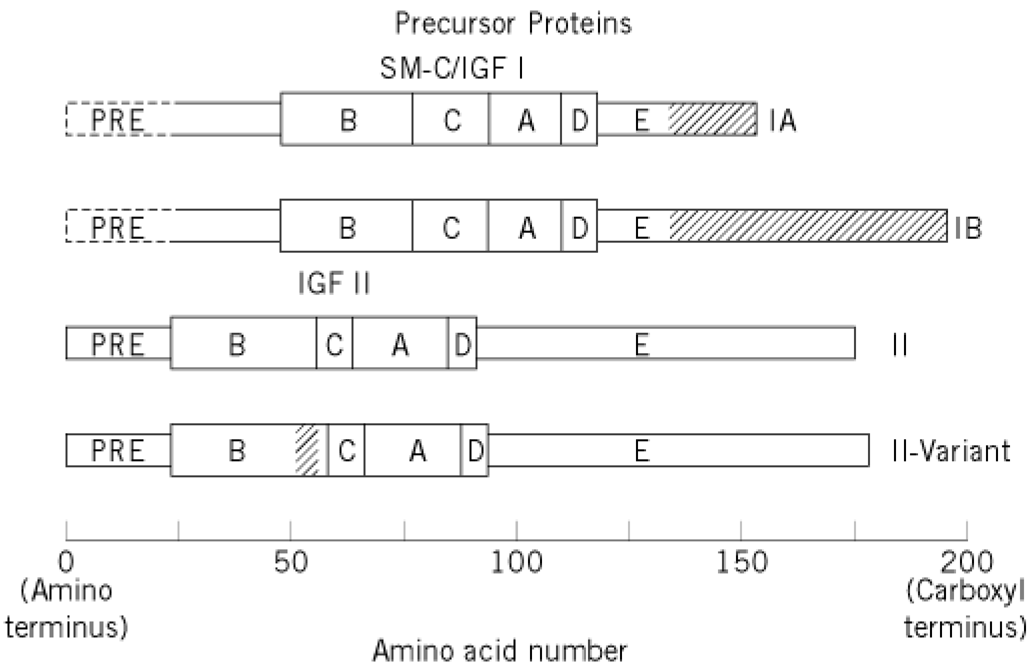
Controlled **proteolysis** of IGFBPs and extracellular matrix molecules is likely to be the key regulatory step in the bioavailability and subsequent actions of IGF-I and -II.

1. IGF gene structure

1.1. IGF-I

The human IGF-I **gene** is located on the long arm of chromosome 12 (6). It comprises at least five exons (see Introns, Exons) spread over more than 90 kbp (7). The gene encodes two precursor forms of IGF-I, represented by transcripts with distinct 3′ regions that arise by alternative splicing of the premessenger RNA (Fig. 1). Each transcript includes sequences of the three 5′ exons (exons 1, 2, and 3) but only one of the two 3′ exons (exons 4 and 5) of the gene. The resulting precursors, IGF-Ia and IGF-Ib, have identical amino-terminal segments of 48 residues that are encoded by exons 1 and 2. The identities of IGF-Ia and -Ib are maintained in their mature IGF-I regions, which comprise 70 amino acid residues encoded by exons 2 and 3, and in the first 16 residues at their *C*-terminus, encoded by exon 3. They are different in the remainder of their C-terminus, where IGF-Ia has an additional 19 amino acid residues encoded by exon 5 and IGF-Ib has an additional 61 residues encoded by exon 4.

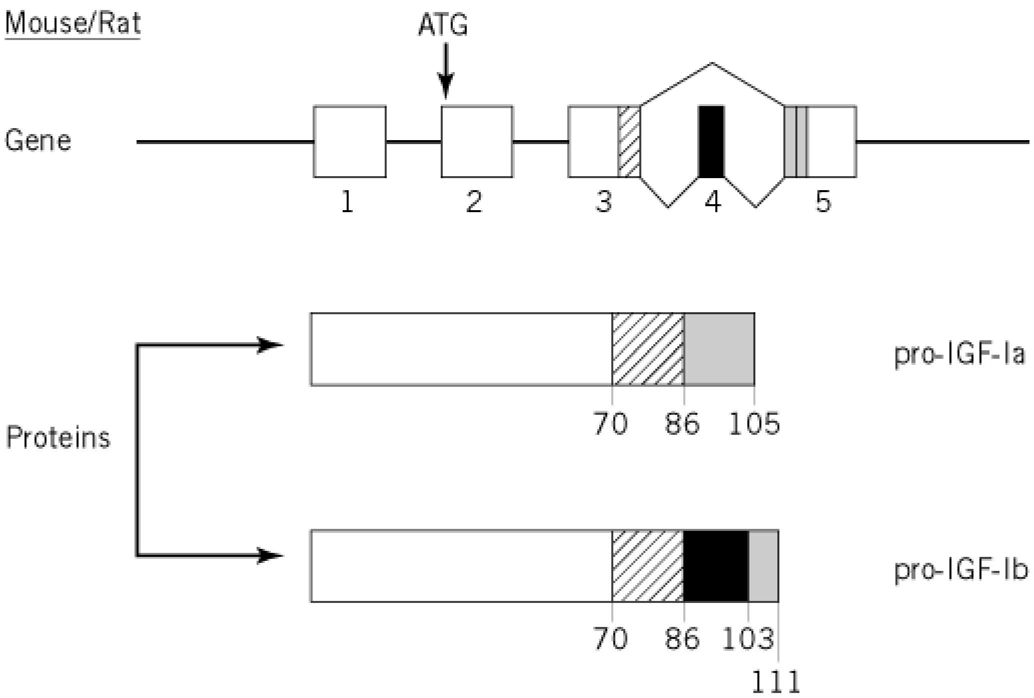
Figure 1. **Schematic representation of human IGF-I and -II precursor proteins**. The hatched areas in IGF-Ia and IGF-Ib highlight the alternative sequences arising from alternative splicing (exon 3 to exon 4 in IGF-Ia, and exon 3 to exon 5 in IGF-Ib). The hatched area in the predicted IGF-II variant highlights the area at the juncture of the B and C domains close to an RNA splice site, where differences in the variant human IGF-II molecule tend to occur.



The rat IGF-I gene has six exons, of which five are **homologous** to those of the human gene, with extensive identity of nucleotide sequences (8). The two alternative **signal sequences** (I and IA) encode variant amino-termini for the pre-pro-IGF-I signal peptide, depending on which translation initiation codon is used *in vivo*. IGF-I cDNA clones with alternative 5′-untranslated regions have also been identified in the mouse (9) and other species. Like the human gene, the rat IGF-I gene encodes two precursors, represented by distinct mRNA transcripts. The rat IGF-Ia precursor is analogous to the human product, having a *C*-terminus encoded by exons 3 and 5. However, the *C*-terminal region of rat IGF-Ib is dissimilar to that of human IGF-Ib (which is encoded by exons 3 and

4), comprising sequences encoded by exons 3, 4, and 5 (Fig. 2).

Figure 2. **Representation of alternative splicing resulting in the formation of alternative IGF-I precursor peptides in the rodent**. Exons are represented by the open boxes. Introns are represented by a thin line. The rodent (and human) IGF-I gene contains five exons. It is assumed that translation is initiated at the indicated ATG codon. Exon 2 contains the signal peptide and residues 1 to 25 of the B domain. Exon 3 contains the remainder of the B domain; the complete C, A, and D domains; and residues 70 to 86 of the E domain (hatched). Exons 4 and 5 contain alternate sequences for the remainder of the E domain and the 3′-untranslated region. Splicing of exon 3 to exon 5 gives rise to the IGF-Ia precursor (protein-coding region of exon 5 is stippled). The IGF-Ib precursor arises by splicing exon 3 to exon 4 (protein-coding region of exon 4 is solid), which is spliced to exon 5. Pro-IGF-Ib terminates earlier in exon 5 than pro-IGF-Ia (indicated by the vertical line in the stippled area of exon 5).

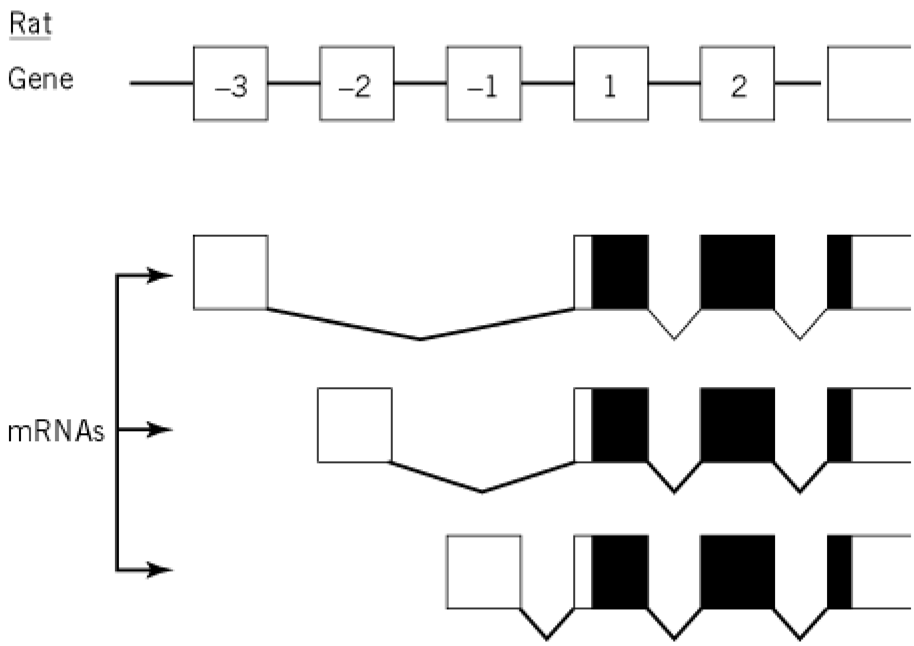


Messenger (mRNA) species encoding IGF-I of at least three size classes are detected by **Northern blot** analysis, ranging from approximately 0.8 kb to 7.8 kb. At least three factors contribute to this size heterogeneity. Alternative splicing pathways can account for two classes of transcripts encoding the precursors IGF-Ia and IGF-Ib. Additionally, transcripts have been identified with distinct 5′-untranslated sequences in mouse and rat and with variable lengths of 3′-untranslated sequences. Using probes that distinguish IGF-Ia and -Ib mRNAs in tissues of humans, it was shown that transcripts encoding both precursors are represented within each of the three size classes of IGF-I transcripts. In all rodent tissues, transcripts encoding IGF-Ia are more abundant than those encoding IGF-Ib, although the relative abundance of these mRNA species differs between hepatic and nonhepatic tissues; transcripts encoding IGF-Ib represent approximately 13% of IGF-I mRNAs in the liver of adult rats but only 2 to 5% of the total elsewhere. When growth hormone was given to hypophysectomized rats, the levels of both mRNA types were elevated coordinately in nonhepatic tissues, but in liver IGF-Ib mRNA was raised threefold more than that of IGF-Ia mRNA. The functional significance of the two pre-pro-IGF-I precursors remains unknown. Most of the heterogeneity in IGF-I transcript size is due to differing lengths of 3′-untranslated sequences. These arise from multiple polyadenylation signal sequences previously within exon 5 of the rat gene, and they may affect the stability of IGF-I mRNAs, providing a mechanism for posttranscriptional regulation of expression. Evidence for multiple polyadenylation sites in IGF-I gene also exists for the mouse, human, and sheep proteins.

1.2. IGF-II

The IGF-II genes in human, rat, and mouse each encodes a 180-residue precursor (pre-pro-IGF-II), consisting of a 24-residue *N*-terminal signal peptide, a 67-residue mature IGF-II, and an 89-residue *C*-terminal pro-peptide. As with pre-pro-IGF-I, the pre- and pro-peptide fragments are removed during protein biosynthesis. Sequences for the cDNA diverge within the 5′ and 3′ noncoding regions, indicating the existence of IGF-II transcripts differing in their untranslated sequences. The human IGF-II gene is found on the short arm of chromosome 11, where it is closely linked to the insulin locus (10). The rodent IGF-II gene is similarly adjacent to the insulin gene on chromosome 1 in the rat, or chromosome 7 in the mouse (11). The genes for both human and rat IGF-II cover at least 30 kbp and 12 kbp, respectively, and contain multiple exons and **promoters**. Exons E4, E5, and E6 encode pre-pro-IGF-II protein, while exons EI, E2, and E3 are noncoding and used differentially, forming alternative, 5′-untranslated regions of different RNA molecules (Fig. 3). The human IGF-II gene uses three additional noncoding exons. Consensus eukaryote promoter sequences, such as a TATA box and GC boxes (SPI recognition sequences), are present in the regions upstream of human and rat exons E2 (promoter P2) and E3 (promoter P3). The promoter region (Pl) upstream of rat, human, and mouse exon EI lacks TATA and GC boxes, and the transcription start sites are heterogeneous. The region upstream of human exon I (Pl) lies within 1.4 kbp of the insulin gene. A polyadenylation signal, conforming to the **consensus sequence** AATAAA, is located 20 nucleotides from the 3′ end of exon 6, and further potential polyadenylation sites are also present in exon 6 of both the human and rat IGF-II genes.

Figure 3. **Schematic representation of the rat IGF-II gene**. Transcripts arising at each of three promoters and terminat
Proptein-coding regions are solid, untranslated regions are open.



IGF-II mRNAs differ predominately in their 5¢-untranslated sequences, with the major transcripts in and 4.8 kbp, and in rodents approximately 3.8, 4.6, and 8.6 kbp. These arise from the promoters P1, of the noncoding exon EI, E2, or E3 spliced to the three coding exons, E4, E5, and E6, with transcrip polyadenylation site. Transcripts derived from P2 are most abundant in human tissues, whereas those tissues. Transcripts arising from P1 are least abundant in both species. Termination of transcription a (consensus AATAAA) in exon 6 gives rise to short transcripts of 1 to 3 kb found in rat and human ti

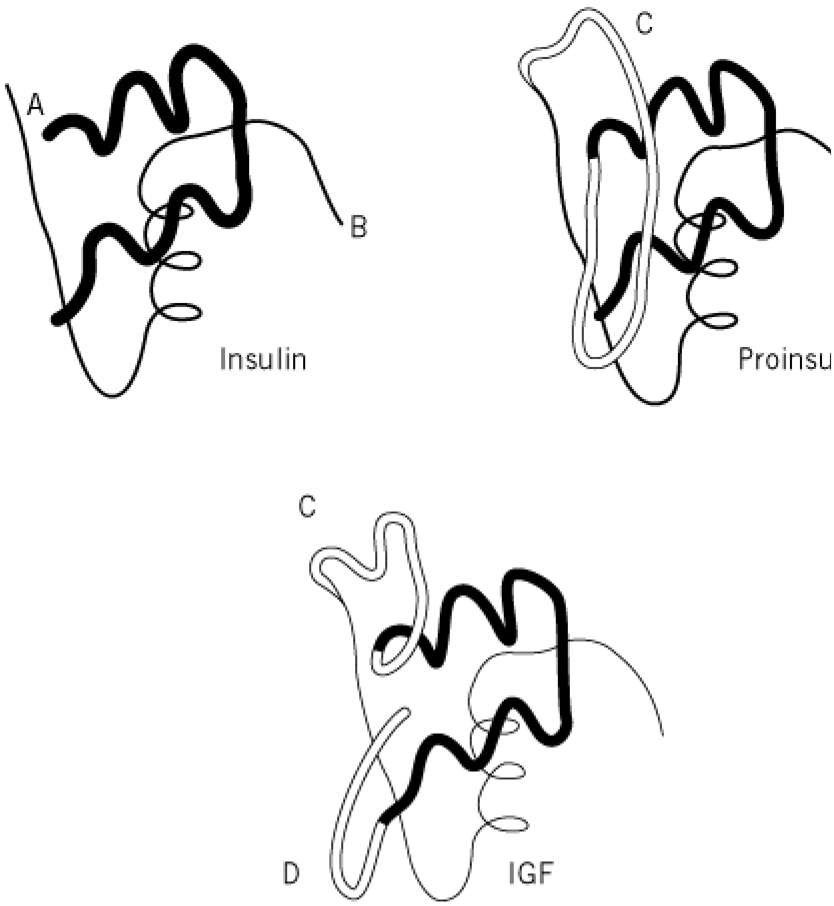
IGF-II cDNAs encoding variant proteins have been found in humans (12). These transcripts arise by weak splice-acceptor site upstream of the major splice-acceptor site of exon 5. The additional nine n sequences predict the replacement of Ser-29 with the tetrapeptide Arg–Leu–Pro–Gly, and this IGF-I

(13). The expression of IGF-II is regulated by p53 through interaction with the IGF-II P3 promoter, tumorigenesis when variant p53 forms are present (14).

2. Structure of IGF-I and -II peptides

The IGFs are single-chain polypeptides that show amino acid sequence homology with pro-insulin. allows the recognition of equivalents of the insulin B, C, and A domains within the IGFs, together w domain, which is not found in pro-insulin (Fig. 4). All amino acid residues common between species IGFs with the exception of residue A21, which is Asn in insulin but Ala in the IGFs. Conservation o in a tertiary structure similar to that of insulin, and the **hydrophobic** core of insulin, consisting of A B24 Phe, is also conserved. The most obvious differences from pro-insulin are in the C domain. The insulin are identical. IGF-I consists of 70 amino acid residues, with a predicted molecule weight of 7 detected by mass spectrometry (15). Its isoelectric point is 8.8. Human IGF-II consists of 67 amino a molecular weight of 7469, which was reported as 7440 by mass spectrometry. IGF-II has an isoelect between predicted and detected sizes may be due to covalent changes caused by the extraction proce

Figure 4. **Structural homology of insulin, pro-insulin, and IGF**. Schematic representation of the three-dimensional s insulin (with additional C chain) and the insulin-like growth factors (with C chain and D chain) demonstrating their clo



There are two different IGF-I precursors, one derived from exons 1, 2, 3, and 5 (IGF-Ia) and the othe (16). They differ in their *C*-terminal precursor sequence (E domain) and result in identical mature pe IGF-I lacking the first three *N*-terminal residues [des(1–3)IGF-I] was reported by Sara et al. (17) in Des(1–3)-IGF-I has a 100-fold reduction in affinity for IGFBPs-1 and -2 as compared to IGF-I. The is only two to three times lower than is intact IGF-I. Studies on receptor interaction and biological a and recombinant des(1–3)IGF-I. The truncated molecule has a much increased biological activity an intact IGF-I. The *in vivo* half-life of the peptide is shorter than that of intact IGF-I in the rat, due to tl in growth-deficient animals it stimulates growth in length more than does recombinant IGF-I (18).

Variation also exists in IGF-II molecules. Jansen et al. (19) isolated and characterized a cDNA deriv liver encoding an IGF-II variant in which B29 Ser is replaced by the sequence Arg–Leu–Pro–Gly as This cDNA was obtained from the same library that contained the cDNA encoding classical IGF-II a splicing of the pre-mRNA. The peptide has been isolated from human serum and found to constitute (13). Its functional characteristics have shown a two- to threefold reduction in affinity for purified IC placenta and reduced mitogenicity. Another IGF-II variant described by Zumstein et al. (20) is a 10-l Ser is substituted by Cys–Gly–Asp, and it contains the first 21 residues of the *C*-terminal precursor e substitution does not occur at an intron-exon junction, allelic variation must be responsible for its oc been found in human spinal fluid, serum, and brain (21-23). Presumably these molecules represent u precursor forms.

3. IGF binding proteins

The amino acid sequences at the NH_2- and COOH-termini of the six IGFBPs are highly conserved, v terminus of exon I, including 12 cysteines, identical in human and rat IGFBP-1–5 (4) (Fig. 5). Huma in a Gly–Cys–Gly–Cys–Cys segment that is conserved in other IGFBPs. Species differences also oc terminal segment. In the COOH-terminal region, 18 residues, including four cysteines, out of 28 are human and rat. Related molecules designated by some as IGFBPs-7 to -10 have been identified, but biologically meaningful homology. The middle region of the IGFBP proteins, corresponding to the C most of exon 2, is not conserved in different IGFBPs. It includes N-glycosylation sites that are used additional cysteine residues in IGFBP-4. IGFBP-1, -2, and -3 proteins are encoded by four exons; IC comprised exclusively of 3′-untranslated sequences. There is no evidence that alternative splicing co variation. The IGFBPs do not appear to be synthesized as larger precursor proteins.

Figure 5. **Alignment of the amino acid sequences of the six rat IGFBPs**. Amino acid residues are shown in one-lette maximal homology alignment. Identical residues at corresponding positions in more than three of the IGFBPs are show residues are marked by asterisks, except for the additional two cysteines (underlined) present only in IGFBP-4. The RG indicated by an arrow. The internal amino acid sequences that could not be aligned were grouped by parentheses.

The major carrier protein for IGFs in blood is IGFBP-3 (24). It is also able to bind an acid-labile non predominant 150-kDa IGFBP complex in adult serum. Concentrations of ALS in human plasma are a longer half-life in the circulation when it is associated with the 150-kDa complex. The human IGF of four protein-coding exons homologous to those of the IGFBP-1 and IGFBP-2 genes, and a fifth ex gene is located on chromosome 7, 20 kbp from the IGFBP-1 gene, in tail-to-tail orientation. The tran 132 bp upstream from the adenine–thymine–guanidine (ATG) translation initiation codon. IGFBP-3 abundantly in liver but was also present at high levels in kidney, stomach, heart, adrenal, ovary, and contains a TATA box 30 bp upstream from the transcription initiation site, a GC element (97 bp ups overlap the GC element.

The human IGFBP-1 gene is 5.2 kbp in length and contains four protein-coding exons. It has been lo mRNA is abundant in decidua in late pregnancy but was not detected in placenta. The other major si where a 1.5-kb mRNA transcript is found. IGFBP-1 mRNA was increased 100-fold in rat liver two d streptozotocin and was reversed after three days of insulin treatment. The increase in hepatic IGFBP kidney results primarily from increased transcription of the IGFBP-1 gene. Insulin treatment decreas and IGFBP-1 mRNA levels within one hour, most likely by direct effects on gene transcription. IGF potentiating effects *in vitro*. The presence of an Arg–Gly–Asp (RGD) sequence at the COOH-termin with cell-surface receptors for proteins in the extracellular matrix. Serine **phosphorylation**–dephosp biological action of IGFBP-1. Dephosphorylation decreases the affinity of IGFBP-1 for IGF-I, prom inactive complex.

The IGFBP-2 gene has been localized to human chromosome 2 and to the homologous mouse chrom genes are organized into four exons, each of which contains coding sequences. The human gene is 3 large size of intron 1 (27 kbp). In Northern blots of RNA from fetal rats, a 1.5-kb IGFBP-2 mRNA w kidney, and lung and was less abundant in intestine, muscle, heart, and skin. In midgestation rat brai the epithelium of the choroid plexus, suggesting that IGFBP-2 might participate in the transport of I IGFBP-2 mRNA in rat liver increased 10-fold after 48 hours of fasting, which was reversed after one mRNA was increased 10- to 20-fold in streptozotocin-treated rats, and this was reversed by insulin t sequence at its COOH-terminus. Human IGFBP-2 binds IGF-II with 10-fold greater affinity than IG similar for rat IGFBP-2. IGFBP-2 inhibits the mitogenic effects of IGFs *in vitro*.

The IGFBP-4 gene is located on chromosome 17, and IGFBP-4 mRNA has been estimated as 2.5 kb
hybridization is seen in liver, and a weaker hybridization signal exists with RNA from adrenal, testes
hypothalamus, and brain cortex. In addition to the 18 cysteine residues found in other IGFBPs, IGFE
the nonconserved middle region of the molecule. Glycosylated and nonglycosylated forms of IGFBI

This suggests that an additional receptor to the type 1 form may also contribute to IGF-II signaling.
receptor is deleted in a naturally occurring gene deletion identified by the lack of the imprinted locus
embryonic stage (29). Whether this receptor can contribute to IGF-II signaling *in vivo* is not clear.

The aforementioned series of studies demonstrates that neither IGF-I nor IGF-II is crucial for key m
development, but that they act as "true" growth factors, contributing to the expansion of stem cell po
differentiation.

Integrases

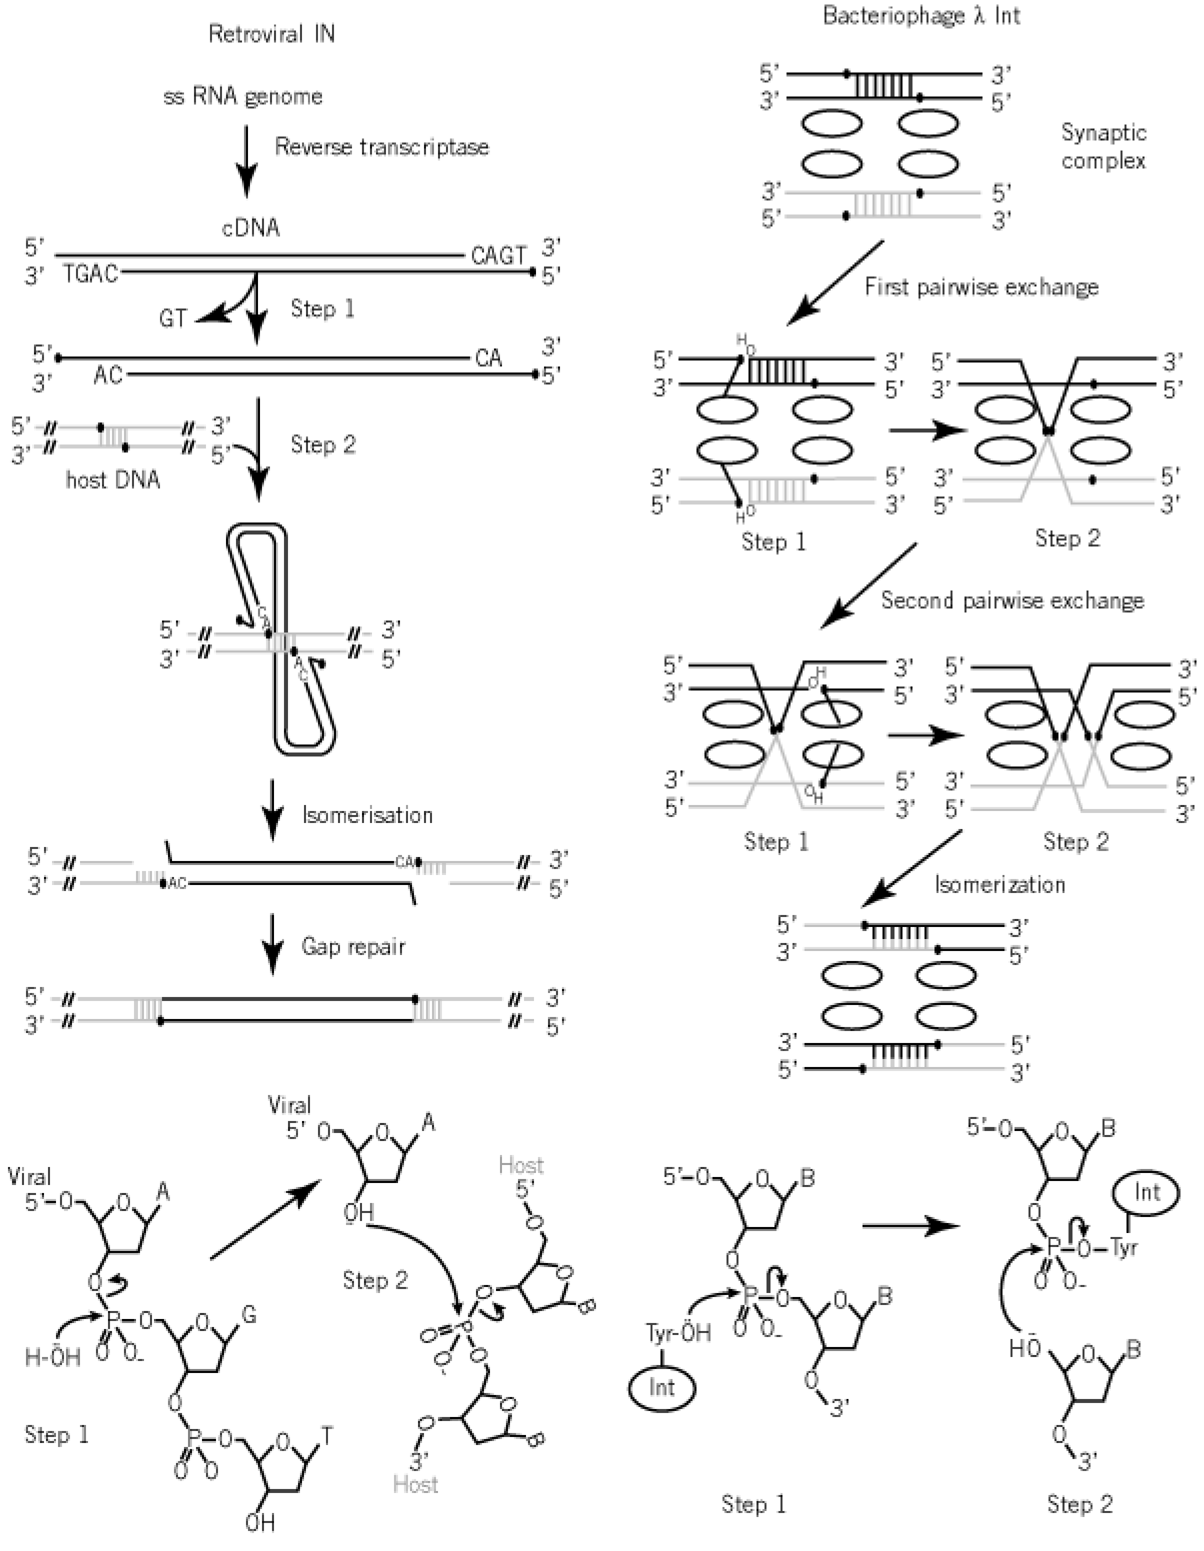
Integrases represent a subset of DNA (poly)nucleotidyltransferase enzymes each of which catalyzes the insertion of a specific extra**chromosomal** segment of **DNA** into the genome of its host. They form central elements in the replicative cycles of several prokaryotic and eukaryotic **viruses** and in the intracellular translocation of retrotransposons. The best studied of these are the integrases encoded by the pol gene of various retroelements, such as the retroviridae, and those of temperate bacteriophages, most notably lambda phage. The different strategies employed to break and reunite the host DNA with the incoming polynucleotide distinguish two distinct families of integrases. A key difference is whether or not the reaction takes place by forming a covalent integrase-DNA intermediate. In the lambda Int family of site-specific recombinases, the integrase forms a transient covalent linkage with the 3′-ends of the bacteriophage and host DNA at the points of recombination. In contrast, retroviral integrase (IN) catalyzes DNA insertion via a noncovalent intermediate, using a process that is chemically similar to the “cut and paste” mechanism of classical transpositional recombination. Unraveling DNA integration in molecular terms will necessitate understanding just how the underlying chemical steps are harnessed by each distinct integrase nucleoprotein complex to meet the different DNA site specificities and topologies demanded by their diverse genetic rearrangements.

1. Retroviral Integrases

1.1. DNA Integration Mechanism

DNA integration is a critical step in the replicative cycle of all single-stranded (ss) RNA retroviruses, including notably **HIV**-1, the causative agent of AIDS. Following **reverse transcription**, the resultant complementary DNA copy of the retroviral ssRNA genome must be inserted into a chromosome of the infected host cell to elicit a productive infection. The retroviral integrase (IN) catalyzes two consecutive nucleophilic substitution reactions in this process (Fig 1a; Steps 1 and 2) at the phosphodiester bonds that ultimately form the sites of attachment between the viral and host DNA. The first reaction, known as 3′-OH end processing, results in the nucleolytic expulsion of the two external nucleotides from both 3′-ends of the linear viral cDNA. Here, the 5′-phosphoryl group of the leaving dinucleotide is transferred directly to the electronegative group of the attacking nucleophile, generally donated by a water molecule. In the second step (polynucleotidyl transfer), the recessed 3′-OH groups are in turn coordinated as nucleophiles to attack specific positions on the phosphodiester backbone of the host DNA. In line with the displacement of a host 5′-phosphoryl group, a direct transesterification with the attacking viral 3′-OH end results in the insertion of the viral DNA at this site.

Figure 1. Comparison of retroviral cDNA and bacteriophage l DNA integration. Both mechanisms involve two consecutive nucleophilic substitution reactions (Steps 1 and 2), shown side-by-side at bottom of figure. (a) Retroviral IN. Step 1: Endonucleolytic 3′-OH end processing. The two outermost bases of the cDNA adjacent to a subterminal CA dinucleotide are removed from both 3′-termini, yielding a staggered intermediate with 5′-protrusions. Step 2: Polynucleotidyl transfer. Each processed 3′-OH end is reattached in a staggered fashion to opposite strands of the host DNA (for HIV-1 at phosphodiester bonds positioned 5 bp apart). Gap repair, probably by host proteins, results in duplication of the host DNA (shown in gray) at the proviral junction. (b) Bacteriophage l Int. Step 1: Breakage of partner strands. A pair of Int protomers (ovals) attack the scissile phosphodiester bonds (black dots) at parallel positions on the juxtapositioned recombination strands, resulting in the formation of covalent 3′-phosphotyrosine linkages and free 5′-OH ends. Step 2: Polynucleotidyl transfer (resolution). Each 5′-OH end rejoins with the 3′-phosphoryl of its facing partner strand by branch migration and resolution of the covalent protein–DNA intermediate. Recombination intermediates with the target DNA (shown in gray) are drawn to emphasize the crossover sites [after (20)] rather than its topological structure, which more accurately corresponds to a **Holliday junction** intermediate.



(a) (b)

Two notable hallmarks of this type of DNA integration mechanism persist at the borders of the resultant proviral–host DNA junction. First, the provirus is two bases shorter than the preintegrated cDNA, where its 3′-boundaries with the host DNA are delineated at each end by a highly conserved CA-3′ dinucleotide. Secondly, a region of 4 to 6 bp of host DNA is duplicated at the junction of proviral attachment that arises from the staggered integration of each viral end on opposite stands of the host DNA. The length of this duplication is specific to each retrovirus rather than its host.

Although retroviral DNA integration is clearly nonrandom, it may occur at any one of a large number of potential sites within the genome, which are dictated principally by the accessibility and structure of the chromatin (1). Yeast retrotransposons (Ty elements) integrate much more precisely, despite an essentially identical DNA integration mechanism, at or near nonessential genes or transcriptionally "silent" regions of the genome. Ty3 cDNA is drawn into the required locus by protein–protein interactions between a component of the Ty3 integration complex, possibly the Ty3 IN itself, and a polIII promoter-bound protein complex composed minimally of the transcription factors TFIIIB and TFIIIC, thus securing the DNA integration functions at that site (2). A similar, but as yet unsubstantiated, proposition has been put forward for HIV-1 IN, which interacts functionally with integrase interactor 1 (INI 1), a homologue of the yeast transcription factor SNF5, which could potentially direct integration into regions of open chromatin (3).

Unlike bacteriophage integrases, the IN proteins of retroelements cannot excise the integrated viral template from the host genome. Instead, viral propagation occurs via new generations of transcribed ssRNA progeny, which are packaged into virions with retroviral proteins and released to infect a new host cell. Nevertheless, IN can resolve the partial integration intermediates formed in this process and catalyzes the excision of the viral DNA from "one-ended" intermediates of a Y-type structure by a process named "disintegration" (4). During excision of the viral part, the broken target DNA strand is resealed by a similar phosphoryl transfer mechanism to that of the forward integration reaction, although the "reverse" process differs in the sense that it displays a relaxed specificity for viral sequences.

1.2. The IN Protein

Retroviral cDNA (>8 kb) exists in the cytoplasm of infected cells as a high molecular weight preintegration complex (PIC) and copurifies with several retroviral, and at least some host proteins. One of these is the high mobility group (**HMG**) protein HMG1(Y) (5), which among other global activities bends DNA and stimulates the concerted integration activity of purified IN (6). Increasing evidence suggests that such accessory proteins contribute important architectural features necessary to guide the integration functions of the PIC (7). Nonetheless, purified IN alone encompasses all of the minimal requirements for catalyzing both nucleophilic substitution (end processing and transfer) reactions with synthetic viral termini *in vitro* (reviewed in Ref. 8).

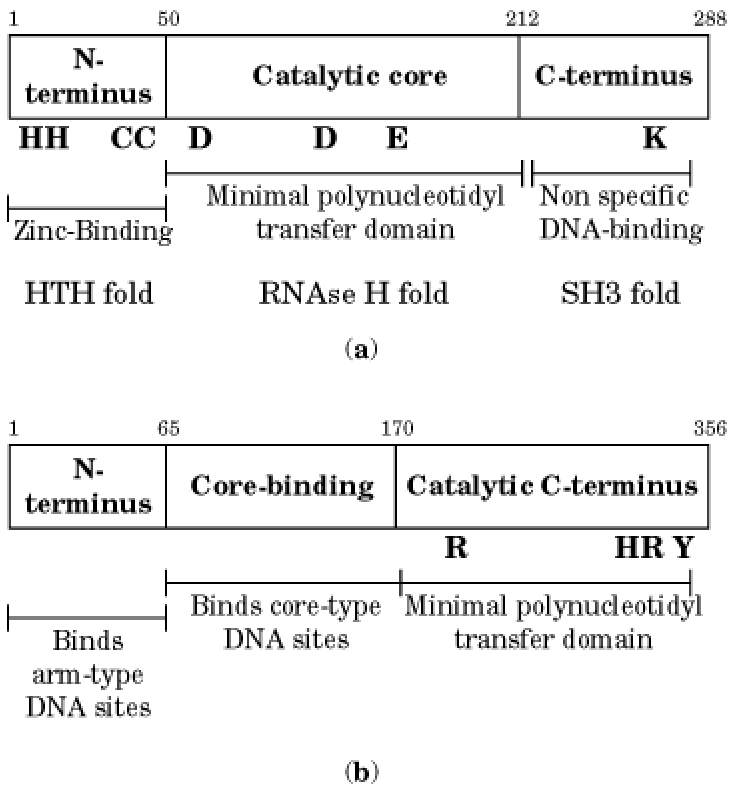
Although the IN-catalyzed functions exhibit some degree of specificity for the nucleotide sequence (s) of the viral termini and for the CA dinucleotide in particular, purified IN does not bind preferentially to its cognate sequence. The factors within the virion that direct IN to the two distal termini of the nascent cDNA and coordinate their concerted integration at a discrete host target site remain to be established. Neither function is reproduced efficiently *in vitro* with the purified protein.

Structure-function studies on deleted derivatives of the integrase indicate that the protein is organized into three major **domains** (Fig. 2a). Although crystallizing the full length protein has proven difficult because of its inherent aggregative properties, now the structures of each of the isolated domains of the human immunodeficiency virus type-1 (HIV-1) integrase have been determined independently.

1. The N-terminal region (residues 1 to 50) bears a highly conserved HHCC motif (His-X_{3-7}-His-X_{23-32}-Cys-X_2-Cys) that binds Zn^{2+} stoichiometrically (9). Contrary to the organization of a classical **zinc finger**, its structure more closely resembles that of helical DNA-binding proteins that possess a helix-turn-helix (HTH) motif and is most akin to that of the trp repressor (10) (see TRP Operon). The helical bundle arrangement is ordered by Zn^{2+}, which is tetrahedrally coordinated by the conserved His and Cys residues. The binding of Zn^{2+} stimulates multimerization and the catalytic functions of the integrase (9, 11). The N-terminus is essential for 3-OH processing and integration but is dispensable for the disintegration reaction, which minimally requires the core region.

2. The central **protease**-resistant core domain (residues 50 to 212) comprises a minimal active site for the polynucleotidyl transfer reaction. This domain carries a triad (D,D,E or Asp,Asp,Glu) of essential catalytic residues (organized Asp-$X_{39\text{-}58}$-Asp-X_{35}-Glu) that coordinate a divalent cation (Mg^{2+}, and also Mn^{2+}) necessary for phosphoryl transfer. The core domain binds and catalyzes the resolution of Y-structure disintegration intermediates but cannot alone catalyze the forward reactions of the integration mechanism with linear DNA substrates. Several residues of the core are highly conserved in retroviral and retrotransposon integrases and in analogous prokaryotic transposases (12). Most remarkable is its structural homology to the ribonuclease H and RuvC enzymes, comprising a central 5-stranded beta-sheet flanked by **alpha-helical** regions (13). Despite the fact that these proteins do not catalyze DNA integration or transposition, nonetheless, they are involved in similar transesterification reactions using aspartic acid and glutamic acid catalytic residues. The catalytic residues superimpose well on the corresponding structures, indicating a general structural fold for a topologically related superfamily of DNA nucleotidyltransferases, all of which catalyze nucleophilic substitutions at the phosphodiester bonds of polynucleotides.
3. The C-terminal region is less well conserved both in sequence and in size and exhibits an independent nonspecific DNA-binding activity. Several integrases also possess C-terminal nuclear localization signals that, it is proposed, direct the active uptake of the large PIC structure through the undisrupted nuclear membrane [eg (14)] (see Nuclear Import, Export). The organization of its 5 beta-strands into a b-barrel consisting of two antiparallel b-sheets is very similar in structure to Src-homology 3 (SH3) domains, which are often associated with protein–protein interactions (15) (see SH2, SH3 Domains). It is likely that the basic character of this domain that has solvent-exposed lysine and arginine residues is involved in long-range electrostatic interactions with the negatively charged DNA phosphate groups. A saddle-shaped groove formed between two of the b-strands may provide a channel for this interaction (16).

Figure 2. Structure and functional organization of the domains of (a) retroviral (HIV-1) IN and (b) bacteriophage l Int proteins. Numbering is of the amino acid residues.



All three domains form dimers when analyzed as isolated polypeptide chains. Most likely, interactions between the domains of IN play a central role in forming the requisite multimeric configuration (17). The precise oligomeric form adopted by the protein *in vivo* is still not known, although high-order assemblies have been implicated in forming stable, catalytically active nucleoprotein complexes *in vitro* [eg (18)]. Despite progress made in this respect via protein–DNA cross-linking studies (19), the overall three dimensional view of these nucleoprotein intermediates remains sketchy.

2. Bacteriophage Lambda Integrase

2.1. DNA Integration Mechanism

The chromosomal integration of the viral genomes of temperate bacteriophages, exemplified by the reaction catalyzed by lambda integrase (Int), is a conservative site-specific recombination mechanism in which the recombination partner (*att*) sites are reciprocally exchanged by a set of isoenergetic cleavage and rejoining reactions (20). Like retroviral integration (see previous discussion), each strand-exchange reaction takes place via two consecutive nucleophilic substitutions, except, in this case, (1) a covalent Int–DNA intermediate is formed with each of the four recombination strands, and (2) the strand exchange is precise, neither adding nor deleting nucleotides at the site of insertion (Fig. 1b). Integrative recombination takes place through two sequential sets of such strand exchanges. Each is begun by the nucleophilic attack of Int at equivalent positions on the donor (*att*P) and target (*att*B) recombination strands. The energy of the primary substitution reaction is conserved via a 3′-phosphotyrosine (Fig. 1b, Step 1), which, after strand migration, is subsequently resolved by the exposed 5′-OH end of the corresponding recombination partner (Fig. 1b, Step 2). This second substitution results in covalently rejoining the two strands, and, in doing so, liberates the unmodified Int protein. Excision of the integrated viral genome (between *att*L and *att*R sites generated by the original recombination) is also catalyzed by Int. Although this occurs by the same reaction chemistry, the stimulation of excision versus integration is accomplished with the assistance of other viral and host factors. Xis and Fis promote excision, whereas IHF is required for both.

2.2. The Int Protein

The bacteriophage l integrase (Int) is a 40-kDa (356 amino acid residue) site-specific DNA-binding protein that has type I topoisomerase activity. It recognizes *att* regions that contain two distinct types of Int binding sites distributed over ~270 bp: (1) a central, imperfectly symmetrical region equating to the crossover site (~30 bp) that consists of two inverted “core” DNA-binding sites, separated by the 7 bp that delineate the overlap between the boundaries of the points of recombination, and (2) more distant flanking motifs, termed “arm” DNA-binding sites. In conjunction with other accessory protein-binding sites, arm sites are control points through which the higher order synaptic complex may adopt the appropriate **tertiary conformation** for the correct positioning and hence, efficient recognition of the core-binding sites.

Several structure-function studies have pinpointed the primary DNA-binding properties of l Int to within discrete domains of the protein (Fig. 2b). The N-terminus (residues 1 to 169) is required for site-specific binding to the core site but is devoid of catalytic activity, whereas the first 64 residues are sufficient to bind tightly to arm-type DNA substrates. The central domain (residues 65 to 170) recognizes core-type sites, albeit with a low binding affinity. The C-terminal domain (residues 170 to 356) contains the minimal catalytic site required for polynucleotidyl transfer. Sequence alignments show that several residues are highly conserved with other site-specific recombinases (21), particularly in the position of the catalytic tyrosine residue, Tyr342, and three essential active-site residues (Arg212, His308, and Arg311, or R-H-R). Its overall topology is that of a mixed a-b structure comprising a bundle of seven a-helices cradled by seven b-strands (organized into one b-sheet at the foot of the structure and two flanking beta-turns) (22). The catalytic R-H-R triad clusters at the base of a shallow groove, proposed as the DNA-binding surface, that runs along one face of the protein. These residues are separated by ~20 Å from the catalytic tyrosine residue, which is located on an exposed and highly flexible 17-residue loop. The speculative function of the loop may be to bend backward bringing the Tyr342 nucleophile into the vicinity of the clustered R-H-R residues (cis-acting) or alternatively to extend outward and reach into the catalytic pocket of a paired Int protomer (trans -acting).

Integrative Suppression

Initiation Of DNA Replication of a replicon depends on an interaction between an initiator **protein** and a replication origin sequence specific for each replicon. In *Escherichia coli*, the DnaA protein binds to the origin and melts the duplex DNA strands to recruit the machinery for DNA synthesis, and it is the sole essential protein required specifically for the initiation of the chromosomal replication. **Conditional lethal** *dnaA* mutants defective in the initiation of replication under nonpermissive conditions can be rescued if the initiator gene and the replication origin of another replicon are integrated somewhere in the host chromosome. Such cells can survive by initiating chromosome replication from the origin of the integrated replicon, instead of the native origin. This phenomenon is called integrative suppression. In contrast, integration of the other replicon cannot relieve mutations in genes that are required for the replication of the integrated replicon.

The integrative suppression of *E. coli dnaA* mutations was observed using **plasmid** replicons, such as **F factor** and R1, and phage replicons, such as P2 (1). Furthermore, deletion mutants of the *dnaA* gene or the *oriC* sequence could be obtained. Similar integrative suppression was reported recently for *Bacillus subtilis* (2). The initiation site and frequency of chromosome replication could be changed artificially using integrative suppression mutations, and the regulation of cell cycle progression in bacteria has been studied based on the **phenotypic** changes in the mutants (2, 3).

Integrins

Integrins are a large family of related, transmembrane, cell surface **receptor** proteins that bind extracellular matrix (ECM) and cell adhesion molecules (CAMs). Almost all cell types express some type of integrin, as these receptors are often responsible for positioning cells within their specific environment by associating them with ECMs or CAMs on adjacent cells. Integrins play crucial roles in cell–matrix and cell–cell interactions important in the development and function of organisms ranging from plants to Drosophila to humans. Many cells require an attachment to the extracellular matrix to survive and grow. Cells also make use of integrins during migratory events that are important in neural development, inflammation, and metastasis.

1. Integrin structure

Integrins are noncovalently associated heterodimers consisting of an alpha and a beta subunit, both of which span the membrane lipid bilayer. The ligand binding site outside the cell requires contributions from both subunits. Both subunits have a single membrane-spanning domain and short cytoplasmic domains. The latter interact with the actin cytoskeleton and transmit signals to the interior of the cell. When ligand is bound, integrins signal across the membrane by altering actin polymerization and activating a tyrosine kinase. The name *integrin* derives from the way that these receptors “integrate” fibrils of ECM on the outside of the cell in direct register with actin filaments underneath the plasma membrane.

Alpha subunits range in size from approximately 200 to 120 kDa and are 25% to 45% identical in amino acid sequence. The alpha subunits are characterized by a series of 3 to 4 repeated EF-hand motifs in the extracellular domain that are important for binding divalent cations. Mn^{2+} and Mg^{2+} ions are required for integrin binding, and disruption of integrin activity with EDTA is often used to dislodge tissue culture cells from the substratum. These divalent cations participate in the binding of ligand. Some integrin alpha subunits contain an extra inserted **domain** in the N-terminus, called an *I domain*, which is thought to expand the **ligand binding** ability of integrins. Some alpha subunits are proteolytically cleaved in the extracellular domain near the membrane, and the resulting heavy and light chains are linked by disulfide bonds. Just cytoplasmic to the transmembrane domain, all alpha subunits have a highly conserved GFFKR motif (-Gly-Phe-Phe-Lys-Arg-) whose function is unknown. Other than this sequence, the cytoplasmic domains of the alpha subunits are generally not highly conserved. Differential RNA splicing is known to occur for some alpha subunit messenger RNA (eg, alpha-6, alpha-7), and the alternative splicing variants have specific patterns of expression and may have altered binding properties as well.

The beta subunits are about 95 to 120 kDa in size, with the notable exception of the 200-kDa beta-4 subunit. The amino acid sequences, again about 40% to 50% identical between subunits, include four conserved cysteine-rich domains in the extracellular region. The short cytoplasmic domain (40 to 50 amino acid residues) is generally more conserved in the beta subunits, except for beta-4, which has an intracellular domain of 1000 residues containing fibronectin type III domains. Interestingly, the beta-4 integrin interacts with intermediate filaments rather than with the actin cytoskeleton as other integrins do. Splice variants of the beta subunit mRNA have been identified which, in the case of the beta-1 subunit, is thought to result in different signaling properties, with one such variant displaying a dominant negative activity. The beta-1 subunit cytoplasmic domain also contains NPXY motifs (-Asn-Pro-X-Tyr-), thought to be important in mediating endocytosis by clathrin-coated vesicles.

2. Integrin Signal Transduction

A conformational change is propagated across the lipid bilayer to alter proteins associated with the cytoplasmic domains. The beta-1 subunit, and probably also other beta subunits, interacts with the actin cytoskeleton via associations with the proteins talin and alpha-**actinin**. These proteins colocalize at structures called *focal adhesions* (adhesion plaque, focal contact), which are areas closely opposed to the substratum in cultured cells. Protein tyrosine kinases also associate with focal adhesions, and *focal adhesion kinase* associates with the cytoplasmic domain of the beta-1 subunit and is activated on integrin ligation. This kinase activity is thought to alter the dynamics of actin and to signal to the nucleus to regulate **gene expression**. Integrins also bring about cellular alkalization and can lead to increases in the cytoplasmic calcium ion concentration and activation of protein kinase C (see Calcium Signaling). A variety of enzymes are known to increase their activity after integrin stimulation, including phospholipase A2, the GTPase **Rho**, and phosphatidyl inositol phosphate kinase (PIP 5-kinase), and enzymes associated with the Ras/MAP kinase pathway.

Growth Factors, such as platelet-derived growth factor, are known to synergize with ECM integrin ligands to stimulate cellular replication, and this results from a convergence of signaling pathways. Other cell surface receptors may interact with integrins and activate integrin signaling.

Integrin activity is regulated post-translationally in a cell-specific manner. For example, transfection of the same alpha-2 complementary DNA into different cell types that express the beta-1 subunit can result in either an inactive **receptor**, a collagen receptor, or a dual-function collagen and laminin receptor. The activity appears to be regulated by altering the integrin conformation, but the factors controlling this process are not understood. Activating antibodies have been generated that bind to the extracellular domain of integrins and activate increased ligand binding. Intracellular changes can also activate integrins through an inside-out signaling mechanism. For example, in T lymphocytes, the alpha-l/beta-2 integrin is activated to bind I-CAM only after the T cell receptor binds antigen. In this way, the T cell becomes more adhesive to endothelial cells lining the blood vessels in the area surrounding the antigen. This type of affinity modulation is also seen in platelets, where ADP or thrombin can induce high-affinity fibrinogen binding in the alpha-IIb/beta-3 integrin, which is important for blood clotting. Tyrosine phosphorylation of the beta-1 subunit by pp60src inhibits ligand binding.

Regulation of integrin function is crucial to many processes in development. For example, decreasing integrin expression in skin epithelial cells leads to their movement away from the basal lamina and their terminal differentiation. Inactivation of integrins in retinal neurons is correlated with the timing of axon pathfinding, and this may lead to a turn by the growth cone away from ECM ligands and towards CAM ligand.

3. The Integrin Family

At least 16 alpha subunits and 8 beta subunits, constituting at least 21 heterodimers, have been discovered to date. Different alpha-beta combinations give rise to receptors with different ligand-binding specificity, although not all possible alpha-beta pairings have been detected (Table 1). Receptors are often multifunctional, with abilities to bind more than one ligand. In addition, there is an apparent redundancy in function among the heterodimers. For example, at least seven integrin laminin receptors have been identified. It has become clear that some integrins bind to different sites on the same ligand and bind different ligand isoforms with varying avidity. For example, integrin alpha-5/beta-1 binds to the RGD site in fibronectin, but the alpha-4/beta-1 receptor binds to an LDV motif in an alternately spliced fibronectin. Some beta subunits are able to pair with multiple alpha subunits and, likewise, some alpha subunits are capable of forming heterodimers with more than one beta subunit.

[a] Key: C, collagens; F, fibronectin (RGD site or LDV site indicated); L, laminin (isoform number indicated); V, vitronectin; VCAM, vascular cell adhesion molecule 1; T, thrombospondin; Tn, tenascin/cytotactin; ICAM, intercellular adhesion molecule 1,2,3; MadCAM, mucosa addressin cell adhesion molecule. Fb, fibrinogen; W, von Willebrand factor; FX, factor X; C3bi, inactivated component of complement 3B; O, osteopontin; B, bone sialoprotein; Ch, chondroadherin.

The beta-1 family of integrins includes receptors for fibronectin, laminins, collagens, vitronectin, thrombospondin, and a variety of other matrix ligands. These integrins mediate many types of interactions between cells and the ECM. Beta-1 integrins are involved in important basic developmental cellular movements, such as **gastrulation**. Beta-1 laminin receptors are important in the development of neurons and muscle cells, from migration of neuroblasts and myoblasts to axon and dendrite outgrowth to synapse formation. The alpha-2/beta-1 collagen/laminin receptor mediates the contraction of collagen gels by resident cells during the remodeling of the interstitial ECM, and the alpha-5/beta-1 receptor has been implicated in organizing fibronectin networks. The alpha-4/beta-1 receptor, which binds both fibronectin and the vascular **cell adhesion molecule**-1 (VCAM-1), allows white blood cells to bind to inflamed endothelial cells (which express VCAM-1) and to exit out of the blood vessel to mediate an immune response. Some beta-1 integrins are also thought to interact with each other or to associate with other integrins on adjacent cells.

The beta-2 integrins are expressed by white blood cells and mediate cell–cell interactions important to the immune response by interacting with immunoglobulin super family molecules (ICAMs) and other ligands. Once neutrophils are activated, the alpha-L/beta-2 on their surface adheres to ICAMs on the endothelial cell surface, working in concert with the alpha-4/beta-1 receptor to allow the cell to exit the circulation. Beta-3 integrins include vitronectin receptors on bone and blood vessel endothelial cells (alpha-v/beta-3), and the alpha-IIA/beta-3 fibrinogen receptor important in platelet aggregation. Angiogenesis can be blocked by inhibitors of the alpha-v/beta-3 receptor on endothelial cells, which causes them to undergo apoptosis, and this same receptor is also involved in phagocytotic processes.

Other beta-subunit families, although smaller and less well characterized, may prove to be equally important. For example the alpha-6/beta-4 integrin is part of the hemidesmosomes in epithelial cells that attach cells to anchoring filaments made of laminin-5, and the beta-8 integrins are abundantly expressed on neurons.

The importance of integrins is underscored by genetic studies in a variety of species. In the fruit fly *Drosophila melanogaster*, integrin homologues were first identified as “position-specific antigens” with interesting patterns of expression during development. Loss of function of one beta subunit results in the myospheroid **phenotype**, where muscle cells cannot adhere to the matrix and assume a nonfunctional rounded shape. Loss of the alpha-PS3 gene results in numerous defects in tissue morphogenesis and cellular movements. Another alpha subunit is required for short-term memory in flies, suggesting a new role for integrins at the synapse. Nematode mutants show defects in cellular migrations, and mouse **knockout strains** in individual subunits have thus far proved lethal. For example, knockout of the alpha-4 subunit results in lethality at embryonic day 10, in part because of defective heart formation. Cellular interactions during heart development may require interactions between alpha-4/beta-1 and VCAM-1. Beta-1 subunit mutants fail to implant in the uterus. In humans, nonfunctional beta-2 subunit results in leukocyte adhesion deficiency disease, which renders patients prone to bacterial infections. Loss of the beta-3 subunit results in a clotting disorder called Glanzmann's thrombasthenia, and mutations in the alpha-6/beta-4 heterodimer lead to a blistering skin disease known as epidermolysis bullosa.

Interallelic Complementation

1. What counts as allelic?

The use of complementation tests for defining the gene as a unit of function is explained under the headings Complementation and Complementation tests. It was assumed as a general rule in those articles that complementation between two mutants occurs only when their mutations are in different **genes** (**cistrons**). Complementation tests carried out, for example, on auxotrophic (nutritionally exacting) mutants of the budding **yeast** *Saccharomyces cerevisiae* or the filamentous **fungus** *Neurospora crassa*, indeed split the mutants cleanly into different complementation groups. Little or no complementation occurs within groups, and universal complementation occurs between them (see Fig. 3 of Complementation Tests). However, the patterns that emerge from complementation tests are not always clear-cut, and many examples can be cited of complementation between mutants that one would want to call allelic on other grounds.

An **allele** is a particular form of a gene, and so what counts as allelic complementation depends on how the gene is defined. As a working rule, most would agree to define the gene as a segment of DNA that is transcribed into a single molecule of RNA, although that definition needs qualification to accommodate various special systems of gene organization. It may also be considered reasonable to include within the definition those adjoining *cis*-acting, nontranscribed DNA sequences that regulate gene transcription, though this extension of the definition may lead to difficulties in deciding how far the gene's territory extends and whether it is allowed to overlap with other genes.

In the great majority of the eukaryotic organisms studied, genes that have protein-encoding functions are virtually always units of translation and of transcription. Each gene specifies just one polypeptide chain. In bacteria, however, and in the nematode *Caenorhabditis*, many genes are organized in operons, which are units of transcription that contain two or several nonoverlapping sequences each of which is translated into a different polypeptide chain. Thus, the *Escherichia coli lac* operon messenger RNA encodes b-**galactosidase** (*LacZ*), b-galactoside permease (*LacY*), and galactoside **transacetylase** (*LacA*). Here the term gene refers to the single-protein units rather than the whole unit of transcription. Even though *LacZ* and *LacY* are within the same unit of transcription, they have sufficient independence of function to rank as separate genes, and the normal phenotype of a $Z-Y+/Z+Y-$ partial diploid (see Complementation Tests) poses no problem and is not counted as allelic complementation.

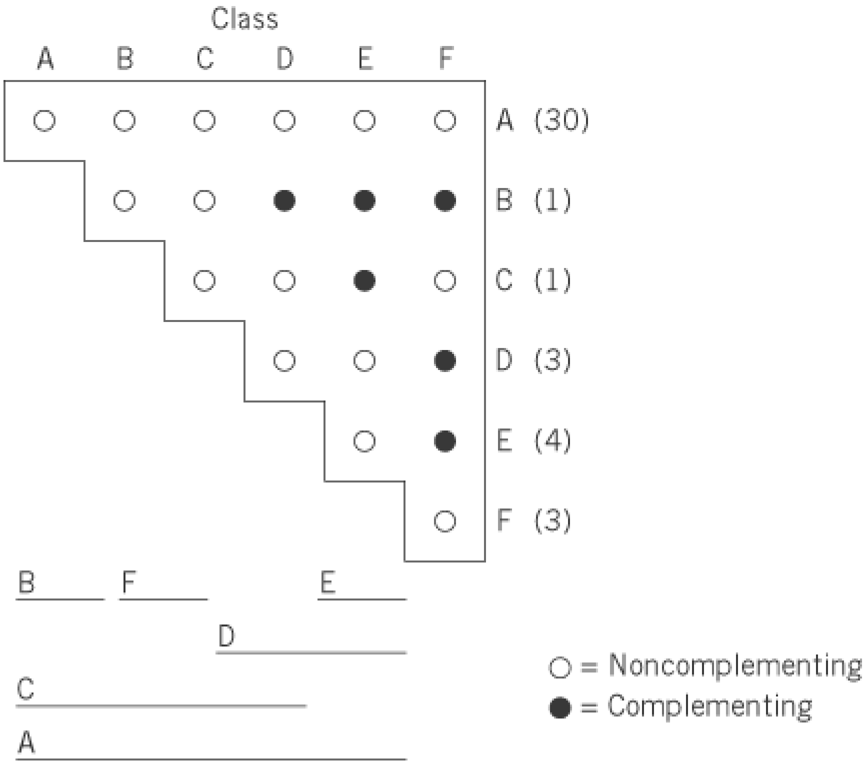
Attention was first focused on allelic complementation as a result of intensive studies of auxotrophic (nutritionally exacting) mutants of microorganisms, first in the fungus *Neurospora crassa* and then in budding yeast and bacteria. The *Neurospora* mutants gave the main early encouragement to the view that each gene is responsible for the specificity (at first rather vaguely defined, but later taken to mean amino acid sequence) of a single enzyme. Each enzyme was expected to catalyze a single reaction, and indeed, nearly all auxotrophic mutants were defective in carrying out just one biosynthetic step. The finding, in *Escherichia coli*, that **tryptophan synthetase** deficiency results from mutation of either of two clearly distinct genes was clarified by the demonstration that this enzyme consists of two different polypeptide chains, one for each gene. Subsequently it was recognized that "one gene—one polypeptide" was a better working hypothesis than "one gene—one enzyme."

2. Complementation Maps

Because genes were expected to encode single polypeptide chains, there was no obvious possibility of allelic complementation. That would require recombination between polypeptide chains, which did not occur. However, as more mutants were screened, it was commonly found that, although most mutants defective in some single biosynthetic step were indeed noncomplementing in all pairwise combinations, testing of larger numbers revealed a few that showed complementation with some of the other members of the series, though still noncomplementing with most of them.

The complementation relationships within a series of mutants of the same enzyme were summarized in the form of complementation maps, in which mutants were represented as linear segments, nonoverlapping or overlapping depending on whether or not they complemented one another. Figure 1 shows a relatively simple example. Each group of mutants had some unity and justified their being called allelic because many or most of them were noncomplementing with all of the others. The overlaps in the complementation maps were crucial because they made it difficult to consider that the series of mutants falls in more than one gene, perhaps encoding different polypeptide components of the same enzyme. In principle, the overlaps could represent deletions of DNA that extended between genes, but deletions as a general explanation could be ruled out on two grounds. First, the mutational sites of "overlapping" mutations often recombined in **meiosis**. Secondly, they could, in many cases, undergo reverse mutation to wild type.

Figure 1. Complementation matrix and complementation map for a set of 42 *Neurospora crassa arg-1* mutants that are deficient in the enzyme argininosuccinate synthetase. The number of mutants in each of the complementation classes A–F is shown in parenthesis (1).



Up to a point, it was possible to place all of the segments of most complementation maps in a simple line (eg, Fig. 1), encouraging the view that perhaps the map had some relationship to the linear structure of the gene. But with the inclusion of more mutants, it usually became impossible to accommodate all of them without making the map two-dimensional with closed loops and tails. And where a complementation map and a fine-structure gene map were both available, usually a simple and consistent relationship did not exist between the two (3).

No general theory explains the many and various forms of complementation maps, but at least some special explanations have emerged from studies of particular cases. Much depends on the whether the enzyme (or other protein) gene product has one function or several.

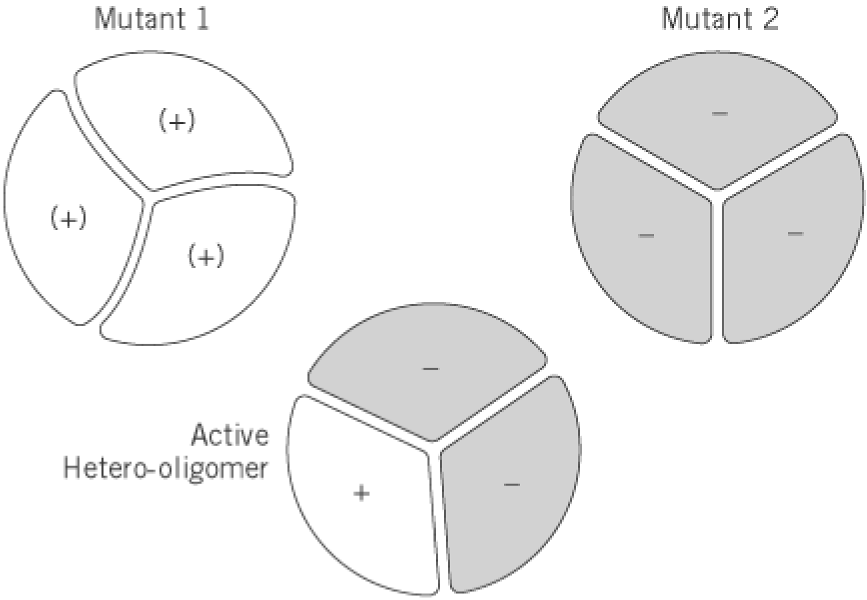
3. Dimeric/Oligomeric Enzymes with Single Functions—Conformational Correction

In the first *Neurospora* examples, it was clear that the mutations affect single enzymes that catalyze single reactions. Thus the *ad-4* mutants, unable to make adenine, are defective in adenylosuccinase (4), and the *am* mutants that require a-amino nitrogen lack NADP-specific glutamate dehydrogenase (GDH) (5). Within each of these mutant series, some pairs show complementation, and in both cases it was shown that, under certain conditions, some degree of enzymatic activity could be obtained from mixed protein preparations of complementing mutants. The mutually complementing *am* mutants produce inactive, but physically nearly normal, forms of GDH protein, and active GDH is readily obtained by freezing and thawing mixtures of purified complementing mutant proteins in the presence of 0.1 M sodium chloride. This is a procedure that brings about dissociation and reassociation of protein subunits in other systems (6). NADP-specific GDH is a hexamer (six identical polypeptide subunits), and the enzymically active complementation products are mixed hexamers, though the complex mixture of hybrid proteins (all combinations from 5:1 to 1:5) was resolved only partly into its components (7).

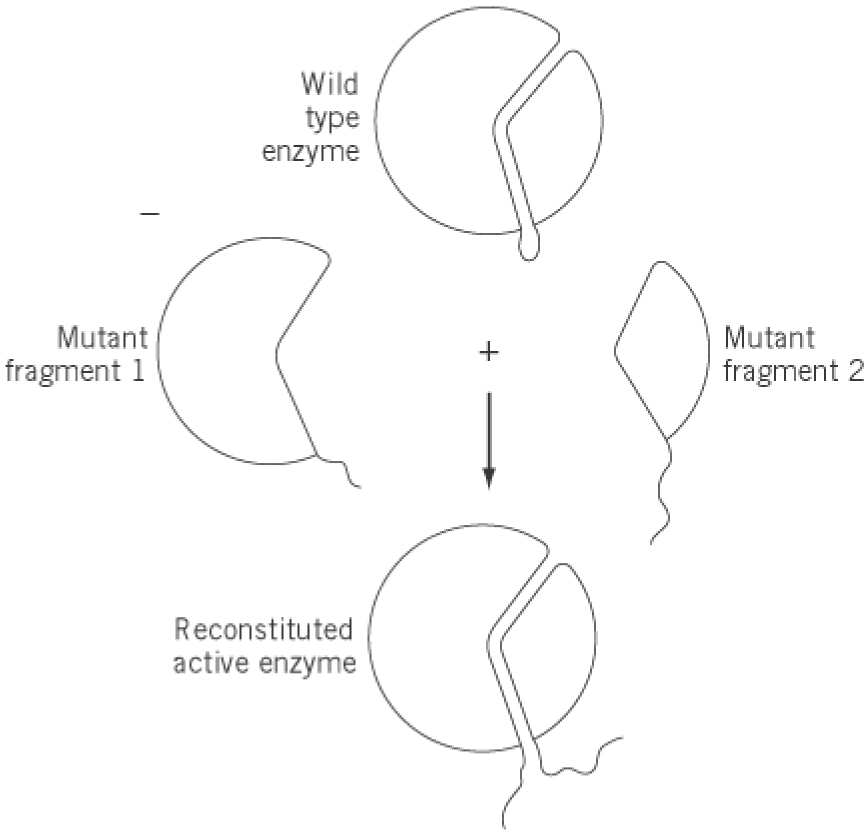
The hybrid protein hypothesis for allelic complementation had already gained support from experiments by Schlesinger and Levinthal (8) on mutants of *Escherichia coli* deficient in alkaline phosphatase, a dimeric enzyme. Here a mixture of two individually almost inactive mutant forms of the enzyme dissociated to monomers by acidification and then allowed to reassociate was to form highly active mixed dimers (8).

Crick and Orgel (9) proposed that individually inactive monomers of dimeric enzymes might remedy each other's defects through mutual correction of their folded conformation. This is especially likely when the enzyme involved is allosteric and switches between active and inactive forms by ligand binding. One likely reason for mutational inactivation of an allosteric enzyme is excessive stabilization in the inactive form. Allosteric proteins are generally dimeric or oligomeric and, according to the simplest version of allosteric theory, their constituent monomers shift their conformation in a concerted, all-or-none, fashion. If so, one would expect that the conformational preference of the majority or more strongly stabilized component would prevail in a mixed oligomer. The idea is explained diagrammatically in Fig. 2a. It receives some support from studies of the *Neurospora am* mutants. Neurospora NADP-GDH is indeed an allosteric enzyme and, in most of the complenting pairs of mutants, one partner produces a GDH variety that is potentially active, but switches to the active conformation only under unphysiologically extreme conditions. In the best investigated examples, the other partner is a form of the protein that is unconditionally inactive because it has lost an essential side-chain in a substrate-binding site (see Enzymes), but is conformationally nearly normal. The potential activity of the first component was realized upon **hybridization** with the second (6). Another *am* mutant (10) that complements either of the first two kinds is best interpreted as producing a GDH variety that cannot form stable hexamers by itself.

Figure 2. Two modes of complementary interaction between mutant derivatives of the same protein. (a) Formation of mixed oligomers (shown here as trimers) that have one mutant monomer potentially active (+) but stabilized in an inactive conformation and the other always inactive but conformationally normal. In the mixed trimer (hetero-oligomer), the activity of the (+) component is realized by conformational correction. (b) Formation of active enzyme by association of two independently folded fragments. The shapes depicted in this figure are imaginary.



(a)



(b)

These examples of allelic complementation still leave some possibility of rescuing complementation as a criterion for allelism. Instead of insisting that alleles should never complement each other, one can adopt a softer criterion, namely that they should never complement to form a truly wild-type protein product. Then, the *cis*/*trans* criterion for allelism survives in modified form, and the crucial *cis-trans* difference is no longer between function and no function but between full function and (perhaps marginally) subnormal function. In the case of the *Neurospora am* mutants, it was fairly easy to demonstrate that their complementation products are subwild and have relatively low activity per unit protein and reduced **thermostability**. But this amended criterion for allelism is not always easy to apply. The best indication that a series of mutants belongs to a single gene is that, notwithstanding complementation between some pairs, a substantial proportion fails to complement any of the others.

On the conformational correction hypothesis, complementation maps that relate to single enzymatic functions must be presumed to represent interactions within the three-dimensional structures of proteins. Though most are too complex to interpret, a limited number of nonoverlapping segments can be explained in terms of global properties of mutant proteins, as in the case of the *Neurospora am* mutants mentioned previously. In any case, conformational correction applies only when the protein is a dimer or oligomer.

4. Fragment Complementation with a Monomeric Enzyme

At one time allelic complementation was seen as diagnostic of a dimeric or oligomeric gene product. What was overlooked, however, was the possibility of piecing together a functional monomeric protein from fragments. There is good evidence from several sources that this happens.

The best known example (11) involves *Escherichia coli* b-**galactosidase**, the *LacZ* product. This enzyme consists of a single, long (1025-residue) polypeptide chain. Mutants that have deletions of the N-terminal ("upstream") end of the chain complement virtually any mutant that has a defect in a substantial section at the C-terminal or downstream end (the w-region) provided that the deletion does not extend into that region. The uptream deletions were called w-donors and the downstream deletions complementing mutants w-acceptors. The latter class includes chain-terminating mutants in which the w region is hardly present at all. Thus an interaction between complementary fragments of a single polypeptide chain, called in this case w-complementation, result in reconstituting active enzyme.

The general explanation for complementary interaction of polypeptide fragments is that each of the two polypeptide sequences, whether continuous as in the wild type or separated as in w-complementation, fold up independently to form three-dimensional "**domains**"—protein globules that fit closely and stably together like two pieces of a three-dimensional jigsaw puzzle. Their mutual affinity enables the initially separated domains to find one another when synthesized in the same cell or, indeed, when mixed *in vitro*. w-Complementation creates a fully active and stable b-galactosidase, and the lack of a covalent connection between the two fragments does not matter. The overlap between them increases the molecular weight of the enzyme somewhat but does not impede its function.

Now, complementation between *LacZ* sequences is used routinely in **plasmid** technology (12). An *E. coli lacZ* deletion mutant, M15, lacks just 30 amino acid residues at the N-terminus of the b-galactosidase chain, and this nearly complete polypeptide is complemented by many different short N-terminal fragments that evidently can repair the N-terminal (a) domain. A number of different cloning plasmids have been constructed so as to encode one of these a fragments, and, if introduced into M15, signal their presence by producing active a-complemented b-galactosidase and the appearance of blue colonies on a growth medium containing a substance that is cleaved by the enzyme to give the color, **X-gal**.

It is still not clear how important interactions between polypeptide fragments, as opposed to formation of mixed oligomers, will prove to be an explanation of allelic complementation. For oligomeric proteins, the two possibilities are not mutually exclusive. Their occurrence together within the same allelic series could be responsible for the complexity of some complementation maps.

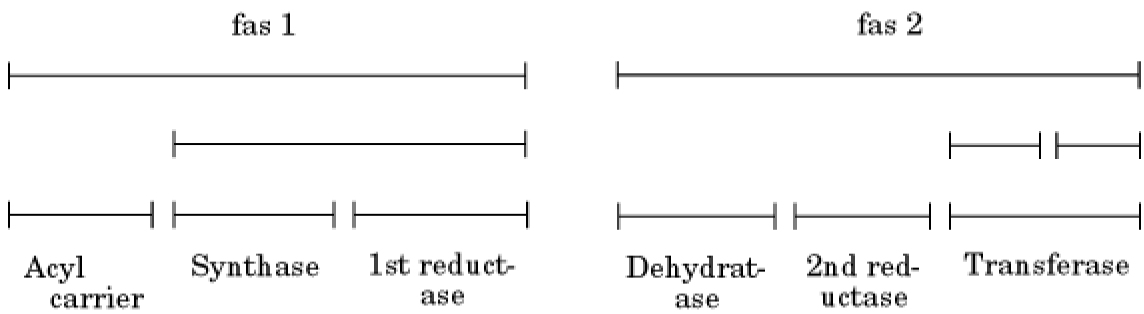
5. Enzymes with Multiple Functions

Another explanation for allelic complementation, which applies more commonly than at one time thought, is that the protein product of the gene has several enzymatic functions, usually involved with different steps in the same biosynthetic pathway. An amino acid replacement that eliminates one enzymatic activity does not necessarily have any critical effect on the others. In terms of protein structure, this means presumably that the polypeptide chain is folded into a number of domains that function largely independently. In this kind of situation, different mutant alleles can in principle complement one another without mutual conformational correction or even the formation of mixed oligomers, though these interactions may also occur.

The genetic control of multifunctional enzymes has been most thoroughly investigated in filamentous fungi and budding yeast because extensive collections of relevant mutants have been available in these organisms. Here we briefly review three examples, two from the yeast *Saccharomyces cerevisiae* and one from *Neurospora crassa*.

Schweizer and his colleagues (13, 14) collected a large number of yeast mutants that had lost the ability to synthesize fatty acids. The pathway of synthesis, starting with acetic and malonic acids and leading to long-chain fatty acids, could be divided biochemically into six steps, corresponding to separately assayable enzymatic activities. The whole pathway was catalyzed by a protein complex composed of just two long polypeptide chains. The mutants were assigned by genetic mapping and complementation tests to two genes, *fas1* and *fas2*, unlinked to each other Every *fas1* mutant complemented every *fas2* mutant. Extensive complementation also occurred within *fas1* and within *fas2*. The complementation maps are shown in Fig. 3. Three complementation groups in each map are complementary in all combinations, and these correspond to losses of different single enzymatic activities. In both *fas1* and *fas2*, there are also mutants that failed to complement any of the others and some that have more restricted overlaps in the map. The comprehensively noncomplementing mutants are mostly chain terminators or, less often, frameshifts, which failed to synthesize a complete polypeptide chain (see Frameshift Mutation) and, as a result have lost all the enzyme activities normally associated with it. Although the different domains of the polypeptide chains could function independently so long as complete chains were produced, a shortened chain failed to form any of the active domains.

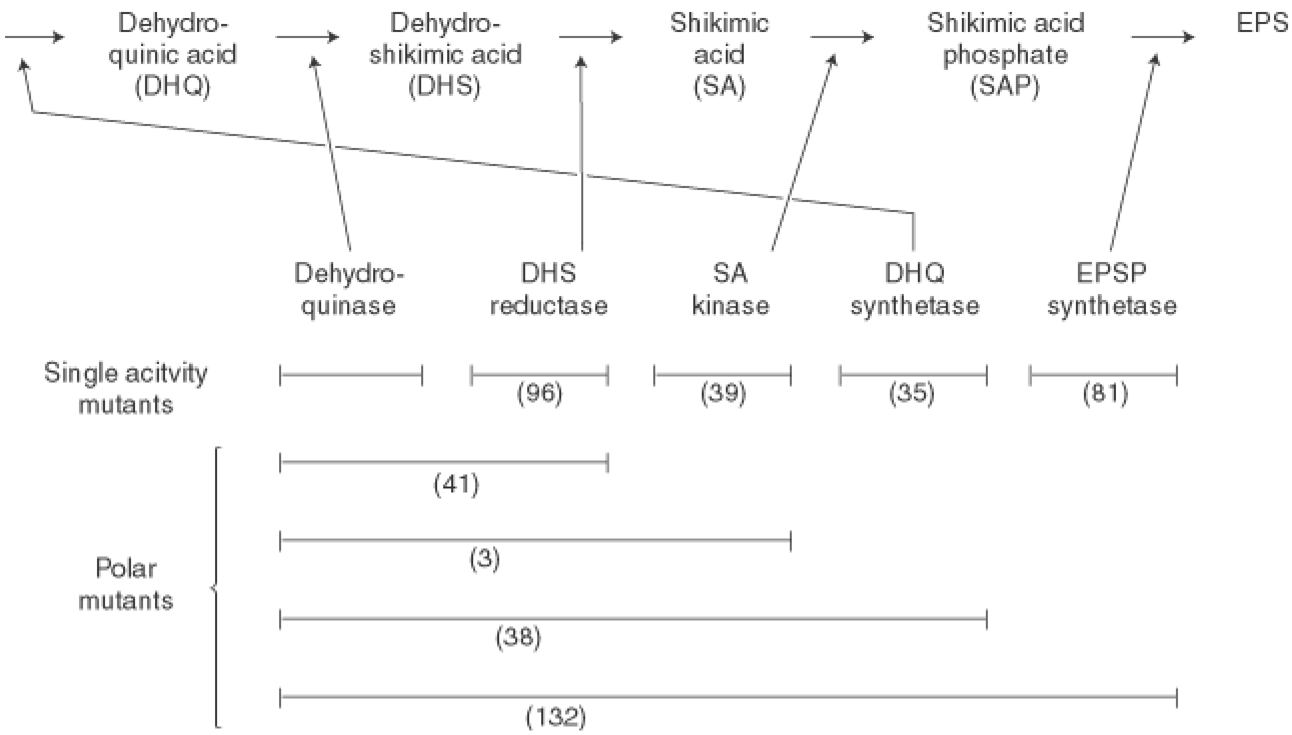
Figure 3. Complementation relationships of *Saccharomyces cerevisiae fas* mutants deficient in one or more activities of the fatty acid synthesizing enzyme complex. By complementation testing, they split into two distinct groups, *fas1* and *fas2*, that correspond to two unlinked genes and two different polypeptide chains. Within each group are three mutually complementing classes that correspond to losses of three different enzymatic activities of a single polypeptide chain and numerous mutants (mostly chain-terminating) that fail to complement all of the others (13, 14).



The *Neurospora* example, probably the most complex and extensively analyzed of any, involves the pathway for synthesizing aromatic compounds. Mutants blocked in this pathway have to be supplied with a complete mixture of essential aromatic metabolites (phenylalaline, tyrosine, tryptophan, and *p*-aminobenzoic acid) because they cannot make the common precursor of the benzene ring, chorismic acid. The pathway segment relevant here comprises the five steps leading to enol-pyruvylshikimic acid phosphate, the immediate precursor of chorismate. The five distinct enzymatic activities were at first thought to be due to separate proteins encoded by a close cluster of genes because a number of closely linked and mutually complementing mutants were found that lack single enzymatic activities. However, doubt was thrown on the separate gene interpretation by the numerous mutants that failed to complement two or more of the single-activity groups.

The complementation map is shown in Fig. 4. The map shows a polarized pattern, and all the overlaps start at the left (DHS reductase) end of the map and extend for different distances to the right. The situation became much clearer following the biochemical demonstration that the entire complex of reactions is catalyzed by a dimeric multifunctional enzyme that has just one kind of polypeptide chain. As with yeast *fas1*/*fas2*, the mutants represented as overlaps on the complementation map are largely chain terminators. But the aro protein differs from the *fas1*/*fas2* complex in the polarized pattern of its complementation map. The obvious explanation for this is that the gene, as represented in Fig. 4), is transcribed and translated from right to left, and prematurely terminated forms of the polypeptide chain retain the enzymatic activities of the domains upstream of the termination point. A remaining anomaly is that, to give coherence to the complementation map, the EPSP synthetase segment has to be placed at the N-terminus of the chain, upstream of DHQ synthetase, whereas in the actual polypeptide chain the two segments are the other way round. The fact that the enzymatic complex is a dimer opens the door to further complications. There is the possibility of conformational interactions between monomers, and the unanswered question of how prematurely terminated monomers are accommodated in the dimeric structure.

Figure 4. Relationships among *Neurospora crassa* mutants that are deficient in one or more of five steps in the synthesis aromatic ring, depicted in the upper line (EPSP, the precursor of chorismic acid, is enolpyruvyl shikimic acid phosphate) different enzymatic activities (second line) are properties of different domains of a single polypeptide chain. The complementation map below shows five classes of *aro* mutants, each of which is deficient in a single enzyme activity, complementing each other in all combinations, and "polar" mutants each of which lacks two or more activities. The num mutants found in each class in the first screen are shown in parentheses. Initially no singly deficient mutants were found DHQase class because this function is duplicated by a catabolic DHQase. The missing class was found after the latter en had been eliminated by mutation (15).



The second example of polarized complementation, this time from yeast, provides a link to similar situations in insects and mammals. Among several classes of **uridine** or **cytidine**-requiring (URA) mutants, the *URA2* group, a tightly linked group, that maps to a first approximation to the same chromosome locus (*URA2*), includes two mutually complementing subgroups, A and C, and other mutants (B) that complement neither (16). When the mutational sites were placed in order in a recombinational gene map, the A and C subgroups mapped in two close but nonoverlapping segments, whereas nearly all of the B mutations, which eliminate both A and C functions, mapped within the C segment. It was shown that the B overlapping class consists mostly of chain-terminating mutations, with some frameshifting insertions or deletions, which are expected to eliminate or make nonsense of "downstream" polypeptide sequences. Essentially the same situation has been found in two other fungi, *Neurospora* and the ink-cap mushroom *Coprinus*.

The enzymological explanation of all three fungal examples is the same. The protein gene product is multifunctional, and has two enzymatic activities, carbamoyl phosphate synthase (CPSase) and **aspartate** *trans* **carbamoylase** (ATCase), that catalyze the first two steps of the pyrimidine biosynthetic pathway. The yeast *URA2*-A mutants lacked ATCase, the C mutants lacked CPSase, the B mutants lacked both, and the same applied to the analogous mutant classes in the other two fungi. The polypeptide also has a third enzymatic activity, glutamine amidotransferase (GATase), an initially unrecognized component of CPSase activity. The single polypeptide chain is synthesized from the GATase/CPSase end, so that downstream chain-terminating mutations could eliminate ATCase and not CPSase, and upstream terminators could only eliminate both.

A similar situation applies in the pyrimidine biosynthetic pathway of *Drosophila*. The difference here is that the analogous gene product has an additional enzyme function, dihydro-orotase, that catalyzes a further step in the pathway, as well as GATase, CPSase and ATCase (17). The gene is called *rudimentary* (*r*) referring to the effect on the wings and bristles of the fly, which are sensitive indicators of pyrimidine limitation. The *r* series of mutants provided the first demonstration in *Drosophila* of allelic complementation comparable to the fungal examples (18). Later work showed that generally the mutually complementing *r* mutants are deficient in different enzymatic activities of the single-gene product.

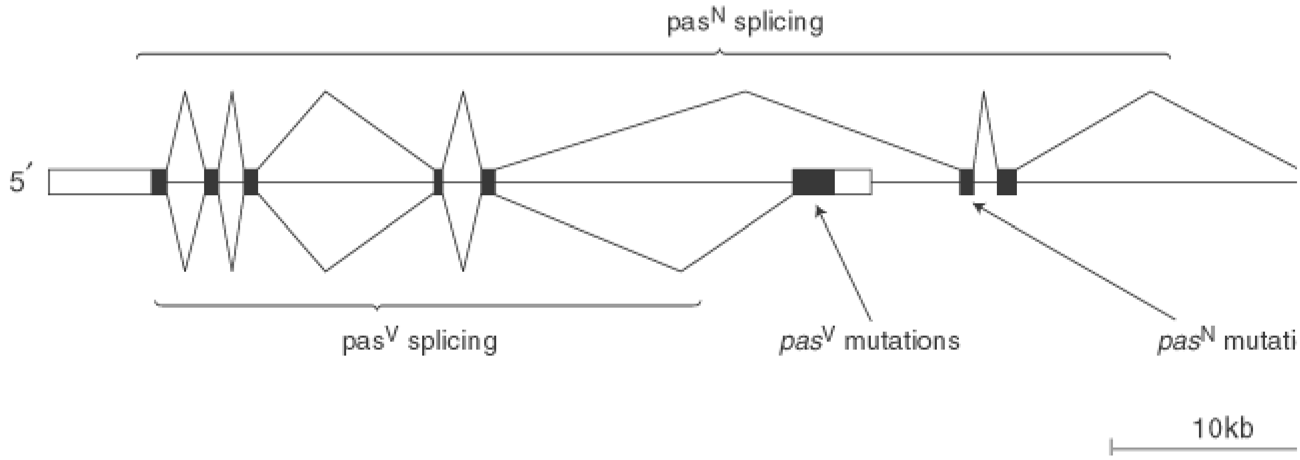
Multifunctional enzymes encoded by single genes (sometimes called "cluster genes" to point out their superficial resemblance to gene clusters) are not uncommon in higher organisms. For example, the first steps of pyrimidine biosynthesis in the mouse are catalyzed by a single protein very like the *Drosophila r* gene product, and in *Drosophila* a single protein (encoded by the *Gart* gene) is responsible for catalyzing several steps of purine synthesis, not all of them sequential. If complementation between mutant alleles has not been a feature of these other systems, it is because the necessary collections of viable mutants have not been obtained.

Although a degree of complementation between different mutant derivatives of multifunctional enzymes is to be expected, it is not clear whether it always, or even ever, results in maximally efficient enzymatic function. The catalysis of several sequential reactions by a single protein suggests that the organism's metabolism derives some benefit from the proximity of the different catalytic protein domains. In the fungal examples just reviewed, the separated enzymatic activities function together well enough to support normal growth under laboratory conditions, but this is perhaps not a very stringent test.

6. Single Genes that Encode More Than One Protein

Investigation of the exon-intron structures of genes has brought the realization that a single gene, that is, with a single primary RNA transcript, can encode two or more different proteins that have different and complementary functions as a result of different modes of splicing of the pre-mRNA (see Alternative Splicing). The different protein products always, at least in the known examples, have much of their amino acid sequence in common, but two alternative products may each have sequences that the other lacks. Mutations in these differentiating segments affect different functions and should show complementation. Thus the *Drosophila Passover* gene (19) encodes two alternative proteins respectively required for normal synaptic connections in the neural system and for some other function necessary for viability. Certain mutations, although allelic in the sense that they affect the same primary transcript, show complementation because they damage different proteins (Fig. 5).

Figure 5. Complementation between alleles at the *Passover* gene of *Drosophila melanogaster* due to alternative modes o splicing introns from the pre-mRNA. The *pas*^{V} (recessive lethal) and *pas*^{N} (recessive neural dysfunction) mutations complement each other to produce a wild-type phenotype. They fall within exons that are mutually exclusive in the diffe spliced mRNAs. Mutations (*pas*^{VN}) that fall within the common upstream exons complement neither *pas*^{V} nor *pas*^{N}. Fill open boxes represent translated and untranslated exon sequences, respectively, and the lines between them are introns (1



7. Morphologically Pleiotropic Genes

Pleiotropic means having two or more distinct effects. If a pleiotropic gene mutates so as to lose one its functions and not the other(s), then there are obvious possibilities for allelic complementation. This point has already been made in connection with genes that encode multifunctional enzymes, and it also applies to pleiotropic genes that have effects at the morphological level.

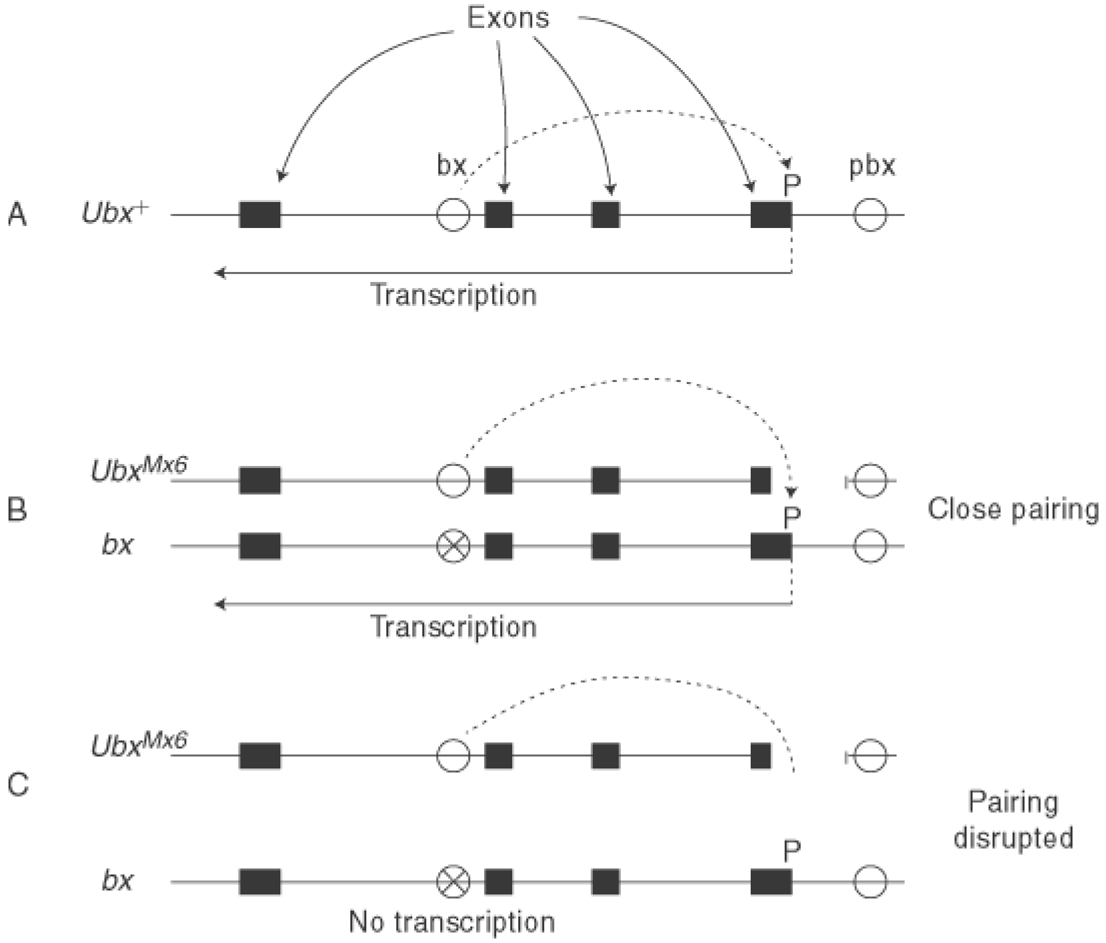
A good example is provided by the *dumpy* (*dp*) gene of *Drosophila melanogaster* (20). Different recessive mutant alleles of this gene, when homozygous, have three different effects: (l) a skewing of the thoracic bristles (called “vortex”, *v*); (2) a shortening and oblique orientation of the wings (*o*); and (3) recessive lethality (*l*). In some alleles, two or three of these functional defects occur together. *o*, *v*, and *ov* alleles complement *l* in diploids, whereas *ol*, *vl* and *ovl* do not. In combination, the effects of the alleles are additive. Each partner supplies that part of normal gene function that it possesses and the other lacks. No new function is created but each allele merely contributes what it can do by itself. A somewhat similar mutational effect but with less variety was discovered many years earlier by N. P. Dubinin in his investigation of the *Drosophila* **achaete-scute** locus (21). Here different mutations eliminated different bristles, and heterozygotes with two scute mutant alleles lacked only those bristles that were missing in both parental homozygotes.

The whole array of *dp* mutants can be attributed to a single gene on two grounds. The mutants that have lost two or three functions cannot be due to deletions overlapping more than one gene because they all form wild-type recombinants in crosses with the single-function mutants; and the sites of the different mutations, mapped by recombinational analysis, do not fall into functionally different segments but are rather intermingled.

To the extent that their multiple functions can be separately affected by mutation, pleitropic morphology-determining genes, such as *dp* in *Drosophila*, bear some formal similarity to the “cluster genes” of fungi. But *dp*, at least, is not resolvable into single-function segments, and the reason for its pleiotropy is likely to be different. Another, better understood *Drosophila* gene, ***Ultrabithorax*** (*Ubx*), that encodes a regulatory protein and is differentially expressed in different tissues, may provide a better model.

The *Ultrabithorax* (*Ubx*) gene in *Drosophila* plays a vital role in establishing segment identity in the developing fly embryo (22). It is expressed in a zone extending from the end of the abdomen to the middle of the second thoracic segment. Loss of *Ubx* function by mutation causes lethal transformation of the third thoracic and first abdominal segments to likenesses of the second thoracic segment. Mutations of less drastic effect in the *Ubx* gene cause losses of *Ubx*+ function in specific **parasegments**, which comprise the posterior half of one segment and the anterior half of the next segment to the rear. These mutations, it is thought, affect parasegment-specific enhancer sequences that are necessary in some way for the local transcription of *Ubx*. Fly embryos homozygous for a recessive mutation called **bithorax** (*bx*), located within the *Ubx* large intron (Fig. 6), fail to transcribe *Ubx* in parasegment 5 that covers the anterior half of the third thoracic segment (T3). T3 normally carries vestigial wings (“balancers” or halteres). The true wings are on the second thoracic segment (T2). In *bx*/*bx* flies, the front half of T3 becomes T2-like, and the front half of the haltere is expanded, tending toward the wing. Another recessive mutant, postbithorax (*pbx*), that maps just upstream of the *Ubx* transcriptional start point, has an analogous effect on *Ubx* expression in parasegment 6 that covers the posterior half of T3. When homozygous, *pbx* causes wing-like enlargement of the posterior half of the haltere. The homozygous double mutant *bx pbx*/*bx pbx*, develops (when it develops at all) into a four-winged fly. Both the *cis* and the *trans* double heterozygotes, *pbx bx*/++ and *bx* +/+ *pbx* are phenotypically normal.

Figure 6. Complementation by transvection in *Drosophila melanogaster*. (a) The normal expression of the *Ubx*+ gene in the posterior thoracic segment depends on an enhancer (○) located in a *Ubx* intron. (b) In the *bithorax* (*bx*) allele (recessive, causing partial segmental transformation with enlarged halteres), this enhancer has been disrupted (Ä). The $Ubx^{M \times 6}$ allele (recessive lethal) has a deletion that takes out the *Ubx* promoter (P). The complementation of the two alleles to give a very nearly wild-type fly (24) is due to the enhancer, still present in *Ubx*M × 6, that acts in *trans* on the promoter P. (c) The effect is due to close somatic pairing of chromosomes. When this is disrupted by a structural rearrangement, the *bx* mutant phenotype reappears. The position of the upstream enhancer disrupted in *pbx* mutants is also shown. *bx* and *pbx* complement each other fully in *trans* (see text).



Based on their complementation in *trans*, one might, in the absence of further information, regard *bx* and *pbx* as mutations in different genes, This, indeed, is how they were originally interpreted. However, neither allele is complemented to more than a very limited extent by a *Ubx* null mutant allele, and so by this criterion they are functionally part of *Ubx*—complementary regulators of the same transcription unit. So *bx* and *pbx* can be regarded as alleles of *Ubx*, and the wild-type *bx*/*pbx* phenotype provides an example of another kind of allelic complementation, based on its tissue-specific controls of expression, not on the structure of the gene product or on the multiplicity of its effects (though it does have multiple effects).

The *Ubx* gene bears on the topic of allelic complementation in another and more surprising way. E. B. Lewis (23) discovered that *Ubx*/*bx* heterozygotes have a more extreme mutant phenotype when the somatic pairing of homologous chromosomes (which is characteristic of flies) is disrupted by a structural rearrangement with a breakpoint close to the *Ubx* locus. He called this phenomenon ***transvection***. The idea is that the two mutant alleles somehow help each other toward normal function when they are physically close. It has been found in a few other *Drosophila* genes as well as *Ubx*.

More recently, the *Ubx*/*bx* phenomenon has been reinvestigated and given a new interpretation (24). One of the *Ubx* alleles used in the recent work, $\mathrm{Ubx}^{\mathrm{M\times6}}$, is null (and recessive lethal) by virtue of a deletion that removes the promoter region of the gene. Compared with other null *Ubx* alleles, it shows unusually strong complementation with the standard *bx* allele, which has a *gypsy* transposable element (see Transposon) inserted into the largest *Ubx* intron, disrupting an enhancer of *Ubx* transcription in parasegment 5. The $Ubx^{\mathrm{M\times6}}$/*bx* heterozygote is very nearly wild type morphologically except when the somatic pairing of the homologous chromosomes is impeded by a structural rearrangement, when the front half of the haltere becomes enlarged. The proposed explanation of the strong complementation is that the bx^{+} enhancer, still present in the *Ubx* allele, acts in *trans* on the enhancer-deficient *bx* allele. The idea is shown in Fig. 6. Enhancers are usually supposed to act only in *cis* and bind proteins that help to form the transcriptional initiation complex at the gene promoter on the same chromosome, but this interpretation of transvection suggests that, with close pairing of homologues (as occurs in *Drosophila* polytene chromosomes), an enhancer on one homologue can reach across and help to activate the allele on the other chromosome of the pair. In the case of this particular *Ubx*/*bx* interaction, the *trans* effect may have been particularly strong because, as a result of the deletion in the *Ubx* allele, there was no competition for the services of the enhancer from a promoter in *cis*.

If we grant that the enhancer is a part of the gene (difficult to deny when it is within one of the gene's introns), then transvection is yet another mechanism for allelic complementation.

Interband

The dense bands of polytene chromosomes stain more intensely with **DNA**-sensitive dyes, indicating that the DNA concentration and hence the compaction of chromatin are greater in these regions. These bands broadly correlate with the number and positions of known genetic loci (1). Nevertheless, each band contains much more DNA than found in a typical gene. In certain well-defined cases, a band contains small clusters of genes, such as those encoding the chorion proteins. In contrast, the interband regions contain less condensed DNA and chromatin, as has been shown directly for the *Notch* gene. In situ hybridization reveals that the 5′ regulatory regions of the *Notch* gene lie in the interband, and the gene itself occupies a single cytologically defined band (2). Transcriptionally active bands become differentiated structures known as **puffs**, in which the chromosomal structure is disrupted as a consequence active transcription.

Intercalation

Virtually any molecule with sufficiently large aromatic chromophore will bind to the double-helical DNA structure by insertion of the flat chromophore between the base pairs . The primary driving force for intercalative binding is stacking (charge-transfer and dipole-induced dipole) interactions between the intercalator and the adjacent base pairs, and many compounds have larger and more electron-deficient chromophores than a DNA base pair. The residence time of the intercalator at a particular site varies widely according to its structure, ranging from a few milliseconds to many hours. Intercalation disrupts the DNA structure, forcing the base pairs apart by about 3.5 Å and unwinding the helix by 10–25° (depending on the structure of the intercalator) (1). **Acridines** are classic examples of DNA intercalators, and this DNA interaction is considered integral to their activity as frameshift mutagens.

A wide range of other planar polyaromatic molecules apart from acridines have been shown to intercalate and also to cause frameshift mutations (2, 3). The most common types of frameshift mutations involve the gain or loss of one or two base pairs, typically in repetitive sequences of DNA. In these cases, every codon after the mutation site is altered within a coding region, typically resulting in the formation of truncated proteins because of the generation of nonsense mutations. Nonfunctional gene products are thus a common result of frameshift mutations, and these may have major phenotypic effects, depending upon the role of that specific gene function in cell viability and metabolism.

In 1966, Streisinger et al. (4) developed a model in which he suggested that frameshift mutations are generated because of a localized pairing out of register, or slippage, during DNA replication. This slippage occurs at repetitive runs of one or more bases, leaving an unpaired base or a few bases out of register, ultimately resulting in the incorporation of an inappropriate number of bases during DNA replication. Intercalating agents may bind to the DNA bulges associated with the mispairing, thereby stabilizing these structures and enhancing the spontaneous rates of frameshift mutagenesis at this site. This model, albeit with modifications, still provides a useful explanation of most of the data available to the present day (5, 6).

Interferons

1. General Introduction to the Interferon System

Interferons (IFNs) are members of the group of secretory proteins called cytokines and are defined by their ability to interfere with viral infection. However, IFNs are multifunctional proteins that also inhibit cell proliferation, regulate cell differentiation, regulate apoptosis (programmed cell death), and modulate activities of the immune system. A wide range of cell types produce IFNs in response to infection by viruses, bacteria, and mycoplasma. Noninfectious agents such as growth factors, other cytokines, and double-stranded RNA (dsRNA) molecules also induce IFN expression. In fact, dsRNA may be a physiologically relevant mediator of IFN synthesis since it is an important intermediate in viral replication. IFNs are extremely potent biological response modifiers with specific activities of at least 10^6 units per milligram of protein, with 1 unit defined as the amount of IFN necessary to inhibit virus replication by 50%.

IFNs were originally classified according to the cell types that generally produce them. The type I IFNs (IFNa and IFNb) are usually produced by leukocytes and fibroblasts, respectively, while type II IFN (IFNg) is produced by lymphocytes. However, cloning of individual human type I IFN genes has shown that the family is rather large and includes 15 different IFNa subtypes (with four pseudogenes), one IFNb, and two IFNw (with five pseudogenes). Type I IFNs are acid-stable, have similar protein structure and biological activities, bind and transduce signals through a common multiprotein cell surface receptor, are induced in response to viral and other inducers, and share a common gene locus on human chromosome 9. All the genes for type I IFNs are devoid of introns. In contrast, the single type II IFN, IFNg, is acid-labile, and its expression is limited mainly to T cells and NK cells. The structural gene for IFNg is located on human chromosome 12 and contains three introns.

Although IFNs share similar biological actions, there are distinctive differences in the biological actions of type I and type II IFNs. For example, only IFNg induces class II histocompatibility antigens (all IFNs induce class I expression) and inhibits the Th2 subset of helper T cells, thereby altering the balance between the humoral and cellular immune responses. Therefore, while IFNg is more active in immunomodulation than type I IFNs, type I IFNs in general are more efficient antiviral agents. Thus, although all IFNs are antiviral, the biological roles of the different IFNs in vivo are distinct, as shown in mouse models for infectious disease. Mice lacking a functional type I IFN system (by knockout of one of the type I IFN receptor genes) were highly sensitive to a wide variety of viral infections (1, 2). In contrast, mice lacking a functional type II IFN system (by knockout of the IFNg gene or a IFNg receptor gene) were more sensitive to bacterial and parasitic infections, but generally remained resistant to viral infections (1).

IFNs are not directly antiviral, but elicit their biological effects by first binding to specific receptors on the surface of target cells. The interaction of the ligand with its cognate receptor transduces signals to the nucleus that results in new gene expression: the transcription of new mRNAs and their translation into new proteins. While many of the proteins induced by type I and type II IFNs are distinct, there is a certain degree of overlap. Nonetheless, the IFN-induced proteins are ultimately responsible for biological actions of IFNs. The transcription of some IFN-induced genes does not require de novo protein synthesis, such as the family of immediate early genes called IFN-stimulated genes (ISGs). Other IFN-induced genes require protein synthesis and are involved in the delayed response to IFNs, such as class II histocompatibility antigens and IFN-response factors (IRFs).

2. IFN Receptors

All type I IFNs (IFN a, b and w) bind to a ubiquitously expressed cell surface receptor, varying in number from 500 to 20,000 high-affinity ($K_d \approx 20–100$ pM) receptors/cell (3, 4). The cDNAs coding for two subunits of the type I IFN greceptor, IFNAR1 and IFNAR2, have been cloned; both of these are located on human chromosome 21 (5-8). The human IFNAR1 chain (~110–135 kDa glycoprotein) is a 557–amino acid protein, with a 100–amino acid intracellular domain and a 21–amino acid transmembrane segment. The IFNAR1 chain is a signal transducing subunit, but does not directly bind IFN (9). The major ligand binding chain of the type I IFN receptor is IFNAR2, which exists as three different polypeptides due to alternative splicing and differential use of polyadenylation sites (7). The longest form, IFNAR2c (~100 kDa glycoprotein), is a 515–amino acid protein that acts as a functional receptor in type I IFN signaling.

Two subunits of the type II IFNg receptor, IFNGR1 and IFNGR2, have also been cloned (10-12). The human IFNGR1 chain (90-kDa glycoprotein) is the ligand-binding subunit of the receptor and is a 472–amino acid protein with a cytoplasmic domain of 221 amino acids and a 23–amino acid transmembrane segment. The gene for IFNGR1 is located on human chromosome 6. Although transfection of the human IFNGR1 gene into murine cells confers high-affinity ligand binding, a species-specific component (IFNGR2) encoded by human chromosome 21 is necessary for a fully functional receptor. The human IFNGR2 chain (~65-kDa glycoprotein) is a 316–amino acid polypeptide with a 66–amino acid cytoplasmic domain and a 24–amino acid transmembrane segment.

Cytokine receptors have been classified into two groups on the basis of structural similarity in their extracellular domains. The class I cytokine receptor family includes receptors for growth hormone, prolactin, erythropoietin, interleukins-2, -3, -4, -6, and -7, granulocyte-CSF, and granulocyte macrophage-CSF and are typified by conserved tryptophan, NH2-terminal and COOH-terminal cysteine pairs, and a membrane proximal WSxWS box. The IFNAR1, IFNAR2, IFNGR1, IFNGR2 and the interleukin (IL)-10 receptor constitute the type II cytokine receptor family, based on a characteristic 200–amino acid extracellular domain (13). These receptors have no inherent enzyme activity, but on ligand binding generate cytoplasmic signals in combination with JAK tyrosine kinases and STAT proteins. Members of this family in general have a ligand binding chain with either low or high affinity, and at least one chain involved in signal transduction, which has either relatively low binding affinity for the cytokine or no detectable binding activity at all. Receptor activation by this family of cytokines requires the ligand-dependent interaction between receptor subunits to form oligomers.

3. Signal Transduction by IFNs Through the JAK-STAT Pathway

IFNs elicit their biological effects by transducing a signal to the nucleus, which results in selective gene expression (14, 15). ISGs are a family of genes that are transcriptionally activated within minutes by IFNs. ISG transcriptional activation is regulated through the tyrosine phosphorylation of STAT proteins (for *S*ignal *T*ransducers and *A*ctivators of *T*ranscription), which is mediated by members of the Janus family of nonreceptor protein tyrosine kinases (JAKs) (16-19). JAKs are so named because they have a functional kinase domain as well as a second kinase-like domain, and hence are two-faced like the Roman god Janus. JAKs constitutively associate with membrane proximal regions of the intracellular domains of IFN receptor subunits to provide catalytic activity and transduce intracellular signals by phosphorylating a variety of substrates on tyrosine residues (20). In the case of the type I IFN receptor, the TYK2 and JAK1 Janus kinases are constitutively bound to the IFNAR1 and IFNAR2 subunits, respectively (8, 21). On ligand binding the JAKs cross-phosphorylate each other, with Tyk2 becoming phosphorylated first on type I IFN addition. In the case of the IFNg receptor, the JAK1 and JAK2 kinases are constitutively bound to the IFNGR2 and IFNGR1 subunits, respectively, and on ligand binding JAK1 appears to be activated first (22, 23). The activated JAKs phosphorylate specific tyrosine residues within the cytoplasmic tails of the IFN receptor chains to provide docking sites for STAT proteins (24, 25). STAT proteins are transcription factors and hence contain DNA-binding domains (with the exception of STAT2, which apparently can only function in a complex with STAT1). STAT proteins also contain src homology-2 (SH2) regions (19), which are modular noncatalytic domains of about 100 amino acids that are found in various cytoplasmic signaling proteins. SH2 domains recognize phosphotyrosine motifs, with specificity dictated by the primary sequence immediately COOH-terminal from the phospho-Tyr (26). The separate docking sites for the binding domains of SH2 domains from different signaling molecules have been mapped on many receptors and cytoplasmic signaling proteins.

Type I IFNs activate STAT1 and STAT2 by inducing their phosphorylation on discrete tyrosine residues. These STATs dimerize, complex with a 48-kDa DNA-binding protein, and then move into the nucleus, recognizing a highly conserved IFN-stimulus response element (ISRE) in the promoter of ISGs to directly activate these genes (27, 28). This conserved 15-base pair element (consensus: AGTTTCNNTTTCNC/T) is present in the promoters of nearly 20 type I IFN-inducible genes examined so far and is both necessary and sufficient for gene induction.

As an added complexity, some type I IFN-inducible genes like IRF-1 do not contain an ISRE and are activated by STAT1 dimers (29). Type I IFNs also activate STAT3, the transcription factor for acute phase response genes. STAT3 recognizes a conserved promoter element found within these genes and is activated by a wide variety of cytokines, suggesting that it may integrate diverse signals into common transcriptional responses (25, 30-32). STAT3 binds directly to the tyrosine-phosphorylated IFNAR1 chain and also undergoes IFN-dependent tyrosine phosphorylation (25). In addition, other members of the STAT family (STAT4, STAT5, and STAT6) have been reported to be activated by type I IFNs in a cell type–restricted manner (33, 34). Although much is known about the role of STAT1-STAT2 dimers in ISG transcriptional activation, the physiological role of other STAT protein complexes in IFN-induced gene expression is not known.

For type II IFNs, a variety of response elements have been described for genes regulated by IFNg. Most notable is the IFNg-activated sequence (GAS, consensus: TTNCNNNAA), which is found in IFNg-induced genes such as the genes for guanylate binding protein, interferon response factor (IRF)-1, and the Fcg receptor I. IFNg induces the oligomerization of the IFNGR1 and IFNGR2 chains of its cognate receptor and the activation of JAK1 and JAK2 kinases (35). The cytoplasmic tail of the IFNGR1 chain undergoes tyrosine phosphorylation and hence provides a docking site for STAT1. Subsequently, STAT1 also undergoes phosphorylation, forms homodimers, translocates to the nucleus, and binds to the GAS element, resulting in the transcriptional activation of IFNg-induced genes. As is the case for type I IFNs, IFNg also activates several members of the STAT family, but the physiological relevance of this remains to be established.

Besides STATs, a number of other *trans*-acting factors (such as IFN-regulatory factors 1 and 2, IFN consensus sequence-binding protein, etc.) also appear to regulate IFN-inducible gene expression. For example, type I IFNs activate nuclear factor kB (NF-kB) (36). Active DNA-binding forms of NF-kB are dimers of various members of the Rel/NF-kB family of polypeptides (p50, p52, c-Rel, v-Rel, RelA, and RelB). NF-kB normally exists as a dormant complex in the cytoplasm through the binding of inhibitor of kB (IkB) proteins. Viruses, cytokines, and lipopolysaccharides induce inactive NF-kB/IkB complexes to dissociate, allowing NF-kB to enter the nucleus and bind DNA. NF-kB binds to sites in the promoters and enhancers of key cellular genes regulating apoptotic, immune, and inflammatory responses. NF-kB suppresses apoptosis (37-40), and hence activation of NF-kB by IFN protects cells from apoptotic death (36). Blockage of NF-kB nuclear translocation and activation by the introduction of super-repressor forms of IkB enhances apoptotic killing by IFN.

The signal transduction pathway activated by many other cytokines is similar to that of IFNs but involves different combinations of JAKs (there are four: JAK1, JAK2, JAK3, and TYK2) and STAT proteins (there are seven STATs). Thus, the IFN-activated JAK/STAT pathway serves as a paradigm for understanding cytokine signal transduction in general. The critical roles that JAK1, TYK2, STAT1, STAT2, and STAT3 play in type I IFN signaling on the one hand, and that JAK1, JAK2, and STAT1 play in type II IFN signaling on the other hand, have been demonstrated through the use of cell lines with defined individual defects in these signaling components (20, 35, 41). Although the tyrosine phosphorylation of STATs is responsible for transcriptional activation of IFN-stimulated genes, serine phosphorylation events are also critical for optimal IFN-induced transcription and for the biological response to IFN (42-45). A variety of serine kinases have been implicated in IFN signaling, including protein kinase C isoforms, the mitogen-activated protein kinase cascade, phosphatidylinositol 3-kinase, RNA-dependent protein kinase (PKR), and protein kinase B (PKB)/Akt (43, 45-50).

4. IFN-Stimulated Genes and Their Functions

Since there is overlap in the signal transduction pathways activated by all IFNs, there is significant overlap in the genes induced by type I and type II IFNs. However, distinctive expression, as well as significant overlap, of gene transcripts regulated by either type I (a, b) or type II (g) IFNs has been demonstrated by the use of oligonucleotide arrays corresponding to more than 6,800 human genes (51). A short discussion of some of the well-characterized gene products induced by IFNs (there are over 30 different products identified so far) follows (52).

a. Protein Kinase R (PKR) This type I IFN-induced protein kinase requires dsRNA for activity. Activated PKR phosphorylates several key cellular proteins, most notably the eukaryotic initiation factor-2a, resulting in the cessation of polypeptide chain initiation. The major cellular function of PKR appears to be growth control by regulating the rates of cellular and viral protein synthesis.
b. 2′,5′ Oligoadenylate Synthetase (OAS) OAS is a family of type I IFN-induced enzymes that require dsRNA as a cofactor. OAS catalyzes the formation 2′-5′ oligoadenylates and thereby activates RNase L, which cleaves viral and cellular RNAs.
c. Mx Proteins Mx proteins are type I IFN-inducible proteins that are involved in the inhibition of myxovirus (such as influenza virus) replication in mice by a poorly defined pathway. Mx genes and proteins have been identified in other species, including humans, but their antiviral activity is broader than that of murine Mx.
d. Indoleamine 2,3-Dioxygenase (IDO) IDO is a type I and type II IFN-inducible intracellular enzyme that degrades tryptophan to kynurenine and plays a role in the inhibition of the growth of intracellular parasites such as *Toxoplasma gondii*.
e. IFN-Regulatory Factor-1 (IRF-1) IRF-1 is a type I and type II IFN-inducible transcription factor that binds to a DNA element found in the IFNb promoter. IRF-1 appears to play a key regulatory role in growth control and tumorigenesis.

f. Class I Histocompatibility Antigens Class I antigens are induced by both type I and type II IFNs and are broadly expressed on almost all cell types. Class I antigens play critical roles in antigen recognition by cytotoxic T cells (CD8+).

g. Class II Histocompatibility Antigens Class II antigens are induced by IFNg and have a restricted tissue distribution (present on B cells, macrophages, and activated T cells). These antigens participate in antigen recognition by helper T cells (CD4+).

5. Conclusion

This article has focused on the present understanding of the highly complex IFN system. IFNs were the first cytokines to be discovered (over 40 years ago) and characterized. Rapid advances have been made in the last decade on the structure and regulation of IFN genes, the characterization and cloning of the components of the multisubunit IFN receptors, and the signal transduction pathways by which IFNs exert their effects. However, many gaps remain in our knowledge. Future work will undoubtedly refine our understanding of this complex cytokine system.

Interleukin-1 Motif

The interleukin-1 motif is a common protein motif found in protein structures. It is present in those of interleukin-1, fibroblast growth factors, and Kunitz-type trypsin inhibitors. The motif is characterized by an unusual pseudo-threefold symmetry. The secondary structure of the interleukin-1 motif has 12 b-strands that form six **hairpins**. Three of the hairpins form a six-stranded **antiparallel b-barrel** with a **hydrophobic** core; the other three form a hairpin triplet structure that caps the barrel (Fig. 1). There is little sequence identity between proteins adopting this three-dimensional structure, apart from a preference for large hydrophobic residues in those regions of the sequence that form the core.

Figure 1. Schematic representation of the backbone structure of human interleukin-1b (1) showing the characteristic fold. Strands are shown as arrows, and connecting loops are in yellow. The three roughly equivalent repeating b-structural uni shown in different colors (red, green, and blue) to highlight their similarity. Two orthogonal orientations are shown. (**Le** The six-stranded b-barrel forms the lower half of the structure and is capped by the triangular array of b-hairpins. (**Right** view is shown looking down the axis of the triangular array and b-barrel showing the pseudo-threefold symmetry of the structure. This figure was generated using Molscript (2) and Raster3D (3, 4). See color insert.

The interleukin-1 motif is sometimes called a b-trefoil, because it can be dissected into three equivalent Y-shaped (or trefoil) b-structural units. However, the b-trefoil terminology should not be confused with the "trefoil peptide domain" that represents a very different structural motif of gastrointestinal protective peptides. Furthermore, it should be noted that the known structures of all other interleukins (apart from interleukin-1) are **four-helix bundles**.

Interleukins

Multicellular organisms are composed of a few hundred cell types whose survival, growth, differentiation, and effector function in specific tissues or organs need to be exquisitely controlled. This is accomplished mostly by a myriad of secreted regulatory proteins, broadly classified as cytokines (1), that are secreted locally and modulate the cell physiology of each tissue. Cytokines embrace a wide variety of regulatory proteins that include growth factors, colony-stimulating factors, interleukins, lymphokines, monokines, and interferons . Typically, the molecular masses of cytokines range from a few thousand to a few tens of thousands. Cytokines, in contrast to hormones, are synthesized locally in a transient manner, often by a variety of nonspecialized cells, and function locally at their sites of production. In general, their half-life is short. Classical hormones (eg, insulin), on the other hand, are produced by specialized cells within particular organs, are disseminated throughout the body via the circulatory system, and act at a distance from their sites of production.

The interleukins constitute a subset of cytokines that are produced by and regulate cells involved in immune defense mechanisms. The generic term interleukin (IL) and a corresponding numbering system of nomenclature were introduced in 1979 (2) to reflect that these regulatory proteins are communicating signals for leukocytes, and not just lymphocytes. However, this system has not been completely successful, because now it has been shown that some interleukins may be produced by nonleukocytes and act on other cell types. At present, new leukocyte regulatory proteins are always assigned IL numbers upon establishing a gene sequence. IL-18 is the most recent.

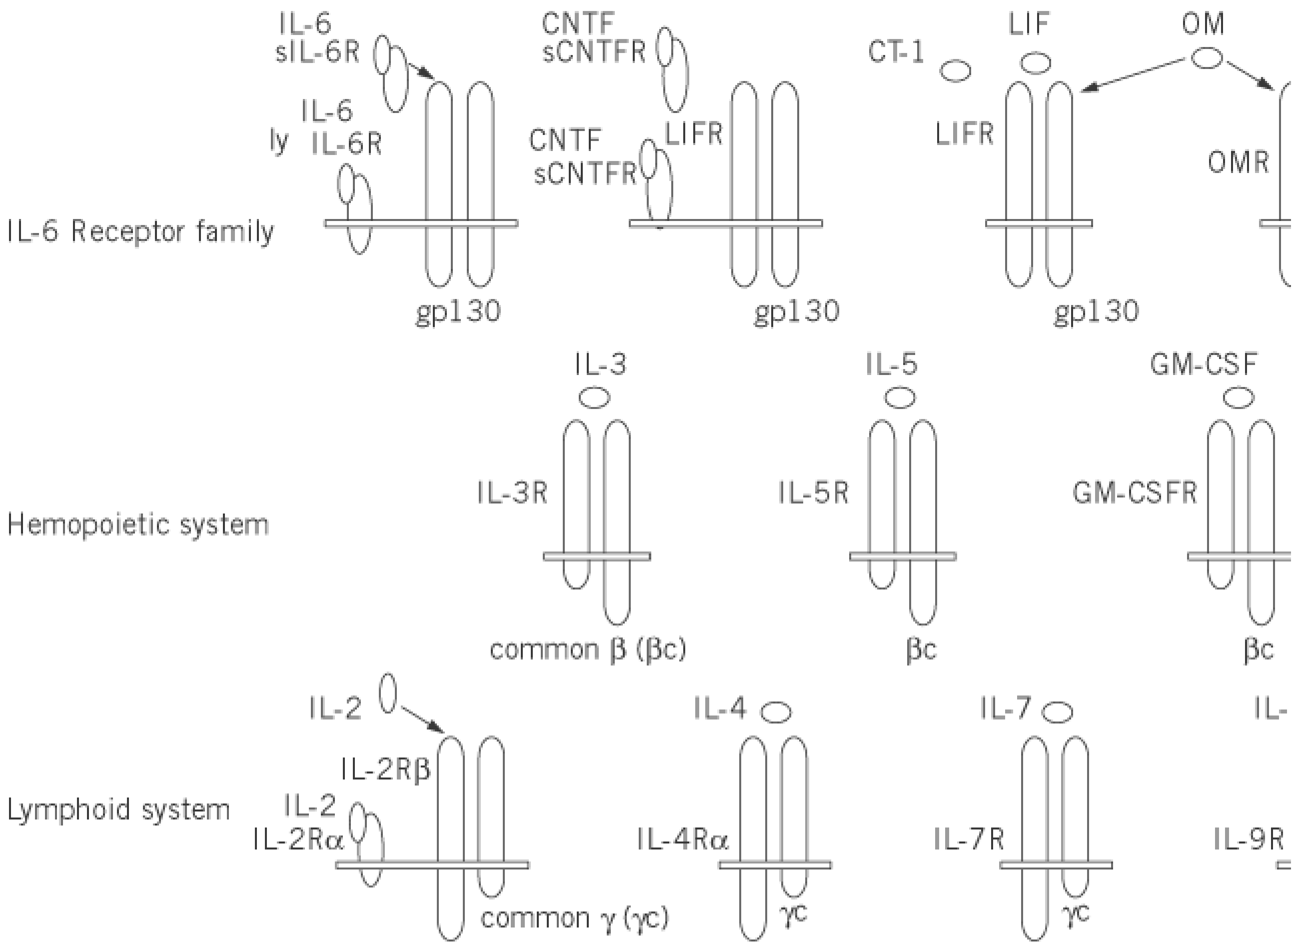
1. General Properties of Interleukins

Table 1 lists the major biological actions of the interleukins. These proteins, which have been characterized most thoroughly in the human and mouse systems, are noted for their pleiotropy and redundant biological activity. The receptors for many of the interleukins, such as IL- 1, -2, -3, -5, and -6, have been well characterized. Typically, they consist of multiple protein subunits. Shared signalling receptor subunits are seen for a number of cytokines, for example, IL-3/IL-5/granulocyte-macrophage colony stimulating factor and also IL-2/IL-4/IL-7/IL-9/IL-15 (see Fig. 1.). To illustrate this further, Fig. 1 shows the structure of the IL-6 receptor complex as a paradigm for the interleukins. The biological activity of IL-6 is exerted upon binding with low affinity to its cognate receptor (IL-6 receptor or alpha-subunit) located on the surface of its target cells. Then, the low-affinity IL-6/IL-6 receptor complex binds with high affinity to the beta-subunit of the receptor complex, the **signal-transducing** molecule gp130, to exert the biological activities of this interleukin. The subunit gp130 is also shared by IL-11 and even other cytokines (eg, ciliary neurotrophic factor, leukemia inhibitory factor, oncostatin M, and cardiotropin-1) which, in part, explains the overlapping activities of these cytokines at the molecular level.

Table 1. Biological Actions of the Interleukins

Interleukin	Action	References
IL-1a/b	Stimulates thymocyte proliferation; acute phaseresponse	5, 6
IL-2	Supports proliferation and activation of T lymphocytes	7
IL-3	Stimulates hematopoiesis; production of cells in all myeloid lineages	8
IL-4	Stimulates proliferation of B lymphocytes	9
IL-5	Activation and differentiation of eosinophils; accessory factor neutrophils	10, 11
IL-6	Stimulates hemopoietic progenitor cells, B-lymphoid, and myeloma cells; induction of acute phase protein synthesis in the liver	12, 13
IL-7	Stimulates proliferation of thymocytes, T lymphocytes including cytotoxic T cells, and early B-lymphocyte precursors	14
IL-8	Stimulates chemotaxis by neutrophils and other cell types	15
IL-9	Stimulates growth of T-lymphoid cell lines; activation of mast cells; potentiates prolferative effect of IL-2 on fetal lymphocytes	16
IL-10	Suppresses cytokine production by T lymphocytes	17, 18
IL-11	Hematopoietic growth factor; induces acute phase protein synthesis	19
IL-12	Stimulates cytokine production by natural killer cells and T cells	20
IL-13	Regulates the function of monocytes and B cells; anti-inflammatory action	21
IL-14	Stimulates proliferation of B cells	22
IL-15	Stimulates proliferation of T cells	23
IL-16	Lymphocyte chemoattractant factor; modulates T-cell activation	(24)
IL-17	Stimulates production of proinflammatory and hemopoietic cytokines in epithelial, endothelial, fibroblastic, or stromal cells	25
IL-18	Stimulates proliferation of T cells; induces IFN-g production	26

Figure 1. Structure of the Inteleukin-6 receptor complex as a paradigm for interleukins. IL-, interleukin; R, receptor; CN
leukemia inhibitory factor; OM, oncostatin-M, GM-CSF, granulocyte macrophage-colony stimulating factor; gc, commo



The signal-transduction mechanisms used by the interleukins is presently being unraveled. Although binding of interleukin to its cognate receptor complex stimulates protein **tyrosine kinase** activity, the receptors themselves do not possess any intrinsic tyrosine kinase activity. Rather, nonreceptor tyrosine kinases, such as members of the **src** and **JAK** families, may become associated with the interleukin receptor signaling subunits (typically, binding a ligand to its receptor induces the dimerization of signaling subunits) leading to phosphorylation of tyrosine residues of the signalling subunit. These events lead to the activation of multiple signal-transduction pathways, such as the **STAT**, Ras-**MAP kinase** and phosphatidyl inositol kinase pathways (3, 4).

Recent reviews for all of the interleukins that outline their role in pathogenesis and disease therapy are listed in Table 1. Other features of the interleukins are listed in Table 2. For access to current information regarding the interleukins (as well as other cytokines), the reader is referred to the following internet web sites:

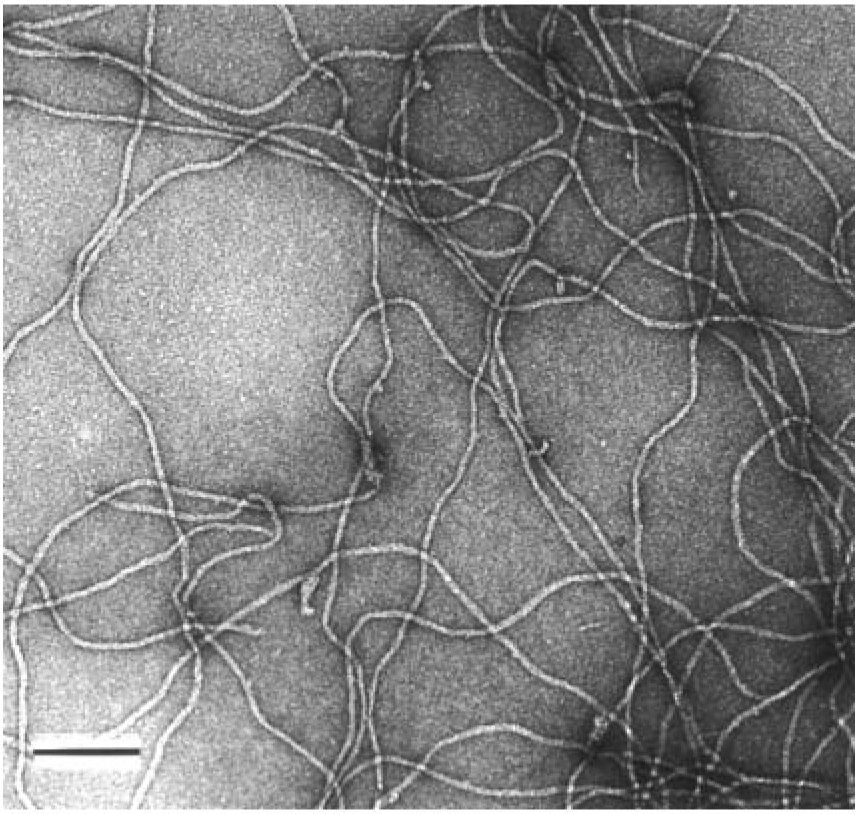
Intermediate Filaments

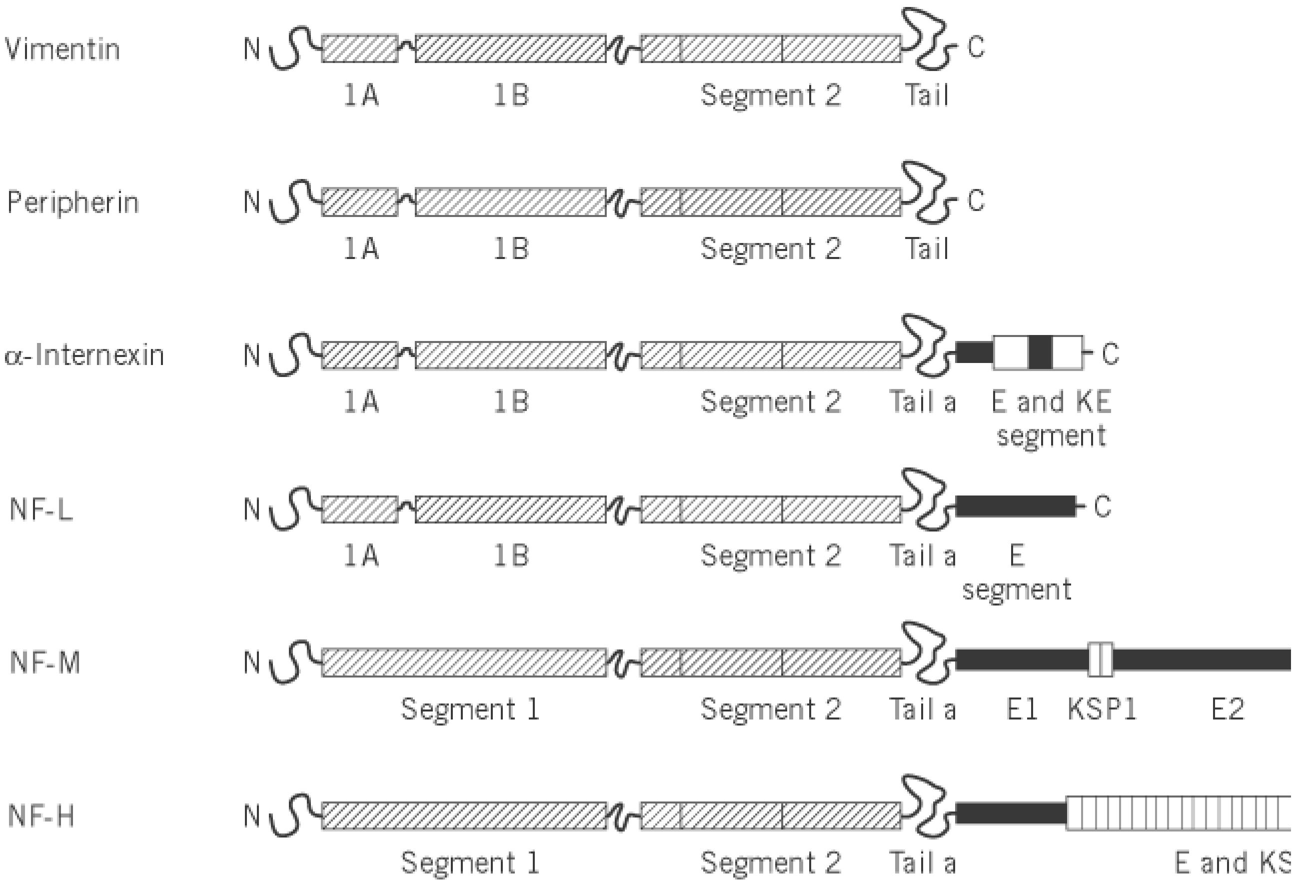
Intermediate filaments (IFs), which are about 10 nm in diameter, are so named because they were thought to be intermediate in size between the well-known microtubules and the **actin**-containing microfilaments. They are ubiquitous components of virtually all eukaryotic cells (Fig. 1), being found not only in the **cytoplasm** but also within the cell nucleus. The IF are dynamic structures capable of assembling and disassembling during cell division and of making and breaking interactions with microtubules, microfilaments, and other cellular components.

Figure 1. Electron micrograph of vimentin IF showing long sinuous filaments about 10 nm in diameter. Bar = 100nm. (From Ref. 4, with permission.)



Sequence analysis of IF protein chains has shown common and variable **domains**. In essence, each protein has a largely conserved central, **heptad repeat**-containing domain that separates regions at either end of the chain that are chemically and structurally diverse (Fig. 2). These similarities and differences, together with subsequent data on their **gene** structures, have allowed a simple classification system to be formulated. Type Ia and IIa IF chains occur in hard a- keratin, type Ib and IIb chains occur in epidermal keratin, type III chains occur in **desmin, vimentin**, glial fibrillary acidic protein and peripherin, type IV chains occur in a-internexin and light-, medium- and heavy-neurofilament chains, type V chains occur in the nuclear **lamins**, and type VI chains occur in nestin. The lamin group is unique in their nuclear localization and in the insertion of six additional heptads within the central domain. (Note, however, that invertebrate IF also contain a six-heptad insert in the same place.) One IF family, the cytokeratins, is discussed in detail in that entry. The keratins form obligate heterodimeric structures (type I/type II) in contrast to the homodimeric conformations of type III IF (and type IV and type V IF too). Nonetheless, heterodimers of the form III/IV and III/VI are also found *in vivo* . The heptad-containing regions thus form a coiled-coil rope of predicted length 45.7 nm in hard a-keratin, 46.2 nm in epidermal keratins, and 45.3 nm in vimentin, other type III molecules and in type IV molecules too. Type V IF molecules are about 52 nm in length. The values for epidermal keratin and vimentin are determined from an analysis of the disposition of the residues that are cross-linked (1-3). Electron micrographs of rotary shadowed IFs have been obtained that are in agreement with these values. Scanning transmission electron microscopy (STEM) data indicate that native IFs *in vivo* contain about 32 chains in cross section, although some aggregates with about 16, 24, and 40 chains have also been observed *in vitro*. This has been taken to indicate that the IF may contain an eight-chain protofibrillar substructure. *In vitro* two, three, four, or five such protofibrils may aggregate, but *in vivo* it seems more probable that only the 32-chain (four-protofibril) possibility occurs. The data thus show that the rod domains form the core of the IF and that the *N*- and *C*-terminal domains lie on the surface, where they may interact with other elements of the cell. As noted before, some types of IF in either the cytoplasm or the nucleus are able to assemble and reassemble during certain stages of the cell cycle, most particularly **mitosis**. It now seems clear that **phosphorylation** generally plays a significant role in this process. Almost all IF chains contain phosphorylation sites in their *N*- and *C*-terminal domains. Phosphorylation resulting from the action of a range of possible **kinases** results in the disassembly of preformed IF or prevents formation of IF *in vitro*. Conversely, dephosphorylation allows reassembly to proceed. The complete story is somewhat more complicated than indicated here, but without doubt phosphorylation/dephosphorylation plays a central role in regulating the formation of IF.

Figure 2. Domain structures of intermediate filaments of type III (vimentin and peripherin) and type IV (a-internexin an While the rod domains of all IF proteins, segments 1 (or 1A and 1B) and 2, are **homologous** (though distinct), the *C*-tern proteins display considerable variation. KSP, for example, refers to the multiple Lys–Ser–Pro motifs that are important a glutamic acid-rich regions.(From Ref. 4, with permission.)



IF function has long been a controversial topic, but real progress has been made in recent years. Consider, for example, just one of the IFs, namely, neurofilaments. The long, highly phosphorylated *C*-terminal domains in the medium and heavy neurofilament chains (NF-M and NF-H) are critically involved in determining the caliber of the axon, as well as its organization and function. The *C*-terminal sequences, when phosphorylated, are believed to control slow axonal transport down the microtubule and to have enhanced flexibility that allow them to modulate the density of the neurofilaments, as well as their separations. Overexpression of NF-L and NF-H produce experimental phenotypes that resemble motor neuron disease. Furthermore, mutations in the 52 –Lys–Ser–Pro–phosphorylation sites in the *C*-terminal domain of NF-H are the proximal cause of some cases of sporadic amyotrophic lateral sclerosis. The *C*-terminal domains of the NF-M and NF-H chains are known to interact with the *C*-terminal ends of the a- and b-tubulin subunits in microtubules, although microtubule-associated proteins such as q (**tau protein**) and MAP2 are also believed to be intimately involved in this phosphorylation-regulated interaction. Terminal domains in other IF proteins are also important in specifying their functions.

Intermediate Junction

The intermediate or adherens junction (see Cell Junctions) is a cell–cell adhesive that occurs in a number of different forms. The category includes the zonula adherens of simple epithelial cells (1), forming a subapical ring beneath the tight junctions, spot-like punctae adherentes (2) of small intestinal mucosa, and the ribbon-like fasciae adherentes of the intercalated discs of cardiac muscle

(3). Ultrastructurally, these junctions are characterized by membrane separation of 20 nm and a cytoplasmic plaque or membrane undercoat that is associated with the actin or microfilament cytoskeleton. The principal functions of adherens junctions are (i) cell adhesion, (ii) organization of the basolateral domain/terminal web of epithelia, (iii) signal transduction, and (iv) contractility.

The principal adhesion molecules of adherens junctions are classical cadherins such as E-cadherin and *N* -cadherin (Figs. 1 and 2) (4). These mediate homophilic binding between the apposed plasma membranes of adjacent cells. The cytoplasmic domains of cadherins are linked to the actin cytoskeleton via molecules known as **catenins** (5). b-Catenin is a member of the armadillo family of junctional/signaling molecules (6); a-catenin is an actin-binding protein that binds to E-cadherin via b-catenin (7). a-catinin is related to vinculin, another actin-associated protein located in intermediate junctions (8). Alternatively, g-catenin or plakoglobin may participate in this linkage in place of b-catenin. A large number of other proteins that participate in actin cytoskeletal assembly and function have also been found in association with junctions of the adherens type (see Table 1). The actin filaments extend toward the membrane with the barbed ends outwards after heavy myosin decoration. Several candidates for actin-capping and -binding proteins are present. These include vinculin, ezrin, radixin and moesin, and a-actinin (9). E-cadherin may be found in epithelial cells as a complex with fodrin, adducin, and ankyrin, members of the submembrane cytoskeleton. The latter group of molecules also form complexes with the basolaterally located sodium potassium Na^+/K^+ ATPase. These associations between adhesive components of the adherens junction and components of the membrane cytoskeleton of the basolateral epithelial cell membrane are believed to be important in establishing epithelial cell polarity (10). It is significant that the **tyrosine kinases** c-src and c-yes associate with the junction, since tyrosine **phosphorylation** appears to be an important regulator of the adhesive function of E-cadherin and adherens junctions. In particular, tyrosine phosphorylation of b-catenin had been shown to down-regulate the adhesive function of the junction, resulting in loss of cell adhesion, and to promote invasive behaviour on epithelial cells (11). Tyrosine phosphorylation of another armadillo protein, p120, also appears to regulate junctional adhesion (12). Association of the epidermal growth factor receptor (EGF-R) tyrosine kinase with b-catenin has been reported (13). This emphasizes the role of tyrosine phosphorylation in regulating the function of the junction.

Figure 1. Zonulae adherentes of mouse small intestine stained with a monoclonal antibody to E-cadherin. The zonula form of the junction is evident in transverse sections of cells (arrowheads). In vertical sections, the concentration of stain in the junctions is clearly seen (large arrows), as well as the presence of weaker staining along with the entire lateral borders of the cells (small arrows).(Reproduced from Ref. 23, with permission of Chapman and Hall.)

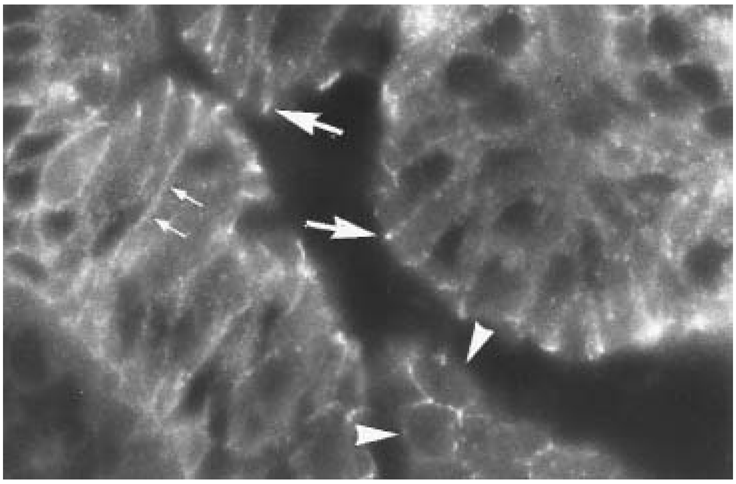

Figure 2. Diagram showing the various cellular roles of the adherens junction protein b-catenin. (1) b-Catenin associates with the cytoplasmic domain of the adhesion molecule, E-cadherin where its function is to provide a regulatory link, via a-catenin, to the actin cytoskeleton. This link is essential for the adhesive function of E-cadherin in the intermediate junction. (2) Cytoplasmic b-catenin, when phosphorylated by GSK3b, associates with APC protein and is degraded. (3) Wnt or wingless signaling inhibits GSK3b, allowing unphosphorylated b-catenin to associate with LEF-1 transcription factor to enter the nucleus and regulate gene activity.

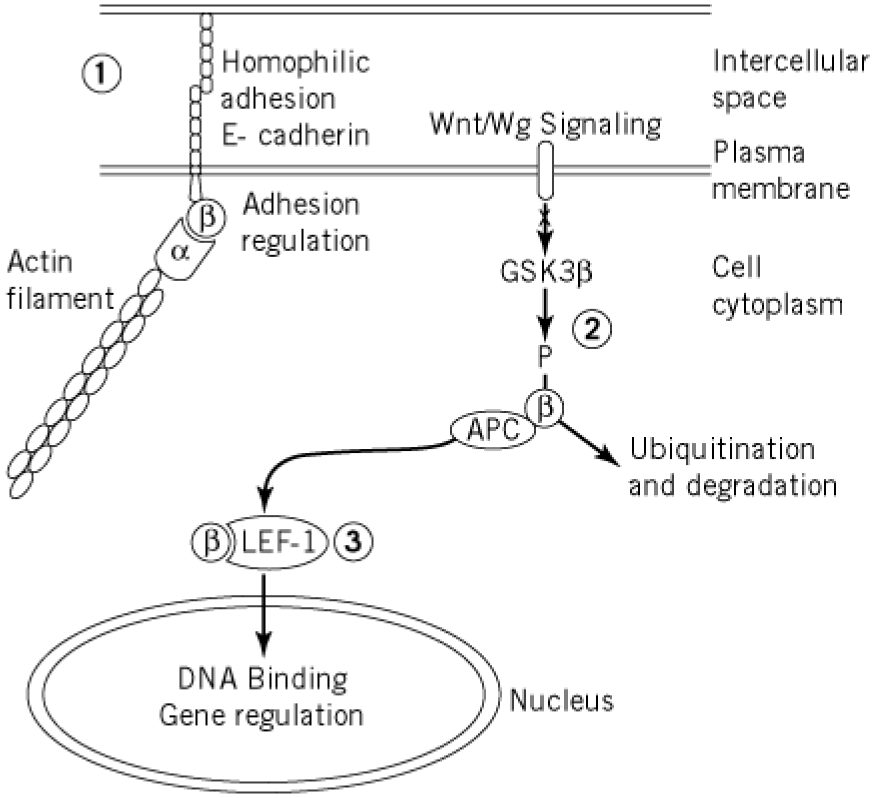

Table 1. Components of the Zonula Adherens Junction in Simple Epithelial Cells[a]

	MW (M_r) ($\times 10^3$)	Function
E-cadherin	120	Calcium-dependent cell adhesion molecule.
b-Catenin	88	Mediates E-cad, binding to cytoskeleton. Signaltransduction.
Plakoglobin (gamma-catenin)	83	Mediates E-cad, binding to cytoskeleton. Signaltransduction.
Armadillo (*Drosophila*)	116	Mediates cad binding to cytoskeleton. Signaltransduction.
p120	120	Signal transduction.
Vinculin	130	Actin-associated protein.
a-Catenin	102	Links E-cad, to cytoskeleton via b-cat.
a-Actinin	100	Actin binding protein.

Ezrin	85	
Radixin	82	Membrane-actin cytoskeleton interaction
Moesin	75	
Fodrin (spectrin)	240 / 220	Membrane skeletal protein: binds ankyrin, actin,band 4.1, adducin.
Ankyrin	200–220	Links membrane to cytoskeleton
Protein 4.1	78	Links spectrin to actin and membrane.
Adducin	103+93	Mediates actin-spectin binding.
Zyxin	82	Actin binding (via a actin).
Tropomyosin	35	Actin binding.
Myosin II	260	Actin binding contractile.
c-src	60	Tyrosine kinase
c-yes	60	Oncogene products

[a] The proteins in this table may be found to be associated with cell–cell adhesive junctions of the zonula adherens type but are not restricted to the zonula adherens.

b-Catenin, like other members of the armadillo family, including plakoglobin or g-catenin and the *Drosophila* armadillo protein itself, have a dual function as adherens junction components and in signal transduction and the regulation of gene activity. These proteins participate in the wingless signaling pathway in *Drosophila* and the Wnt pathway in vertebrates. Thus, both b-catenin and g-catenin have been shown to cause axis duplication when overexpressed in Xenopus embryos (14). Furthermore, each may form a complex with the LEF-1 transcription factor and enter the cell nucleus to regulate gene expression (15). The adenomatous polyposis coli (APC) **tumor suppressor** protein, another member of the armadillo family, is important in regulating the cytoplasmic level of b-catenin. Thus, b-catenin may associate either with E-cadherin at the cell surface or with APC (16). In the latter complex, it is targeted for attachment to ubiquitin and **protein degradation**. This complex forms when b-catenin is phosphorylated by the **serine-threonine kinase** glycogen kinase synthase kinase-3 b (GSK3b). However, dephosphorylation causes dissociation of the b-catenin-APC complex and increases the cytoplasmic level of b-catenin. This promotes complex formation with T-cell-factor/lymphoid enhancer-binding factor 1 (TCF/LEF-1) and entry into the nucleus. Activation of this signaling pathway may occur either by Wnt signaling or through mutation of APC (17). Mutations of the latter are associated with familial adenomatous polyposis coli, where patients form numerous colonic polyps, an important risk factor in colorectal cancer. The equivalent pathway in *Drosophila*, the wingless signaling pathway, is important in development of segment polarity (18). Mutations of E-cadherin and b-catenin are also important in tumor promotion. Inherited mutations in E-cadherin have been shown to predispose affected individuals to carcinomas (19).

The contractile function of the actin microfilament ring associated with adherens junctions is important in aspects of morphogenesis during embryonic development. In neural tube rolling in the amphibian embryo, for example, contraction of apicolateral microfilament rings in the cuboidal epithelial cells of the neural plate results in curvature of the epithelium by narrowing of the apical surface (20, 21). The adhesive components of the adherens junctions to which the microfilament rings attach bind the cells together. It has also been shown that reagents, such as cytochalasin, that affect actin microfilament assembly modulate the permeability of tight junctions (See Tight Junction) in simple epithelia. This may indicate that the zonula adherens plays a role in regulating the function of tight junction (22).

Internal Guide Sequence

In the group I self-splicing introns, the 5′ splice site is determined by the formation of intramolecular base pairing (1). The site is located in the 5′ half of the stem in a stem-loop structure known as P1. A short, **intron**-encoded sequence in the 3′ half of the P1 stem is called the internal guide sequence (or

IGS) and pairs with the end of the 5′ exon (see "Splice Sites"). The name suggests that it binds to both splicing junctions to bring the two exon ends together, but this original idea has been proven to be unnecessary. The functionally similar element in group II introns is the exon-binding site (or EBS). Intron-encoded guide sequences have also been observed at the RNA Editing sites of glutamate receptors by the double-stranded RNA adenosine deaminase.

In connection with the RNA world hypothesis, a resemblance between the **codon-anticodon** interaction and the IGS-exon pairing has been pointed out (2). It has been reported that an **fMet-**oligo RNA in which the RNA sequence is complementary to an artificial IGS created in a group I intron-derived **ribozyme** can be hydrolyzed at the acylation bond, mimicking a prototype of **peptidyl transfer**.

Internal Ribosome Entry Site (IRES)

Most eukaryotic messenger RNAs have the Cap structure at 5′ termini (see Cap), where 40 S **ribosomal** subunits enter the mRNA with association with the eIF-4F complex (cap-binding protein complex; see Initiation Factor (IF)). The 40S initiation complex then scans the 5′ untranslated region (or 5′UTR) to find the initiation codon (see Scanning Hypothesis). The mRNAs of picornaviruses, represented by poliovirus, however, have no 5′-Cap structure, but contain an internal ribosome entry site (IRES) on the 5′-untranslated region (UTR), which functions as an alternative entry site for the ribosome (1). Upon infection, poliovirus produces a proteinase that cleaves eIF-4G, the largest subunit of eIF-4F, thereby shutting down the Cap-dependent initiation of cellular mRNAs, while activating the viral translation by IRES-dependent initiation. Picornavirus mRNA has a long 5′UTR (600 to 1200 nucleotides), and the IRES corresponds to the 3′ proximal 450-nucleotide region that involves multiple stem-loop structures (Fig. 1). One motif that may act as the actual ribosome binding site is a pyrimidine-rich region of about 20 nucleotides preceding an AUG triplet with a spacer of 20 to 25 nucleotides. In some types of picornavirus, including poliovirus, ribosomes do not initiate translation at this AUG triplet but at the next available AUG. On the other hand, the other picornaviruses, such as encephalomyocarditis virus, initiate translation at the first AUG. The IRES-dependent initiation requires a subset of ordinal initiation factors, as well as specific cellular factors such as La protein and polypyrimidine-tract binding protein. Viruses other than picornavirus, such as hepatitis C virus (HCV) and plant RNA viruses, also contain IRES. In addition, at least two cellular mRNAs, **antennapedia** mRNA of *Drosophila* and BiP mRNA of mammals, show IRES activities. No sequence resemblance has been noted among the IRES of picornavirus, HCV, and the cellular mRNAs.

Figure 1. Schematic representation of the predicted stem-loop structure of the poliovirus IRES (1).

Interspersed DNA Elements

To understand the architecture of the human genome, we need a complete definition of all *interspersed DNA elements*, the families of sequences repeated throughout the genome, as these make up the majority of human DNA. These repeat sequences are arbitrarily classified into CpG Islands, Sines (short interspersed DNA sequence elements comprising Alu sequences in primates), Lines (long interspersed DNA sequence elements), **minisatellites** and **microsatellites**. All these entities are repeated many times in the genome, and are arbitrarily defined as about 10^4 copies or more per **diploid** genome.

Introns, Exons

Introns are sections of primary RNA **transcripts** that are removed as part of the maturation of functional **messenger** RNA or, rarely, of ribosomal RNA. They are also known as *intervening sequences*. The sections between the introns that are retained in the mature RNA product are called *exons*. Introns occur very widely in the nuclear genes of **eukaryotes**, and nuclear introns command the most attention. But there are two other, rather different kinds of intron, called **Group I** and Group II, that have been found in eukaryotic **organellar** genomes and occasionally in **bacteria** and **bacteriophage**. Introns of another kind have been found in a few species of **Archaebacteria** (1), but these are not covered in this article.

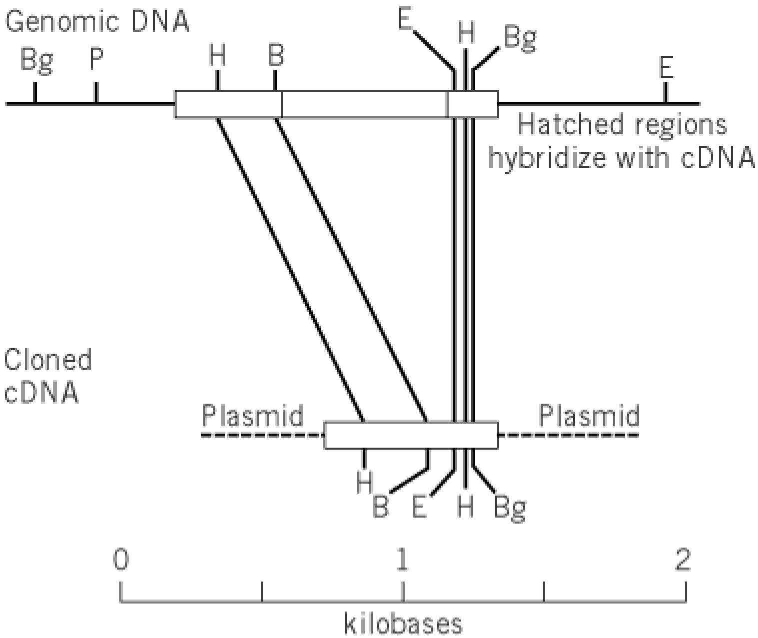
1. Eukaryotic Nuclear Introns

1.1. Occurrence and Detection

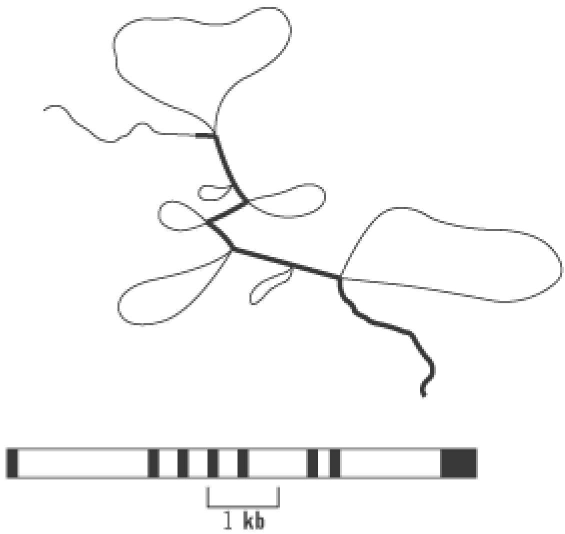
Introns are found in some **genes** of all eukaryotes thus far studied, but their frequency and average size increase enormously as genomes become larger and organisms more complex. In the budding **yeast** *Saccharomyces cerevisiae*, most genes do not have introns, and, where they occur, the introns are seldom more than 100 bp long. In filamentous **fungi**, such as *Neurospora* and *Aspergillus*, most genes that have been sequenced so far have introns but seldom more than two or three and usually in the size range 50 to 100 bp. The nematode worm *Caenorhabditis elegans* has some much longer introns, but the transcribed sequences still consist mostly of exons. In the fruit fly *Drosophila* many genes are interrupted by long introns, sometimes kilobases long. In mammals most genes are often expanded 100-fold or more by numerous introns that far exceed the exons in average length, though their coding sequences may not amount to more than a few kilobases. Some examples of exon/intron proportions and arrangements from a number of representative eukaryotes are presented in the article on Gene Structure.

Introns are defined by comparisons between the sequences, or restriction maps of chromosomal (genomic) DNA and complementary DNA (cDNA) obtained by **reverse transcription** of processed mRNA. cDNA is also used as a probe to search for homology with ordered genomic restriction fragments. Some of the first discovered introns were made visible by electron microscopy of artificially constructed genomic DNA/cDNA or genomic DNA/mRNA heteroduplexes. The introns appeared as unpaired single-stranded loops (Fig. 1). Shorter introns are identified, at least tentatively, as segments interrupting **open reading frames** with intron consensus sequences at their ends (Table 1).

Figure 1. Two ways of detecting introns (**a**) Comparison of restriction-site maps of the rabbit b-globin gene and cDNA, reverse transcribed from the b-globin messenger RNA (2). A second, smaller intron was not revealed by this analysis and is not shown in the diagram. (**b**) The appearance of a heteroduplex formed between chicken ovalbumin gene DNA and its mRNA, drawn from the electron micrograph of Dugaiczyk *et al.* (3).



(a)



(b)

Table 1. Intron Consensus Sequences in Various Organisms [a], [b]

Organism	5′ Splice	Branch Point	3′ Splice
Vertebrates	AG/*GU*AAGU	UNCUR*A*C	(Y-rich)NC*AG*/G
Saccharomyces	AG/*GU*AUGU	*UACUAAC*	(Y-rich)*YAG*/
Plants	AG/*GU*AAGU	UA-rich	(U-rich)UGC*AG*/GU

[a] From Ref. 4.

[b] Key: Y = pyrimidine; R = purine; N = any nucleotide. underlined residues are invariant, or nearly so. The slash (/) divides exon from intron.

Although the internal sequences of nuclear introns bear no relationship to each other (or, indeed, to anything else), they show some consensus at or near to their 5′ and 3′ (i.e., upstream and downstream) termini, sometimes called the donor and receptor sites (Table 1). At the upstream end, the consensus is 5′-GUAUGU for *Saccharomyces* and 5′-GUPuAGU in mammalian introns. The GU is nearly universal, and the following bases are somewhat variable (U in the messenger RNA corresponds to T in the DNA coding strand). Introns are terminated virtually universally at their downstream (3′) ends by YAG (Y for pyrimidine), usually immediately preceded by a pyrimidine-rich sequence. Some 15 to 40 bp upstream of the 3′ AG is a sequence called (for reasons that will emerge) the *branch point*, which in yeast has the invariant sequence 5′-UACUAACA, reduced in other fungi to CURAC, and represented in mammals by the barely recognizable YXYYRAY (X standing for any base and R for either purine). The conserved A is most important. The somewhat different consensus sequences in different groups of organisms are shown in Table 1).

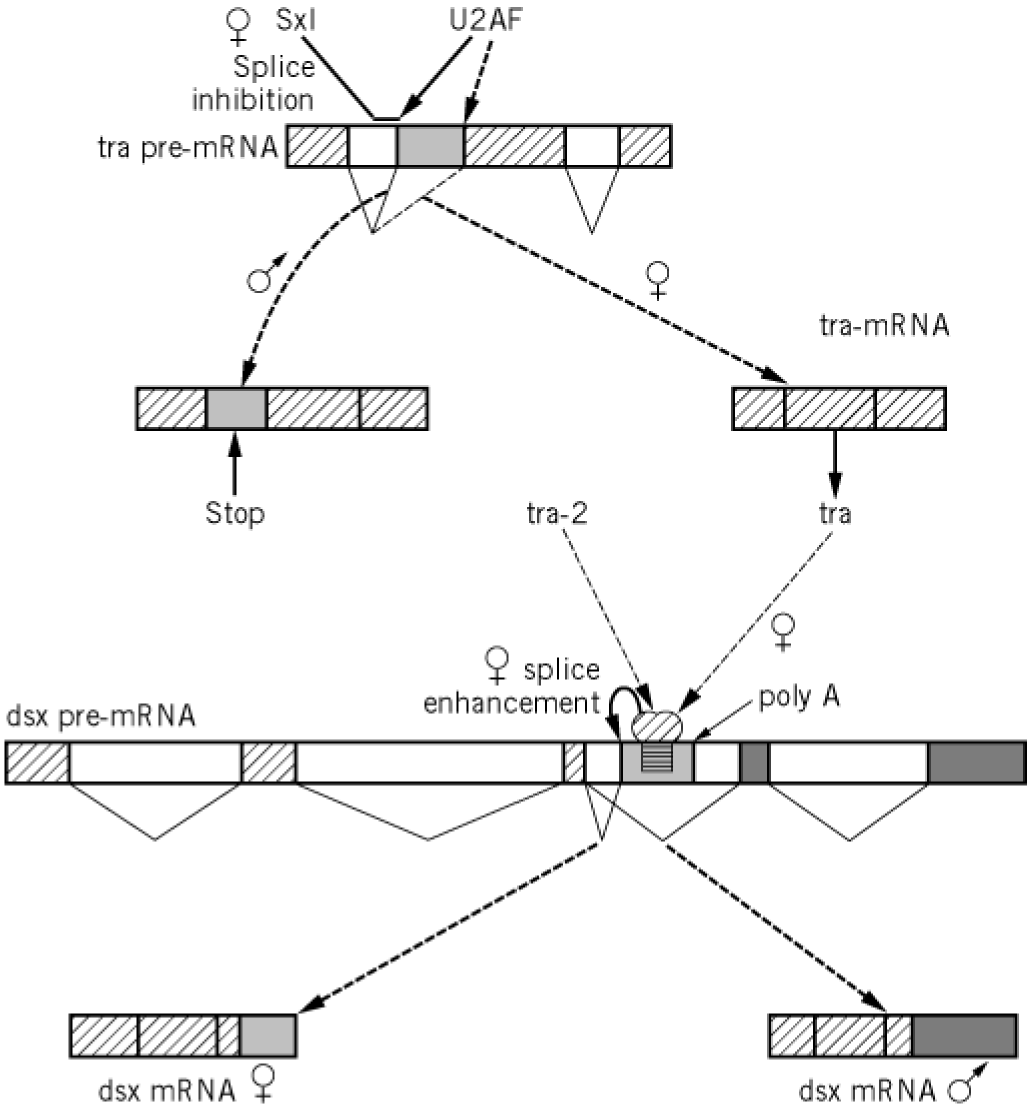
Intron excision occurs in two steps. First, the upstream guanosine 5′-phosphate is cleaved from the upstream exon and condensed with the 2′-hydroxyl group of the branch-point adenosine to form a loop, often called a **"lariat" structure**, still joined to the downstream exon (see Fig. 4 later). Then the freed 3′-hydroxyl of the upstream exon attacks the phosphate diester link between the lariat and the downstream exon to free the lariat and join the two exons. This sequence of interactions is catalyzed by an array of five **small nuclear ribonucleoprotein** complexes (snRNPs), U1, U2, U4, U5, and U6, each of which contains a short unique RNA molecule and a number of proteins, some of which, the Sm proteins, are RNA-binding. Collectively the U complexes form a supercomplex, called the spliceosome.

To a considerable extent, the process of splicing can be explained in terms of **Watson–Crick base pairing** between RNA sequences, shown by suppression of the effects of **mutation** in splicing sequences by compensating changes in U-RNAs or by chemical cross-linking of the paired sequences. Just as with **codon**–anticodon pairings in messenger RNA translation, most of the RNA–RNA pairings must be too weak to hold by themselves, and presumably they act by guiding much stronger protein–RNA and protein–protein interactions, about which much remains to be learned. The course of events has been most thoroughly worked out for *Saccharomyces*. With only minor variations, it is the same in mammals and presumably in eukaryotes generally. (see **Splicing RNA**).

1.2. Splicing Options

Some intron excision is regulated in all eukaryotes that have introns in tissue or cell-specific ways. Thus, in *Saccharomyces* yeast, which has relatively few introns, the splicing-out of the intron in the *MER1* gene, which functions in meiotic recombination, depends on the protein product of the **meiosis**-specific *MER2* (5). In *Drosophila*, one of the three introns in the transposase gene of the mobile **P-element** is spliced out only in the **germ line**, which explains why the element does not transpose in somatic tissues (6). Sexual development in the fly depends on a splicing cascade. The *Sexless* (*Sxl*) gene product, produced only in females, promotes both the splicing of its own pre-mRNA and that of the *transformer* (*tra*) gene, so that the latter encodes a protein which, acting together with the product of another gene *tra2*, splices the sexless (*sxl*) pre-mRNA to produce mRNA for female development (Fig. 2). The alternative ("default") splicing option is female-determining (8). In mammals that have their abundant introns, the splicing of pre-mRNAs in different ways in different tissues is almost more the rule than the exception. Two other examples of alternative patterns of pre-mRNA splicing are illustrated under Gene Structure and Interallelic Complementation.

Figure 2. Two examples of splicing option control from *Drosophila*. (**a**) The female-specific *Sxl* (*sex-lethal*) protein binds at the 3′ end of intron 1, blocking the otherwise favored male splicing option and diverting splicing action of U2AF to a splice site in exon 2, bypassing a stop codon and allowing formation of functional female-specific mRNA. See text for further explanation. (**b**) *tra-2* and female-specific *tra* proteins bind to a splicing-enhancer region (shown horizontally hatched) in exon 4 of the *dsx* (doublesex) gene to activate splicing at the 3′ end of intron 3, thus preempting the otherwise favored alternative of splicing exon 3 directly to exon 5. The two modes of splicing result in two functional mRNAs, one for males and one for females. There is a polyadenylation signal at the 3′ end of exon 4, thus effectively terminating the female mRNA at this point. Information from Ref. 7.



So far as it is understood, selective splicing of introns depends mostly on splicing enhancers, RNA motifs to which proteins bind to facilitate splicing at nearby sites. A family of RNA-binding proteins, the so-called SR proteins, have been especially implicated in enhancer function (7, 9). Characteristically, they have two kinds of domains, one RNA-binding and the other rich in arginine-serine dipeptide sequences (hence the designation SR). The latter, it is thought, are involved in protein–protein binding and recruiting of components of the splicing apparatus.

One of the most thoroughly investigated systems of splicing control by an enhancer is the final step of the *Drosophila* sex-determining splicing cascade, alluded to previously (10) (Fig. 2). The enhancer sequence that determines male-type splicing of Drosophila *dsx* mRNA and interacts with the protein products of *tra* and *tra2* is located in the fourth exon between 300 and 570 base pairs downstream of the splice junction that it controls. It includes six tandemly arranged approximate tandem repeats, each 13 bp, with an 18-bp purine-rich sequence between the fifth and sixth repeats. Both of the repeats and the purine-rich element are necessary for efficient splicing of the preceding intron. *In vitro* protein–RNA binding studies have shown that the *tra2* protein binds to the repeats and the *tra* protein to the purine-rich segment (10). Both are proteins that have SR domains, and their binding to the RNA is reinforced by cooperative interaction with one or more other SR proteins, which would not bind specifically to the enhancer by themselves. It is thought that the whole SR complex so formed binds to splicing factors, perhaps U2 components, and relays them to the 3′ splice site located 300 to 320 bp upstream (Fig. 2). A problem to which evolution has presumably found an answer is that of reconciling the two quite different functions of the *dsx* splice enhancer. On the one hand, it has to provide binding sites for the splice-promoting proteins, and on the other hand, it encodes a part of the amino acid sequence of the female-specific *dsx* protein that has its own special functions.

Purine-rich splice-enhancer sequences are found in other genes, including some from mammals (11). Binding to SR proteins, either site-specific or more general in function, is likely to be a general property of splice enhancers.

A different method of splice-site regulation is exemplified by the first step of the Drosophila sex cascade (12). The *Sxl* protein, which acts in the female on *tra* pre-mRNA to produce the female-specific messenger, is a kind of degenerate SR protein that retains its RNA-binding domain but has lost its SR domains. It binds with high affinity and specificity to the polypyrimidine tract adjacent to the 3′ splice site of the third *tra* intron to the exclusion of a complete SR protein, called U2AF, which is necessary for recruiting the U2 complex, a function that SR-less *Sxl* protein is unable to perform. As a result, the third exon becomes spliced to the fifth instead of the fourth exon ((12); Fig. 2).

In both of the Drosophila examples just reviewed, the splicing control is exercised at the 3′ end of the intron. Other splicing options involve choices among different 5′ splice sites. It is presumed that, here too, the options are controlled by specific RNA-binding proteins, particularly of the SR class, that have either enhancing or inhibitory effects on specific splice sites. A very great deal remains to be discovered in this field.

2. Group I and Group II Introns

These introns are most commonly found within the genes of mitochondria and chloroplasts and more rarely in **bacteria** and **bacteriophages** (Table 2). **Group I introns** are particularly prevalent in mitochondrial DNA of fungi, also accompanied at least in *Saccharomyces* by group II (Fig. 3). Both groups are common in **plastid** DNA of many kinds of photosynthetic eukaryotes. Group I introns are found particularly in transfer RNA genes. With the exceptions shown in the Table 2, they are not found in nuclear genes.

Figure 3. Group I and group II introns in mitochondrial genes of *Saccharomyces cerevisiae*. *COB* and *COX1* encode cytochrome b and subunit 1 of cytochrome oxidase. The L-rDNA transcript is processed to form large ribosomal RNA. Open, stippled, and hatched boxes represent, respectively exons, group I introns, and group II introns. Straight arrows indicate intron open reading frames. Note that several of them start in upstream exons. Curved arrows indicate that the protein products facilitate the splicing of their own introns or, in one case, an intron in another gene. The asterisks indicate high-frequency transfer to intronless alleles. This diagram is a composite. These introns are not all present together in any one yeast strain. Information from Ref. 1.

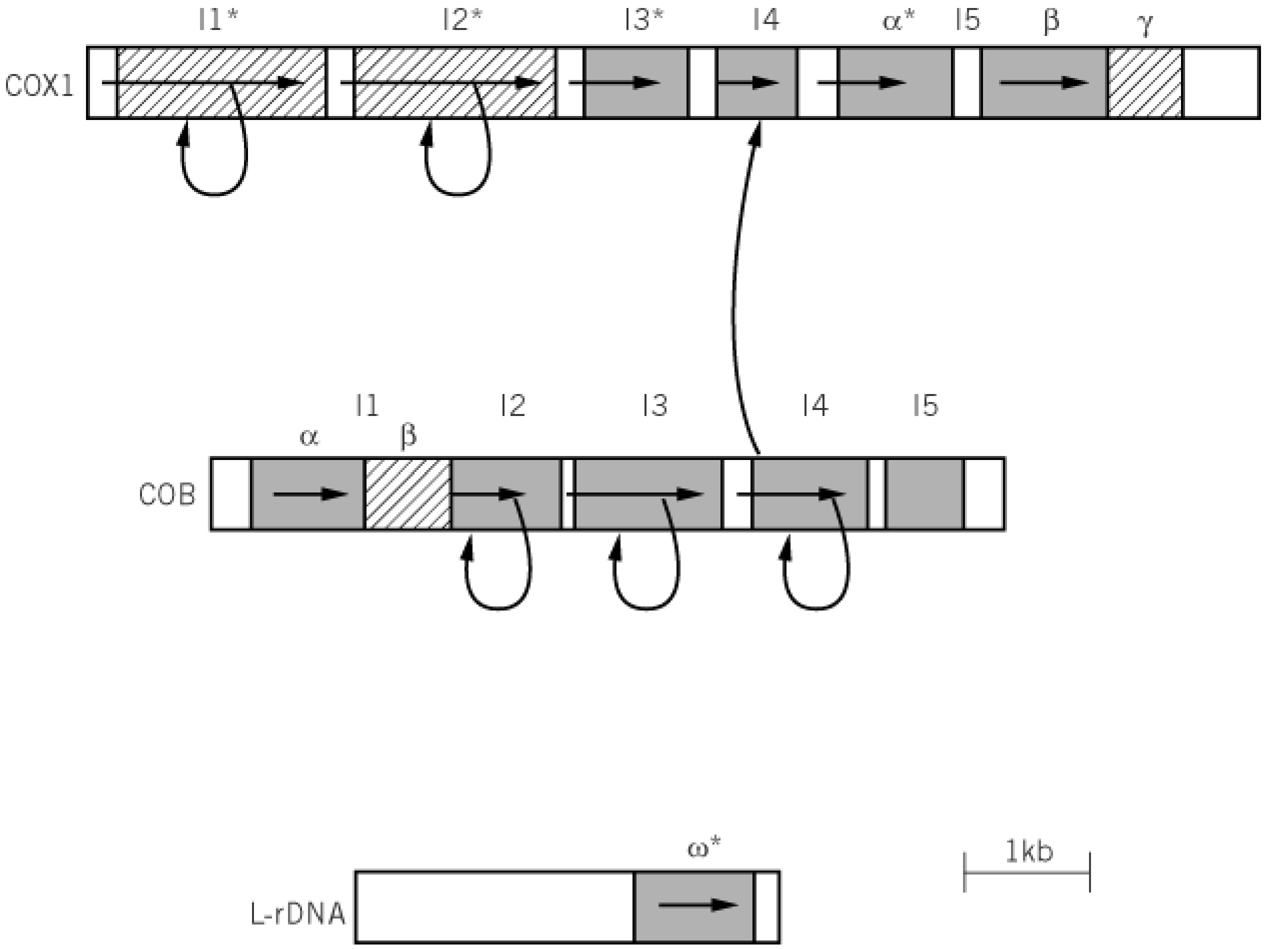


Table 2. Distribution of Group I and Group II Introns[a]

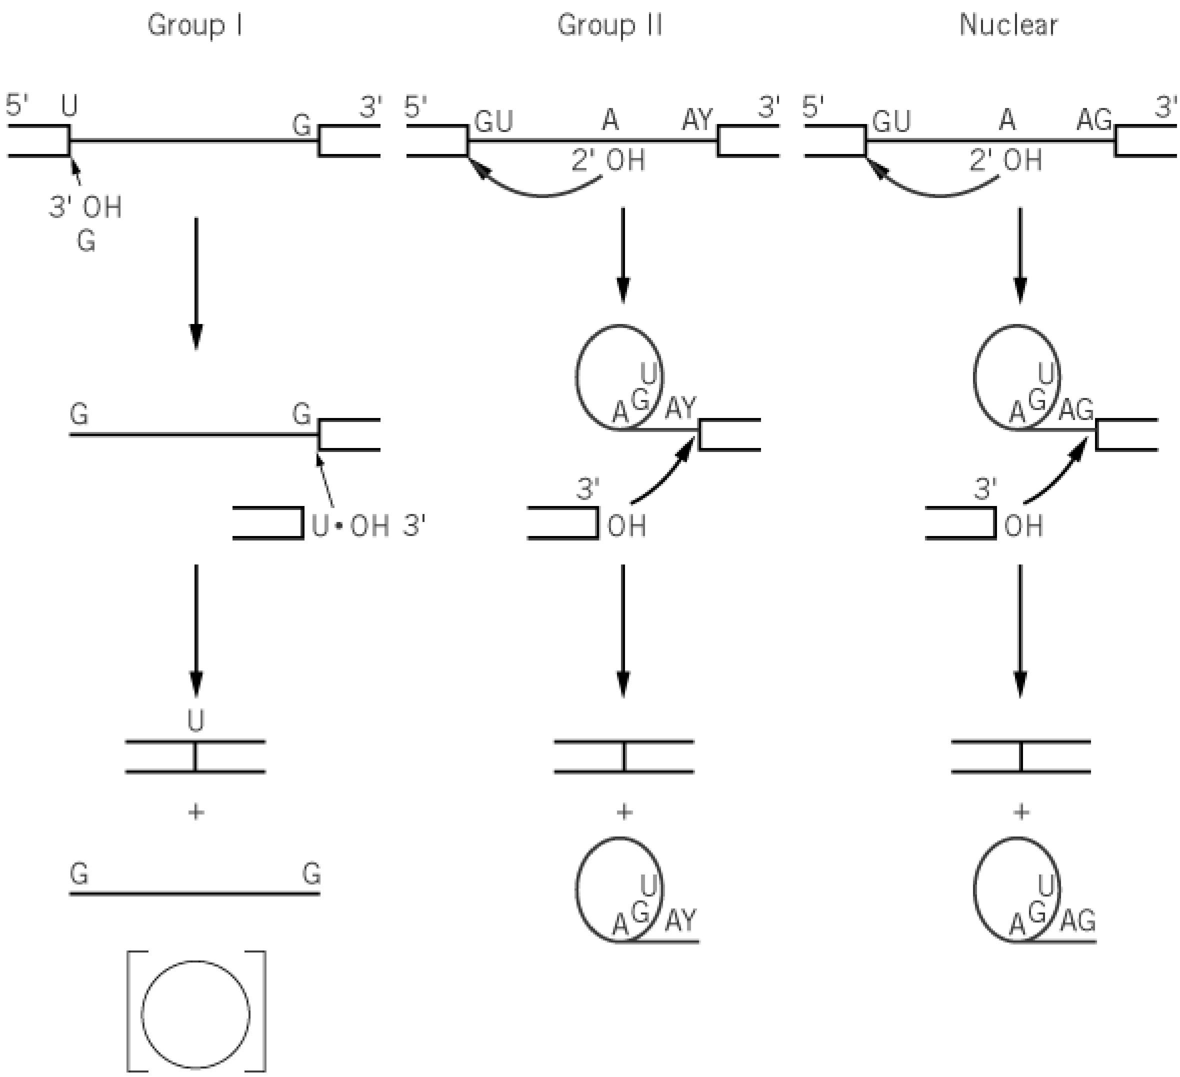
Group I and group II introns differ fundamentally from the common introns of nuclear pre-mRNAs in their requirements for splicing. They have characteristic internal secondary structures that differ between the two groups, in the form of double-stranded stems, stabilized by base-pairings, and single-stranded loops. This internal structure, it is thought, serves the same purpose in aligning the intron ends for splicing as does base pairing with the RNAs of the snRNPs in splicing nuclear introns.

At least some group I and (to a lesser extent) group II introns act as **ribozymes** to catalyze their own splicing *in vitro* without the aid of protein, though mostly under unphysiological conditions, such as high temperature and high magnesium ion and general salt concentration. *In vivo*, their splicing is facilited by proteins, generally called *maturases*, some of which are encoded in open reading frames within the introns themselves (1, 13, 14). This has been shown genetically for some of the *Saccharomyces* introns (Fig. 3), where mutations in the open reading frames result in failure to splice, a deficiency that can be remedied by the same kind of nonmutant introns acting in *trans*. For example, in the *Saccharomyces cerevisiae cob* and *cox1* genes, that respectively encode cytochrome b and subunit 1 of cytochrome oxidase, numerous introns, some group I and some group II, depend mostly for their splicing on intron-encoded proteins, and some require nuclear-encoded proteins, either instead or in addition.

Groups I and II are distinguished from one another in their secondary structures, in the nature of the proteins encoded by their open reading frames (see later), and in the chemistry of their splicing reactions (Fig. 4). In Group I, the phosphodiester linkage at the 3′ end of the upstream exon is attacked by the 3′-hydroxyl of a free guanosine molecule. A trans-esterification reaction leaves the junction cleaved with a free 3′-hydroxyl on the exon side and the guanosine attached to the free 5′ end of the intron. Then, in a second transesterification step, the 3′-hydroxyl of the upstream exon reacts with the phosphodiester bond at the 3′ end of the intron (always a guanylate residue), releasing the intron, sometimes but not always as a circle, and ligating the exons together (Fig. 4). In one case, a group I intron in the fungus *Podospora anserina*, the excised circles reverse-transcribed into DNA, has embarked on a damaging career of its own, replicating freely in the mitochondria and causing senescence (1).

Figure 4. The modes of excision of group I, group II, and nuclear introns compared. Based on Ref. 1 by permission.



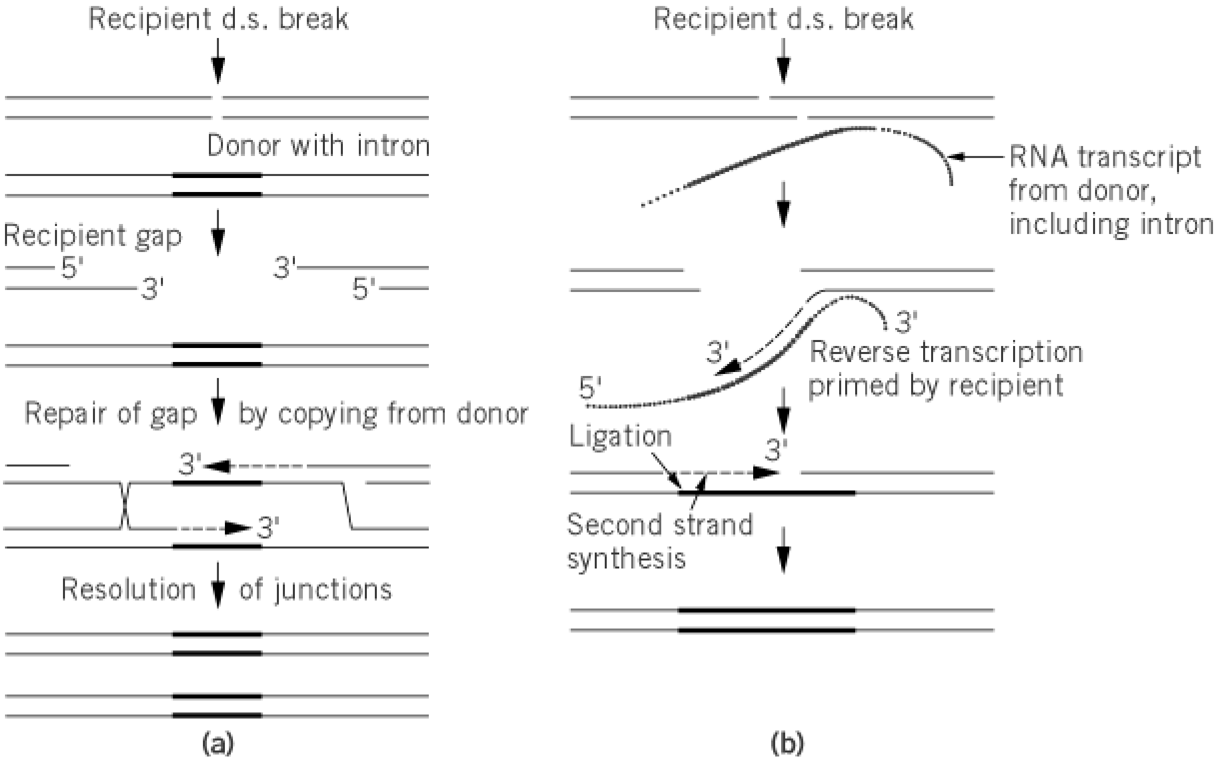
The splicing of group II introns is similar to that of nuclear pre-mRNA introns (Fig. 4), and a lariat intermediate is formed. G is always at the 5′ end of the intron (consensus GUGYG), and generally AY (not AG) is at the 3′ end. A crucial A also serves as a branch-point residue, although the sequence surrounding it, usually composed of U and/or C residues, has little similarity to the corresponding sequences of nuclear introns. The 5′ G interacts with the branch-point A to form the lariat and then, again as in nuclear introns, the free 3′-hydroxyl of the upstream exon attacks the phosphodiester linkage at the 3′ end of the intron to fuse the exons and release the intron as a lariat.

An extraordinary feature of group I introns, found also but less frequently in group II, is their ability to transpose as DNA from one allele to another. The transposition is conservative in the sense that the recipient acquires the intron without the donor losing it. One of the most thoroughly investigated examples involves the group I w-intron in the mitochondrial large rRNA gene of some strains of *Saccharomyces cerevisiae* (14). When a strain possessing the intron (w+) is crossed with one that lacks it (w–) (the mitochondria of the two strains are distinguished by drug resistance or other markers), the progeny emerging from the cross have recombined as well as predominantly parental-type mitochondrial genomes, virtually all now carrying w. And although most of the mitochondrial genetic markers are inherited from either parent with equal probability, two drug-resistance markers, chloramphenicol and **erythromycin** resistance, located within the rRNA gene and hence close to w, are inherited predominantly from the w+ parent. Apparently w is unilaterally transferred from one mitochondrial genome to the other and carries flanking DNA of variable length along with it. The explanation for this conversion (and coconversion) is that w includes an open reading frame that encodes a double-strand **endonuclease** that is specific for a site within the rRNA gene. This enzyme makes a double-strand break in the mitochondrial DNA of the w– parent, which is then enlarged to a gap that is repaired by copying from the w+ parent (1, 14). This explanation bears a strong resemblance to the double-strand break model currently proposed for recombination in meiosis.

The high-frequency transposition of w is strictly homologous, that is to say, it is targeted to a sequence similar to the that from which it came, a process sometimes called “homing.” The same property has been identified in a number of other group I introns (Fig. 3), and the same explanation applies to these, namely, the intron encodes an endonuclease that makes a double-stranded cut at or close to the intron's home site. As indicated before, at least some of the group I-encoded endonucleases also act as maturases to facilitate splicing.

The open reading frames in the approximately 20% of group II introns that possess them encode proteins of quite a different family. Virtually all have a consensus domain, called X, a possible but unproved function of which is maturase activity (15). Many of them also have two other recognizable domains, one characteristic of **reverse transcriptase** and the other **zinc-finger**-like with double-strand endonuclease activity specific for the homing site (16). The transposition of the yeast *COX1* intron, which has been analyzed *in vitro*, occurs by reverse transcription, primed by the 3′ OH-terminated transcribed DNA strand on one side of the double-strand break, followed by ligation of the 3′ end of the single-strand, reverse transcript into the recipient DNA and the repair synthesis of its complementary strand (Fig. 5).

Figure 5. Proposed mechanisms of “homing” transposition of group I (a) and group II (b) introns. Dotted lines are RNA, broken lines new synthesis, and thick segments intron sequence. After Refs. 1 and 14 by permission.



An interesting feature of many of the open reading frames in both class I and class II introns is that, although they are mainly within the intron, they start in the upstream exon (Fig. 3). This mutual adaptation of exon and intron must mean that their association is very ancient and that the intron cannot be a recent invader. This conclusion is borne out by observations of positional conservation of some group I introns over great lengths of evolutionary time. However, their patterns of distribution that have similar kinds of introns present in diverse genes and homologous genes with different sets of introns are hard to explain except on the assumption that both group I and group II introns can move, even if rarely, to new sites. In some instances, such movement has been directly demonstrated. To further complicate the picture, there is evidence that open reading frames within introns can sometimes transpose from one intron to another (17). Again, the most plausible, though unsubstantiated, explanation for such events is that transcripts can be reverse-transcribed and the cDNAs reintegrated into the genome, usually into sequences homologous to those from which they came from but occasionally at nonhomologous, that is, ectopic, sites.

3. Uses for Introns

From the elaborate mechanisms that organisms have evolved to cope with introns, one would suppose that they must confer some benefit. There are several ways in which they can contribute to the function of the organism.

First, introns in nuclear genes give additional flexibility to gene function. Splicing options allow a gene to encode two or more different proteins to serve different functions at different times. Some sequences are in common and others are unique. Some examples were given before and others can be found in the articles on Gene Structure and **Allelic Complementation**. Investigating the control of pre-mRNA splicing is still at an early stage, but it promises to reveal a degree of complexity to rival that existing in control of gene transcription.

Secondly, introns can be involved in controlling transcription. There are fairly numerous examples of downstream enhancers located in introns of genes. One, the *bithorax* enhancer within the *Drosophila Ubx* gene, is mentioned under Gene Structure.

Thirdly, there are several examples, which may become much more numerous as more of the very long introns in mammalian genes are sequenced, of open reading frames that encode significant looking protein sequences, "nested" within the introns of other genes. An example is cited in the article on Gene Structure. The *Drosophila Gart* gene, identified because of its function in **purine biosynthesis**, has an open reading frame in its largest intron that encodes cuticle protein, used at the pupation stage. Here the mRNAs of *Gart* and the nested gene are transcribed from opposite strands of the DNA, and therefore, presumably, cannot, both be produced at the same time. There are also a few examples of genes nested within mitochondrial introns. The sea anemone *Metridium senile* harbors a group I intron within its mitochondrial gene for subunit 5 of NADH dehydrogenase, and this intron includes the genes for subunits 1 and 3 of the same enzyme (18). In this case all three genes use the same DNA strand for transcription, and so the excised intron becomes a bicistronic mRNA for the nested genes.

A less well-substantiated, but very real possibility is that introns are sometimes used as timing devices for gene expression. Transcription is not instantaneous. In *Drosophila* it has been estimated that it proceeds at the rate of about 1.4 kb per minute. This implies that, for a gene expanded to 60 kb because of its intron content, as is sometimes the case in *Drosophila* and often in mammals, there is an interval of nearly an hour between the start and completion of transcription. There is one example in *Drosophila* where intron length is crucial (19). Two genes, *knirps* (*knr*) and *knirps-like* (*knr-1*) encode very similar proteins but differ greatly in intron length, about 1 kb in *kni* and 19 kb in *knr-1*. The gene *kni* is essential at the blastoderm stage of embryonic development, when nuclear division proceeds very rapidly. Mutants that have no functional *kni* can be partially rescued by transcription of *knr-1* cDNA, which lacks introns, but not by genomic *knr-1*, presumably because the latter does not have time to be transcribed between one nuclear division and the next. Although it has not been demonstrated, it may be that for some developmental genes a long lead-time between transcription-induction and expression of the protein product is appropriate. In all events, organisms have become adjusted to the various transcriptional times of their genes, and hence to some extent depend on maintaining their accustomed intron lengths.

4. The Origin of Introns

Discussion about the origin of introns has been dominated by the idea, first put forward by Walter Gilbert (20), that exons were once separate genes and that introns are the present-day relics of the gaps between them when they were first brought together early in evolution. This is sometimes called the "introns early" hypothesis. The strongest evidence in favor of this view is the observation that where proteins consist of different **domains**, somewhat separate in the three-dimensional structure, and distinct even if mutually dependent functions, they are encoded by different exons (20). The heavy and light chains of immunoglobulins are good examples. And where pre-mRNA are spliced in different ways to yield functionally different protein products, it is clear that at least some of the introns mark the boundaries between rearrangeable protein domains that are functionally distinct modules. It is also true (see Gene Structure) that numerous multifunctional genes in eukaryotes are clearly homologous to separate single-function genes in bacteria, which are generally seen as more akin to the earliest organisms (though, in fact, they have been evolving for just as long as anything else).

There are difficulties, however, in imagining how introns that have an elaborate splicing-out mechanism could have evolved independently in such a similar form in all of the spaces between originally separate domains when they were first brought together. The alternative, the "introns late" hypothesis, is that genes, however complex their functions and however they were formed, came into existence without the benefit of introns and that the introns came in later, perhaps in a form akin to present-day group II introns, which are both mobile and similar to nuclear introns in their splicing mechanism. Natural selection could explain the correlation between intron positions and interdomain regions, since that these are likely to be the positions where any disruption due to insertion would do the least damage.

Comparisons between homologous genes in different organisms give contradictory messages. Some introns have retained their positions, although not their internal sequences, over vast tracts of evolutionary time, but others come and go even between quite closely related organisms, often into and out of positions that cannot be considered boundaries between functionally distinct domains. The strict introns-early hypothesis, if anyone held strictly to it, would suppose that every intron position that we see now was there from the origin of the gene and that the reason that all the positions are not occupied now is that introns can be lost, most plausibly by gene conversion, when patches of cDNA replace the intron-containing genomic sequences. But as has been pointed out (22), if introns were present in the primeval gene in all their present-day positions, the exons must have been so short as to be incapable of encoding any functionally distinct part of a protein.

An unanswered, perhaps unanswerable, question is whether the longest introns were always so long and, if not, how they grew.

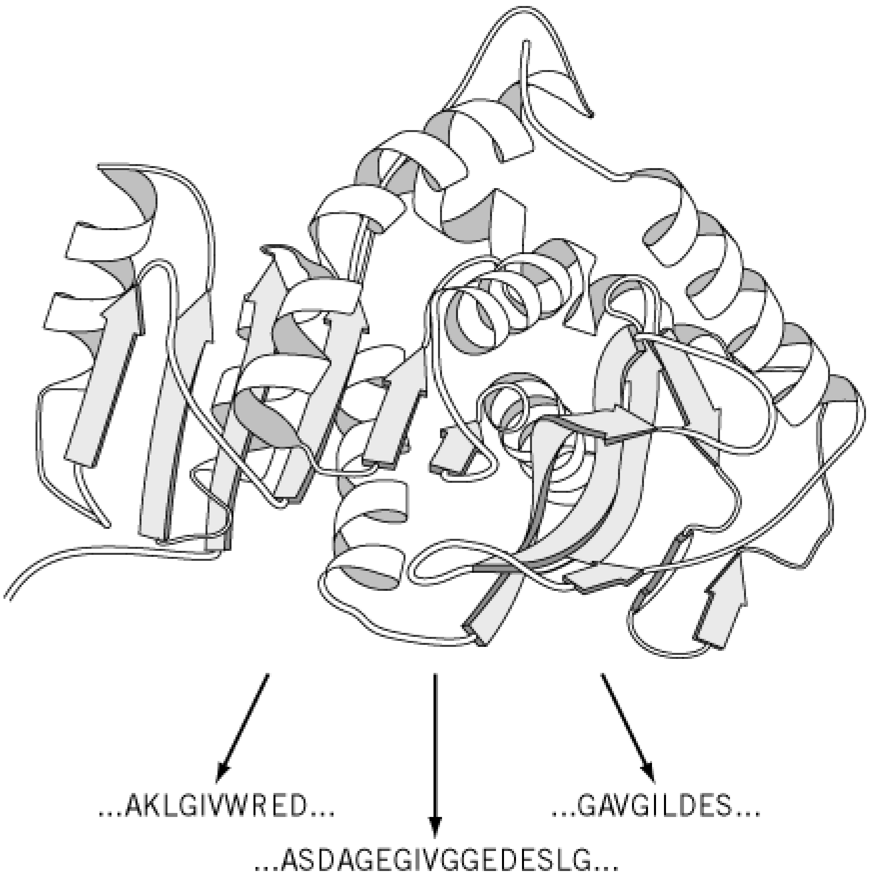
Inverse Folding Problem

This problem arose from attempts to design proteins *de novo*. Here one begins by selecting a certain known target protein structure, for example, the globin fold, and freely designs amino acid sequences (primary structures) that should adopt this conformation spontaneously. There will be a number of sequences compatible for a particular target because **homologous** proteins are known to adopt the same fold (see Homological Modeling). A solution becomes unique, however, if one searches for the sequence that would fold and would give the most stable structure. Such a sequence is likely to differ even from the native sequence of the target structure. In this procedure, one starts from a 3-D structure and works toward a sequence (Fig. 1), opposite to the direction of **protein folding** and protein structure prediction, where one starts with the sequence and tries to find the 3-D structure.

Figure 1. Inverse folding problem. Given a particular 3-D structure, search for any amino acid sequence that would preferably adopt the fold. Note that the thinking is reversed in direction compared with that of protein folding.



One of the obstacles in solving the inverse folding problem is dealing with the amino acid residue side chains. The protein backbone can be fixed just the same as in the target structure, but the side chains vary with the sequence. At each stage, the optimal packing of the atoms of the side chains within the protein interior needs to be determined. To avoid this annoying task, a simplified treatment of side chains has been introduced (1); each of the 20 side chains of the normal amino acids is represented by one point (the C_b atom for all residues except glycine), and its bulkiness and other physicochemical properties are effectively included in the interaction potential used, which is called the “mean-force energy potential” or the “Sippl potential.” The position of the C_b atom is fully determined by the dihedral angles of the backbone alone (see Ramachandran Plot), so it is not necessary to worry about the side-chain conformation. The Sippl potential is a function of the distance between the C_b atoms of two side chains and of the amino acid type. The quality of the side-chain packing is given quantitatively by the sum of the interaction energies estimated by the Sippl potential between the side chains. The applicability of the Sippl potential has been established by the "Sippl test (2)." The native amino acid sequence *a* of one structure (A) is selected from a structural library of various known structures and mounted onto another structure (B) that is larger in size than A. Mounting sequence *a* onto structure B is possible with various alignments, shifting residues one-by-one without introducing any gaps. Each time, the total energy of the structure is estimated by using the Sippl potential. Upon completion, structure B is replaced by the next structure of the structural library, including structure A itself. If the native combination of sequence and structure gives the lowest energy among all the alternatives, it is concluded that the potential function is effective and useful. The Sippl test has been performed successfully with various Sippl-type potentials (3, 4), but this is not sufficient for the inverse folding problem. The Sippl test is a recognition test for sequence recognizing structure, just opposite to the inverse folding problem of structure recognizing sequence.

Another difficulty with the inverse folding problem is whether the energy values of different systems (proteins with different sequences) can be compared to each other (5, 6). Of course, it is almost meaningless to compare the energy of two different substances, such as ethane and ethanol. Apart from the absolute energy, however, the energy of protein stability is defined as the energy difference between the folded and **unfolded** protein states, which can be compared among different proteins. Ota et al. (7) introduced a simple approximation to estimate the energy of protein stabilization in combination with the Sippl-type potential energy and applied the method to analyzing the thermal stability of mutant proteins. Similar treatments could conceivably deal with the inverse folding problem and achieve the *de novo* design of proteins.

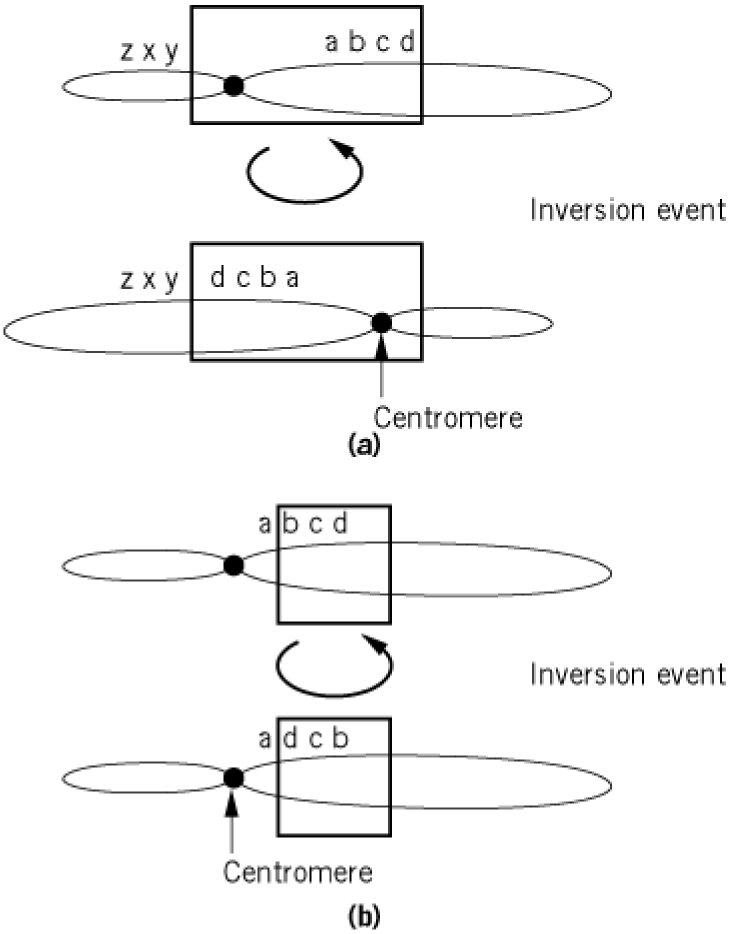
Inversion, Chromosomal

The major sources of variation in the eukaryotic genome are chromosomal breakages and reunions, leading to inversions and translocations. If two breaks occur in a chromosome and the excised fragment is rotated 180° before being reunited, then an inversion occurs. Three breaks in a chromosome can lead to an intrachromosomal translocation. In humans, both pericentric (the position of the centromere is changed) and paracentric (the position of the centromere is not changed) inversions occur in 1 to 2% of the population. Surprisingly often these gross chromosomal inversions do not have any **phenotypic** consequence (1). Most of these inversions are pericentric and involve nonrandom chromosomal breakpoints (Fig. 1).

Figure 1. Chromosomal inversions. Those that change the position of the centromere are called pericentric inversions (**a**), and those that maintain the position of the centromere are called paracentric (**b**).



The polytene chromosomes of *Drosophila* are especially suited for studying gross chromosomal rearrangements. It has been shown that the evolution of distinct species of *Drosophila* was associated with the accumulation of many paracentric and pericentric inversions, so that on average two new inversions can be identified in each species (2). Comparison of the chromosomal banding patterns of humans with that of various apes also reveals that several chromosomes have undergone inversions leading to detectable differences (3). Inversions have also been well documented in **plants** and **fungi**. Nevertheless, inversions are an unwelcome occurrence for sexually reproducing organisms because of the consequence for **meiosis**. Chromosomal inversions cause homologous chromosomes to become locally heterozygous, which can create problems during the chromosomal alignment process that happens in meiotic **prophase**. This heterozygosity is normally overcome by the formation of an inversion loop, so that chromosomal alignment is maintained where possible. Inversions also create problems for the appropriate segregation of chromosomal material if **crossovers** occur within the inversion loop.

In humans, fertility is reduced because paracentric inversion prevents appropriate chromosomal segregation when a crossover occurs within an inversion loop. The products of a paracentric inversion are an acentric fragment and a dicentric chromosome, which breaks during **anaphase**. Only the two chromatids that are not involved in the crossover remain normal. The embryos generated from **gametes** without the full complement of chromosomes are generally inviable. With pericentric inversions, the risk of producing an abnormal embryo is increased, depending on the origin of the gamete. The products of a pericentric inversion have gene duplications and deficiencies.

These duplications potentially lead to defective gametes. With male gametes, there is a 4% risk of abnormality, and with female gametes there is an 8% risk. This presumably reflects the greater contribution of the female gamete and the maternal chromosomes to early embryonic development. Comparable decreases in fertility are found in flowering plants. This leads to a strong evolutionary selection against chromosomal inversion (4).

Inverted Repeats

A repeat, or repeating, **nucleotide sequence** is any of two or more identical segments of a longer sequence or identical segments in a double-stranded **DNA**. If two such DNA fragments are inserted into a long DNA duplex with opposite polarity (one “head on,” the other “tail on”), the corresponding pair are known as inverted repeats . The various types of repeats are schematically outlined in the Figure for Tandem Repeats. The sequences of the pair of inverted repeats, if read from the same strand, are complementary to one another. Inverted repeats placed immediately after one another make a palindrome. If the separation between the inverted repeats is comparatively short (up to a few tens of bases), the repeats may correspond to a hairpin in a RNA transcript generated from such a structure, or to a cruciform structure in DNA under torsional constraint (1).

Inverted repeats are an important element of several types of mobile DNA elements, or transposons (2). They are located at the ends of the transposons when integrated into a genome. For example, bacterial **insertion sequences** (IS) are flanked by 10- to 40-bp inverted repeats. The insertion sequences themselves can make a pair of inverted repeats, as in the case of the bacterial transposon Tn10, which is flanked by 1400-bp IS10 sequences of opposite polarity. The inverted repeats are involved in the recombination events that occur during integration or excision of the transposons.

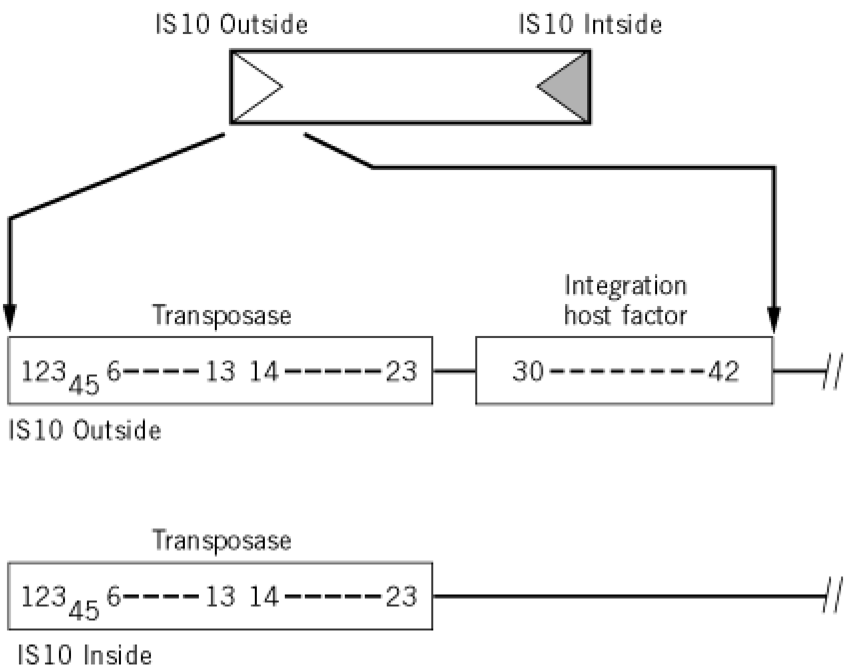
Inverted Terminal Repeat

The movement of transposable elements from place to place in genomes results from the actions of a special element-encoded recombinase on special DNA sequences at the tips of the element. In virtually all such elements, these special recombination sequences at the ends of the transposon include transposase binding sites arranged as inverted repeats. It is these sites that define where the breakage and joining events must occur. Because identical (or nearly identical) terminal sequences are arranged as inverted repeats, the disposition of the transposase at both ends relative to the transposon ends is identical, so that the breakage and joining will occur in the same relative positions at both ends.

The terminal inverted repeats are usually composed of special sequences at the extreme tips of the transposon that signal exactly where that breakage and joining should occur, plus more internal binding sites for the transposase (1, 2) (Fig. 1). In some elements, there are multiple binding sites for the transposase, including the one that is part of the terminal inverted repeat and others internal (3). These interior sites probably play a role in loading the transposase appropriately onto the termini and may be dispensable after the initial stages of transposition have occurred, for example, after synapsis of the transposon ends. For some elements, a binding site for a host factor important for recombination may also be part of the terminal repeat.

Figure 1. The ends of IS10. Special sequences at the ends of the element specify the position of transposase binding and also provide signals to prompt DNA breakage and joining. Transposase binding is specified by sequences from position 6 to position 23, and the positions from 6 to 13 are most critical. Although particular sequences at positions 1, 2, and 3 are not required for transposase binding, they are necessary to prompt the chemical steps of DNA breakage and joining. The identity of positions 4 and 5 is not critical. The outside and inside ends of IS10 have the same transposase binding motifs, but the outside end has in additional a binding site for integration host factor (positions 30–42), a bacterial protein, that is a cofactor in reactions involving the outside ends.



Although multiple transposase binding sites may be present, breakage and joining is restricted to the terminal inverted repeats because of the presence of a transposase binding site adjacent to the special sequences at the extreme tips of the element that provoke cleavage (1, 2). Alteration of these "cleavage signal" nucleotides generally blocks cleavage, but transposase binding still occurs. Often there is a spacer region of a few nucleotides between the transposon binding site and the cleavage nucleotides at the tip.

Iodine Isotopes

Iodine is element number 53 in the periodic table and has valence states of 1, 3, 5, or 7 (1). Iodine is an essential element in humans in small amounts, and lack of iodine causes thyroid goiter. The thyroid concentrates iodine, synthesizes and stores the thyroid hormone **thyroxine**, and releases it to maintain physiological balance. Excessive exposure to chemical iodine can cause skin, eye, and mucous membrane irritations. Iodine compounds are used as chemical reagents, as antimicrobial agents, as radiopharmaceuticals in medicine, and in photographic chemicals.

Thirty-five isotopes of iodine have been identified (2), ranging in atomic mass from ^{108}I (half-life = 36 ms) to ^{142}I (half-life = 0.25 s) (see Radioactivity and Radioisotopes). Only one isotope of iodine is stable (^{127}I). The longest lived isotope (^{129}I) has a half-life of 15.7 million years.

The four most important radioactive isotopes of iodine (or *radioiodine*) for biomedical use are: ^{123}I, ^{124}I, ^{125}I, and ^{131}I (Table 1). Each radioiodine is prepared uniquely and has a variety of different applications, advantages, and disadvantages (3). Iodine is a useful **radiolabel** for many studies, as it can be chemically incorporated into proteins relatively easily. All radioiodine compounds must be handled with care, as radioiodine is volatile and readily concentrated in the human thyroid gland.

Table 1. Principal Radioisotopes of Iodine in Medicine and Research: Their Radioactive Emissions, Yields, and Energies (2)

Element	Mass (amu)[a]	Physical Half-life	Beta-Particle Yield	Average Beta Energy (MeV)[b]	Gamma-Ray Yield	Gamma Energy (MeV)
Iodine	123	13.22 hours	—	—	0.833	0.159
	124	4.18 days	0.229	0.824	0.453	0.511
					0.611	0.603
					0.101	0.723

				0.105	1.691
125	59.6 days	—	—	0.0667	0.0355
131	8.021 days	1.0	0.182	0.0606	0.284
				0.812	0.364
				0.0727	0.637

[a] Atomic mass units.

[b] Million electronvolts.

High purity iodine-123 is usually produced in an accelerator by the reaction ^{127}I(*p*,5*n*) ^{123}Xe→^{123}I + b^{-}, or by the reaction ^{124}Xe(*p*,g) ^{123}I. Iodine-124 is an undesirable impurity in ^{123}I preparations. Iodine-123 is used as a diagnostic imaging agent in nuclear medicine for thyroid imaging and uptake studies. Its relatively short half-life of 13 h. is a disadvantage for transportation from site of production to hospitals for clinical use.

Iodine-124 can be prepared in an accelerator by deuteron bombardment of tellurium according to the reaction ^{124}Te(*d*,2*n*) ^{124}I. Iodine-124 is a positron (beta-plus) emitter having useful applications in positron-emission tomography in diagnostic nuclear medicine. Iodine-124 has also been used as a label for 5-iodo-2′-deoxyuridine, an analog of thymidine, for DNA uptake studies, and tumor imaging. It has potential application as a therapeutic radionuclide.

Carrier-free ^{125}I is prepared in a reactor using an ^{124}Xe target according to the reaction ^{124}Xe(*n*,g) ^{125}Xe → ^{125}I + b^{-}. It may also be prepared in an accelerator by deuteron bombardment of tellurium according to the reaction ^{124}Te(*d*,*n*) ^{125}I. Iodine-125 emits low energy (0.035 MeV) gamma rays and thus is *not* useful for external imaging. However, ^{125}I is used extensively to **radiolabel** small specimens and proteins for a variety of applications in molecular biology, including radioimmunoassay, autoradiography, and fluorography. Iodine-125 is a common label for 5-iodo-2′-deoxyuridine in DNA uptake and **hybridization** studies. It has possible applications as a therapeutic radionuclide because of the high linear energy transfer of Auger electrons emitted by ^{125}I-labeled DNA in cell nuclei. Iodine-125 is also used in permanent seed implants (brachytherapy) for treatment of slowly growing tumors, such as carcinoma of the prostate.

Iodine-131 may be prepared in an accelerator according to the reaction ^{130}Te(*d*,*n*) ^{131}I. It is more commonly prepared in a reactor by tellurium capture according to the reaction ^{130}Te(*n*,g) ^{131}Te → ^{131}I + b^{-}, or as a ^{235}U fission product. Iodine-131 was discovered and used for thyroid function studies in 1938 (4). It was the first radioisotope to be approved (in 1951) by the U.S. Food and Drug Administration for human use as a new drug.

Today, ^{131}I is used extensively in clinical nuclear medicine for many purposes (3). These include thyroid uptake studies (555 kBq, or kilobecquerels, administered), scans with metastatic thyroid cancer in athyroid patients, and treatment of benign thyroid disease (185 MBq), for thyroid carcinoma ablation (5.55 GBq), and as a labeled monoclonal antibody in targeted-cell therapy of lymphoma and leukemia (up to 30 GBq). Other applications are radioiodine labels for dyes, macromolecules, proteins, and hormones, including ^{131}I-norcholesterol for diagnosis of aldosterone-producing tumors in the adrenals and ^{131}I-metaiodobenzylguanidine for imaging pheochromocytoma and other neuroendocrine tumors. Iodine-131 has the advantage of a relatively long half-life (8.021

days) for production, transportation, and labeling, but the disadvantage of abundant gamma rays, which can be a radiation hazard.

Iodoacetamide, Iodoacetate

Iodoacetamide and iodoacetate are two of the most common reagents used for chemically modifying thiol groups irreversibly. They have a long history, dating back to 1874 when it was reported that bromoacetate injected subcutaneously into frogs killed them, as a result of progressive respiratory and cardiac depression; iodoacetate was subsequently found to be more reactive. These studies were important in elucidating the mechanism of glycolysis, which led to the realization that iodoacetate and other such compounds acted by reacting with the thiol groups of proteins, in this case at the active site of the enzyme glyceraldehyde-3-phosphate dehydrogenase. Iodoacetamide became popular because it can cross cell membranes much more readily than can iodoacetate and therefore is more potent with cells and organs.

Both iodoacetamide and iodoacetate react rapidly and specifically with the ionized form of thiol groups, to generate very stable adducts:

$$-S^- + I - CH_2CONH_2 \rightarrow -S - CH_2CONH_2 + I^- \tag{1}$$

$$-S^- + I - CH_2CO_2^- \rightarrow -S - CH_2CO_2^- + I^- \tag{2}$$

These adducts are commonly known as the carboxamidomethyl and carboxymethyl, respectively. They are stable to conditions routinely used to hydrolyze proteins to their substituent amino acids, except that the carboxamidomethyl group gets hydrolyzed to the carboxymethyl (see Amino Acid Analysis).

The reaction with iodoacetamide or iodoacetate occurs by the thiolate anion attacking and displacing the iodine atom in a nucleophilic reaction. Consequently, the rate of the reaction increases with increasing pH, up to just beyond the pK_a of the thiol group, which typically is about 9 for most biological substances. The pH dependence of the rate of the reaction can be used to measure the apparent pK_a value of the thiol group, although there are exceptional cases in catalytic proteins where the results are misleading, presumably because the protein modifies the energy of the transition state for the reaction (1). The reaction occurs rapidly with thiol groups. The second-order rate constant for reaction at 25°C of iodoacetamide with a fully ionized cysteine thiol group, with a pK_a of about 8.7, is approximately 25 $s^{-1}M^{-1}$. Consequently, the half-time for modification of such a thiol group upon adding 0.1 M iodoacetamide is only 0.3 sec. Iodoacetate reacts about three times less rapidly than does iodoacetamide.

It is important to realize that protons are released by the reaction. Frequently, high concentrations of a thiol reagent are used to reduce all cysteine residues, and then a large excess of iodoacetate or iodoacetamide is added to react with both the protein and the reagent. In this case, the pH will drop and the rate of the reaction will slow, and even stop before completion, unless very high concentrations of a buffer are present.

The two reagents differ only in one being an amide, and neutral, and the other an acid, and negatively charged. This charge difference is useful for counting residues of thiol groups in a protein. Mixtures of the two reagents are reacted with a protein containing *N* thiol groups, to produce a spectrum of molecules with net charge differences of 0 to *N*. If this spectrum is resolved by electrophoresis, isoelectric focusing, ion-exchange chromatography, or other techniques dependent only upon the charge of the protein, the number of species with different charges present can be counted, giving the integer value of *N*.

Both iodoacetamide and iodoacetate also react with amino groups, but at a lower rate, and primarily at very alkaline pH values, where the reactive nonionized amino groups are present. Both lysine and histidine residues can be modified in this way. The reaction of **ribonuclease A**, which has no free thiol groups, with the two histidine residues at its active site, each reacting with different N atoms, was important in demonstrating the specificity of the interactions that could take place in enzyme-active sites (2). They can also react with the sulfur atom of **methionine residues** to generate the positively charged sulfonium salt, but at a much lower rate (3). This rate is essentially independent of pH, however, so it can become the predominant modification reaction of a protein at very low pH values. The reactions of iodoacetamide and iodoacetic acid can be used in diagonal methods to isolate specifically cysteine- and methionine-containing peptides.

Many variants of iodoacetate and iodoacetamide have been devised by adding further groups with absorbance and fluorescence properties that serve as reporters of structure in proteins.

Ion Channel Receptors

A diverse group of neurotransmitter receptors are ligand-gated **ion channels**. These can be subgrouped into receptors that are either excitatory (acetylcholine, glutamate, serotonin) or inhibitory [g-aminobutyric acid (GABA), glycine]; they have similar structural features, but different regulatory properties. These receptors are characterized by fast- and short-acting responses to ligand. Additionally, these receptors are subject to targeting by docking proteins that induce aggregation. The increased permeability to ions results in the influx of second messengers, resulting in activation of downstream targets.

1. Receptor Structure

Because it was one of the first receptors studied in detail, more is known about the nicotinic acetylcholine receptor than any other (1). This receptor consists of four different **polypeptide chains**, with the composition $a_2$bgd. Each subunit has a single **transmembrane** domain. Although the structure of the channel is not known, the five subunits are thought to assemble together to form a pore, with the neurotransmitter binding site located in the extracellular domain of the asubunits. Numerous mutational analyses have led to an understanding of the molecular dynamics of the regulation of the channel by ligands. Thus, acetylcholine binding induces a conformational change, opening the gate to allow influx of Na^+ and K^+ ions (1).

The structures of the inhibitory ligand-gated anion channels are similar to the nicotinic cholinergic receptor. Both GABA and glycine activate Cl^- channels, in a manner analogous to the regulation of K^+ and Na^+ channels by acetylcholine.

2. Regulation of Ligand-Activated Channels

Ligand-activated channels are generally found to be clustered on the postsynaptic side of a synapse. Recent studies have suggested that the clustering is mediated by interactions with a group of targeting proteins, such as PSD-95 and GRIP, that contain PDZ domains. These regions are **domains** involved in protein-protein interactions and are known to interact with specific sequences in the *C*-terminal regions of transmembrane proteins (2).

Ligand-gated ion channels are also known to be regulated by **phosphorylation**. The primary structures of these receptors contain numerous **consensus sequences** for various protein kinases. Both *in vivo* and *in vitro* experiments have demonstrated phosphorylation of both excitatory and inhibitory receptors, by both **tyrosine kinases** and **serine/threonine kinases**. These phosphorylations are likely to play a role in modulating the activation of the receptor by ligands, and they may have consequences for understanding long-term modulation of receptor function (3).

Ion Pair

An ion pair is two molecules or groups of opposite electric charge in close proximity due to favorable electrostatic interactions between them. The term ion pair is generally used in all fields of liquid chemistry, in contrast to a salt bridge, but in biochemistry the term frequently refers to a salt bridge.

Ion-Exchange Chromatography

Ion exchange is the reversible interchange of ions of the same charge between a solution and a solid, insoluble material in contact with it. It proceeds by equivalents. One chemical equivalent of one kind of ion enters the solid, and one chemical equivalent of another kind of ion must leave. Therefore, electrical neutrality is always maintained. An ion exchanger consists of an insoluble matrix to which charged groups have been covalently bound. The charged groups associate with mobile counterions. These counterions are reversibly exchanged with other ions of like charge (ie, ion exchange) without altering the matrix. Two main forms of ion exchangers are commonly used: anion exchangers and cation exchangers. Positively charged exchangers have negatively charged counterions (anions) available for exchange and so are termed anion exchangers. Negatively charged exchangers have positively charged counterions (cations) and are termed cation exchangers.

Ion-exchange chromatography is an inclusive term for all **chromatographic** separations of ionic substances carried out by using an insoluble ion exchanger as the stationary phase. As an ionic solution passes over and through the exchanger, ions from the solution exchange for those already on the solid matrix. This technique came into prominence during World War II as a separation procedure for the rare earth and transuranium elements. The technique was first used by Taylor and Urey (2) to separate lithium and potassium isotopes using zeolite resins, and Samuelson (3) demonstrated the potential of synthetic resins. In the mid 1950s, Sober and Peterson (4-6) synthesized the diethylaminoethyl (DEAE) and carboxymethyl (CM) derivatives of cellulose, still in use today for ion-exchange chromatography of proteins.

Although all ion exchanges are reversible, the equilibrium distributions vary widely, and this variation makes ion-exchange chromatography possible. In other words, the basic principle of ion-exchange chromatography involves competition between different ions of the same charge for binding to an oppositely charged chromatographic matrix, the ion exchanger. The interaction between the analytes and the ion exchanger depends on several factors: the charge properties of the analytes; the ionic strength and the nature of the particular ions in solution; the pH; and the presence of other additives in the mobile phase, such as organic solvents. Because retention in ion-exchange chromatography involves an electrostatic interaction between the fixed charges of the ion-exchange matrix and those of the analytes, it is clear that the more highly charged an analyte, the more strongly it binds to a given, oppositely charged ion exchanger. Similarly, more highly charged ion exchangers, those with a greater degree of substitution with charged groups, bind analytes more effectively than weakly charged ones. It should be mentioned that the terms strong and weak ion exchangers derive from the pK_a values of their charged groups and do not say anything about the strength with which they bind analytes. At pH values far from the pK_a, binding equally strong either to a weak or a strong ion exchanger. In addition to the ion exchange effect, other types of binding also occur in the ion-exchange process. These effects are generally small and are mainly due to **van der Waals** forces and polar interactions.

Because of its versatility, its high resolving power, its high capacity, and its straightforward basic principle, ion-exchange chromatography is one of the chromatographic techniques used most often in biochemical studies [see section IV of Ref. 1 (pp. 170–270), Ref. 7]. Detailed operational protocols and the lists of its applications are beyond the scope of this volume, and the interested reader is directed to several excellent reviews (7-10).

Ionization

Ionizable groups in biological macromolecules are either protonated or deprotonated to have positive or negative ionic charges, depending on the pH condition of the solvent. At a neutral pH, the phosphate groups in nucleic acids are all ionized, and the bases are almost neutral. In contrast, in proteins at a neutral pH, the charge states of the ionizable groups are exquisitely dependent on the individual pK_a values of the ionizable residues. They directly affect the electronic structures around active sites, and the stabilities of protein structures (see Electrostatic Interactions).

The degree of ionization of an acid, i, is $10^{-pK_{ai}}/(10^{-pK_{ai}}+10^{-pH})$, and the degree of ionization of a base, j, is $10^{-pH}/(10^{-pK_{aj}}+10^{-pH})$. Therefore, the total net change of an amphoteric molecule, such as a protein, is given by

$$-\sum_i 10^{-pK_{ai}}/(10^{-pK_{ai}}+10^{-pH})+\sum_j 10^{-pH}/(10^{-pK_{aj}}+10^{-pH})$$

The charge state of an ionizable group is governed by its intrinsic acidity and also by the electrostatic environment, which depends on the ionic strength of the solvent. When an ionizable group is surrounded by other anions, the pK_a value increases. In contrast, when it is surrounded by cations, the pK_a value decreases. Therefore, when a salt bridge is formed between an acid and a base, the pK_a of the acid decreases, and the pK_a of the base increases. Thus, each ionizable group in a protein has a unique pK_a value, and this changes with changes in the ionization of nearby groups. The apparent pK_a value is determined by titration experiments or estimated by theoretical calculations based on the tertiary molecular structure. Even when the only structural information about a protein is its amino acid composition, the total net charge of the protein can be approximated, and the isoionic point estimated, by using only the intrinsic pK_a^{int} values, listed in Table 1 of Electrostatic interactions.

Iron-Binding Proteins

Iron is the most abundant transition metal in the earth's crust, but it is poorly available as a nutrient because it forms insoluble ferric hydroxides in the presence of O_2 at neutral pH. Organisms have coped with this challenge by evolving various uptake strategies based on chelation. Once internalized, free iron is quite toxic to cells: Fe^{2+} and Fe^{3+} ions react with H_2O_2 and O^-_2 to generate hydroxyl radicals, which indiscriminately oxidize cellular constituents. Hence, there is a clear need for some form of iron homeostasis (1).

Microbial iron metalloregulation (2) is best understood in *Escherichia coli*. In this bacterium, the ferric uptake regulation (*fur*) gene regulates many genes, including more than a dozen associated with siderophoric biosynthesis and transport. The monomeric Fur protein is approximately 18 kDa in mass and binds a single Fe^{2+} ion. With Fe^{2+} bound, Fur targets a GATAATGATAATCATTATC **consensus sequence** near the **promoter** of iron-regulated genes and acts as a dimeric repressor.

Corynebacterium diphtheriae (and other bacterial and fungal pathogens) experiences a state of iron starvation upon entering a mammalian host, and it responds by producing diphtheria toxin at maximal rates. The diphtheria *tox* repressor (DtxR) plays the primary role in regulating toxin biosynthesis. Fe^{2+}-activated DtxR is a functional dimer, which binds at the *tox* **operator** locus. **X-Ray crystallographic** structures of DtxR suggest that ferrous ions cause a caliper-like conformational change in the relative orientation of the monomers in the dimeric protein structure, leading to a decrease in the distance between the two DNA-recognition alpha-helices to match that in the target DNA (3) (see DNA-Binding Proteins and Repressors).

Bacteria sequester iron during times of plenty and produce bacterioferritins. Mammalian analogs of these iron storage proteins, ferritins, are much better understood.

Iron-Response Elements

The messenger RNAs for iron-binding proteins, such as the transferrin receptor and both subunits of ferritin, contain so-called iron-response elements (IREs). These are RNA structures that contain a stem and a loop that has the **consensus sequence** CAGUGX (1). The transducer proteins, termed iron-responsive proteins (IRPs), bind to the IRE loop when the free iron concentration is low, whereas they are inactivated by high cellular iron levels. Formation of the IRE–IRP complex has a variety of physiological effects, as indicated in Table 1. IRP-binding stabilizes the transferrin mRNA against **RNA degradation**. Regulation of the transferrin receptor expression occurs at the **transcriptional** level. On the other hand, ferritin IRE–IRP complexes block association of the small **ribosomal** subunit with the mRNA of both ferritin subunits and prevent their translation. Consequently, regulation of ferritin expression occurs at the translational level.

Table 1. Physiological Effects of Key Mammalian IREs

mRNA-Containing IRE	Low [Fe]	High [Fe]
Transferrin receptor	Fe uptake Ý	Fe uptake ↓
Ferritin H- and L-chains	Fe storage ↓	Fe storage Ý
5-Aminolevulinate synthase	[porphyrin] ↓	[porphyrin] normal

5-Aminolevulinate synthase, the first enzyme in the heme biosynthetic pathway, is also regulated by IRPs. One of its two IRPs is strikingly homologous to aconitase, an iron-sulfur enzyme in the Krebs cycle. Interestingly, nitric oxide inhibits iron uptake by both IRPs (they remain active and capable of IRE recognition) and hence functions as a vertebrate hormone.

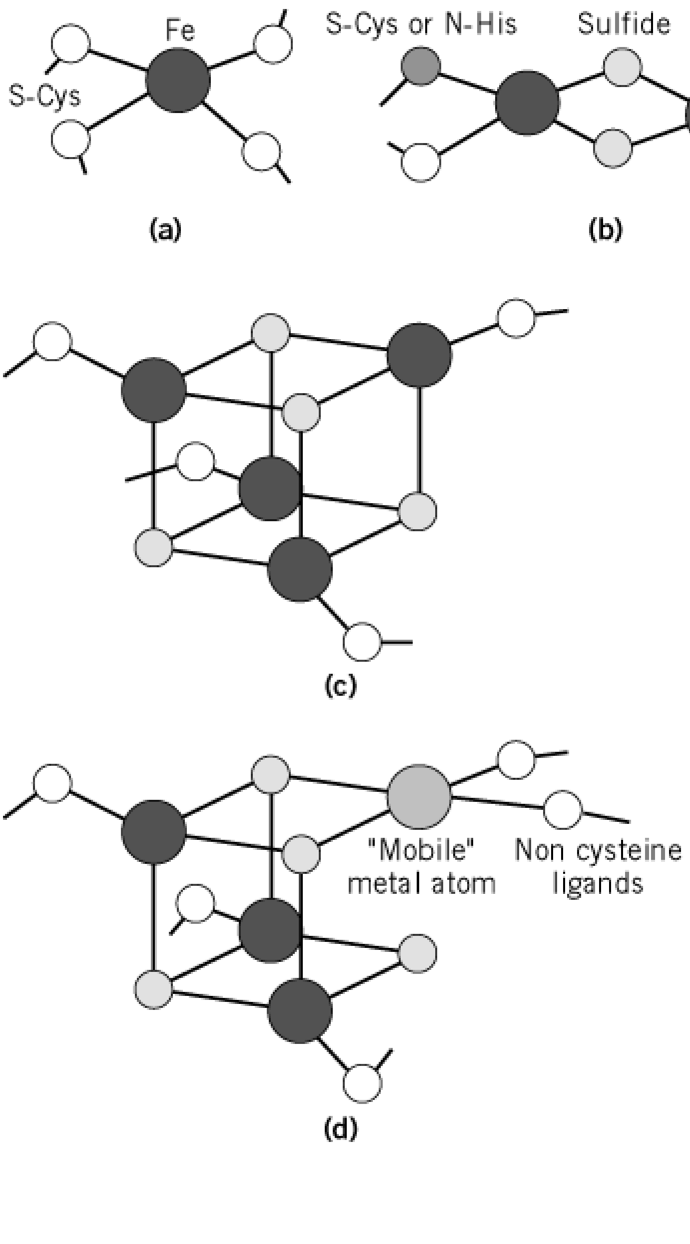
Iron–Sulfur Proteins

This class of proteins comprises several types of proteins and enzymes that contain iron atoms coordinated by sulfur atoms in clusters of different types (Fig. 1). The simplest FeS proteins are the rubredoxins (1Fe, no inorganic sulfur) and the ferredoxins (2Fe, 3Fe and 4Fe). In more complex FeS proteins, other **prosthetic groups** (FAD, FMN, heme, Mo, Ni, etc.) are present, in addition to the iron-sulfur cluster(s). Thus, FeS proteins fulfill several roles: **electron transfer** and storage, catalysis, structural, and regulatory functions (1, 2).

Figure 1. Schematic structures of iron-sulfur clusters found in FeS proteins as determined by X-ray crystallography studies: (**a**) the $Fe(S\text{-}Cys)_4$ unit in rubredoxin; (**b**) the 2Fe–2S cluster in eukaryotic ferredoxins and in Rieske proteins; (**c**) the cubane-like 4Fe–4S structure of bacterial ferredoxins, HiPIPS, IRPs, and active aconitase; (**d**) the cuboidal 3Fe–4S structure found in some bacterial ferredoxins, in inactive aconitase, and in some complex redox enzymes; (**e**) the P cluster of dinitrogenase; (**f**) the FeMoCo cofactor of dinitrogenase.



1. High Potential Electron Carriers: Rubredoxins, HiPIPs, and Rieske Proteins

The simplest of all FeS proteins is rubredoxin, containing a single Fe atom ligated by a four-cysteine-residue unit (Fig. 1a), and no inorganic sulfide, in a polypeptide of 50 to 60 amino acid residues. Rubredoxins are found in strictly anaerobic bacteria and archea (*Clostridia*, *Desulfovibriacee*, *Pyrococcales*) and have oxidation/reduction potentials (+30 to 60 mV, relative to the hydrogen electrode) that appear to be too high to be relevant for bacterial metabolism. Although assumed to function as electron carriers, the redox partners of rubredoxins in anaerobes have not been identified. Recently, a rubredoxin–oxygen oxidoreductase was found to function *in vitro* at the end of a soluble electron transfer chain that couples NADH oxidation to oxygen consumption in *Desulfovibrio gigas*. There is another protein in *D. gigas* containing a single $Fe(Cys)_4$ unit in each of its two small subunits, named desulforedoxin. Rubredoxin-like proteins that contain two $Fe(Cys)_4$ clusters are also found in *Pseudomonacee*. These aerobic rubredoxins transfer electrons to enzymes that catalyze the oxidation of alkanes.

Photosynthetic microorganisms such as *Chromatium spp* and *Rhodospira spp* contain the so-called HiPIPs (high-potential iron–sulfur proteins). These proteins contain a single, cysteine-coordinated 4Fe–4S cubane-like structure (Fig. 1c), but these protein structures favor the high-potential 3+/2+ transition of the metal cluster (reduction potentials +90 to +450mV), rather than the 2+/1+ transition typical of [4Fe–4S] clusters in bacterial ferredoxins.

Among the high-potential FeS proteins of the **mitochondrial** and photosynthetic electron transfer chains, a singularity is represented by the so-called “Rieske” protein in the cytochromes b-c_1 and b_6-f complexes. These “Rieske” proteins contain a 2Fe–2S cluster with two histidine and two cysteine ligands in a unique binding motif (Fig. 1b). The same type of coordination is found in other FeS proteins, most notably in ferrochelatase (found in the intermembrane space of mitochondria and required for inserting iron in tetrapyrroles) and in some bacterial dioxygenases.

2. Complex FeS Proteins

The redox properties of FeS clusters are utilized in multielectron transfer systems, which can be made more efficient by combining donors and acceptors into a single, often multimeric structure. This evolutionary advantage led to the appearance of complex FeS proteins, in which 4Fe–4S or 2Fe–2S clusters are combined with other inorganic or organic cofactors.

Desulfovibriacee and some *Clostridia* also contain what apparently amounts to a natural chimeric protein, in which a rubredoxin-like **domain** is linked to a domain that contains a binuclear, oxo-bridged iron center, such as those found in ribonucleotide reductase or in hemerythrin—hence the trivial names of these proteins: rubrerythrin and nigerythrin. Rubrerythrin was found to have ferroxidase activity, and an oxygen-scavenging function was hypothesized for these proteins. Yet another combination of metallic clusters has been found in *D. gigas* desulfoferrodoxin, a protein in which a desulforedoxin site is associated with an iron site having nitrogen ligands. No biological function is known for desulforedoxin or desulfoferrodoxin.

Nitrogenase components 1 and 2 represent the best-known examples of combinations of different and unusual metal–sulfur centers. In the dimeric component 2 (dinitrogenase reductase), a 4Fe–4S cluster (Fig. 1c) is bound at the dimer interface. Each of the subunits provides two of the coordinating cysteine residues, and the cluster structure and properties are modified upon adenylylation of the dimer. The a_2b_2 nitrogenase component 1 (the true dinitrogenase) contains a number of the so-called P-clusters (derived from 4Fe–4S cubanes) (Fig. 1e), again harbored jointly by adjacent subunits. In the same intersubunit fashion, dinitrogenase also binds FeMoCo, the metal cluster at which the multielectronic reduction of dinitrogen to ammonia occurs. FeMoCo is a modified double cubane structure, in which one of the corners is occupied by a Mo rather than a Fe atom, and is coordinated also by histidine and by an isocitrate molecule (Fig. 1f). Another elementary process in bacterial physiology is hydrogen evolution, which uses an enzyme containing an Ni–FeS cluster, along with 4Fe–4S clusters.

FeS proteins containing multiple iron centers and organic cofactors (most typically flavins and pterins) abound in the electron transport chains of both prokaryotes and eukaryotes. These membrane-bound enzymes are typically made up of several subunits, with a variety of arrangements, and types of clusters and cofactors spanning a broad range of reduction potential values, often modulated through the binding of suitable effectors. Also, an active role for FeS clusters in energy transduction has been proposed. Soluble complex iron–sulfur enzymes play key roles in bacterial metabolism (glutamate synthase or anaerobic ribonucleotide reductase) and in the assimilation pathways of inorganic nutrients in plants (as in sulfite, nitrate, and nitrite reductases), often in conjunction with unique cofactors. A mammalian soluble protein of great complexity is xanthine oxidase, containing flavin, iron–sulfur, and a molybdopterin cofactor. Formylmethanofuran dehydrogenases are FeS proteins found in methylotrophs, which contain Mo or W and a pterin dinucleotide.

3. FeS Proteins Having No Electron-Transfer Function

There is a remarkable structural similarity between the $Fe(Cys)_4$ unit found in rubredoxin-like proteins and the $Zn(Cys)_4$ unit found in DNA-binding **zinc fingers**, and transcription factors containing a $Fe(Cys)_4$ unit have been reported for a number of organisms. No DNA-binding activity has been reported for rubredoxins themselves. Examples of FeS proteins displaying the ability of binding polynucleotides are not limited to rubredoxin-like proteins. *Escherichia coli* endonuclease III contains a single 4Fe–4S cluster, which apparently only plays a structural role.

To alleviate the toxicity of the byproducts of aerobic respiration, *E. coli* induces the synthesis of protective enzymes, and this induction is controlled by the regulatory FeS proteins SoxRS, OxyR, and ArcAB. ArcAB, Fnr, SoxRS, and OxyR function in concert, so that *E. coli* can optimize its energy production and growth rate. Fnr and SoxRS are DNA-binding proteins, and they utilize 4Fe–4S and 2Fe–2S clusters as direct sensors of the redox environment (3).

Perhaps the best-known example of the regulatory function of FeS proteins is represented by the RNA-binding proteins involved in iron homeostasis in mammalian cells. When cells are depleted of iron, iron regulatory proteins IRP1 and IRP2 bind with high affinity to specific RNA stem-loop structures (**iron responsive elements**, IREs) in messenger RNA transcripts. Binding of IRPs to IRE stabilizes the mRNA coding for the transferrin receptor against degradation, while blocking the translation of the mRNA coding for the iron-storage protein, ferritin. In the presence of iron, IRP1 assembles a 4Fe–4S cluster and loses its IRE-binding properties, whereas IRP2 is rapidly subject to **protein degradation**. Thus, the presence of iron allows synthesis of ferritin (as well as of d-aminolevulinate synthase, mitochondrial succinate dehydrogenase, and aconitase), while repressing the synthesis of the transferrin receptor and therefore diminishing iron import into the cell (4).

The role of iron in citrate isomerization catalyzed by aconitase was recognized many years ago, and aconitase was found to contain a 4Fe–4S cluster, which can be converted reversibly to an inactive 3Fe–4S form (Fig. 1d). This conversion is made easier by the absence of a coordinating cysteine residue to the “labile” iron atom. Also complex FeS proteins are not limited to redox reactions. A FAD and 4Fe–4S enzyme from *Clostridium aminobutyricum* catalyzes the reversible dehydration of 4-hydroxybutyryl-CoA to crotonyl-CoA, a reaction involving the cleavage of an unactivated C–H bond; similar activities have been reported for other bacteria.

4. Processing of FeS Proteins and Cluster Assembly

From a chemical standpoint, iron–sulfur clusters are among the easiest cofactors to assemble. Synthetic FeS complexes containing 1, 2, 4, or more iron atoms and an appropriate complement of sulfide readily self-assemble in mixtures of iron, thiol groups, and a suitable source of sulfide (1). This observation, plus the positive charge of the pyrite-like fundamental unit of FeS clusters, and evolutionary considerations, prompted some hypotheses on a role of FeS clusters in the emergence of life in the reducing and acidic environment near submarine hot springs in primordial oceans (5).

A different situation is encountered in the cell, where the toxicity of iron and sulfide must be accounted for, and where **protein folding** or assembly of multimeric proteins must occur, along with **protein targeting** of nuclear-encoded proteins to the appropriate compartments. In cells and organelles, sulfide may be derived from cysteine or from thiosulfate through appropriate enzymes, while the actual carriers of iron remain unknown. FeS proteins are imported into organelles as metal-free precursors, and cluster insertion and acquisition of a native structure are very often assisted by more or less complex scaffolding systems. These scaffolding systems are most relevant when assembly of interprotein multimetallic clusters (as in dinitrogenase) or of multiple-component, multiple-cofactor enzymes is required.

Isochores

The vertebrate genome is compartmentalized into compositionally homogeneous regions, the *isochores* , originally identified (1) as segments of DNA longer than 300 kb that are homogeneous in base composition over segments at least 3 kb long. Isochores can be arranged into several families distinguished by different base compositions, as shown initially by density gradient centrifugation of DNA molecules derived from isochores through the breaks occurring during DNA preparation. Typical of the genomes of most mammals, the human genome has two GC-poor isochore families, L1 and L2 (which have few G and C bases, primarily A and T), which together represent 62% of the genome. Two GC-rich families H1 and H2 represent, respectively, 22 and 9% of the genome, and a very GC-rich H3 family represents only 3–4%. The remaining 4% of the genome consists of satellite and **ribosomal** DNA (2).

The localization of specific genes to defined isochores indicates that genes are not distributed randomly in the human genome. The density of genes is low in GC-poor isochores, increases with increasing GC content in the H1 and H2 families, and reaches a maximum in the very GC-rich family H3, where the gene concentration is at least 20-fold higher than in the GC-poor isochores. The H3 family corresponds to **telomeric** bands of **metaphase** chromosomes, and the L1 + L2 families correspond to **Giemsa bands**, whereas reverse bands comprise both GC-poor and GC-rich isochores.

1. Isochores and Evolution

The compositional distributions of large genome fragments (greater than 100 kb, such as those comprising standard DNA preparations) of **exons** and their codon positions and of **introns** are correlated with each other. They represent compositional patterns and are very different between the genomes of cold- and warm-blooded vertebrates, mainly because the former are much less heterogeneous in base composition and never reach the high GC levels attained by the latter. Only small compositional differences are found among the genomes of either cold- or warm-blooded vertebrates. Compositional patterns allow defining two modes of genome evolution: a conservative mode with no compositional change and a transitional (or shifting) mode with compositional changes. The conservative mode is observed among both cold- and warm-blooded animals. The transitional mode comprises both major and minor compositional changes. In vertebrate genomes, the major changes are associated with GC-rich and very GC-rich isochores in mammalian and avian genomes. Thus, the compositional changes reflect genome **phenotypes** differing not only between warm and cold-blooded vertebrates (eg, *Xenopus* versus mammals and birds), but also between mammals and birds (human and mouse versus chicken), and even among mammals. For a comprehensive review, see refs. 3 and 4.

Isochromosome

Isochromosomes are chromosomes that contain multiple identical chromosomal arms. They may arise during the cell cycle when the two sister chromatids of an **acrocentric** or telocentric chromosome remain fused at their centromeres, leading to the creation of a **metacentric** isochromosome. Alternatively, if homologous chromosomes fail to pair during the first division of **meiosis**, the centromere of the univalent chromosome might split transversely, i.e., between the two arms, which results in two telocentric chromosomes that could be segregated during cell division. These telocentric chromosomes are unstable, and they may fuse to form an isochromosome in which one whole chromosome arm is deleted and the other duplicated. Isochromosomes in humans have been used to demonstrate that the centromere has variable activity, dependent on chromosomal context. For example, an isochromosome X containing two centromeres can be stably inherited through **cell division** if one is inactivated.

Isocratic Elution Chromatography

Continuous elution of analytes in a **chromatographic** separation with only one mobile phase (a single solvent or a constant-composition solvent mixture) throughout the separation is known as isocratic-elution chromatography. This method is frequently very time-consuming, and the analytes are eluted as broad bands if they are strongly adsorbed on the column. Therefore, it is common to follow an initial period of isocratic separation with an elution gradient, in which the polarity of the initial mobile phase is progressively changed by the continuous programmed addition of increasing quantities of a second mobile phase to speed up the rate of elution and to sharpen eluent zones that are trailing or fronting. A description of the theory of isocratic-elution chromatography is beyond the scope of this article, and interested readers are directed to the excellent chapter written by Jandera and Churácek (1).

Isoelectric Focusing

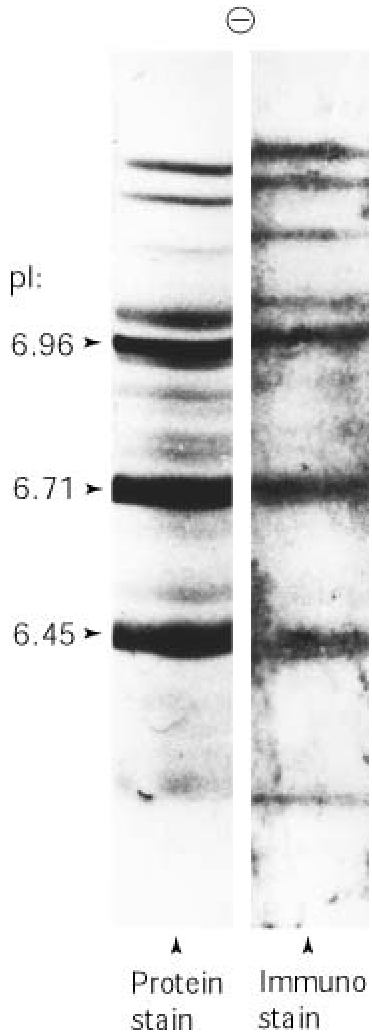
Conventional isoelectric focusing (IEF) in soluble, amphoteric buffers known as carrier ampholytes (CAs) was reported by Svensson-Rilbe in 1961 (1-3). In this technique, the macromolecules of interest are subjected to electrophoresis in a continuous pH gradient. They migrate electrophoretically toward the pH of their isoelectric point (pI), where they have zero mobility. Therefore, the system comes to equilibrium, with each species of macromolecule tightly focused at its pI; any diffusion away is reversed by the electrophoretic migration. At about the same time, Meselson et al. (4) described **isopycnic centrifugation**, a related high-resolution technique that is another member of a family called isoperichoric focusing by Kolin (5). Unlike conventional **chromatographic** and **electrophoretic** techniques, where peaks of material are constantly dissipated by diffusion, IEF and isopycnic centrifugation have built-in mechanisms opposing this. As the analyte reaches an environment (the *perichoron* in Greek) in which its physicochemical parameters are equal (*iso*) to those of its surroundings, it focuses, or condenses, in an ultrathin zone, kept stable and sharp in time by two opposing force fields: diffusion (tending to dissipate the zone) and external fields (voltage gradients in IEF or centrifugal fields in isopycnic centrifugation) forcing the “escaping” analyte back into its “focusing” zone.

Both conventional IEF using carrier ampholytes and the new version using immobilized pH gradients (IPG) (6) rely on the equation for resolving power (expressed as DpI, i.e., the difference in isoelectric points between a protein and a just resolved, nearest contaminant) (7):

$$\Delta \mathrm{pI} = 3.17\sqrt{(D_t[\partial(\mathrm{pH})/\partial x]/E[\partial u/\partial(\mathrm{pH})])}$$

where D_t is the protein translational diffusion coefficient, E is the voltage gradient (V/cm) applied, $\partial(\mathrm{pH})/\partial x$ is the slope of the pH gradient along the separation axis, and $\partial u/\partial(\mathrm{pH})$ is the titration curve of the protein in terms of its mobility as a function of pH. Experimental conditions minimizing DpI offer the greatest resolution, which are shallow pH gradients and high voltage gradients. The best DpI attainable is of the order of 0.01 pH unit in CA-IEF but 0.001 in IPG, where more shallow pH gradients and higher voltages are possible. Consequently, complex mixtures of macromolecules can be resolved into very many species, and what appears to be a single species by many separation techniques is frequently resolved into several by IPG (Fig. 1). A brief description of both methods will be given.

Figure 1. An example of the separations possible with isoelectric focusing. This soluble form of the **receptor** for epidermal growth factor (EGF) gave a single band on SDS-PAGE, but it was resolved by IPG into three major isoforms and several minor bands. The pH gradient was from pH 5 to pH 8, in a 10-cm-long 5% T, 4% C **polyacrylamide gel** equilibrated with 30% ethylene glycol. A total of 50 µg of protein was loaded at the anode, and focusing was carried out with the cathode uppermost. The resulting gels were stained with Coomassie Brilliant Blue R-250 (in ethanol, acetic acid, and copper sulfate) on the left and by Western blotting on the right. The pI values of the major components are indicated.(From Ref. 18, with permission.)

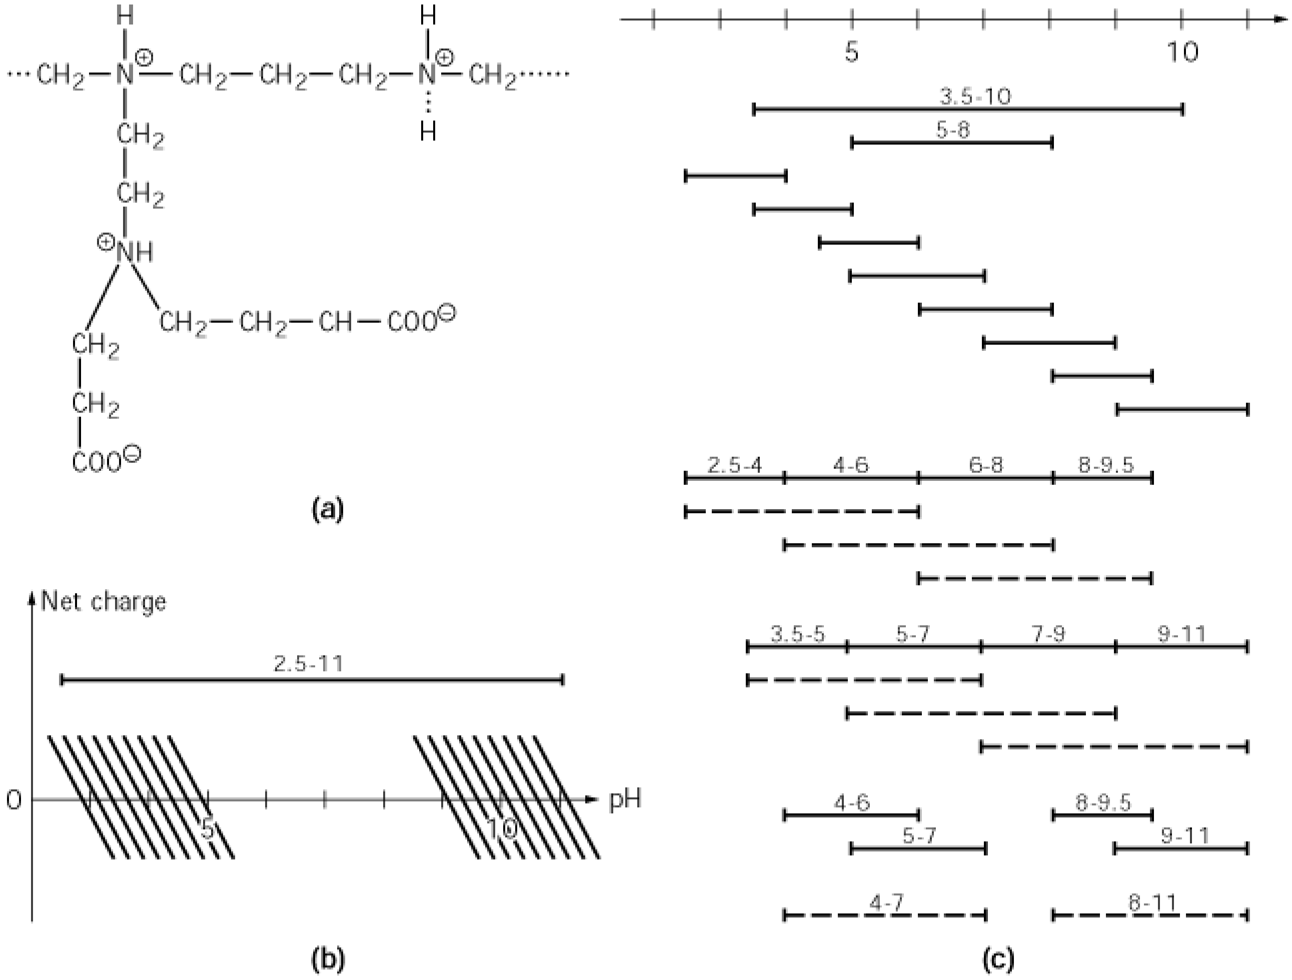


1. Conventional Isoelectric Focusing in Soluble, Amphoteric Buffers

Carrier ampholytes set up the pH gradient for IEF by distributing themselves electrophoretically at their isoelectric points. For a range of pH values, an appropriate mixture of ampholytes is necessary. They must not only be amphoteric, but must also have suitable buffering power and conductivity at their pI (7). The hallmark of a carrier ampholyte is the absolute value of the difference between its pI and the p K_a of its buffering groups; the smaller this value, the greater its conductivity and buffering capacity at its pI (8). Very few natural compounds have this property.

A breakthrough came in 1964 with Versterberg's synthesis of Ampholines (trade name of the commercial product from LKB). They are “oligoprotic amino carboxylic acids, each containing at least four weak protolytic groups, at least one being a carboxyl group and at least one a basic nitrogen atom, but no peptide bonds” (9). Figure 2 reports a hypothetical general structural formula of these ampholytes. Very narrow pH ranges of ampholytes are produced, except for the very extreme pH 2.5 to 4 and pH 9 to 11 ranges, by subfractionating the “wide pH-range” mixture in multicompartment electrolyzers. The synthesis of Ampholines is a genuine “chaotic” process, in that very heterogeneous mixtures of different oligoamines (typically pentaethylene hexamine, tetraethylene pentamine, and triethylene tetramine, including their branched isomers) were reacted with an a-b unsaturated acid (typically acrylic acid) at an appropriate ratio (usually 2 N atoms/1 carboxyl group); b-propionic acid residues result. By this synthetic approach, >600 ampholyte species could be generated in the pH 3 to 10 interval. Subsequently, Pharmalyte species containing >5000 chemically distinct amphoteres in the pH 2.5 to 11 interval were produced. Almgren (10) had predicted theoretically (assuming equimolar distribution of the CA species, even distribution of their DpI along the pH scale, and the same DpK_a) that only 30 amphoteres/pH unit had to be present to generate a stepless pH course. Because the oligoamines prepared had pK_a values well distributed along the pH scale, they could provide the buffering power and conductivity required for IEF. Additionally, the extra p K_a value of the “titrant” acrylic acid grafted onto the oligoamino backbone endowed acidic carrier ampholytes with extra buffering power. This is one of the reasons why focusing with CA buffers is usually more successful in acidic pH ranges than alkaline. The other reasons are that this synthesis generates fewer alkaline ampholytes and that open-face IEF gel slabs at pH >8 absorb atmospheric CO_2, unless submerged under a thin layer of light paraffin oil.

Figure 2. Composition of ampholines. (**a**) Representative chemical formula (aliphatic oligo-amino, oligo-carboxylic aci(**b**) Portions of hypothetical titration curves of Ampholines. (**c**) Different pH cuts for wide- and narrow-range carrier ampholytes.(Courtesy of LKB Producter AB.)



CA–IEF offers unrivaled resolving power in a vast number of separations and is now a standard technique in molecular biology. In addition to its current uses, at least two particular applications are worth mentioning: (a) its use in **two-dimensional** (2-D) electrophoresis to generate 2-D maps (11, 12) and (b) for generating titration curves of macromolecules. In the latter case, the CA–IEF slab gel is focused to generate the desired pH gradient. The slab is then turned 90° and the sample is loaded in a long, thin trench spanning from anode to cathode. The sample is then subjected to electrophoresis perpendicular to the stationary pH gradient. As a result, each protein exhibits its own pH/mobility curve in the gel slab (13).

There are, however, a number of problems with the CA–IEF gels: They have uncertain chemical environments of low ionic strength and uneven buffering capacity and conductivity; cathodic drift results in extensive loss of proteins at the gel cathodic extremity upon prolonged runs; and the pH gradients possible are limited by the nature of the carrier ampholytes available. The low ionic strength within the gel often induces near-isoelectric precipitation and smears of proteins, even in analytical runs with small amounts of protein. For all these reasons, the technique of IPG was launched in 1982 (6).

2. Immobilized pH Gradients

Immobilized pH gradients (IPGs) are unique in that they are based on the insolubilization of the entire set of buffers and titrants responsible for generating and maintaining the pH gradient along the separation axis. Contrary to CA–IEF, where a multitude of soluble, amphoteric buffers is expected to create and sustain the pH gradient during the electrophoretic run, IPGs are based on only a few well-defined, nonamphoteric buffers and titrants, able to perform in a highly reproducible manner.

Advantages of the IPG technique are: (a) increased resolution (by at least one order of magnitude); (b) unlimited stability of the pH gradient; (c) flexibility in the choice of pH interval; (d) increased loading ability; (e) high reproducibility; (f) minimal distortion by salts in the sample; (g) full control of pH, buffering capacity and ionic strength; and (h) easy separation of sample from buffering ions in preparative runs.

In IPGs, the pH gradient exists prior to the IEF run and is copolymerized, and thus immobilized, within the polyacrylamide matrix. This is achieved by using, as buffers, a set of six nonamphoteric weak acids and bases, having the general chemical composition $CH_2CH—CO—NH—R$, where R denotes either two different weak carboxyl groups, with pK_a values of 3.6 and 4.6, or four tertiary amino groups, with pK_a values of 6.2, 7.0, 8.5, and 9.3 (available under the trade name Immobiline from Pharmacia-LKB). A more extensive set, comprising 10 chemicals (with the addition of a pK_a 3.1 acidic buffer, a pK_a 10.3 alkaline species, and two strong titrants, a pK_a 1 acid and a pK_a >12 quaternary base), is available as “pI select” from Fluka AG, Buchs, Switzerland. During gel polymerization, these buffering species are efficiently incorporated into the gel (84% to 86% conversion efficiency at 50°C for 1 h). Immobiline-based pH gradients can be cast in the same way as conventional gradient polyacrylamide gels, by using a density gradient to stabilize the Immobiline concentration gradient, with the aid of a standard two-vessel gradient mixer (see Transverse Gradient Gel Electrophoresis (Tgge)). The buffers are not amphoteric, but are bifunctional: At one end of the molecule is located the buffering (or titrating) group, and at the other is the acrylic double bond, which will participate in the polymerization process. Acidic and alkaline Immobilines have different temperature coefficients ($\partial pK_a/\partial T$), so temperature affects Immobiline pH gradients, as do the ionic strength and additives that change the water structure (chaotropic agents, such as urea) or lower its dielectric constant. The largest changes are due to the presence of urea: Acidic Immobilines increase their pK_a values in 8 M urea by as much as 0.9 pH units, and basic Immobilines increase their pK_a values by only 0.45 pH unit. Detergents in the gel (up to 2% *w/v*) do not alter the Immobiline pK_a, suggesting that acidic and basic groups attached to the gel are not incorporated into surfactant micelles. For generating extended pH gradients, one should use two additional strong titrants having pK_a values well outside the desired pH range: QAE (quaternary amino ethyl)-acrylamide (pK_a >12) and AMPS (2-acrylamido-2-methyl propane sulfonic acid, pK_a ≈1).

With the IPG technology, ultranarrow (0.1), narrow (1.0), and extended (up to 8.0) pH gradients can be engineered with high precision and reproducibility. Recipes have been tabulated listing 58 1-pH-unit-wide gradients, separated by 0.1 pH unit increments, starting with the 3.8 to 4.8 pH interval and ending with the pH 9.5 to 10.5 range (14). If a narrower pH gradient is needed, it can be derived from any of the 58 pH intervals tabulated by a simple linear interpolation of intermediate Immobiline molarities. Recipes for gradients with pH spans from 2 pH units up to 6 pH unit spans are available (15). All the formulations are normalized to give the same average value of buffering power of 3mequiv.$L^{-1}pH^{-1}$, adequate for producing highly stable pH gradients. For pH intervals covering >4pH units, the best solution is to mix a total of 10 Immobiline species, 8 of them buffering ions and two the strong acidic and basic titrants. Nonlinear (eg, concave and convex exponential, as well as sigmoidal) IPG gradients can be generated and optimized (16).

After casting, IPG gels should be washed extensively, so as to remove nonpolymerized material, salts, and polymerization catalysts. This also produces clean matrices, devoid of toxic materials (eg, unreacted acrylic double bonds) that could modify proteins by reacting with thiol groups and terminal amino groups. As IPG gels are cast onto plastic supports and are rather thin (0.5 mm) and porous, they can be stored dry and then reswollen with any desired additives just prior to use. IPG are very reproducible and effective at very alkaline pH values, up to pH 12, where CA–IEF would simply fail; histones could thus be focused to steady state (17).

Isoelectric Point (PI)

The isoelectric point is the pH at which the total net charge of an amphoteric molecule becomes zero. The isoelectric point depends on the ionic strength of the solvent, the counterion species, and the solute concentration, whereas the isoionic point is the isoelectric point in the absence of counterions and at low solute concentrations. The isoelectric point is readily measured as the pH at which the molecule is immobile in an electrophoresis experiment (see Isoelectric Focusing). The isoelectric point approaches the isoionic point at low ionic strength, when all bound ions are removed. At the isoelectric point, amphoteric molecules aggregate and become insoluble because there are no electrostatic repulsions between molecules with the same net charge.

Isofunctional Proteins

In some instances, it is necessary for an organism to produce two or more forms of the same protein, *isofunctional proteins* that have the same function, so as to optimize their metabolic regulation. Cells generally have two primary mechanisms for regulating their metabolic reaction rates in response to changes in the levels of various metabolites: (i) **allosteric** inhibition or activation of the activities of certain enzymes and (ii) regulation of the biosynthesis of the enzymes.

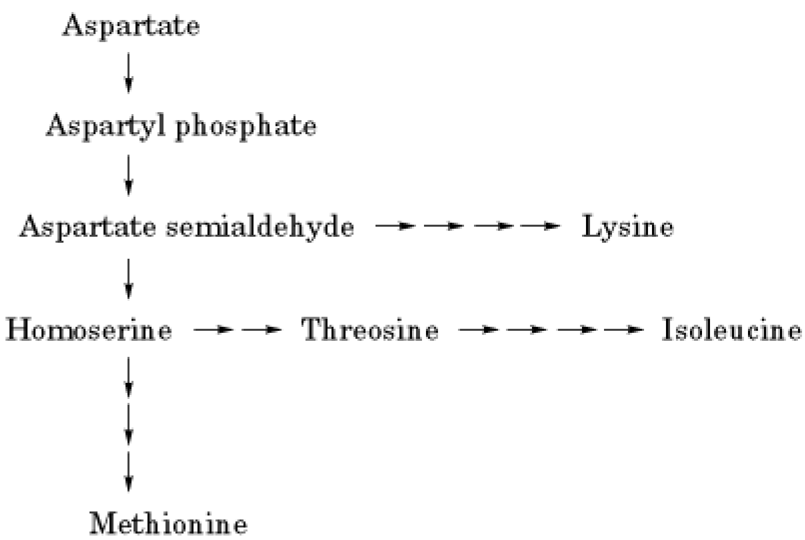
1. Regulation of Biosynthetic Pathways

Consider a linear sequence of reactions

$$A \longrightarrow B \longrightarrow C \longrightarrow D \longrightarrow E \longrightarrow M$$

leading to the synthesis of the essential metabolite M. In the presence of excess M in the intracellular pool, the enzyme carrying out the conversion A → B will often be subject to **feedback inhibition** by M if, as is generally the case, this enzyme is an allosteric protein. M may also **repress** the synthesis of the enzymes of the entire pathway. These control phenomena are economical and efficient ways of keeping the pool size of M relatively constant and do not cause any detrimental side effects.

Now consider a branched reaction biosynthetic sequence, such as that of the aspartate family of amino acids:



Regulation of this pathway by feedback inhibition of the first enzyme, aspartokinase, or by repressing expression of the enzymes of the entire pathway by the various end products (lysine, threonine, isoleucine, and methionine) could not ensure balanced production of all end products when one or just a few are present in excess. The solution to this potential dilemma differs according to the organism studied, but that of *Escherichia coli* illustrates the use of isofunctional proteins.

2. Three Aspartokinases in *Escherichia Coli*

Of all the natural amino acids occurring naturally as protein constituents, only two, L-lysine and L-threonine, influence the aspartokinase activity of crude extracts of *E. coli*. Neither totally inhibit the activity, and the total inhibition, when they are present simultaneously, is the sum of that observed for each independently because one aspartokinase is sensitive to inhibition by lysine and another is sensitive to threonine (1). The synthesis of the enzyme aspartokinase is repressed by lysine, and that of the latter is subject to a multivalent repression by threonine and isoleucine ((1),(2)). A third aspartate kinase is inhibited by none of the end-products of the pathway, but its synthesis is repressed by methionine (see Methionine Regulon). The three aspartokinases are highly homologous and share a common ancestor (3-5).

The rational solution in *E. coli* to the dilemma posed by the regulation of branched biosynthetic pathways was the synthesis of multiple, *isofunctional* enzymes that catalyze the synthesis of the common precursor, aspartyl phosphate. Each of these enzymes is independently subject to feedback inhibition and to repression by different end-product metabolites. Another example is encountered in the *E. coli* biosynthetic pathway of aromatic amino acids. Three distinct isofunctional 3-deoxy-d-arabino-heptulosonate-7-phosphate synthetases are, respectively regulated by allosteric inhibition and/or repression by the three end products, phenylalanine, tyrosine, and tryptophan (6) (see TRP Operon).

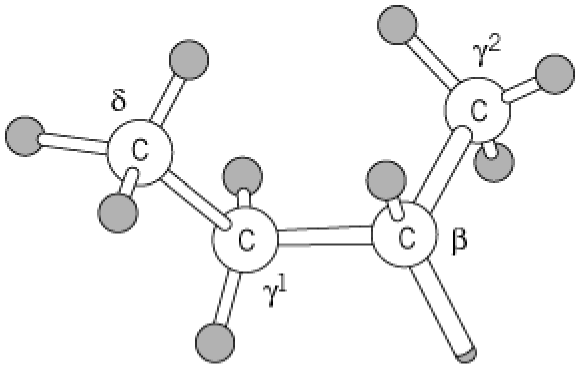
Isoionic Point (Isoionic pH)

The isoionic point is the pH at which the total net charge of an amphoteric molecule becomes zero in pure water. The ideal isoelectric point is that in the complete absence of salt and at very low solute concentrations. No counterions should be present except for the protons and the hydroxyl ions of the solvent. Any metal ions bound to the macromolecules should be removed. The isoionic point can be estimated from the pK_a values of the individual ionizable groups.

Isoleucine (Ile, I)

The amino acid isoleucine is incorporated into the nascent polypeptide chain during **protein biosynthesis** in response to three **codons**—AUU, AUC, and AUA—and represents approximately 5.2% of the residues of the proteins that have been characterized. The isoleucyl residue incorporated has a mass of 113.16 Da, a **van der Waals volume** of 124 $Å^3$, and an accessible surface area of 182 $Å^2$. Ile residues are frequently changed during divergent evolution; they are interchanged in **homologous** proteins most frequently with valine, leucine, and threonine residues.

The Ile side chain is nonpolar with no functional or reactive groups:



Consequently, Ile is one of the most **hydrophobic** amino acid residues, and 60% of Ile residues are completely buried in native protein structures. Ile residues do not favor the **alpha-helical** conformation in model peptides, and they occur most frequently in the beta-sheet type of **secondary structure** in native proteins. Note that the Ile side chain has a center of asymmetry, at C^b, and that only the one isomer occurs naturally and is incorporated into proteins.

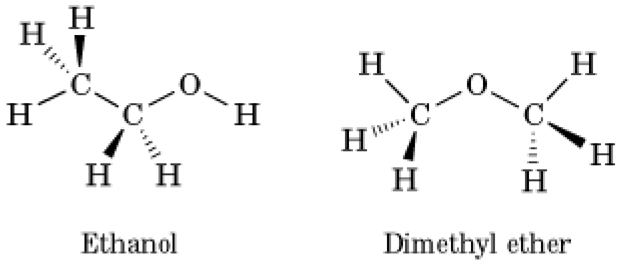
Isomer

The word isomer indicates that two molecules share the same elemental formula, being derived from the Greek isos, for "equal" and meros for "part." The importance of isomers in chemistry and biochemistry derives from the historical importance of elemental analysis in determining structural identity. A simple example of isomers is ethanol and dimethyl ether, both compounds having the elemental formula C_2H_6O (Fig. 1).

Figure 1. The structural differences between the isomers ethanol and dimethyl ether. These demonstrate how two molecules having the same elemental formulas can have different covalent structures.

Structural isomers



Since two molecules of common elemental formula can differ in many ways, many times the mode of differentiation is indicated. Ethanol and dimethyl ether are structural isomers, as are glucose and fructose, because the number and type of bonds are different. Geometric isomers differ in geometrical arrangement of bonds, eg, fumarate and maleate. Stereoisomers, diastereomers, and enantiomers are specialized cases of isomerism, where the differences in the molecules are determined solely by the spatial orientation of the bonds. Tautomers are another specialized class of isomers that are differentiated by their ability to equilibrate rapidly.

A common mistake is to regard conformers as isomers. Conformers are generated by rotation about a single bond and not a difference in the structure or configuration of the bonds present, which is required for isomerism (1).

Isomerases

Isomerases form a broad group of enzymes that catalyze intramolecular rearrangements. The subdivisions within this class are:

- *Racemases*. Act on amino acids and hydroxy acids with **chiral** centers.
- *Epimerases*. Act on carbohydrates and their derivatives, as well as other compounds with chiral centers.
- *Isomerases*. Catalyze cis trans isomerization reactions, keto-enol transformation, the interconversion of aldoses and ketoses, shifts of double bonds, and the rearrangement of disulfide bonds.
- *Mutases*. Transfer acyl, phosphoryl, amino, and other groups from one intramolecular position to another

Isomorphous Replacement

To determine the structure of a macromolecule using X-ray crystallography, an electron density map of the structure is computed as a Fourier summation:

$$\rho(xyz) = \frac{1}{V}\sum_h \sum_k \sum_\ell |F(hk\ell)| \times \exp[-2\pi i(hx + ky + \ell z) + i\alpha(hk\ell)] \quad (1)$$

where r(*x y z*) is the electron density at position *x*, *y*, *z* in the unit cell and *F*(*h k* ℓ) is the amplitude of the structure factor for reflection *h k* h. Apart from correction factors, *vbm*0;*F*(*hk*h) *vbm*0; = <*rad*><*rcd*>*I*(*hk*h)</*rcd*></*rad*>, where *I*(*h k* h), is the intensity measured for the reflection *h k* h. The phase angle for this reflection is a(*h k* h). The value of a(*h k* h) cannot be derived directly from the experimental data for macromolecular structures (see Phase Problem). Several methods do exist, however, to find the values for the phase angles. For macromolecular structures, such as proteins, isomorphous replacement is the oldest and the most general method. It was applied for the first time by Perutz to solve the structure of hemoglobin (1).

It requires the X-ray diffraction pattern of native protein crystals and also of one or more derivatives that contain heavy atoms attached to the native protein. The attachment must be isomorphous, which means that the structure of the protein itself should not be affected by the binding of the heavy atom reagents. A first check for isomorphism is comparing the unit cell dimensions of the native and derivative crystals. An easy way to introduce heavy atoms is to soak a native crystal in an appropriate solvent that contains the heavy atom. It uses the large voids and channels filled with the solvent that are present between protein molecules in a crystal. Small reagents easily diffuse into the crystal and reach reactive sites on all of the molecular surfaces.

After processing the diffraction data, the position of the heavy atoms in the unit cell must be found. This can be done with a difference Patterson summation which has as coefficients (D*F*)^2 = (*vbm*0;F_{PH}*vbm*0;–*vbm*0;F_P*vbm*0;)^2 and all phase angles equal to zero:

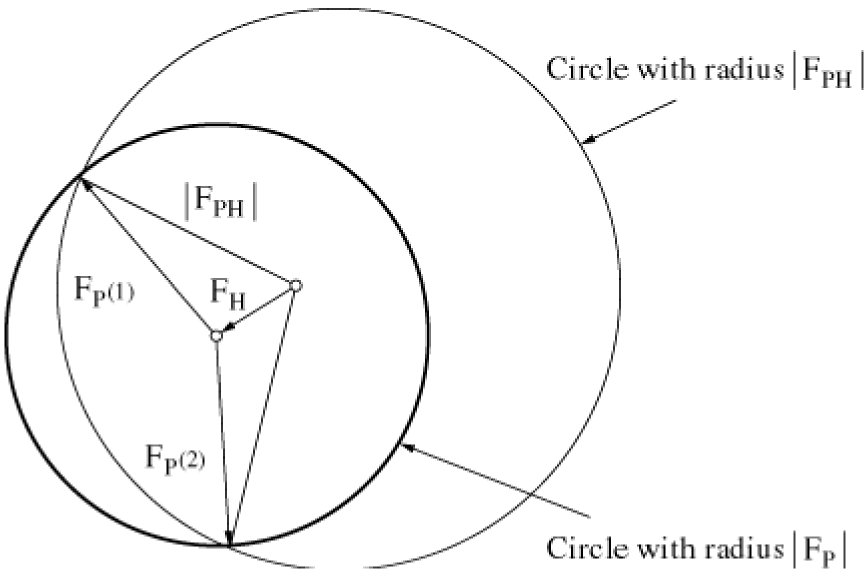
$$P(uvw) = \frac{1}{V}\sum_h \sum_k \sum_\ell \{\Delta F(hk\ell)\}^2 \cos[2\pi(hu + kv + \ell w)]$$

where *u*, *v*, and *w* are coordinates in the Patterson cell [see Patterson Map]. F_{PH} and F_P are the amplitudes of the structure factor for one reflection of the derivative and the native structure, respectively.

After determining and refining the heavy atom position and parameters, the heavy atom contribution of the vector $\mathbf{F_H}$ to the structure factor can be calculated. The knowledge of F_{PH}, F_P and $\mathbf{F_H}$is sufficient to determine the phase angle of the reflection from the crystal that contains only the protein. In principle, this is done by a circle construction method due to Harker. In this method, the structure factors are regarded as vectors in a plane (Argand diagram). The length of such a vector is equal to the amplitude of the structure factor and its direction is given by the phase angle of the reflected beam. For each reflection, a circle is drawn whose radius is F_P (Fig. 1). Next, the vector $\mathbf{F_H}$

is pointed to the center of this F_P circle. A second circle is drawn with radius F_{PH} whose center is at the origin of vector $\mathbf{F_H}$. The points of intersection of the two circles are possible end points of the structure factor of the protein, because only at those positions is the principle of isomorphous replacement obeyed: $\mathbf{F_P} + \mathbf{F_H} = \mathbf{F_{PH}}$.

Figure 1. The Harker construction for determining the protein phase angle in the isomorphous replacement method.



The choice between the two possible vectors, $\mathbf{F_P}$ (1) and $\mathbf{F_P}$ (2), can be made by repeating the procedure with a second, or even further, heavy atom derivatives. This is called multiple isomorphous replacement (MIR). Because of experimental errors and nonideal isomorphism, the correct phase angle may differ somewhat from the exact point of intersection. Therefore, weighting probabilities are introduced in most procedures for calculating the phase angle, depending on the degree of closure of the vector triangle $\mathbf{F_P} + \mathbf{F_H} = \mathbf{F_{PH}}$ (2). With only one derivative, the method is called single isomorphous replacement (SIR). With SIR, the protein electron density map is calculated from $\mathbf{F_P}$ (1) + $\mathbf{F_P}$ (2). It is expected that the correct values for the many $\mathbf{F_P}$'s contribute to a correct electron density map and the incorrect values contribute to noise.

Isopropyl-1-Thio-b-D-Galactopyranoside

Escherichia coli grown in lactose (1-4-b-galactosyl-glucose) produces about a thousand times more **b-galactosidase** than when grown in glucose. What happens? The kinetics of the process could be revealing, but lactose is a substrate of b-galactosidase. Lactose is hydrolyzed into glucose and galactose by this enzyme, and it is also isomerized. In fact, one of the isomerization products, *allolactose* (1-6-b-galactosyl-glucose) is the actual **inducer**. Lactose itself does not induce! Therefore, lactose is badly suited for the kinetic study of this induction process.

What would possibly be an ideal inducer that is not hydrolyzed by b-galactosidase? The German biochemist Otto Meyerhof had left a collection of glycosides in Paris when fleeing the German army in 1940. One of them was phenyl-1-thio-b-D-glucopyranoside, synthesized in 1912 by Konrad Delbrück in Emil Fischer's laboratory in Berlin. In contrast to ordinary glycosides, it is stable under extreme conditions. Jacques Monod found the collection after the war. He picked up the idea and interested two German chemists, Dietmar Türk and Burckhardt Helferich in Bonn, in synthesizing a whole set of 1-thio-b-D-galactopyranosides. The best inducer was isopropyl-1-thio-b-D-galactopyranoside (IPTG). Because IPTG is not measurably hydrolyzed by b-galactosidase, it was called a gratuitous inducer. Using IPTG, it could be shown that induced b-galactosidase synthesis starts three minutes after addition of the inducer and continues from then on at with a constant rate (1) (see Lac Operon). Later, **radiolabeled** IPTG was used to isolate Lac repressor (see Lac Repressor) (2). See Lac Operon for further details and reference 3 for its general history.

Isoschizomer

Isoschizomers are distinct, different restriction endonucleases (see Restriction Enzymes and Restriction–Modification Systems) that recognize the same DNA sequence and cleave at the same position in the DNA. Isoschizomers are derived from different organisms and sometimes have different amino acid sequences. For example, R•*Eco*RI (from *Escherichia coli*) and R•*Rsr*I (from *Rhodobacter sphaeroides*) are isoschizomers that both recognize the duplex DNA sequence G ^ AATTC and cleave (designated by the caret symbol " ^ ") the phosphodiester bond after the G on each strand (G ^ AATTC). Another isoschizomeric pair are the type IIs enzymes *Ksp*632I and *Ear* I, which recognize CTCTTC and cleave (1/4) to the right side (3′) of the sequence (1). The (1/4) designation indicates that the (5′–3′) strand is cleaved one nucleotide residue to the right of the canonical sequence and that the complementary strand is cleaved on the same side 4 nucleotide residues beyond the site.

Except in a few cases, like the R•*Eco*RI/R•*Rsr*I pair, isoschizomers show little amino acid sequence similarity to one other. DNA methyltransferases (MTases; see Methyltransferase, DNA), the companion enzymes of endonucleases, isolated from different organisms and having the same DNA sequence and methylation specificity, are referred to as *isoprostomers* or *isomethylators* (2). For example, M•*Eco*RI and M•*Rsr*I both recognize GAATTC and methylate the second adenine base to give GAmATTC, where mA represents the methylated adenine product.

A related type of isomeric restriction endonucleases is termed *neoschizomer* or *heteroschizomer* (2). These endonucleases are also derived from different organisms and have the same sequence specificity, but cleave at different positions within the sequence. For instance, R•*Asp*718I and R•*Kpn*I are neoschizomers that produce G ^ GTACC and GGTAC ^ C cleaved sequences, respectively. Another neoschizomeric pair are R•*FoK*I and R•*Sts*I, which recognize the sequence dGGATG and cleave (9/13) and (10/14) nucleotides beyond the recognition sequence, respectively (3). MTases that have the same sequence specificity but methylate at different positions are termed *heteroprostomers* (2). For example, M•*Hpa*II and M•*Msp*I both recognize CCGG, but M•*Hpa*II methylates the first C to give mCCGG and M•*Msp*I, the second C to give CmCGG.

Depending on the particular endonuclease or MTase, one **isoenzyme** may provide a more economical or suitable alternative to another. Some isomers are less costly to produce, have less star activity, can be more easily freed of nuclease contamination, or have greater stability or different sensitivities to methylation. Isomeric endonucleases and MTases are useful in several applications. For example, some isoschizomers can be used to analyze the methylation state of DNA. For instance, to determine the level of 5-methylcytosine in CG dinucleotides in mammalian genomes, isoschizomers with different sensitivities to methylation may be used. R•*Msp*I, R•*Hpa*II, and R•*Hap*II all recognize and cut after the first C of C ^ CGG. R•*Msp*I cuts at methylated sequences CmCGG, whereas the isoschizomers R•*Hpa*II and R•*Hap* II do not. In a related example, MTase isomers can be used to modulate endonuclease activity. M•*Hpa*II (CmCGG) and M•*Msp*I (mCCGG) are a heteroprostomeric pair. M•*Msp*I methylation inhibits R•*Msp*I and R•*Hpa*II but not R•*Hap*II, whereas M•*Hpa*II methylation inhibits R•*Hpa*II and R•*Hap*II but not M•*Msp*I.

Neoschizomers are also useful in molecular cloning. For instance, R•*Sac*I generates a 5′ overhang, staggered cut on cleavage of the canonical sequence GAGCT ^ C. Its neoschizomer, R•*Eco*ICRI, generates a blunt cut: GAG ^ CTC. *Blunt-end* DNA generated by R•*Eco*ICRI can be ligated (see DNA Ligase) to other blunt-end DNA fragments, thereby eliminating the need for compatibility of cohesive termini for ligation of DNA fragments produced by R•*Sac*I cuts. The existence of restriction–modification isoenzymes expands our capacity to manipulate DNA.

Isotachophoresis

Isotachophoresis (also known as “stacking”) is an application of discontinuous buffer systems for electrophoresis in which sequential moving boundaries of all the components present (the stack) are set up and displaced in the electric field at a single velocity. In principle, such a system does not differ from the stacking phase of disc electrophoresis . The sequential leading and trailing ion moving boundaries may be separated from each other by proteins or other ionic species with intermediate net mobilities (“spacers”). Both amino acids and carrier ampholyte mixtures (see Isoelectric Focusing) have been used as spacers between stacked protein zones. At equilibrium, contiguous zones of stacked proteins or spacers migrate at the same velocity; hence the name *isotachophoresis* . The width of each zone is proportional to the amount of protein or spacer in the zone. Thus, when the sample load is increased, the distance between the leading and trailing edges of a moving boundary (the zone within the stack) increases, making it possible to isolate a homogeneous protein from the center of each zone of the "extended stack." The concentration of protein is "regulated" at very high values by the mobilities and concentrations of the ions constituting the discontinuous buffer system that generates the stack, and so isotachophoresis is an ideal preparative technique. Theoretically, isotachophoresis is not only synonymous with steady-state stacking and disc electrophoresis but becomes also mechanistically the same as isoelectric focusing when the concentration of the common counterion approaches zero.

The spaced zones can be detected by differences in their temperature or conductance, because each moving boundary at the steady-state is characterized by a specific field strength that provides an equal ("iso") mobility in spite of the differences in net mobility between components of the stack. Such detectors affixed to capillaries are the preferred instrumentation of analytical isotachophoresis, and they preceded by many years the use of absorbance and fluorescence detectors in capillary zone electrophoresis.

Isotope Exchange at Equilibrium

Measuring the rate of exchange of isotopes between substrates and products in the presence of an enzyme has been very useful for determining the **kinetic mechanisms** of enzyme-catalyzed reactions. It relies on the incorporation of **radioactive** atoms from a substrate (or product) into the product (or substrate) under conditions where there is no net reaction. Thus, it differs from other kinetic techniques that rely on the measurement of the rates of product formation. The procedure that is utilized depends on the mechanism under study

A single-site ping-pong mechanism consists of two partial reactions, so the overall reaction is a double displacement (see **Kinetic mechanisms**); First, substrate A is converted to P, leaving a modified form of the enzyme that then converts substrate B to product Q. For the first partial reaction

$$\mathrm{E} + \mathrm{A} \rightleftharpoons (\mathrm{EA} - \mathrm{FP}) \rightleftharpoons \mathrm{F} + \mathrm{P}$$

the addition of only substrate A to the enzyme will result in the release of P and the production of a modified form of the enzyme F. The maximum amount of P that can be released is equivalent to the enzyme concentration and that will occur only when the equilibrium of the partial reaction lies far to the right or the concentration of A is high. Usually, the concentration of enzyme that is used to detect a partial exchange reaction is low and in the micromolar region, so the release of P is small. In the absence of substrate B, the system is at thermodynamic equilibrium, and the A and P reactants are shuttling back and forth. Thus, on the addition of isotopically labeled P (or A), it will be converted to A (or P) and the isotope is incorporated into A (or P). Given sufficient time, the label will be distributed in the same proportions in A and P, and the specific radioactivities of A and P will be identical. The rate at which A is converted to P must be the same as that for the conversion of P to A. It is this partial exchange reaction in the absence of the other substrate that characterizes a ping-pong mechanism. But it is important to demonstrate that the exchange reaction occurs with both halves of the reaction, ie, with both A/P and with B/Q. If only one exchange reaction occurs, it could be due to the presence of an impurity in the enzyme preparation.

The equation for the initial rate of the exchange reaction observed between A and P, starting with labeled A, v_{A-P}, is given by the expression

$$v_{A-P} = \frac{(V_1 K_{ia}/K_a)AP}{K_{ia}P + K_{ip}A + AP} \tag{1}$$

Here, V_1 is the maximum rate of the enzyme-catalyzed reaction, A and P are the concentrations of the two reactants, and K_a is the $\boldsymbol{K_m}$ of A. The equation has the same form as that for the initial velocity of a ping-pong mechanism (see **Kinetic mechanisms**), except that the denominator contains **dissociation constants** for the EA (K_{ia}) and FP (K_{ip}) complexes (1). In the absence of the formation of a dead-end FA complex (see Substrate Inhibition), a plot of $1/v$ against $1/A$ at different concentrations of P yields a family of parallel straight lines (see Lineweaver–Burk Plot). Analysis of the kinetic data can give values for K_{ia} and K_{ip} as well as for the apparent maximum velocity of the isotope exchange reaction, which is equal to either V_1K_{ia}/K_a or V_2K_{ip}/K_p, where V_2 is the maximum rate of the reverse reaction. An equation of the same form applies for measurement of the initial rate of the B–Q exchange:

$$v_{B-Q} = \frac{(V_1 K_{ib}/K_b)BQ}{K_{iq}B + K_{ib}Q + BQ} \tag{2}$$

The maximum velocity of the exchange reaction, relative to the maximum velocities of the overall chemical reactions, depends on the values of the dissociation and Michaelis constants. But there is a relationship between the maximum rates of the chemical (V_1 and V_2) and exchange (V_{A-P} and V_{BQ}) reactions (Eq. 3):

$$\frac{1}{V_{A-P}} + \frac{1}{V_{B-Q}} = \frac{1}{V_1} + \frac{1}{V_2} \tag{3}$$

A further relationship that holds for a single-site ping-pong mechanism is given in Equation 4:

$$\frac{1}{V_{A-Q}} = \frac{1}{V_{A-P}} + \frac{1}{V_{B-Q}} \tag{4}$$

The addition of both substrates or both products to measure the rate of the overall exchange reaction would reduce the rate of exchange of the partial exchange reactions because of the formation of the FB and/or EQ complexes, which would reduce the concentration of the forms of enzyme that participate in the partial exchange reactions.

The procedure that is utilized for the study of exchange reactions with sequential reactions differs from that for a ping-pong mechanism, because sequential mechanisms do not exhibit partial exchange reactions. The technique is applied by allowing the sequential reaction to come to equilibrium and then disturbing that equilibrium by the addition of a small chemical concentration of a highly **radiolabeled** reactant. The initial rate of the exchange of the label from substrate to product is measured as a function of the concentration of a substrate–product pair that is increased in its equilibrium ratio. For the Bi–Bi reaction

$$A + B \rightleftharpoons P + Q$$

K_{eq} is equal to $(P)\,(Q)/(A)/(B)$ and it is possible to raise the concentration of any one of four pairs of reactants, P/A, P/B, $Q/\,A$, or Q/B, without disturbing the equilibrium. The exchange rate can be measured for any one of three possible pairs, but for the most part, exchanges are measured between like substrate–product pairs with the absolute concentration of the same pairs being raised in constant ratio. For the creatine kinase reaction

$$\text{Creatine} + \text{MgATP}^{2-} \rightleftharpoons \text{phosphocreatine} + \text{MgADP}^{-}$$

the three possible exchanges would be creatine-phosphocreatine, ATP-phosphocreatine, and ATP-ADP. No atoms are exchanged between creatine and ADP.

The exchange patterns for ordered and rapid equilibrium, random mechanisms are given in Table 1. A straightforward ordered mechanism is characterized by the fact that the A–Q exchange is inhibited as the concentration of the B/P pair is increased (1). This result contrasts with that for a rapid equilibrium, random mechanism where there is no inhibition of the A–Q exchange rate with increasing concentrations of the B/P pair. The latter mechanism is further characterized by the equality of all three exchange reactions, as demonstrated for the creatine kinase reaction (2). This will not be the case unless catalysis is the sole rate-limiting step of the reaction sequence (3). An enzyme that catalyzes a Bi–Bi reaction which conforms to a rapid equilibrium, random mechanism has distinct binding sites for each of the two substrates involved in the reaction. Thus, it becomes possible for one substrate and the product of the other substrate to be present on the enzyme at the same time. Two such dead-end complexes could form. The one involving the smaller substrate and smaller product (EBQ) will always form, whereas the other dead-end complex may, or may not, do so. Increasing the concentration of the reactant pair that is involved in dead-end complex formation will lead to inhibition of all three exchanges.

Table 1. Isotope Exchange Patterns

Mechanism	Varied Substrate–ProductPair	Exchange Measured	Type of Double-reciprocal Plot
Ordered	A/Q	A – Q	Linear
		B – P	Linear
	B/P	A – Q	Substrate inhibition[a]
		B – P	Linear
Rapid equilibrium, random	A/Q	A – Q	Linear
		B – P	Linear
	B/P	A – Q	Linear
		B – P	Linear

B/Q	A – Q	Substrate inhibition
	B – P	Substrate inhibition
	A – P	Substrate inhibition

[a] This term is used to describe the fall-off in the initial rate of isotope exchange as the concentration of a substrate–product pair is raised in constant ratio.

The equations that describe the initial rates of isotope exchange for sequential reaction mechanisms are considerably more complex than those for the partial exchange reactions with a ping-pong mechanism. The equations for ordered (2), and rapid equilibrium, random (3) and partly random (4) mechanisms have been presented, and these references also contain a more complete discussion of isotope exchange at equilibrium for sequential reaction mechanisms.

Isotope Filtering, Editing

Selective detection of the nuclear magnetic resonance (NMR) signals of hydrogen atom (proton) spins that are **scalar coupled** to another type of nucleus produces an isotope-filtered, or isotope-edited, proton NMR spectrum. NMR experiments are now well established as a means of determining the tertiary structures of biological macromolecules and examining the complexes formed between these molecules and various ligands. Most such experiments involve observation of proton (^1H) NMR signals, often with the goal of determining nuclear Overhauser effects (NOEs) between specific atoms of the system. As the size of the molecule increases, the number of hydrogen atoms in the structure increases. The proton NMR spectrum then becomes so crowded that resolution of a particular signal from nearby signals is difficult. Achieving the necessary resolution is further hindered because the widths of the NMR spectral lines generally also increase with increasing molecular size. One way to overcome these difficulties is to introduce ^{13}C and ^{15}N atoms into the molecule at nearly 100% abundance, rather than the much lower natural abundance. The ^1H NMR signals for protons directly attached to these isotopes can be detected selectively, producing a proton spectrum of the system that is simplified and, thus, easier to analyze for the desired information.

A wide variety of experimental methods are available to achieve isotope editing or filtering of one-, two- or three-dimensional NMR spectra (1-5). All experimental methods depend on the existence of a substantial spin coupling (J-coupled) interaction between ^{13}C or ^{15}N atoms and the hydrogen atoms that are attached to them. The one-bond coupling constant $^1J_{CH}$ is typically 120–160 Hz, whereas $^1J_{NH}$ for the peptide proton–peptide amide nitrogen interaction is about 90 Hz; thus, the necessary conditions for a successful isotope filtering experiment are well met in systems that have been enriched in these isotopes. The filtering experiments can potentially also be extended to other isotopes. For example, Cd^{2+} in metalloproteins couples strongly to nearby hydrogen atoms, and the proton NMR signals for these can be deduced by an isotope filtering experiment that relies on Cd-H coupling.

A particularly powerful application of isotope filtering is the study of complexes formed between a receptor and a **ligand**. If the receptor molecule is used in a form in which carbon and nitrogen positions are enriched to high levels with ^{13}C and ^{15}N, isotope editing would permit selective detection of the proton signals from the receptor when a complex forms between the receptor and a ligand. Alternatively, positions of the ligand could be enriched with these isotopes, in which case an isotope editing experiment with the receptor-ligand complex would display proton signals from the only ligand (6, 7). (See also Triple Resonance, Nuclear Overhauser Effect (NOE).)

Isotope

Isotype specificities were first described by Oudin for **immunoglobulins** as a characteristic of one molecule of one given animal species. Immunoglobulin isotypes designate the different classes or subclasses that differ from each other by the structures of their heavy chains, leading to the classical IgG, IgM, IgD, IgA, and IgE, corresponding to the g, m, d, a, and ε heavy chains, respectively. IgG are furthermore divided into four subclasses that are also discrete isotypes, numbered from IgG1 to IgG4, whereas IgA has two subclasses, IgA1 and IgA2. The word also applies to light chains, with the **kappa (k) and lambda (l) light chain** isotypes. Each isotype is encoded by a separate constant-region gene that is split in as many **domains** (including the hinge regions) as are present in the corresponding chain. Kappa and lambda chains are present in all Ig classes and subclasses, whereas heavy chains are isotype-specific. The discrete isotypes have distinct effector functions, such as **complement** fixation, active transplacental transfer, and binding to discrete **Fc receptors**, thereby ensuring a selective fixation to different cell types.

During immunization, IgM antibodies appear first, a few days after immunogen administration. They are rapidly replaced by IgG that will acquire somatic hypermutations, thus becoming of higher affinity. Replacement of IgM by IgG involves rearrangement at the DNA level, known as isotype class switching . The switch may involve any switch region present at the 5′ position of each CH region gene (with the exception of IgD), leading to the expression of either isotype. Targeting of the isotype that will be involved in switching is under the control of **cytokines** produced by T cells and therefore only occurs in T-dependent **immune responses**.

Orphons

Orphons are a class of dispersed, solitary genetic elements of the genome derived from tandem multigene families. These displaced elements arise from genes that do or do not code for proteins, including those of histones in the sea urchin *Lytechinus pictus*; ribosomal genes in *Saccharomyces cerevisiae*; ribosomal genes and H3 histone genes in *Drosophila melanogaster* (1); the amylase multigene family of mice (2); the spliced-leader small RNA gene family of *Trypanosoma brucei* (3) and of the nematode *Angiostrongylus cantonensis* (4); and the human 28S ribosomal DNA (5).

An interesting case is that of the human immunoglobulin V kappa gene regions. They have been transposed during evolution from the site of the kappa locus on chromosome 2 to chromosomes 1, 22, and other chromosomes. These orphons are very similar and may have derived from a single ancestral gene. The DNA sequences at the junction of chromosome 22 and other orphon regions are direct and inverted repeats and in one case an Alu sequence repeat. These unusual features may have predisposed the orphon regions to transposing by serving as target sites for enzymes involved in recombination (6).

Orthologous Genes

Orthologous genes are two or more genes whose follows the speciation process, and they have usually the same function in each resulting species; that is, a particular gene in the ancestral will be duplicated in the two different species following speciation and will usually be maintained in each, because both species will require the function of that gene (Fig. 1) (1). These genes differ from , which diverged before or after speciation as a result of and usually have different functions. For example, the genes for the a and b polypeptide chains of hemoglobin and that for myoglobin are homologous but paralogous, whereas the hemoglobin a chains from different species are orthologous; similarly, the b chains and myoglobins from different species are orthologous. Only comparisons of orthologous genes can be used to reconstruct species phylogenies.

Figure 1. Generation of orthologous and paralogous genes (1).

It is often difficult to distinguish orthologous genes from paralogous genes. However, analysis has shown that some genes have a single version in a genome. Therefore, if this is the case in two or more species, there is a strong probability that these genes are orthologous. If the gene is a member of a known , there is a distinct probability that it is a paralogous gene, depending on the number of genes in the family, because the gene could be a product of gene duplication before or after speciation.

Orthologous gene pairs are useful for estimating the rate of nucleotide substitution and species phylogenies. When the time since two species diverged (T_s) is known from the fossil record, it follows that the orthologous pairs should also have diverged at the time of species divergence. Therefore, the rate of nucleotide substitution for the gene (v) can be estimated by dividing the number of nucleotide substitutions (K_n) between orthologous gene pairs by two times of the divergence time between the two species $v = K_n/(2T_s)$.

Two homologous genes sampled from the gene family between two species are often paralogous, rather than orthologous. If the two genes are paralogous, the divergence time of these genes (T_g) must have been earlier than the speciation time ($T_g > T_s$). If the divergence time of those genes is mistakenly assumed to be the divergence time between the species, the divergence time of the genes will be underestimated and will lead to overestimation of the rate of nucleotide substitution ($K_n/(2T_g) > v$). Thus, it is important to use only orthologous genes in estimating the rate of nucleotide substitution and the times of speciation.

There have been many recent advances in genome analysis, and as a result complete genomes are known. Those of two species can be compared to determine whether the physical order of genes in the genomes is conserved between different species. To accomplish this, it is vital to distinguish orthologous genes from paralogous genes. By focusing on orthologous genes, it is possible to trace changes in gene location during evolution because of the one-to-one correspondence in gene location between genomes, unless gene duplication takes place after speciation.

Oskar Gene

The oskar is a maternal effect gene in Drosophila melanogaster whose primary function is to organize a specialized cytoplasm, termed the germ plasm or pole plasm, at the posterior pole of the maturing egg (1). This germ plasm contains factors required for abdomen formation and germ-cell formation. The oskar messenger RNA is synthesized during oogenesis. It is deposited into the egg, where it becomes localized to the posterior pole through sequences in its 3′ untranslated region (UTR). Only posteriorly localized RNA is translated into Oskar protein. The site of Oskar protein synthesis determines where germ plasm is assembled, and the quantity of Oskar protein determines how many germ cells form. oskar is a member of the posterior group of genes (named for their effect on development of the abdomen in the posterior half of the embryo). Most of the posterior group genes facilitate localization and translation of oskar mRNA, while a small number of posterior genes act together with Oskar in the assembly of the germ plasm or are specifically required for either germ cell or abdomen formation.

1. oskar Protein and RNA Structure

oskar encodes a 2.9-kb mRNA that is expressed in the germ line of the adult female and is present at the posterior pole of early embryos. oskar mRNA has a 14-nucleotide 5′ UTR and a 1045-nucleotide 3′ UTR. Two different in-frame start codons are used to produce Oskar protein isoforms of 606 amino acids residues (69 kDa) and 468 residues (54 kDa). The short isoform has full oskar activity, although the long isoform is necessary to maintain localization of the oskar mRNA at the posterior of the oocyte (2, 3). The 3′ UTR contains regulatory elements for RNA localization and translation, while the region between the two start codons contains sequences necessary for translational regulation (4). The Oskar protein is novel, in that no known sequence or structural motifs are present. The only known homologue is from Drosophila virilis (5).

2. oskar RNA Localization and Translation

Oskar protein synthesis is regulated at the level of mRNA localization and translation and occurs during oogenesis. Each Drosophila ovary consists of approximately 16 ovarioles, each of which contains a series of developing egg chambers. At the tip of each ovariole, a germ-line stem cell produces a new stem cell and a cystoblast by asymmetric cell division. Each cystoblast undergoes four rounds of division with incomplete cytokinesis, giving rise to 15 nurse cells and the oocyte. The nurse cell–oocyte cluster is interconnected by cytoplasmic bridges called ring canals and surrounded by somatic follicle cells. oskar RNA is produced in the nurse cells and deposited into the developing oocyte, where it accumulates from the earliest stages of oogenesis. By stage 8 of oogenesis, the RNA is concentrated at both the anterior margin and the posterior pole of the oocyte. By stage 10, oskar RNA is localized exclusively to the posterior pole, where it remains until it is degraded in the early embryo after germ-cell formation [see Fig. 1 (6, 7)]. Oskar protein is translated once the mRNA becomes localized to the posterior pole, while unlocalized RNA is translationally repressed. This ensures that protein is made only at the posterior pole of the oocyte and embryo (2, 3).

Figure 1. A Drosophila melanogaster ovariole. oskar mRNA is detected by in situ hybridization. In the earlier stages of oogenesis (top of figure), oskar mRNA accumulates in the oocyte. As each egg chamber matures, the oskar mRNA is localized within the oocyte to the posterior pole (center and bottom of figure). Anterior is to the top, posterior is to the bottom.

The site where oskar RNA is localized and Oskar protein is synthesized determines where germ cells form and the posterior body region, the abdomen, develops. Therefore processes that lead to the localization of oskar RNA are directly linked to the establishment of anterior–posterior polarity within the oocyte. All aspects of oskar RNA localization are mediated by sequences within the oskar 3′ UTR (8). Early aspects of oskar RNA transport into the oocyte and localization to the posterior pole of the oocyte require the correct organization of the microtubule network. Genes involved in the polarization of the early microtubule network that extends from the nurse cells to the oocyte also affect the transport of oskar into the oocyte. These genes include egalitarian, Bicaudal-D, (coiled-coil domain protein), orb (an RNA-recognition motif protein with similarity to mammalian CEBP), and cytoplasmic dynein (9). Subsequently, the establishment of anterior–posterior polarity within the oocyte is controlled by cell–cell signaling between the oocyte-bound Gurken protein, a member of the transforming growth factor-a (TGF-A) family, and its receptor, the Drosophila EGF receptor (DER or torpedo). Mutations in either gene disrupt localization of oskar RNA to the posterior pole, presumably by altering the polarity of the microtubule network within the oocyte. Indeed, inhibitors of the microtubule, but not of the microfilament, cytoskeleton disrupt the localization of oskar RNA during oogenesis (10). Other maternal effect genes that affect oskar localization and affect the microtubule organization in the oocyte include cappuccino (for min homologue), spire, and mago nashi (a novel protein that is highly conserved from plants to humans). A role of microfilaments in oskar mRNA localization is suggested by the effect that mutations in the tropomyosin II gene (an actin-binding protein) have on oskar RNA localization (11). It has been proposed that the actin cytoskeleton is required for high levels of oskar mRNA localization or the firm anchoring of the RNA at the posterior pole (11).

Staufen, a double-stranded RNA-binding protein, has been proposed as the best candidate to mediate directly the localization of oskar RNA. staufen mutants do not affect the organization of the cytoskeleton, and Staufen protein and oskar RNA colocalize during oogenesis (12). A direct physical interaction between Staufen and oskar RNA has not been demonstrated. Staufen is also required for localization of bicoid mRNA to the anterior of the oocyte and prospero RNA to the apical side of dividing neuroblasts (12).

oskar mRNA that is not localized to the posterior pole is translationally repressed. If the RNA is translated prematurely, posterior body patterning will be specified throughout the embryo. Translational repression is mediated through specific RNA-binding sites in the 3′ UTR of oskar mRNA. The RNA-binding protein Bruno (which corresponds to arrest gene independently identified on the basis of its early arrest maternal effect phenotype) binds specifically to Bruno response elements (BREs) in the oskar RNA (13). The bicaudal-C protein (a KH-domain protein) has also been implicated in repressing translation of unlocalized oskar RNA. Only at the posterior pole, where oskar RNA is localized, is the RNA translationally active. Activation of translation depends on derepression mediated through sequences between the two alternative start codons of the oskar mRNA (4). Translation of oskar RNA or the stability of Oskar protein is further dependent upon the gene aubergine as well as upon the Vasa protein, an RNA helicase that interacts physically with Bruno protein (14, 15).

3. Role of oskar in Germ Plasm Assembly

Homozygous mutant oskar females are viable, but produce embryos that lack germ plasm. These embryos fail to form germ cells and do not develop an abdomen. Mislocalization of the oskar coding region (via the RNA localization element in the 3′ UTR of bicoid mRNA) to the anterior of the oocyte results in the assembly of ectopic germ plasm, a mirror image duplication of the abdomen, and formation of ectopic germ cells (16). Thus oskar is both necessary and sufficient for assembly of germ plasm and for formation of both the abdomen and germ cells.

Assembly of the germ plasm is also dependent upon other factors that act downstream of oskar. Vasa is a DEAD-box helicase that physically interacts with Oskar. The products of the tudor and valois genes are also required for germ plasm assembly. Vasa, Tudor, and Oskar are components of electron-dense particles, known as polar granules, that are found only in the germ plasm (17).

The effect of *oskar* on abdomen formation is mediated through the *nanos* gene. Oskar is responsible for localizing *nanos* mRNA to the posterior pole of the embryo, where Nanos protein is translated and acts to facilitate abdomen formation through repression of the *hunchback* mRNA. While the mechanism of *nanos* localization to the posterior pole is not clear, *oskar* is both necessary and sufficient for *nanos* localization. Overexpression of *oskar* or mislocalization of the *oskar* mRNA results in an excess of *nanos* activity at the site of *oskar* localization.

oskar also recruits several factors to the posterior pole that play a role in germ-cell formation. These include: *germ cell-less* mRNA, which encodes a protein that associates with the nuclear envelope; mitochondrial large ribosomal RNA (*mtlrRNA*) that is found outside of the mitochondria, where it associates with polar granules during the early stages of embryogenesis; and *polar granule component 1* (*pgc1*), which codes for an untranslated RNA. A number of different experiments suggest that *germ cell-less* and *mtlrRNA* are required for germ-cell formation (18, 19), while antisense experiments with *pgc1* suggest a role for this gene in germ-cell migration or development (20). Other maternal factors localized to the posterior pole in an *oskar*-dependent manner include maternal *hsp83* mRNA, whose RNA is stabilized in the posterior depending on the germ plasm; the cell cycle regulator *cyclin B*; *outspread*; and the Fat-facets protein that is a sequence-specific de-ubiquitinating proteinase. The roles of these genes in germ-cell formation, migration, or development are unclear.

Ouchterlony Double Diffusion

A direct extension of the precipitin reaction to immunoassays is the Ouchterlony double diffusion technique (1). Here, two or more wells are cut in an agar slab and filled with either antigen or antibody. The two materials slowly diffuse throughout the slab. As the antibody and antigen molecules encounter each other and react, a precipitate forms in the gel. Because of the highly cooperative nature of immunecomplex lattice formation, the precipitate forms an extremely sharp line between the two wells. The position of the precipitin line, compared to lines generated from other dilutions of antigen or antibody, gives a semiquantitative measure of the relative concentration of the reactant. However, the true value of the Ouchterlony technique is the remarkable number of details that can be inferred from the precipitin patterns formed. From the presence of multiple lines, or complex precipitin patterns formed at the intersection with multiple antigen or antibody wells in the agar slab, conclusions can be drawn about such properties as antigen heterogeneity, antigen molecular weight, shared antigenic determinants, and cross-reactivity of different antisera (2). The Ouchterlony technique is now obsolete, but it is commonly described in older literature.

Ovalbumin

The major protein in egg-white is ovalbumin. It has the typical highly ordered structure of a serpin (see Fig. 1 in that entry), but has lost the ability to refold the loop that would correspond to its reactive center; consequently it has no proteinase inhibitor activity. Its smallness relative to other serpins, and its conformational stability, make it suitable as a marker for gel electrophoresis. The stability is only relative, however; its reactive-center loop can be cleaved proteolytically to produce a form known as plakalbumin. It is likely that the induced insertion of this loop, like that that occurs in other serpins, explains a conformation, with increased stability, that forms on long-term storage: S-ovalbumin.

Overlay Assay: Enzyme Zymography of Plasminogen Activators and Inhibitors

Zymography is a gel-based enzymatic assay useful for detection and semi-quantitative analysis of proteases and is performed using overlay or co-polymerization techniques (1, 2). In overlay assays, samples are fractionated by SDS-PAGE and, after removal of SDS, the polyacrylamide gel is overlaid on an agarose indicator gel containing protein substrate. Enzyme diffusion into the indicator gel occurs during incubation of the gel sandwich and results in degradation of protein substrate. The indicator gel is then stained to reveal zones of proteolysis, which appear as cleared bands on a dark background. In co-polymerization techniques, protein substrate is incorporated directly into the polyacrylamide gel matrix and, after electrophoresis and SDS removal, gels are incubated floating in buffer (2). In either method, specificity or sensitivity is tailored by modification of acrylamide gel pore size, substrate choice, incubation time, buffer conditions, and by inclusion of activators or inhibitors in gels or buffers.

Overlay assays are advantageous when substrate preference involves proteins that either bind poorly to acrylamide (albumin, casein) or are irreversibly denatured by SDS (collagen type I) and, thus, are not amenable to co-polymerization methods; gelatin, in contrast, is readily incorporated into the polyacrylamide gel matrix, and co-polymerization has been used extensively for assay of gelatinases (2). Overlay methods are also more appropriate for initial quantitative evaluations because enzyme activity is confined within the gel sandwich and, thus, not susceptible to diffusional loss to surrounding buffer, as may occur with co-polymerization assays (1). Furthermore, overlay assays are the method of choice for analysis of complex proteolytic systems in which zymogens, co-substrates, or endogenous inhibitors are relevant, as multiple components can be incorporated into indicator gels.

Representative of a complex proteolytic system is application of the overlay assay to analysis of the plasminogen activator (PA), inhibitor (PAI) system (3, 4). Briefly, samples containing PAs (urokinase [uPA], tissue plasminogen activator [tPA]) and their endogenous inhibitor (PAI) are resolved by SDS-PAGE on 10% gels. Gels are washed with Triton X-100, to remove SDS and allow protein renaturation, and then overlaid on an indicator gel containing plasminogen (zymogen) and fibrin (protein substrate). During incubation, PAs diffuse into the indicator gel, cleave plasminogen to form plasmin, a serine protease that degrades fibrin. After staining of the indicator gel, lytic zones (PA) appear as cleared bands on a dark background (zymography). In contrast, if exogenous PA is also incorporated into the indicator gel, then lysis occurs everywhere except where inhibitor is present; thus, lytic-resistant zones (PAI) appear as dark bands on a clear background (reverse zymography).

1. Materials and Methods

1.1. Materials

Fibrinogen (plasminogen-rich) from Organon Teknika, Holland; SeaKem garose and Gelbond support backing from FMC BioProducts, Rockland, ME; human uPA and tPA from American Diagnostica, Greenwich, CT. All reagents prepared using ultra-pure water.

1.2. Sample Preparation and SDS-PAGE

Samples were prepared, as appropriate, in 2X Laemmli sample buffer without reducing agent or heating (4). Proteins were resolved by 10% SDS-PAGE (0.75 mm thick slab gels; 20 mA constant current) as previously described (5). After electrophoresis, gels were washed twice (2.5% Triton X-100, 200 mL/gel, 30 min each) to remove SDS and carefully overlaid on indicator gels.

1.3. Preparation of Fibrin Indicator Gel

Plasminogen-rich fibrinogen (5 mg/mL) was solubilized in 0.85% saline (prewarmed to 37°C) with gentle mixing (inversion several times over 1–2 h). Agarose (1%) was separately prepared in PBS (pH 7.4) by heating in a boiling water bath. Dissolved agarose was removed from heat and cooled to 60°C; 15mL of thrombin stock (260 U/mL) and 5 mL fibrinogen solution were then added to the hot agarose (25 mL) in rapid succession and with constant swirling. The agarose-fibrin solution was quickly poured onto the hydrophilic side of a Gelbond support film (~13 × 17cm) using a 25 mL glass pipet and a continuous, vertical motion from left to right; the Galbond support film had been previously stabilized on a glass plate (see below). The agarose indicator gel was allowed to solidify for at least 30 min at room temperature before overlay with the acrylamide gel. Final gel composition was ~0.8% agarose, 0.08% plasminogen-rich fibrinogen, and 0.1 U/mL thrombin (4).

1.4. Fibrin Zymography

Washed polyacrylamide gels were carefully overlain on fibrin indicator gels and incubated (37°C, 18–20 h) in closed containers containing water-moistened paper towels to provide a humidified atmosphere. After incubation, the acrylamide gels were carefully removed, and the indicator gel was stained (<5min; 0.1% amido black, 70% methanol, 10% acetic acid), destained (70% methanol, 10% acetic acid), and allowed to air dry.

1.5. Reverse Zymography

For detection of PAIs, the indicator gel also contained uPA (0.8 U/mL).

1.6. Notes and Tips

1) Excessive or too vigorous mixing during fibrinogen solubilization results in protein flocculation; 2) volume loss during agarose heating should be reconstituted using ultra-pure water; 3) Galbond has hydrophilic (spreads water) and hydrophobic (beads water) surfaces; water placed in the center of a glass plate adheres the hydrophobic surface of the Gelbond providing a flat stable surface for gel pouring and subsequent handling of gel sandwiches; 4) Work quickly, fibrin polymerization and agarose solidification occur rapidly; delay in pouring produces inhomogeneities within the indicator gel; 5) when disassembling glass plates after electrophoresis, cut the bottom of the acrylamide gel for later orientation; 6) acrylamide gels enlarge and become fragile during washing; handle with care; 7) to position acrylamide gels carefully grasp the upper corners; overlay from bottom to top in a continuous motion to avoid air trapping; 8) avoid repositioning of the polyacrylamide gel when constructing the gel sandwich as artifactual lysis and streaking may result; 9) volumes given are for one full-sized indicator gel; 10) up to two indicator gels can be simultaneously prepared; extra gels can be stored at 4°C for 3–4 days in sealed plastic bags humidified with a damp paper towel.

2. Results and Discussion

Samples containing PAs can be readily analyzed by fibrin zymography using a gel overlay assay (Fig. 1). In such assays PAs and PAIs are resolved by electrophoresis on 10% polyacrylamide gels in the absence of reducing agent or heating. Omission of reducing agent is necessary because SDS may cause artifactual activation of thiol-dependent proteases (i.e., lysosomal thiol cathepsins) as well as inactivation of disulfide-stabilized proteases (i.e., plasminogen activators). Similarly, heating is avoided to preclude artifactual aggregation, activation, or inactivation of susceptible proteases.

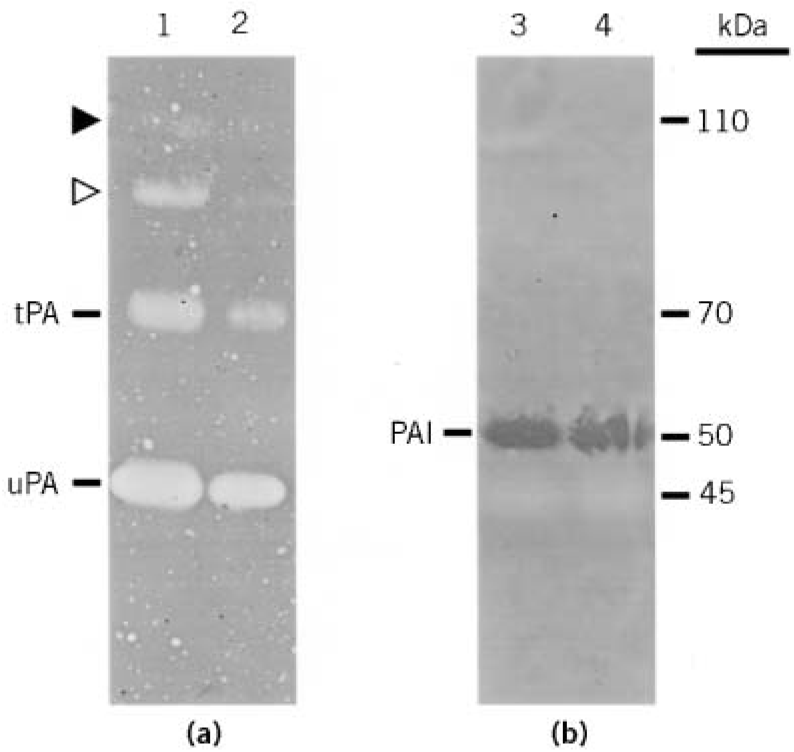
Figure 1. Schematic of fibrin overlay assay. (a) Preparation of the fibrin indicator gel. (b) Overlay of the indicator gel (fibrin zymography). For details see MATERIALS AND METHODS section.

During electrophoresis the partially denatured protease migrates with respect to molecular weight. SDS removal after electrophoresis by the nonionic detergent Triton X-100 allows proteins to renature and regain activity. Wash times should be kept to a minimum and accurately monitored to avoid excessive leaching of protease and to assure reproducibility between experiments, respectively.

The gel sandwich should be constructed without repositioning of the acrylamide gel and should be incubated in a humidified atmosphere to avoid gel drying. Incubation times and conditions (temperature, pH) vary depending on the intrinsic properties of the protease being examined as well as its concentration in biological samples. For quantitative purposes, standard curves should be constructed to determine dose-time relationships with respect to size of the lytic zone. Overlay assay of PAs requires incubation for 6–18 h and is temperature-dependent (37°C).

Indicator gels require only brief staining (<5 min) and, after drying, are readily photographed by back lighting. Overlay zymography of PAs demonstrates fibrinolytic zones at molecular weights corresponding to uPA (45 kDa) and tPA (70 kDa) as well as some high (110 kDa) molecular weight bands (Fig. 2A), presumably representing complexes of PA-PAI (3,4). In contrast, reverse zymography demonstrates fibrinolytic-resistant zones at a molecular weight (50 kDa) corresponding to PAI (Fig. 2B). Protease/inhibitor identification can be verified by parallel zymograms in which indicator gels contain PA-specific antibodies or inhibitors i.e., amiloride to inhibit uPA and erythina to inhibit tPA, as has been described elsewhere (4).

Figure 2. Amido black-stained indicator gels. (a) Fibrin zymogram demonstrating uPA (45 kDa), tPA (70 kDa), and higher molecular weight PA complexes (open and closed triangles). (b) Reverse zymogram demonstrating PAI (50 kDa) as well as uPA shadow (45 kDa). Samples 1–4) were from conditioned media of bovine corneal endothelial cells at different growth stages (4).



In summary, overlay zymography is a versatile assay for the detection and semi-quantitative investigation of proteases, which is readily applicable to complex systems. Unique to the overlay method is the opportunity to incorporate into the indicator gel multiple components including activators, inhibitors, antibodies, zymogens, co-factors, and allosteric modifiers. This enables highly sensitive and specific assays to be developed and, thus, affords extensive biochemical investigation of diverse proteolytic systems.

Oxidation/Reduction Potential

Many of the fundamental physiologic reactions in a cell, both in the metabolic pathways of degradation and in the storage of energy via production of ATP, involve the transfer of electrons from one molecule, the donor (or reducing agent), to another, the acceptor (or oxidant). They are thus called redox reactions and are catalyzed by redox enzymes.

1. Redox Reactions and Redox Couples

The molecule donating an electron is the reductant (red) and becomes oxidized in the reaction, whereas the molecule accepting the electron is the oxidant (ox) and becomes reduced. In fact, each redox exchange:

is composed of two reactions:

The reductant and its corresponding oxidized form constitute a redox couple, in which both partners participate in the redox reaction. Each redox couple is characterized by a standard oxidation-reduction potential ( ) that quantitatively defines its tendency to lose an electron. In a redox reaction, the redox couple that has the higher affinity for the electron will be the oxidant, whereas the couple having a greater tendency to donate electrons will be the reductant. The same redox couple may therefore be either a reductant or an oxidant, depending on the redox potential of the second redox couple in the reaction. Examples of such a mechanism occur in the mitochondrial and the anaerobic bacterial electron transfer chains and in the photosynthesis pathway in chloroplasts, where the reductant of the (i)th step is the oxidant of the (i-1)th step.

2. Electrode Potential

The redox potential can be measured electrochemically as the electromotive force generated by connecting a half-cell of the redox sample with a reference half-cell. The reference half-cell consists of a platinum electrode immersed in a 1 M H^+ solution and saturated with H_2 gas at 1 atmosphere; the sample half-cell consists of an electrode immersed in a solution of the redox couple under standard conditions (1 M of the electron donor and acceptor, 25°C, and pH 7). The electrodes are connected to a voltmeter. A salt bridge (KCl solution) enables electrical continuity between the half-cells. The electrons flow in the direction determined by the redox potential of the sample relative to the reference. This is the voltage observed at the beginning of the experiment (standard concentration of 1 M), as the redox potential of the hydrogen electrode is arbitrarily taken as 0 V. The redox potentials ( ) of redox couples are thus expressed relative to the $\frac{1}{2}H_2/H^+$ couple.

For a redox reaction ($ox + e^- \rightleftharpoons red$), the Nernst equation relates the concentration of the redox species with the redox potential:

where E is the redox potential, $E°$ is the redox potential for components in their standard state at pH 0, R is the gas constant (8.3144 J K^{-1} mol), F is the Faraday constant (9.65×10^4 J V^{-1} mol), n is the number of electrons transferred, and T is the absolute temperature. In biology, the equation is generally written as

where E_h is the redox potential referred to the standard hydrogen electrode, $E_{m,x}$ is the mid-point redox potential (when [ox] = [red] ≠ standard state) at a defined pH (x) of and 2.303 RT/F = 0.06 for 29.4°C. The value of E_m for a defined redox couple depends on the relative stability of the oxidized and reduced states: the more negative the value of E_m, the more stable is the oxidized form and the stronger is the electron donor. Conversely, any factor stabilizing the reduced form makes the couple a better electron acceptor, having a more positive redox potential.

3. Redox Potential, Free Energy, and Equilibrium Constant

The change in free energy associated with a redox reaction ($red_1 + ox_2 \rightleftharpoons ox_1 + red_2$) is related to the difference in redox potentials of the reactants by the formula:

in which n is the number of electrons transferred, F is the energy change as 1 M of electrons falls through a potential of 1 V (23.06 kcal V^{-1} mol^{-1}), and $\Delta E°'$ is the difference in redox potentials of the reactants in volts. $\Delta G°'$ is the free energy change per mole and is expressed in kilocalories.

We know that at constant temperature and pressure a reversible reaction proceeds until an equilibrium is attained, defined by

in which $[ox_1]$, $[red_1]$, $[red_2]$, and $[ox_2]$ are the reactant concentrations, and K_{eq} is the equilibrium constant of the reaction at a certain constant temperature. K_{eq} is related to the $\Delta G°'$ free energy change by;

where R is the gas constant (1.987 cal mol^{-1} K^{-1}) and T is the absolute temperature (K).

We can also say that:

Knowing the redox potentials of a redox couple, the last relationships make it possible to calculate the equilibrium concentrations. Conversely, the redox potential of a solution can be calculated from the relative concentrations of the redox couples at equilibrium.

4. How to measure the redox potential

The oxidation of a reductant (red$_1$) by an oxidant (ox$_2$), at fixed temperature and pH, can be followed potentiometrically by measuring the variation of the electromotive force of a solution of the reductant as it is titrated with the oxidant. In practice, with a Pt electrode connected with a reference electrode (ie, a calomel electrode), the redox potential of the red$_1$ solution is recorded after each addition of ox$_2$. The redox potential increases as the value of [ox$_1$]/[red$_1$] increases and is equal to E_m when the initial reductant is half oxidized, [ox$_1$] = [red$_1$] = 50%. When [ox$_1$] is close to 100%, the redox potential varies rapidly, and the titration comes to an end; the point of equivalence has then been reached, i.e. an equivalent of ox$_2$ has been added to red$_1$. In biological systems, the redox proteins generally carry colored groups that have substantial absorbance in the visible range of wavelengths. This allows precise determination by absorption spectroscopy of the relative concentrations of the oxidized and reduced species.

Many molecules can act as oxidizing and reducing agents in nonbiological redox reactions, whereas in the metabolic pathways of living organisms, few molecules have been conserved during the evolution as redox agents for many different substrates.

The oxidation/reduction potentials of some biologically relevant compounds and free redox groups are presented in Table 1.

Oxidoreductases

Oxidoreductases form a large class of enzymes that catalyze the oxidation of one substrate, with the concomitant reduction of another. For these donor-acceptor reactions, the electron acceptor may be a pyridine nucleotide (eg, NAD), cytochrome, oxygen, quinone or others. The term dehydrogenase is used to describe oxidation-reduction reactions whenever possible, whereas the term oxidase is restricted to enzymes for which oxygen is an acceptor. Dehydrogenases act on primary and secondary alcohols, as well as hemiacetals. They also convert aldehydes to the corresponding acids, and these reactions may involve phosphorylation of the acid or acylation of coenzyme A (CoA). Oxo groups may be oxidized by the addition of water, followed by the cleavage of a bond or dehydrogenation. Dehydrogenases can introduce double bonds by direct dehydrogenation at a single bond. They function as oxidases by utilizing oxygen for the deamination of amino acids that can also undergo direct dehydrogenation reactions. In addition, they can dehydrogenate secondary amines to form double bonds and oxidize NADH or NADPH as well as nitrogenous substrates and donors with sulfur or heme groups.

Oxygen-Binding Proteins

Oxygen-binding proteins are defined as proteins that reversibly bind O_2. They are exclusively metalloproteins.

1. Classification

The classification of oxygen-binding proteins and some of their properties and distribution are presented in Table 1. Protoheme IX is the common oxygen-binding site for myoglobins (Mb), IDO-like Mb, hemoglobins (Hb), compact Hb, and FixL. Dioxygen is bound at the ferrous ion at the center of the heme group (see Myoglobin). The vinyl group normally at position 2 of protoheme IX is replaced by a formyl group in the chlorocruoroheme carried by chlorocruorin (Chl). Hemerythrin (Hr), myohemerythrin (myoHr), and hemocyanin (Hc) are nonheme proteins. The oxygen-binding site for Hr and myoHr is a binuclear iron center, and that for Hc is a binuclear copper center.

Table 1. Classification of Oxygen-Binding Proteins

Name	O_2 Binding Site	Protein Folding	Molecular Mass, kDa	Aggregation State	Color		Distrib
					Deoxy	Oxy	
Myoglobin	Protoheme IX	Globin	17 or 34	Monomer or dimer	Purple	Red	Vertebr muscle gastrop radular
IDO-like myoglobin	Protoheme IX	Unknown	40 or 80	Monomer or dimer	Purple	Red	Gastro buccal
Hemoglobin	Protoheme IX	Globin	17, 34, or 44	Monomer or dimer	Purple	Red	Bacteri unicellu eukaryo and pla
	Protoheme IX	Globin	65	Tetramer	Purple	Red	Vertebr cell
	Protoheme IX	Globin	3500	144mer	Purple	Red	Anneli plasma
Compact hemoglobin	Protoheme IX	Unknown	13–15	Monomer	Purple	Red	Cyanob protozo green a
FixL	Protoheme IX	Unknown	110	Dimer	Similar to Hb or Mb		Rhizobi Bradyrh
Chlorocruorin	Chlorocruoroheme	Globin	3500	144mer	Greenish red	Greenish red	Blood p four po families
Myohemerythrin	Binuclear Fe center	4-a-Helix bundle	14	Monomer	Colorless	Violet	Sipunc muscle
Hemerythrin	Binuclear Fe center	4-a-Helix bundle	40–110	3, 4 or 8mer	Colorless	Violet	Red cel phyla o inverte
Hemocyanin	Binuclear Cu center	a-Helices and b-barrel	450–3300	6, 12, 24, 36, or 48mer	Colorless	Blue	Arthrop plasma
	Binuclear Cu center	Unknown	3500–8700	10 or 20mer	Colorless	Blue	Mollus plasma

The hemoglobins in protozoa (*Paramecium* and *Tetrahymena*), green algae (*Chlamydomonas*), and cyanobacteria are not authentic hemoglobins because their polypeptide chains are about 20% shorter and without substantial amino acid sequence similarities. Several pieces of evidence suggest that the structures of these “compact hemoglobins” differ from the “globin fold” (see Globins), and it is generally considered that they arose from a different evolutionary ancestor (see Convergent Evolution). Likewise, IDO-like Mb evolved from a common ancestor of indoleamine dioxygenase, a heme-containing enzyme that degrades tryptophan. Based on the gene structures and amino acid sequences, myoglobins and hemoglobins are divided into three distinct evolutionary groups: (1) “universal globins”, 17-kDa polypeptide chains, that have about 150 amino acid residues; (2) “truncated globins” or “compact globins”, 13 kDa, that have about 120 residues per chain; and (3) “IDO-like Mb” (1). The second group has been known as “truncated globin”, but “compact globin” is more appropriate because these proteins have no detectable amino acid homology with the universal globins.

2. Distribution, Structure, and Function

Figure 1 illustrates the distribution of oxygen-binding proteins in a simplified phylogenetic tree. Hr and Hc are distributed within certain animal phyla, such as Sipuncula, Brachiopoda, Annelida, Arthropoda, and Mollusca. Hb, the most widely distributed, occurs in bacteria to vertebrates, and even in plants, but only intermittently. The principal physiological function of the circulating proteins (vertebrate Hb, annelid Hb, Chl, Hr, and Hc) is to transport O_2 from the lungs or gills to peripheral tissues. The function of the noncirculating proteins (Mb and myoHr), and probably also of IDO-like Mb, is oxygen storage and intracellular transport.

Figure 1. Phylogenetic distribution of oxygen-binding proteins. Abbreviations undefined in the text are Er, erythrocruor same as Chl (chlorocruorin). Erythrocruorin was the name used for what is now called annelid extracellular hemoglobin. hemoproteins of yeast, paramecium, and legume root nodules are designated as Mb in this figure, they are sometimes de Hb, because they are not contained in muscle and Hb is a more comprehensive name of oxygen carrier. From Van H Miller (1995) (see Reading List).

See Myoglobin for details of Mb and IDO-like Mb and Hemoglobin for details of Hb. The other oxygen-binding proteins are described here.

2.1. Compact Hemoglobin

Only a limited number of structure and functional studies of compact Hb have been carried out. The physiological role of these proteins is uncertain. It is proposed that Hb from the cyanobacterium *Nostoc cummune* is an oxygen scavenger in nitrogen fixation.

2.2. FixL

The FixL that occurs in *Rhizobium meliloti* and *Bradyrhizobium japonicum* is a chimeric protein consisting of a heme-containing domain and a protein kinase domain. Its proposed function is to sense oxygen through its heme domain and to transduce this signal by controlling the phosphorylation of transcriptional activator FixJ, which in turn induces the expression of the genes for nitrogen fixation, thereby providing oxygen-dependent control of nitrogen fixation (2). The heme domain has no significant sequence similarities to globins, suggesting that it arose independently.

2.3. Chlorocruorin

Chl has only a limited phylogenetic distribution. It is found in the blood plasma of four families of polychaeate annelids, the *Sabellidae*, *Serpulidae*, *Chlorhaemidae*, and *Ampharetidae*. The protein structure of Chl is essentially the same as that of extracellular annelid Hb, except for the change in the heme group (3). The vinyl to formyl replacement at position 2 of protoheme produces the characteristic greenish color and low oxygen affinity of Chl due to the enhanced electron-withdrawing properties of the formyl group. Chl shows highly cooperative oxygen binding. As with annelid Hb, its oxygen affinity is pH-dependent (see Bohr Effect) and is increased by divalent cations like Mg^{2+} and Ca^{2+} (4).

2.4. Hemerythrin (Hr) and Myohemerythrin

Hr has been found only in four phyla of marine invertebrates: Priapulia, Sipuncula, Brachiopoda, and one family of annelida, Magelonidae. It is contained in red cells called “hemerythrocytes” that float in the coelomic fluid. A noncirculating Hr is found in muscle fibers of sipunclids and is called “myoHr”, in analogy to myoglobin. Coelomic Hr is found predominantly as the octamer, but also as tetramers, trimers, and dimers. The octamer is composed of two different subunits that have different amino acid sequences (5). The octamer has a mass of 108 kDa, the shape of a square doughnut, and consists of two rings of four subunits each, whose rings are associated in a face-to-face, isologous manner (see Quaternary Structure). Each 13.5-kDa subunit consists of four parallel alpha-helices twisted in a left-handed bundle (6) (see Four-Helix Bundle Motif). The tertiary structure of myoHr (13.9 kDa) is similar to that of one Hr subunit. MyoHr and each subunit of Hr contains a site that has two iron atoms, which bind one O_2 molecule. The iron atoms are bound directly to seven amino-acid side chains of the protein. One of the O_2 atoms binds to one of the iron atoms, and the other oxygen atom forms a hydrogen bond with the oxo bridge that connects the two iron atoms.

The oxygen affinity of myoHr is higher than that of coelomic Hr of the same species. Octameric Hr from two brachiopods (*Lingula unguis* and *Lingula reevii*) show notable cooperativity in oxygen binding and have Hill coefficients of 1.8 to 2.2 (see Hemoglobin), whereas other Hrs are essentially noncooperative, irrespective of their state of aggregation. It has been suggested that the allosteric unit of *L. unguis* octameric Hr is the entire molecule (7). Effects of intracellular cofactors, such as H^+, CO_2, Mg^{2+}, Ca^{2+}, and Cl^-, on the oxygen affinity have been observed with some Hrs, but their physiological significance is not clear.

2.5. Hemocyanin

Hc is found in the blood plasma of two phyla, arthropod and mollusk. The oxygen-binding site of Hc is composed of a pair of copper ions, each of which is liganded by three histidine residues of the protein. It was long thought that O_2 binds as a peroxo ion, serially bridging the two Cu(II) ions, but now there is direct evidence that the mode of O_2 binding is a m-h^2:h^2 coordination, in which both oxygen atoms are bound to both of the copper ions and the O–O axis perpendicular to the Cu–Cu axis.

Arthropod and mollusk Hc exhibit similar optical and ligand-binding properties, but their molecular architectures are quite different. All arthropod Hcs are composed of hexamers. Each 75-kDa polypeptide chain carries one oxygen-binding site. These aggregate into 1, 2, 4, 6, or 8 hexamers, depending on the species, and no intermediate aggregation states are observed in each case. With this mode of assembly, one Hc molecule has from 6 to 48 oxygen-binding sites and a molecular mass ranging from 450 to 3300 kDa. Each hexamer is a “trimer of dimers,” and the shape is a trigonal antiprism. Each polypeptide chain consists of three domains. The first and second are a-helical, whereas the third has an irregular structure that contains a 7-strand b-barrel (see Beta-Sheet). The O_2-binding site is in the second domain.

In contrast to the arthropod Hc, those from mollusks are organized entirely differently. The molecule is composed of one or more cylindrical units, each containing 10 subunits. Each subunit is a long polypeptide chain of 350 to 440 kDa composed of seven or eight globular folded regions, each of which binds one O_2 molecule. It is not known whether each such region is composed of more than one domain, so it is called instead a “functional unit.” Its three-dimensional structure is not yet known.

The quaternary structures of both arthropod and mollusk Hc are stabilized by many calcium ions. The Hc oxygen affinity varies, depending on the species, especially in the Arthropoda, and reflects adaptations to the great variety of life styles and environments of the animals. Most Hcs demonstrate a distinct Bohr effect and varying degrees of cooperativity in oxygen binding. The Hill coefficient ranges between 1 and 12. A higher degree of aggregation is not necessarily accompanied by greater cooperativity. The oxygen dissociation curves of the Hcs that have large multimeric structures are not compatible with the classic allosteric concerted model of Monod, Wyman, and Changeux but are described best by a "nesting" model (8). This assumes that the allosteric units capable of transitions between two states, r and t, are in turn nested within larger structural units that are in equilibrium between two global states, R and T. In addition to the structural calcium ions, other calcium ions, plus magnesium ions, regulate the oxygen affinity.

There is very little sequence similarity between arthropod subunits and molluscan functional units. This and their very different molecular architectures indicate that they probably evolved independently.

Oxytocin

Oxytocin (MW 1007) is a peptide hormone released by the posterior pituitary gland that displays a wide spectrum of biological activities, including a role in reproduction and social behavior (1). It stimulates uterine contraction and lactation, activates myometrial GTPase and phospholipase C, and increases sodium excretion. It consists of only nine amino acid residues, with Cys1 and Cys6 linked by a disulfide bond and with an amidated C-terminus:

The complementary DNA (cDNA) encoding the precursor for human oxytocin has been cloned and DNA sequenced (2). This indicated that the genes for oxytocin and vasopressin are linked on the same human chromosome, 20, and arose through gene duplication (3). The gene for the oxytocin precursor, pro-oxyphysin, is composed of two introns and three exons. The initial gene product contains oxytocin, plus a carrier protein, neurophysin.

The majority of oxytocin is produced in the neurohypophysis and magnocellular neurons of the paraventricular and supraoptic nuclei of the hypothalamus. It is processed proteolytically from its precursor form during transport along the axonal projections to the posterior pituitary. The enzymes and the mechanisms of the specific posttranslational modifications involved in the production of active peptides from the precursor protein are still not completely known. The process by which the prohormones are packaged into the membrane-bound secretory granules and transported down the axon supraopticohypophyseal tract is the subject of ongoing investigation. The hormone and its associated neurophysin are secreted from nerve terminals of the neurohypophysis into the portal system of the neurohypophysis by calcium-dependent exocytosis, although the molecules responsible are not yet known. Oxytocin secretion is initiated by depolarizing electric impulses on the cell membranes. That is followed by calcium influx into the cell, fusion of the secretory granules with the cell membrane, and exocytotic extrusion of the hormone.

The relationship of oxytocin to its four types of receptors (4) and subsequent signaling is not completely understood (5). The human receptor has been sequenced (6); however, its structure analyzed, and its binding sites identified (7).

Oxytocin is primarily associated with lactation and parturition in females. It is used clinically to induce labor or augment labor, when appropriate, because it stimulates the contractions of uterine smooth muscle. Oxytocin release is stimulated by a baby's cry or suckling, and this subsequently releases prolactin, which causes milk to be released, by stimulating the contraction of myoepithelial cells in milk ducts of mammary glands and thereby forcing milk from alveoli in the breast. Oxytocin has been implicated in other functions. These include mating and maternal behavior, natriuresis, modulation of the cholesterol/phospholipid ratio in membranes, and even memory. However, the elimination of oxytocin in transgenic mice did not change their reproductive and maternal behavior (8, 9). Both male and female homozygous knockouts are fertile, and the females are capable of parturition; cross reactivity of vasopressin with the oxytocin receptors explains this apparent contradiction. Milk release was absent, but it was correctable by oxytocin injection. In males, the importance of oxytocin is even less well understood. It has been suggested that oxytocin is involved in prolactin release, penile erection, and various aggressive sexual behaviors.

P Element

The P element is a transposable element in *Drosophila* that can insert into many different positions in the genome (1). In addition to being an element whose transposition mechanism has been interesting to dissect, its transposition is controlled in interesting ways at several levels. Manipulation of P-element transposition has also been an immensely powerful tool for *Drosophila* genetics (2). One widespread use of P elements is to make physically tagged mutations that have allowed the ready isolation of the affected genes through the physical marker provided by the P element. Also, P-element transposition has provided a widely used method for introducing sequences into the *Drosophila* genome.

P elements were discovered by studying the phenomenon hybrid dysgenesis that results when males from certain strains of *Drosophila* are crossed with females of certain different strains. In the germline of the progeny of such crosses, there is a high frequency of mutations and also sterility. Characterization of mutations resulting from such crosses revealed that they resulted from the insertion of a novel 2.9-kbp piece of DNA, the P element (see Fig. 1 in Transposable Elements). Transposition of this element is usually restricted to the germline, because the transposase is assembled from four exons by RNA splicing in the P-element messenger RNA, and factors in somatic cells can both inhibit transcription and block splicing. Hybrid dysgenesis results from a cross of a P-element male with a non-P-element-containing female. The use of the maternal non-P-element strain is important because, in addition to making transposase, the P element also produces a transposition inhibitor from the unspliced P-element RNA, so transposition is inhibited in eggs of P^+ strains.

P-element transposition is promoted by the P-element transposase (3) and a collaboration with at least one host protein that also interacts with the ends of the P element (4). Interestingly, this host protein is related to other proteins involved with DNA repair. The nature of the collaboration between these proteins that promotes transposition is not yet known. P-element transposition occurs via a “cut and paste” mechanism, in which the element is excised from the donor site and then inserted into the target site. The donor gap resulting from transposon excision can be repaired by double-strand break repair using a sister homologue as a template (5).

The P element has been an immensely powerful tool in studying *Drosophila*. Not long after the discovery and molecular characterization of the P element, it was used in a landmark experiment to introduce novel DNA sequences into the *Drosophila* genome (6). A special P-element derivative was constructed that had, in addition to transposase, a further gene whose activity could be scored visually by inspection of flies. It was found that injection of this modified P element into embryos could result in its integration into the germline and expression in adult flies. Such P-element-mediated transformation is now a commonly used method in *Drosophila* analysis (2). P-element derivatives are also widely used as mutagens, so that the mutations generated are physically tagged with the element; this makes isolation of the target DNA containing the mutated gene very straightforward.

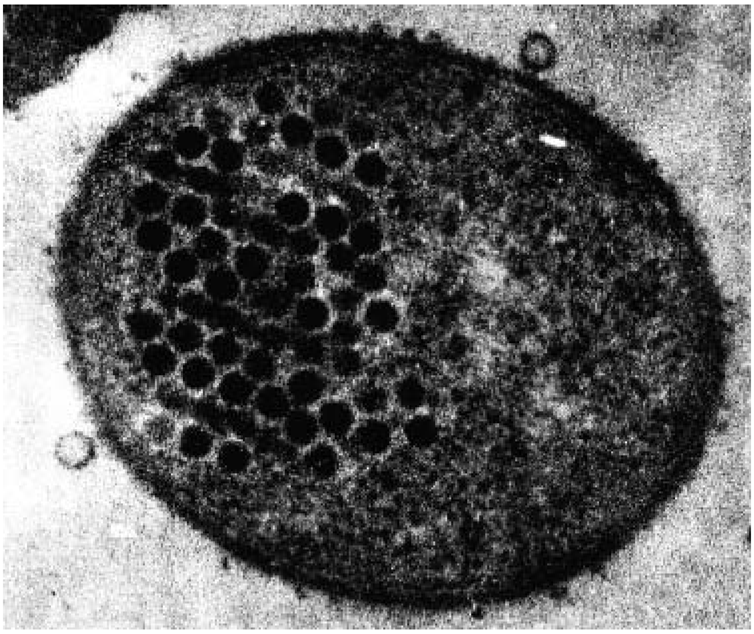
P22 Bacteriophage

The *Salmonella typhimurium* phage P22 is a double-stranded DNA phage of the Podoviridae family that has played a key role in the development of molecular biology. Studies with P22 have contributed to our understanding of genetic exchange, control of gene expression, and biological self-assembly. It has proven itself to be a valuable laboratory tool for genetic manipulation of its host, *Salmonella*. P22 is classified as a lambdoid phage because it shares life cycle similarities with the *Escherichia coli* lambda phage. Comparison of the similarities and differences between P22 and the other lambdoid phage has served to illuminate both the common themes and the range of diversity that nature employs in problem solving (1).

P22 was originally isolated as a lysogen of *Salmonella*, and it has played a key role in the development of bacterial genetics. In 1952, Zinder and Lederberg discovered the phenomenon of generalized transduction of *Salmonella* genes by P22 (2). This observation led to studies on the mechanism of the establishment of lysogeny, which contributed to our current understanding of repressors and anti-repressors. Studies of the assembly of P22 have been instrumental in framing the concepts that guide our thinking about common mechanisms in biological assembly (3). In addition, the well-defined and readily manipulable genetics of P22 have allowed it to lead the way in the development of genetic analysis of protein folding and assembly (3-6).

Bacteriophage P22 is a temperate virus, meaning that following infection two distinct life cycles are available to it: the lytic or the lysogenic life cycles. In the lytic life cycle, a series of viral genes are expressed that ultimately result in the production of several hundred progeny virions per cell. The progeny virions are released approximately one hour after infection, through lysis of the host cell (Fig. 1). In the alternative pathway, termed the lysogenic pathway, the phage chromosome integrates into the host chromosome, and expression of the phage structural genes is suppressed (see Lysogeny). The integrated phage is called a prophage, which is replicated and passed to the daughter cells during cell division. In response to an appropriate environmental signal, such as irradiation with ultraviolet light, the prophage can excise itself, enter the lytic cycle, and generate progeny phage. The decision between whether an infecting phage enters the lytic or lysogenic pathway depends on a number of factors, the most important of which seems to be the number of infecting virions, or multiplicity of infection.

Figure 1. Electron micrograph of a section through a bacteriophage P22-infected *Salmonella typhimurium* cell approximately 30 min after infection. The electron-dense progeny phage within the cell contains double-stranded DNA, whereas the infecting phage that remain attached to the cell at 1 and 8 o'clock do not.



1. Structure

The P22 virion consists of two distinct structural elements: the capsid and the tail. The dsDNA phage genome is contained within the capsid and is thereby protected from environmental insult. The capsid of the P22 virion is a T = 7 icosahedral symmetry lattice approximately 600 Å in diameter, composed of ~420 identical copies of the 47-kDa gene product 5 (gp5) coat protein (7). The capsid itself is a very stable structure, resistant to elevated temperature and drying, as well as nucleases and proteinases. Interestingly, this stability does not arise directly from the coat protein subunits, but rather from their intersubunit contacts (8). The coat protein subunits themselves, prior to polymerization into the capsid, are only modestly stable. The tail is composed of up to six trimers of the 72-kDa gp9 tailspike protein. The tailspike protein serves as the organelle for attachment of the virus to the host cell during infection and is itself also a very stable structure (9).

The 27×10^6–kDa linear dsDNA genome is contained within the capsid of the phage in a highly condensed liquid-crystalline state. The close packing of the phosphate groups in the condensed form requires charge neutralization, which is accomplished through the binding of Mg^{2+} ions. Although the precise packing of the DNA within the capsid is not known, the B form of DNA structure appears to be retained (10).

The structure of the tailed vertex of the phage is surprisingly complex. The tailspike trimers are attached to the capsid through a connector region. The connector is composed of a macromolecular complex composed of 12 subunits of the gp1 portal protein, as well as the connector proteins, gp4, gp10, and gp26. The 83-kDa gp1 portal protein is arranged as a dodecameric complex, approximately 180 Å in diameter with a central channel approximately 30 Å in diameter (11). It is thought that the DNA enters and exits the head through the central channel of the portal complex. Portal complexes have been identified in nearly all the dsDNA-containing bacteriophage. Although there has been debate as to whether portal complexes are composed of 12 or 13 subunits, the existence of the portal complex at an icosahedral vertex poses an interesting structural dilemma: The portal complex exhibits 12- or 13-fold symmetry, but is located at a fivefold symmetrical vertex, resulting in a symmetry mismatch. This means that there cannot be a simple 1:1 interaction between portal and capsid subunits during assembly and function. Although the exact manner in which the portal protein interacts with the capsid is unknown, it has been suggested that such an arrangement would make it possible for the portal complex to rotate within the capsid during DNA translocation

(12).

The tailspike protein folds and assembles independently of the capsid, and then adds subsequently to the capsid to render the phage infectious. The unique biochemical properties of the tailspike protein, coupled with the well-defined genetics of the bacteriophage system, have made it an ideal subject for *in vivo* studies of protein folding. The tailspike folds in a multistep pathway, in which partially folded intermediates associate to form an SDS-sensitive protrimer (13). The protrimer then matures into a very stable SDS-insensitive trimer. The reason for this stability is that the central region of each subunit of the trimer is folded into a right-handed b-helix structure, and the C-terminal regions interdigitate to form b-sheet structures (14, 15). The ability to identify readily and quantify the ratio of partially folded and fully folded proteins by the simple technique of SDS-PAGE analysis has allowed the isolation and characterization of a series of mutations that destabilize the partially folded intermediates. Because these mutations have no effect on the stability of the final fully folded trimer, these mutants have been termed temperature-sensitive for folding (*tsf*) mutants. Analysis of these mutants has lent support to the idea that protein folding and assembly takes advantage of transient interactions between amino acid residues that do not play a critical role in the stability of the final structure. At restrictive temperatures, the *tsf* mutant proteins form aggregates, indicating that aggregation occurs through the interaction of partially folded protein molecules and that alterations in the lifetime of the protein folding intermediates can result in aggregation (6, 16-18).

2. The Infection Process

P22 initially infects the host *Salmonella* cell through the binding of the tailspike to the O-antigenic repeating units of the bacterial lipopolysaccharide. The interaction of the tailspike protein with this receptor defines the host range. Once bound, the tailspike slowly destroys the receptor by cleaving the au (1, 3)-O-glycosidic bond between rhamnose and galactose units. The virion carries up to six tailspikes, but only three are used for binding during infection (9, 19, 20). Once bound, the phage moves laterally across the cell surface through repeated cycles of binding and release, presumably until it locates a second receptor, at which point binding becomes irreversible (21).

The dsDNA is then injected into the host cell in a linear fashion (22). The phage-encoded pilot proteins gp7, gp16, and gp20 are required to ensure that the DNA crosses the plasma membrane in an infectious form. Although the mechanism of their action remains unknown, they translocate from the phage into the host cell during infection (23). Following infection, the dsDNA circularizes by homologous recombination between the terminal redundancy regions, yielding a circular dsDNA that represents a single copy of the phage genome (24).

3. The Lysogenic Pathway

In the lysogenic state, the bacterial chromosome carries an integrated copy of the bacteriophage chromosome, termed a prophage. In the prophage, the genes responsible for growth of the phage and subsequent death of the host are repressed through the action of a specific repressor system. This repression results in a phenomenon known as *immunity*. If a host cell carrying a lysogen is subsequently superinfected by a phage carrying the same repressor system as the prophage, it too will be unable to grow. P22 maintains the prophage in a quiescent state through the action of two repressor proteins (Fig. 2). In this regard, P22 differs from phage, which has only a single repressor, cI. The two P22 repressor proteins are called *c2* and *mnt*, and they give rise to two immunity systems. The *immC* region is similar to the immunity region of l. The P22 c2 repressor acts at O_L and O_R to prevent transcription of the early genes. The unique *immI* region includes an antirepressor, *ant*, and its regulators *mnt* and *arc*. Mnt acts to repress the transcription of the ant antirepressor. If *mnt* is turned off, ant is synthesized. Ant binds to and inactivates the c2 repressor protein, with the result that the prophage enters the lytic pathway. The production of ant itself is regulated through the action of the *arc* gene. In *arc* mutants, high levels of ant are produced, and these levels block phage development. The arc and mnt proteins are two members of a small family of proteins that use antiparallel b-sheet motifs rather than helix–turn–helix motifs to bind their operator DNA (25, 26) (see DNA-Binding Proteins).

Figure 2. Genetic map of bacteriophage P22. The genes are positioned above the line (not to scale), with their function indicated above. Promoter regions and the loci of repressor action are indicated below the line. The c2 repressor protein inhibits synthesis of the early genes, P_l and P_r. The anti-terminators 24 and 23 result in expression of the early and late genes, respectively. Note that genes with related functions are clustered.

The *ant* gene lies downstream of P_{late} and is transcribed during the lytic cycle as part of the late operon, but Ant protein is not synthesized. An additional promoter P_{sar} lies within the *ant* gene and directs the synthesis of a 69-nucleotide long antisense RNA that binds to the *ant* messenger RNA and inhibits its translation (27, 28).

In order to form a stable lysogen, the phage genome has to integrate into the host; otherwise it would be diluted out during cell division. Integration occurs preferentially at a particular site, attB, in the host chromosome and requires the action of the phage-encoded integrase (Int) protein and the host-encoded integration host factor (IHF). The circular phage chromosome carries a similar site, termed attP (29). A single crossover event catalyzed by the Int protein results in integration. For entry into the lytic cycle, excision proceeds by the reverse mechanism but, to ensure that excision does not take place prematurely, requires the additional function of the *xis* gene product, which overlaps *int* in the genetic map (30).

Entry into the lysogenic pathway is controlled by the genes *c1* and *c3*. These gene products stimulate the production of the c2 repressor protein immediately after infection. C1 binds to the P_{RE} (promoter repressor establishment) promoter as a tetramer and stimulates *c2* synthesis (31). High-level expression of c2 appears to be required for entry into the lysogenic pathway, and this is the probable reason that a high multiplicity of infection favors lysogeny.

In addition to the immunity conferred by the immI and immC repressor systems, the phage employs three other mechanisms to prevent superinfection. The first is a modification of the host O antigen, which inhibits the adsorption of P22. This function is encoded by the a1 gene (32). The genes sieA and sieB (superinfection exclusion) block superinfection. Expression of SieB appears to lead to abortive infection; while the superinfecting phage enters the cell, and early functions are normally expressed, late function expression is inhibited. The sieA protein is an 18-kDa protein that partitions into the membrane and acts to block DNA from crossing the periplasmic space and entering the host cell (33). It therefore excludes virion DNA from entering the cells, regardless of the identity of the DNA.

4. The Lytic Pathway

In the lytic pathway, P22 enters the *Salmonella* host cell and begins the process of reproduction. In P22, as in l, the proteins involved in the lytic cycle are expressed sequentially. Control of the timing of the production of mRNA transcripts is achieved through the use of anti-termination proteins that allow the RNA polymerase to ignore encoded termination signals. To take advantage of this, the P22 genome is organized so that these regulatory proteins can exert their influence on a large number of genes (34). The genes themselves are clustered into functional units; for example, all the genes involved in assembly are clustered into the late operon and are under the control of a single regulatory protein. Like lambda, the early genes of P22 are arranged into two operons, P_L and P_R, which flank the P22 c2 repressor gene. The genes in these operons encode proteins involved in DNA replication, recombination, integration, and the regulation of gene expression. Gene 24, which is transcribed off P_L, is similar in function to the lambda N gene. It functions to prevent the termination of transcription at genetically defined sites in the chromosome and allows for complete transcription of the early genes (35, 36). Gene 23, which is transcribed off P_R, is analogous to gene Q in lambda and allows transcription of the late genes (37). The late genes that are driven off the P_{late} promoter code for the proteins necessary for head and tail assembly.

5. Generalized Transduction

Transduction is a process by which bacterial DNA is carried from one cell to another by a phage particle. Generalized transducing particles contain DNA derived entirely from the host-cell chromosome. Bacteriophage P22 transducing particles originate when the host chromosome, rather than the phage chromosome, serves as the substrate for packaging. During a lytic infection, the phage chromosome is replicated as a concatamer, and the concatamers are resolved as the double-stranded DNA is packaged by a headful mechanism. The products of phage genes 2 and 3 are required for packaging and act as a complex. Genetic evidence suggests that gp3 is responsible for recognizing a unique site or region termed a pac site. Packaging proceeds in an ATP-dependent reaction until the head is full, at which point the gp2/gp3 complex cuts the DNA; packaging then continues into another empty phage head. This model is the "sequential packaging model." The P22 head can package 105% of a phage genome, accounting for the observed terminal redundancy and circular permutation of the genetic map (38-41).

Within the *Salmonella* chromosome, there are a minimum of five to six sites, called pseudo-pac sites, which are recognized by the gp2/gp3 complex as pac sites. The nonrandom distribution of pseudo-pac sites therefore leads to a nonrandom distribution of transduced markers (42). Mutants that map in gp3, termed HT mutants, have been isolated in which up to 50% of the phage heads carry host DNA. These mutants have proven extremely valuable for studying the genetics of *Salmonella*. The 44-kbp length of the packaged DNA corresponds to about 50 genes and has made possible linkage analysis and genetic mapping of the *Salmonella* chromosome.

6. Specialized Transduction

Specialized transducing particles carry both host and phage DNA linked in a continuous stretch in a single particle. There are two mechanisms by which specialized transducing particles can arise: from aberrant prophage excision or by insertion into the phage genome of host translocatable elements. P22 has more latitude in its ability to mediate specialized transduction than does bacteriophage l. Because P22 packaging does not use unique ends, it can package extremely long stretches of DNA by segmenting them into multiple heads. If a host cell is multiply infected, an intact oversized genome can be generated by recombination.

7. Capsid Morphogenesis

During P22 morphogenesis, properly folded associated tailspike trimers add to the dsDNA-containing head, to generate an infectious virion. However, the filled capsid is not the first structure that is assembled (Fig. 3). The gp5 coat protein subunits are first assembled into a structure termed a procapsid (37). Like the mature virion, the procapsid has T = 7 icosahedral symmetry, and the portal protein is present at a single vertex in the form of a dodecameric complex (43, 44). However, the procapsid does not contain DNA. The interior volume is filled with approximately 300 copies of the gp8 scaffolding protein. Studies with conditional lethal mutants have demonstrated that the presence of the scaffolding protein facilitates coat protein polymerization and ensures a proper structure. In the absence of scaffolding protein, a variety of morphologically aberrant polymers are formed, while assembly proceeds with high fidelity (45). The procapsid is approximately 10% smaller in diameter and is less stable than the mature head. During DNA packaging, the scaffolding protein exits, and the lattice expands. Three-dimensional single-particle reconstructions from cryoelectron microscopy of the procapsid and mature form revealed that there are ~25 Å diameter holes situated at the center of the hexavalent capsomeres in the procapsid and that these holes are closed during expansion. No proteins are added to the procapsid to close the holes; instead, they are closed by domain movements within the coat protein subunits (46). These holes are likely candidates for the exit ports for the scaffolding protein during DNA packaging (43). The freed scaffolding protein is recycled to participate in further rounds of assembly (47). Thus, the scaffolding protein functions as an “assembly molecular chaperone” whose presence is transiently required to provide positional information. The use of scaffolding proteins is a common theme in the assembly of the lambdoid phages and is also required for the assembly of the herpesviruses.

Figure 3. The morphogenetic pathway of the bacteriophage P22 capsid. The first structure formed is a procapsid, which
coat, scaffolding, and portal proteins. The “pilot” proteins are also incorporated at this stage. The concatameric DNA is
with the exit of the scaffolding protein. The addition of gp4, gp10, and gp26 stabilizes the head, and tailspike binding re

The scaffolding protein of P22, as well as all well-characterized scaffolding proteins, is a highly α-helical molecule that forms oligomers in solution (48). In the case of P22, dimerization of the scaffolding protein plays a key role in assembly. In both P22 and the herpes virus, the region of interaction between the coat and scaffolding protein has been mapped to the C-terminal end of the molecule. In addition to its role in assembly, it has been suggested that the scaffolding protein may function to exclude the chance incorporation of cellular proteins during head assembly, because the presence of cellular proteins within the capsid would result in a decreased internal volume and preclude the encapsidation of a complete P22 genome. P22 scaffolding protein regulates its own levels of biosynthesis, which is decreased if there is a large free pool, but up-regulated if all the scaffolding protein is incorporated into procapsids (49-51). This post-transcriptional control might be a mechanism to insure that all procapsids contain a full complement of scaffolding protein, despite the fact that a full complement is not strictly required for assembly (52).

During morphogenesis, the dsDNA is packed into the procapsid, the scaffolding protein exits, and the capsid lattice expands. The exact sequence of these events is not known, but the expansion is an exothermic process, suggesting that the capsid is “spring loaded” (53). Interestingly, the portal protein is part of the gauge that determines when the head is full; mutants in the gp1 portal protein have been identified that result in packaging a piece of P22 DNA up to 5% larger than normal (54). Following DNA packaging, the portal vertex is closed by the addition of the protein products of genes 4, 10, and 26. These proteins, which add sequentially, serve to stabilize the DNA within the capsid and also to provide the site for tail attachment (55).

There are two genes that are essential for lysis, genes 13 and 19. Gene 13 encodes an 11-kDa protein whose function is to disrupt the cell membrane by forming pores and to allow the hydrolytic enzymes access to the cell wall. Mutations in gene 13 have been isolated that delay lysis for up to several hours, despite the fact that the phage-encoded lysozyme is being produced. Gene 19 encodes the P22 lysozyme, a 16-kDa monomeric protein that attacks and degrades the peptidoglycan layer of the cell wall, leading to cell lysis. The bacteriophage P22 lysozyme is very similar to the well-studied T4 lysozyme with respect to structure and function.

Procapsid-like particles of P22 can be assembled in vitro from purified proteins (52). This has made it possible to perform sophisticated physical chemical studies of virus assembly. These studies have revealed that capsid assembly is a nucleation-limited reaction (56), proceeds along a well-directed pathway (56), and can be inhibited by the binding of small molecules to the coat protein subunits (57).

Over the past 30 years, the bacteriophage P22 system has contributed to our understanding of gene expression, protein folding and assembly, and basic virology. It appears that the lessons that we can learn from these systems is limited only by the creativity of the investigator.

P53

p53 is a well-characterized tumor suppressor gene. It is located on human chromosome 17p13.1 and encodes a polypeptide chain of 375 amino-acid residues. Like the retinoblastoma gene, loss of p53 function results in the onset of oncogenesis (see Oncogenes and Neoplastic Transformation). p53 is a transcription factor that regulates the expression of cell-cycle regulatory proteins. The p53 protein contains an N-terminal transactivation domain, a central DNA-binding domain, and a C-terminal regulatory domain. The C-terminal domain of p53 mediates oligomerization of the protein, which is essential for its DNA-binding activity. This domain also mediates its interaction with other cellular factors that enhance the DNA-binding activity of the protein.

P53 plays a pivotal role during the execution of apoptosis (programmed cell death) pathways induced by DNA damage caused by agents, such as ultraviolet or ionizing radiation (Fig. 1). Current models suggest that DNA damage results in up-regulating p53 gene transcription and accumulation of this protein in the cell (1). Accumulation of p53 appears to result in the enhanced transcription of a group of genes, such as the cell cycle-dependent kinase inhibitor p21/WAF-1/cip-1, that are responsible for stalling the cell cycle in either the G_1 or G_2/M-phase. This mechanism provide the cell with valuable time to make critical repairs in its genetic material. In the event that the necessary repairs cannot be made, the p53 protein initiates a "suicidal" apoptotic program, resulting in cell death, to prevent clonal expansion of a cell with a mutated genome.

Figure 1. Proposed function of p53. (a) P53 is not required for normal cell division. (b) In response to DNA damage,

p53 levels increase and arrest the cell at the first of two “checkpoints” in the G_1 phase of the cell cycle. If all of the repairs have been made to the DNA, the cell divides normally and completes the cell cycle. However, if the cell still contains mutated or duplicated DNA sequences, it dies by a suicidal apoptotic mechanism to prevent its expansion). (
In those cells that have mutated or lost p53 genes, the arrest at G_1 does not occur, and the cells that have mutated genomes proliferate and become cancerous.

Malignant cells have evolved novel strategies to destroy p53 function, and approximately 50% of human tumors contain mutations or deletions in this gene. Normal p53 protein binds to DNA and transactivates the transcription of a distinct set of target genes. Mutated forms of p53 cannot bind DNA in this fashion, however, and therefore behave abnormally. A second mechanism by which normal p53 function is subverted in a cancerous cell is through the MDM2 protein. The MDM2 protein binds to p53, and it is amplified in many tumor cells. When these two proteins are bound, p53 cannot mediate growth arrest at the cell cycle checkpoints (as described previously), which leads to rapid clonal expansion of cells that have unstable, mutated genomes.

P-Glycoproteins

The best characterized form of drug resistance in human cells is due to the overexpression of P-glycoprotein (P-gp). This 170-kDa plasma membrane protein is a member of the ATP Binding Cassette (ABC) superfamily of transport proteins; it can extrude a range of hydrophobic anticancer drugs from the cell against a concentration gradient, and thus protect the cell. Consequently, cells that overexpress P-gp show reduced intracellular concentrations of drugs and greater resistance to them (1). Molecular probes developed to identify P-gp in cancer tissues also strongly suggest that, at least in hematological malignancies, P-gp plays a significant role in multiple drug resistance (MDR) in the clinic.

The mammalian *mdr* gene family consists of two members in humans and three in rodents (2). Of the two human genes, *MDR1* and *MDR2*, only *MDR1* confers drug resistance. The sequences of the mouse *mdr1* and *mdr3* are 80% identical to the *MDR1* human gene product, and they are also capable of conferring resistance to drugs, as are their hamster homologues, *pgp1* and *pgp2*. The human *MDR1* gene encodes a 1280-amino acid membrane protein, P-gp. Hydropathy plots of this protein have led to a secondary structure model for P-gp (see Fig. 1) in which it consists of 12 putative transmembrane regions, with two ATP-binding domains on the cytoplasmic face of the membrane. Each half of the protein consists of six hydrophobic transmembrane putative alpha-helices and one ATP-binding domain; the two halves are 43% identical (3).

Figure 1. A hypothetical two-dimensional model of human P-glycoprotein and its functional domains. This model, with ATP sites (nucleotide binding domains), is based on hydropathy analysis of the amino acid sequence. The ATP sites are indicated. The N-linked glycosylation sites are indicated by wavy lines, and the known phosphorylation sites are shown show the regions labeled with photoaffinity analogues. Filled circles represent amino acid residues in which mutations h transport specificity. This figure is adapted from Ref. 1.

Drug resistance conferred by the human and rodent P-gp's has been extensively studied. However, there continue to be controversies and alternate models vis-à-vis the mechanism by which an extremely broad range of substrates are expelled from the cells. The most widely accepted model is that the P-gp uses ATP to power a molecular pump to remove chemotherapeutic agents from the cell (1). According to this hypothesis, chemotherapeutic agents diffuse down a concentration gradient into the cell, and the pump either acts as a “flipase” to expel them as they enter the bilayer, or the drugs are first transported from the cytosol to the membrane and subsequently pumped out from the membrane. An alternate mechanism has also been suggested in which changes in the intracellular pH and membrane potential alter the transmembrane partitioning or intracellular sequestering of the drugs (4). As these are the two principal models on which most current work is based, the evidence on which each is based will be considered briefly.

The alternative partitioning model is essentially a passive diffusion model (4). The central notion is that the drugs are sufficiently hydrophobic to cross the membrane spontaneously. The subsequent asymmetric distribution of these drugs is then a consequence of the asymmetry of the chemical potential (pH and membrane potential). It is argued that because the cytosol of tumor cells is acidic, the drugs (most of which are weak bases, with pK_a values 7.4 to 8.2) get protonated and are trapped in the cytosol. Conversely, an increased cytosolic pH would decrease the intracellular accumulation of drugs. Experimental evidence in support of this scenario comes from a number of observations. In model systems such as phospholipid vesicles, it is possible to modulate the transmembrane distribution of some of the drugs implicated in MDR by altering the pH. The cytosolic pH is higher in tumor cells exhibiting MDR and those transfected with P-gp. Verapamil, which reverses MDR, causes a partial acidic shift in the pH of cells. The model suffers, however, from a number of shortcomings. It cannot explain how drugs that are not weak bases are effluxed. A number of cells exhibiting MDR do indeed show pH shifts in agreement with the model, but a significant number of cells do not show these changes. More importantly, even where these changes in pH do occur, they are in most instances not of a magnitude sufficient to explain the several hundred-fold increase in resistance that these cells display.

The active transport model for MDR is more attractive and based on a large body of currently available evidence ([5], [6]). Drug binding and photoaffinity studies show a direct interaction between P-gp and many of the substrates. The drugs stimulate the ATPase activity of P-gp in proportion to its ability to transport those drugs. Specific amino acid substitutions alter the substrate specificity of P-gp. Additionally, purified P-gp reconstituted into phospholipid vesicles is capable of drug transport, even in the absence of electrochemical gradients. MDR is a complex phenomenon, and it is conceivable that the changes in electrochemical gradients may be the result of epiphenomena during the prolonged selection of cells in cytotoxic drugs. Perhaps the best prospect of resolving this issue lies in the use of transient expression systems. A vaccinia virus-based expression system has been developed recently that allows high-level expression of P-gp in many mammalian cells ([7]). The use of this system clearly excludes the pleiotropic effects associated with the use of drugs in selecting cultured cells.

Studies with both cultured cells and transient expression systems provide compelling evidence that the substrates interact directly with P-gp. Table 1 lists some of the agents that interact with P-gp. This has also been demonstrated by the use of diverse substrate analogs that photoaffinity label the P-gp and yielded valuable information on the direct interaction of P-gp with its substrates: ^{125}I-labeled iodoazylazidoprazoin (IAAP), an analog of prazosin ([8]); ^{125}I-labeled iodomycin, an analog of daunorubicin ([9]); ^{3}H-labeled azidopine ([10]); and 6-O-[2-[3-(4-azido-3-[^{125}I]iodophenyl) propionamido]ethylcarbamyl] forskolin (AIPPF), an analog of forskolin ([11]). While the nature of these interactions is still unknown, photoaffinity experiments with these analogs and site-directed mutagenesis analysis indicate that the interaction is probably in the regions of transmembrane segments 5, 6, 11, and 12.

Table 1. List of Selected Substrates and Modulators of P-Glycoprotein

Substrates of P-glycoprotein	Agents that Reverse Multidrug Resistance
Vinca alkaloids	Calcium channel blockers
Vinblastine	Verapamil
Vincristine	Dihydropyridines
Anthracyclines	Azidopine
Daunorubicin	Antiarrhythmics
Doxorubicin	Quinine
Epipodophyllotoxins	Quinidine
Etoposide	Antihypertensives
Teniposide	Reserpine
Antibiotics	Yohimbine

Dactinomycin	Antibiotics
Actinomycin D	Hydrophobic cephalosporins
Other cytotoxic agents	Immunosuppressants
Mytomycin	Cyclosporine A
Taxol	FK506
Topotecan	Steroid hormones
Colchicine	Progesterone
Emetine	Megestrol acetate
Gramicidin D	HIV protease inhibitors
Puromycin	Sequinavir
Valinomycin	Indinavir
	Ritonavir

The notion that the energy of ATP hydrolysis is utilized by P-gp to pump drugs actively is central to the active pump model. Consequently, the substrate-stimulated ATPase activity of P-gp has been studied in considerable detail. P-gp consists of two transmembrane segments and two ATP-binding sites. Each ATP site is comprised of three conserved regions: Walker A and Walker B motifs and a hydrophobic dodecapeptide-a signature of ABC superfamily members, also called the "C" region. ATP hydrolysis is abolished by chemical modification with N-ethylmaleimide or mutations in the conserved residues of the Walker A or Walker B region. Orthovanadate, which behaves as an analogue of inorganic phosphate, inhibits the ATPase by trapping Mg-ADP at the catalytic site. Mutational analysis and chemical modification have established that both sites can bind and hydrolyze ATP. Moreover, the interaction of the two sites is essential for ATP hydrolysis and drug transport. Purified P-gp catalyzes substrate-stimulated ATP hydrolysis. The protein, however, also has a basal ATPase activity in the absence of substrate, which may be due to activation by endogenous lipids or peptides. Based on current evidence, an alternating catalytic model of ATP hydrolysis proposes that, while both sites bind ATP, only one site at any given time acts as a catalytic site. The conformation of this site is presumed to prevent the other from hydrolyzing ATP (12).

1. P-glycoproteins in normal cells

The wide distribution of P-gp in normal human tissues, such as the blood–brain barrier, liver, kidney, intestine, adrenal glands, and testes, has long prompted speculation on the role of P-gp in normal cells (1, 5). There is also a more urgent need to understand the normal physiological role of P-gp. Effective inhibitors of P-gp-mediated drug transport are being developed and entering clinical trials. The safe use of these inhibitors requires that the functions of P-gp in normal physiology be understood so as to anticipate, and eventually limit, the potential side effects arising from their use. In recent years, the use of knockout mice (Mouse) with disrupted P-gp genes provided a direct method of studying these functions.

Mice with disruptions of each of the three P-gp-encoding genes (mdr1a, 1b, and mdr2) have been obtained (13). Under laboratory conditions, all the knockout mice are healthy, fertile, normal anatomically and histologically, and have a normal life span. The most striking result obtained with the mice homozygous for a disrupted mdr1a gene was the role of P-gp as an active extruder of molecules that pass the blood–brain barrier. For example, ivermectin, an excellent P-gp substrate, accumulates to levels over 100-fold higher in the brains of mdr1a(–/–) mice than in mdr1a(+/+) mice. The tolerance of mdr1a(–/–) mice to ivermectin was also reduced 100-fold. The results from the double knockout mice (mdr1a + mdr1b) are particularly important because, unlike humans, mice have two functional drug-transporting genes, and only a double knockout can tell us about the untoward effects that may be expected by use of powerful MDR reversal agents. The double knockouts have not yet been analyzed in detail, but there are no gross physiological, anatomical, or pathological abnormalities. Particularly important is the fact that gross disturbances in corticosteroid metabolism, pregnancy, and bile formation, which would reasonably be expected to occur based on earlier speculations of the function of P-gp, are absent in these mice. These studies suggest a protective role against chemical toxicity for P-gp in humans.

P-Loop

The P-loop is a fingerprint sequence that characterizes ATP- or GTP-binding proteins and is part of the nucleotide–binding motif (1). The characteristic P-loop sequence is Gly–X–X–Gly–X–Gly–Lys–Thr/Ser, where X is any residue. In the three-dimensional protein structures that have a P-loop sequence, such as adenylate kinase, the loop is located between a β-strand and an α-helix and forms a binding site for the phosphate group of the nucleotide—hence the name P-loop. The loop wraps around the phosphate, with the glycine residues adopting conformations that are forbidden for other residues. The backbone amides and the conserved lysine residue interact with the phosphate of the nucleotide.

The P-loop fingerprint sequence is used to identify ATP- or GTP- binding proteins from their primary structure (1). It has also been used to classify a broad group of protein structures, the nucleoside triphosphate hydrolase fold (2), which has a P-loop structure within an a/b domain comprising a central b-sheet surrounded by a-helices. Different families within this classification have varying numbers of b-strands and different connectivities.

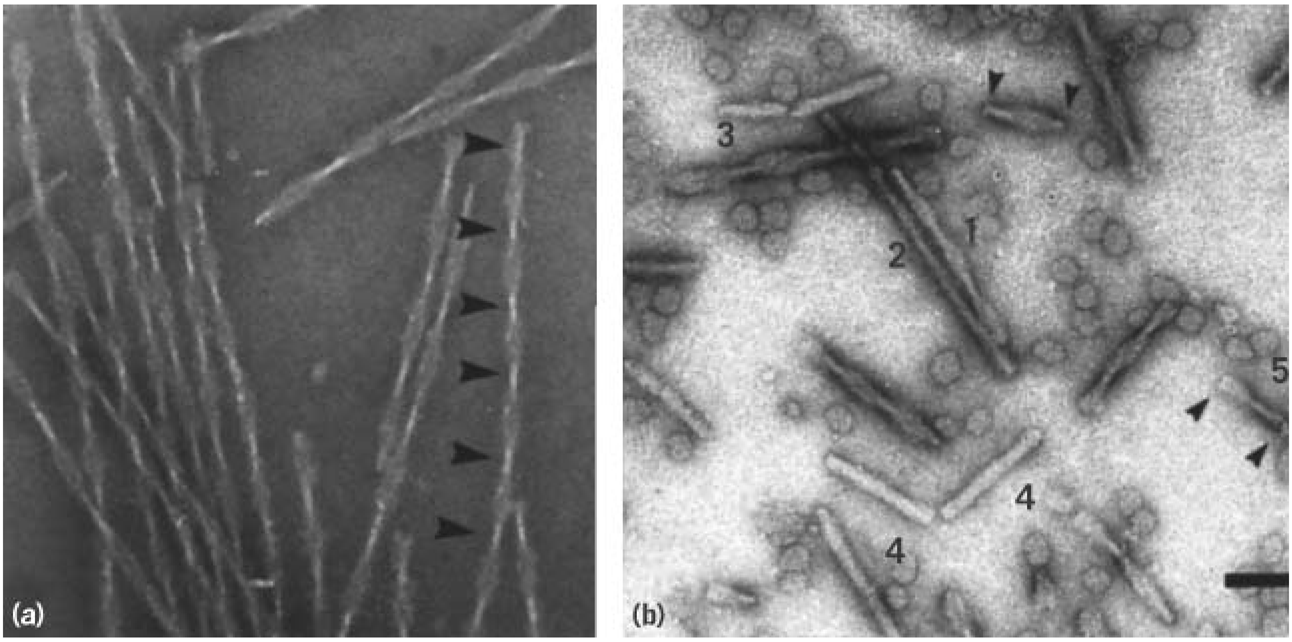
Paired Helical Filaments

Alzheimer's disease is characterized by amyloid plaques and intraneuronal inclusions or tangles in the cell body and the proximal axon and dendrites (1). The tangles are comprised of paired helical filaments (PHFs) (Fig. 1), but these bear no relationship to the neurofilament type of intermediate filaments (IFs). Indeed, PHF are composed of tau (protein), a microtubule-associated protein that is hydrophilic, rich in proline, glycine, serine and threonine residues, and normally highly soluble. In the PHFs, however, the t protein is in an abnormal state of phosphorylation. In adult humans, t is not a single protein but a family of six variants encoded by the same gene generated by alternative splicing. All of the t chains have a related domain structure, a fundamental part of which is three or four tandem repeats, each of which is normally involved in microtubule-binding. These repeats are about 31 or 32 residues in extent and are only imperfectly preserved (2), but they have homology with other microtubule-associated proteins. The human isoforms of t vary also in their N-terminal regions, in that some contain an insert of 29 or 58 residues. Trojanowski and Lee (2) thus note that the largest t isoform contains 441 residues and has a 58-residue N-terminal insert and four tandem microtubule-binding repeats; the smallest isoform is 352 residues long and has no N-terminal insert and only three microtubule-binding repeats. The normal role of t *in vivo* is to stabilize the microtubules in the axon, thus facilitating microtubule-based axonal transport. t can readily be phosphorylated by the action of a variety of kinases; however, specific kinases acting on a serine residue in the first repeat domain cause the dissociation of t from microtubules. Although there is no evidence that any part of t adopts a regular secondary structure, its assembly into PHF is thought to be mediated through the repeat domains. The paired helical filaments thus formed consist of two filaments, each about 10 nm in diameter. They coil around one another with a pitch length of about 150 nm (Fig. 1). Individual t molecules have been observed in the electron microscope, where they appear as rodlike structures with lengths of about 35 nm. Proteolytic removal of the N-terminal region and part of the C-terminal region of t results in PHF with their fuzzy coats removed. Each strand in section appears to have a three-domain C-shaped structure. This also implies that the repeat domains form the core of the PHF and that the terminal ends of the t chains lie on the outer surface.

Figure 1. Electron micrographs of paired helical filaments (PHFs) from Alzheimer brains. (a) PHF from neurofibrillary
et al. (5), stained with 1% phosphotungstic acid. This preparation contains homogeneous long filaments that still retain t
coat." The cross-over repeat is 75 to 80 nm, and the width varies between a minimum of about 10 nm and a maximum
Greenberg and Davies (6). This preparation results in soluble filaments of shorter length than in (a) and is more heterog
nm repeat and a width varying between 8 and 18 nm; (2) is a straight filament with width 8 nm; (3) is a twisted filament
diameter (up to 25 nm); (4) is a straight filament with a wide diameter (18 nm); (5) is a twisted rodlike particle about 80
crossover period. In many cases the particles appear to be broken apart across the filament—for example, the two rod
of (3) and the short stub to the right of it, or the two straight rods above particle (3). Bar = 100 nm. (From Wille et al. (3)
Mandelkow.)



A major problem in this field had been the difficulty in reassembling the entire t molecule in vitro into a structure that closely resembles native PHF, although this has now been achieved. Wille et al. (3) and Schweers et al. (4) have described the reproducible formation of PHF from recombinant t protein and from constructs containing three of the repeating domains. Their results showed that the state of phosphorylation of t was not a determinant of PHF formation, that the repeat domain in t can form antiparallel dimers cross-linked by disulfide bonds to their cysteine residues, and that PHF can be formed from these dimers. Inhibition of dimer formation resulted in no PHF formation, indicating that it might be the key initial step. Schweers et al. (4) have concluded that two residues of particular importance in t are the serine in the first repeat (residue 262 in the htau40 isoform) and the cysteine in the third repeat (residue 322 in htau40): phosphorylation of the serine residue leads to dissociation of t from the microtubules and allows other modes of aggregation to occur, whereas oxidation of the cysteine leads to dimer formation followed by PHF assembly.

Pair-rule Genes

Pair-rule genes play critical roles in the formation of the Drosophila melanogaster body plan, which consists of fourteen contiguous segments arranged along the anterior-posterior axis. This basic plan is established by a cascade of segmentation gene activities that generate spatially repeated patterns of gene expression before the completion of cellularization. Most pair-rule genes are initially expressed in patterns of seven evenly spaced stripes about four nuclei wide that represents the first evidence of a segmental body plan. These stripe patterns are established by integrating crude positional cues provided by asymmetrically localized maternal factors and proteins encoded by the gap genes. These cues are in the form of gradients of transcription factors that interact directly with pair-rule regulatory regions, resulting in position-specific activation or repression. In several cases, pair-rule genes have been shown to contain discrete enhancers that direct the expression of single stripes of pairs of stripes. Each enhancer responds in a unique way to the asymmetric cues, and the seven stripe entire pattern represents the sum of effects of all enhancers. Once initial stripes are established, they are refined by interactions among the pair-rule genes themselves, creating a system of overlapping patterns. This system then directs the expression of segment polarity genes in patterns of fourteen stripes about one cell wide. The fourteen stripe patterns mark cells that will form borders between segmental compartments, and, thus, establish the body plan of the mature animal.

Pair-rule genes were first identified as members of a class of zygotic recessive mutations that affect the organization of the Drosophila body plan (1). Loss of function mutants in pair-rule genes contain only seven segments, and close examination of specific defects in the body plan indicates that every other segment is missing. For example, embryos with reduced even-skipped (eve) gene function contain only odd-numbered segments ("even" numbered segments are "skipped"). Other pair-rule genes lack odd-numbered segments or contiguous portions of adjacent segments that overlap every other border between two segments. These mutant phenotypes suggest that the fourteen segment body plan is established by a mechanism involving genes that specify patterns of cell fate decisions with a pair-rule periodicity.

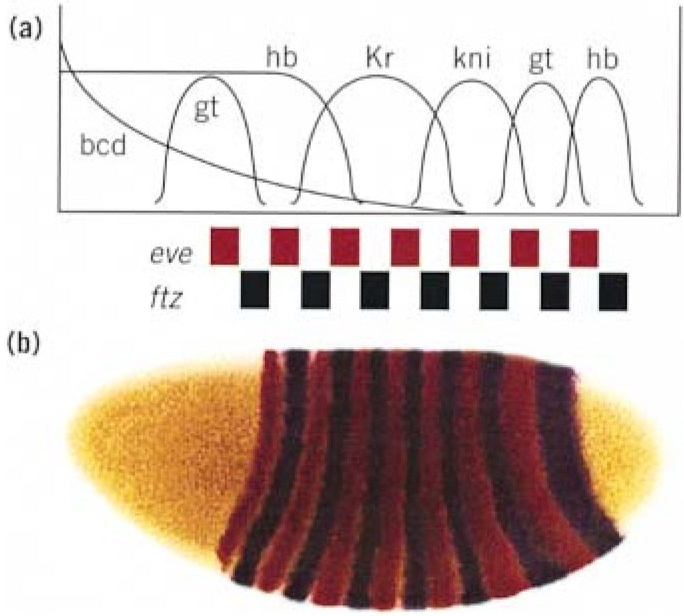
Most pair-rule genes encode proteins with well-characterized DNA-binding motifs, and, thus, function as transcription factors in Drosophila development (Table 1). Many of these genes are expressed in patterns that appear as seven or eight transverse stripes that encircle the cellularizing blastoderm (2-4). The stripes are evenly spaced along the anterior-posterior axis in positions coincident with regions of the body plan that are disrupted in loss of function mutants. This suggests that the pair-rule genes function for the most part within their domains of expression. Interstripe regions where the genes are not expressed are also important for normal development because near reciprocal phenotypes can be generated by ubiquitous expression of pair-rule gene products (5).

Table 1.

Pair-rule Gene:	Protein Motif:	Reference:
hairy (h)	helix-loop-helix	(68)
even-skipped (eve)	homeodomain	(4, 69)
fushi tarazu (ftz)	homeodomain	(70)
runt (run)	runt-domain	(71)
paired (prd)	homeodomain, paired domain	(72, 73)
odd-skipped (odd)	zinc finger	(74)
odd-paired (opa)	zinc finger	(75)
sloppy-paired (slp)	forkhead domain	(76)
outstretched (os)	secreted protein	(77)
odd Oz (odz)	EFG-repeats, TM tyrosine kinase	(78)
tenascin^{M} (ten^{M})	EGF-repeats, ECM protein	(79)

Since the striped patterns of the pair-rule genes represent the first evidence of a metameric body plan, at least some of them must be generated de novo. It has been suggested that reiterated patterns such as stripes might be generated by reaction diffusion mechanisms (6-9). This model is supported by experiments in purely chemical systems that create striped patterns as the result of self-organizing processes (10). However, genetic experiments suggest that pair-rule genes are not self-organizing but are part of a hierarchy of genes that establishes polarity and segmental patterning along the anterior-posterior axis. This hierarchy is initiated by maternal effect genes that establish polarity by depositing mRNAs into the poles of the oocyte during late stages of oogenesis (11). Immediately after fertilization, the mRNAs are translated and their protein products diffuse toward the middle of the embryo creating gradients of proteins with high concentrations at the poles. These gradients direct the zygotic transcription of the gap genes, which are expressed in one or two broad domains along the anterior-posterior axis (Fig. 1). The maternal gradients and gap gene expression domains overlap, creating different combinations and concentrations of these factors according to position along the anterior-posterior axis.

Figure 1. (A) Spatial relationship between stripes of expression of the pair-rule genes even-skipped (eve) and fushi tarazu (ftz) and the positions of gap protein expression domains along the anterior posterior axis of Drosophila. Anterior is to the left. The gap genes hunchback (hb), giant (gt), Kruppel (Kr) and knirps (kni) are expressed in one or two broad domains in response to maternal gradients such as bicoid (bcd) that emanate from the poles of the embryo. (B). A double in situ hybridization experiment detects eve (red) and ftz (black) mRNAs. These genes are expressed in reciprocal patterns that establish the segmental body plan.



Striped patterns of the pair-rule genes are differentially disrupted in embryos lacking the functions of individual maternal effect, gap, and other pair-rule genes (12-16). These experiments are difficult to interpret, however, because removing the function of a single gene causes pattern shifts and disruptions in many other genes. Several experimental approaches have been used to unravel the mechanisms involved in pair-rule patterning. Regulatory interactions can be inferred from transgenic experiments that ubiquitously misexpress segmentation genes under the control of a heat shock inducible promoter (5, 17-20). When short heat pulses are used and the timing of pattern disruptions carefully monitored, it is possible to determine if a gene directly affects the expression of a given target or if intermediary genes must be expressed to induce the response (21, 22). Ectopic expression is also possible using enhancers that activate position-specific expression during early development (23-25). Finally, promoter truncation and P-element transformation assays (26) have identified two classes of cis-regulatory regions (enhancers) that are important for pair-rule patterning in the blastoderm. Enhancers of the first class specify the placement of individual stripes by responding primarily to gradients of maternal effect and gap proteins. Enhancers of the second class specify complete patterns of seven stripes but are active after the first striped patterns are established. These enhancers respond to transcriptional cues provided by the pair-rule genes themselves and are thus important for mechanisms that maintain and refine initial patterns.

1. Regulatory Mechanisms That Control the Initiation of Individual Pair-Rule Stripes

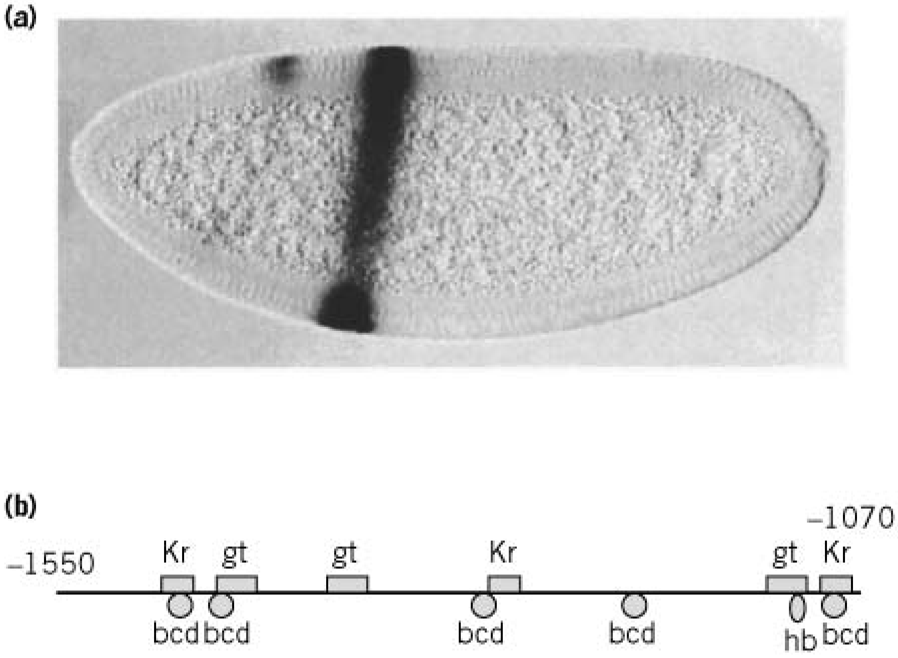
An important breakthrough in understanding how pair-rule patterns are established arose from the analysis of *hairy (h)* mutations caused by translocation breakpoints in the 5' regulatory region of the gene (27). Breakpoints located near the transcription start site cause the deletion of seven segmental units (like *h* null alleles), but those further away delete only a subset of segments. Thus, the regulatory elements controlling *h* function at different positions along the anterior posterior axis are physically separable, suggesting that individual stripes are independently controlled by discrete enhancers. This hypothesis was confirmed by a series of P-element transformation experiment with *h* lacZ reporter genes, which identified discrete enhancer elements that independently control the expression of single stripes or pairs of stripes (28, 29). Similar studies led to the identification of modular enhancers in the *eve* regulatory region (30-32). Interestingly, enhancers that control stripes 2, 3, and 7 are located upstream of the *eve* coding region; those that control the other four stripes are located downstream (Fig. 2).

Figure 2. Stripe-specific enhancers in the eve locus. A map shows the positions of enhancers (rectangles) identified by promoter truncation and P-element mediated transformation experiments. Simple patterns of one or two stripes of reporter gene expression are driven five discrete enhancers. The initial patterns of seven eve stripes represents the sum of the activities of these enhances. A separate enhancer directs a seven stripe pattern that appears after the initial pattern is established. This enhancer is important for maintaining and refining the pattern.

These enhancers control the positioning of individual stripes or pairs of stripes by responding to positional cues set up by the maternal effect and gap genes. The best characterized stripe enhancer controls the expression of eve stripe 2. Truncation analysis has narrowed this enhancer to a 480 base pair (bp) sequence that is sufficient to drive a stripe of lacZ reporter gene expression at the position of stripe 2 (33) (Fig. 3A). Trans-acting factors involved in regulating this enhancer were identified by crossing flies containing the stripe 2 lacZ transgenes into embryos lacking maternal and gap-gene functions. These experiments suggest that the maternal effect gene bicoid (bcd) and the gap gene hunchback (hb) are required for activation, while the gap genes giant (gt) and Kruppel (kr) are required for setting the anterior and posterior borders of the stripe (13, 34). The expression patterns of the proteins encoded by these genes are consistent with their genetically identified functions (Fig. 1A). bcd and hb completely overlap the position of stripe 2, and gt and Kr about the anterior and posterior borders, respectively. Repressive interactions between gt and Kr are important for maintaining the spacing where stripe 2 is expressed (20, 25). All four proteins contain DNA-binding domains and have been shown to bind in vitro multiple sites in the stripe 2 enhancer (34, 35) (Fig. 3B). Most binding sites for activator proteins are located within 50 bp of repressor sites. Mutating binding sites for bcd or hb causes a reduction in expression levels, and deleting gt sites causes a dramatic expansion of the stripe response into anterior regions of the embryo (33, 36, 37). These experiments suggest that the stripe 2 enhancer functions as a binary switch that controls region-specific activation by directly responding to combinations of asymmetrically localized regulatory factors.

Figure 3. (A) lac Z reporter gene expression directed by the 480 bp eve stripe 2 enhancer. Genetic experiments suggest that this enhancer is activated by bicoid (bcd) and hunchback (hb). The anterior and posterior borders of this stripe are

set by repression involving the gap proteins giant (gt) and Kruppel (Kr), respectively (see Fig. 1). (B) Positions of binding sites for proteins that regulate this enhancer. Activator sites are shown below the line, with repressor sites above. These sites enable the enhancer to make on/off decisions based on the combinations and concentrations of these proteins in a given nucleus.



Several other stripe-specific enhancers have been characterized in detail (38-40). These analyses suggest a general model for the initial establishment of individual stripes (41). In this model, factors involved in activating individual stripes are broadly distributed, and stripe borders are set by repressive interactions mediated by gradients of gap proteins. Activations and repression events involve direct binding to closely linked sites within each enhancer. The close linkage of repressor to activator sites suggests that the repressors function over short distances to interfere with the binding or activity of activator proteins. Consistent with this hypothesis, increasing the spacing between activator and repressor sites to an interval greater than ~100 bp can prevent gap protein-mediated repression from occuring (42, 43).

Short-range repression is also important for ensuring that individual enhancers function independently in the context of complex promoters. This has been tested by transgenic experiments using reporter genes that contain the eve stripe 2 enhancer and another 500 bp enhancer that regulates stripes 3 and 7 (40). In the wild-type gene, these two enhancers are separated by a ~1,700 bp sequence. When this sequence is deleted so that the enhancers are juxtaposed, there is a severe disruption of the pattern driven by the reporter gene (44). Inserting shorter spacer sequences (160 bp and 300 bp) between the enhancers restores the correct expression pattern. These results suggest that transacting factors bound to one enhancer interfere with the activity of other enhancers and that spacing between enhancers prevents such interface in the wild-type gene.

2. Regulatory Mechanisms That Maintain and Refine Striped Patterns

Because different mechanisms control the establishment of individual eve and h stripes, they are expressed in a specific temporal order while the embryo is going through the process of cellularization. Each enhancer contributes to a final pattern of seven stripes that are each approximately four to five nucleus diameters wide (Figure 4A). By the end of cellularization, these initial patterns are refined until individual stripes are two or three cells wide. During this process, some seven stripe patterns are replaced by fourteen stripes, either by splitting the initial stripes or by activating new stripes in interstripe regions. Precise overlaps between specific genes are established so that each row of nuclei within a segmental unit contains a unique combination of pair-rule proteins. Genetic experiments suggest that positive interactions among the pair-rule genes maintain the stripes during this process, while negative interactions control spatial refinement. For example, there is a premature loss of *eve* stripes in *eve* and *paired* (*prd*) mutants, suggesting roles for these genes in maintaining the striped pattern (45, 46). In contrast, there is a significant posterior expansion of *eve* stripes in *run* mutants, suggesting that repression by *run* is important for refining the stripes (13, 31). Ubiquitous expression of *run* via heat shock causes a rapid repression of *eve*, consistent with this hypothesis (32). In contrast, *ftz* stripes are prematurely lost in *ftz* and *run* mutants, and expanded in *h* mutants, suggesting that these genes maintain and refine the *ftz* pattern (12, 47, 48).

Figure 4. (A) Interactions among pair-rule genes that maintain and refine initial striped patterns. Four parasegmental units are shown. Arrows represent positive interactions, blunted lines negative. The process of maintenance and refinement narrows stripes from four to five nuclei wide to two to three wide. (B) Spatial relationship between refined pair-rule patterns and the expression pattern of the segment polarity gene *en*. *en* is expressed in cells that contain specific combinations of pair-rule proteins. B is colinear with A.

The molecular mechanisms involved in these interactions are only beginning to be understood. Promoter truncation and P-element transformation experiments have identified enhancers in eve and ftz that direct reporter gene expression in patterns of seven stripes (31, 32, 49). These stripes appear late in the process of cellularization, persisting through the stages of gastrulation and germ band elongation. This timing is consistent with a role for these enhancers in maintaining and refining initial striped patterns. An example is a 300 bp eve enhancer that directs a late pattern of seven stripes coincident with the endogenous pattern (46, 50). This enhancer is inactive in embryos that lack eve or prd function, suggesting that a combination of autoregulation and cross regulation by prd activates transcription of this enhancer. The enhancer contains binding sites for both proteins; mutating these sites causes a loss of expression, suggesting that direct DNA-binding is required for activation (46, 50).

Another autoregulatory element involved in pair-rule refinement is 430 bp ftz enhancer (AE) that contains multiple ftz binding sites; when these sites are mutated, the enhancer is inactivated (51). Further experiments strongly indicate that the in vivo activation of this enhancer involves direct binding by ftz. These experiments take advantage of the fact that the ftz protein, which contains a glutamine residue at position 50 of the homeodomain, binds in vitro with high affinity to a specific class of binding sites (CCATTA) (52, 53). Other homeodomain proteins, such as bed, contain lysine at this position and prefer a different sequence (GGATTA). Changing a single CCATTA binding site in the ftz AE to GGATTA causes a significant loss of AE activity (51). However, activity is restored in trans by a ftz rescue construct in which the glutamine at position 50 is replaced with a lysine residue. This experiment confirms the importance of this residue in specific DNA recognition by homeodomain proteins and demonstrates conclusively that direct DNA-binding by ftz is required for the activity of this enhancer.

It is worth noting, however, that the 430 bp AE represents only a small part of a complex 2,600 bp upstream element (UE) that is important for ftz stripe maintenance (54-57). A separate enhancer, the zebra element (ZE), also direct reporter gene expression in late cellularizing embryos (49). Together, these enhancers integrate positive inputs provided by ftz, the ftz-cofactor Ftz-F1, and run, as well as negative inputs mediated by h that refine the stripes from the posterior (48, 58, 59). Binding sites for gap proteins and other ubiquitously distributed factors such as tramtrack (ttk), have also been identified in these regions, but their exact roles in ftz patterning are still unclear (56, 60).

3. Functions of the Striped Patterns of the Pair-Rules Genes

Precise overlapping patterns of the pair-rule genes are established by the end of cellularization. These patterns comprise a coordinated system that controls the expression of the segment polarity class of segmentation genes. An example is the segment polarity gene engrailed (en), which is expressed in fourteen stripes one cell wide (61, 62). Cells that express en will remain segregated from neighboring cells lacking en throughout development. This segregation establishes a border between the anterior and posterior compartments within each parasegmental unit. Genetic and misexpression experiments suggest that odd and even-numbered stripes within the en pattern are regulated by different mechanisms involving pair-rule genes (21-23, 63-66) (Fig 4). Oddnumbered stripes are activated in cells that contain eve and prd protein, and the anterior and posterior borders of these stripes are set by sloppy-paired (slp) and run respectively. Even numbered stripes are activated in cells than contain ftz and prd protein, and the anterior and posterior borders of these stripes are probably set by slp and odd-skipped (odd), respectively. Very little is known, however, about the cis components that control the expression of either set of stripes or any other segment polarity gene.

In summary, the pair-rule genes make up an integrated system that transduces asymmetrically localized positional information into fourteen stripe patters that establish the segmental body plan of Drosphila. Significant progress has been made in unraveling certain aspects of the mechanisms involved, but the complexity of the system suggests that a full understanding will not possible using only a reductionist approach. Recent attempts have been made to use computer modeling to integrate individual components of the pair-rule system into a gene circuit method (67). This method has successfully generated a complete pattern of seven stripes at the position using quantitative data representing the expression patterns of the maternal and gap proteins. In the future, this type of analysis will be important for synthesizing molecular data and predicting mechanisms that can then be tested experimentally.

Palindrome

A palindromic word or text reads the same in both directions. Strictly speaking, this definition applies only to the same line of the text. The term "palindrome" is traditionally applied to double-stranded DNA (which is "two lines") when the nucleotide sequence is read forward from one strand and backward from the other, complementary strand. The reading proceeds in the same direction in terms of chemical polarity, 5′ to 3′, because DNA is an antiparallel duplex. A more appropriate name for such double-stranded palindromes that is also frequently used is a "sequence or element with complementary symmetry."

The palindromes in the double-stranded sense as discussed above are not only built of two identical sequences, but they also have complementary symmetry (twofold rotational symmetry). One example, the recognition site for the BamHI restriction enzyme, is shown in Fig. 1. Such a peculiar structure is typical of restriction sites. It guarantees that both strands—not just one—will be cut by the enzyme, either simultaneously or after a second approach by the enzyme. Nucleotide sequences of various lengths with complementary symmetry are rather common. For example, they comprise the consensus sequences of many repressor-binding sites, or operators (1).

Figure 1. A nucleotide sequence with complementary symmetry (a) and a double-stranded palindrome (b)—the element with twofold rotational symmetry. Hydrogen bonds between the strands in (b) are not shown.

The condition of identity and complementarity of the two strands of the palindrome also makes the halves of each strand complementary to one another, with the potential for each strand to fold back on itself, forming a hairpin structure. In a palindromic DNA duplex, such hairpins could be made in both strands, so that a cruciform structure is formed (2) (see Fig. 2). The loops of the cruciforms generally could be any size and not necessarily complementary symmetric, as the sequences in the stems of the cruciform. Another obvious property of palindromes is the identity of their double-stranded halves, except for their being placed in opposite polarity, like inverted repeats, but without interruption between the repeats. (Various types of repeats are compared in the scheme presented in Tandem Repeats.) Generally speaking, any head-to-head (or tail-to-tail) fusion of identical fragments of a double-stranded DNA would generate a palindrome. For example, very long palindromes are formed in the process of gene amplification (3), in the size range of many kilobases. Complementary symmetries generally separated by rather long interruptions are characteristic of many transposable elements (4). A whole family of transposable elements also exists: the foldback element transposons, which are about 1 kb in size. These transposons are essentially made of inverted repeats with a very small middle loop region—almost a palindrome.

Figure 2. Schematic presentation of a hairpin structure in a single-stranded DNA or RNA (a) and of a cruciform structure (b). The double lines correspond to antiparallel complementary strands in the duplex parts of the structures.

Palindromes that read the same in both directions of the same strand, ie, proper (or true), palindromes also are known. These sequences possess a mirror symmetry, for example, ATGAGTA. Such elements are frequently encountered in intervening sequences, or introns (5), and may be interpreted as a device to avoid complementary folding of the sequence. Indeed, the absence of complementary sequence elements in the mirror-symmetric sequences of the true palindromes like AT¼TA and TG¼GT causes the sequences to be located in the single-stranded regions of the RNA secondary structure.

Another class of mirror-symmetry palindromes are the polypurine and polypyrimidine stretches in the H-form structure (6, 7). This partially triplex structure is formed in a normal DNA duplex at lowered pH or under torsional stress. The locally separated polypyrimidine strand folds back and binds to the duplex by Hoogsteen hydrogen bonds. The sequence of this third strand can be incorporated into the structure only if it is mirror-symmetric to the sequence of the polypyrimidine strand of the Watson-Crick duplex.

Palmitoylation

Palmitoylation is a post-translational modification process in which eukaryotic and viral proteins become ester- or thioester-linked to the 16-carbon saturated fatty acid, palmitic acid. Palmitoylation occurs on the thiol group of cysteine residues (S-palmitoylation) or on the hydroxyl groups of serine and threonine residues (O-palmitoylation). S-palmitoylation (see Fig. 1) of cysteine residues close to the N- or C-terminus provides a membrane anchor for some cytosolic proteins, and is important for their correct localization within the cell. However, S-palmitoylation also occurs on polypeptide-anchored and integral membrane proteins, and its role in these proteins is uncertain.

Figure 1. Modification of a cysteine or serine residue by a palmitoyl group. An internal cysteine residue in the protein is thioester-linked to the 16-carbon saturated fatty acid, palmitic acid to give an S-palmitoyl group. Palmitic acid can also be ester-linked to serine (or threonine) residues to give an O-palmitoyl group. The cysteine and serine residue in each figure is indicated by a dotted line.

In contrast to the other lipid modifications of proteins (see Membrane Anchors), palmitoylation has proven relatively difficult to study. Even though palmitoylation was discovered more than 20 years ago and occurs on at least 50 different types of proteins, this process is still poorly understood at the biochemical level [for a comprehensive description of the early work in this area, see the review articles by Schmidt (1989) and Towler et al (1988)]. Apart from detailed studies of S-palmitoylation of cysteine residues in signal transduction components (eg, Src family tyrosine kinases, G-protein ÿ subunits, Ras proteins, etc; see below), many of the initial reports of protein palmitoylation have not been substantiated in the last decade, and their functional significance is difficult to assess. There is essentially no recent information on O-palmitoylation of proteins. The lack of recent progress in these areas is due to several reasons.

1. For most of the "palmitoylated" proteins, the evidence for palmitoylation is based solely on the incorporation of ^{3}H-labeled palmitate into cellular proteins followed by immunoprecipitation, SDS-PAGE, and autoradiography. It is usually possible to distinguish ester, or O-palmitoylation of serine and threonine from thioester or S-palmitoylation of cysteine in the ^{3}H-labeled proteins by selective chemical deacylation procedures. However, more detailed analysis of ^{3}H-labeled palmitoylated peptides is generally not practicable, because their unpredictable chromatographic behavior makes them very difficult to purify. This technical problem has thwarted attempts to identify the precise location of the incorporated ^{3}H-label in most of the palmitoylated proteins. Indeed, for several "palmitoylated" proteins, it was subsequently shown that the incorporated palmitate is part of a completely different structure, the GPI anchor.
2. The ^{3}H-labeled palmitate can be converted to other fatty acids before incorporation into some of the proteins. This suggests that the acyltransferase responsible for acylating the protein may be non selective and/or that different cells contain variable amounts of distinct acyltransferases with different specificities.
3. Protein S-palmitoyltransferase activities that can catalyze the transfer of a palmitoyl group from palmitoyl CoA to cysteine residues in protein or model peptide substrates have been identified in mammalian membrane fractions (1–5). Removal of the palmitoyl group by thioesterase activities has also been described. However, none of these activities has been thoroughly characterized at the molecular level, and it is difficult to tell if they are responsible for palmitoylation/depalmitoylation *in vivo*. Non enzymatic palmitoylation (autoacylation) of cysteine residues by palmitoyl CoA was also reported for several proteins, and this may account for some of the difficulties encountered in isolating and characterizing the protein S-palmitoyltransferase(s).
4. The criteria that determine which particular cysteine residue(s) in a protein will become palmitoylated are also uncertain. The presence of other lipid anchors (eg, prenyl or myristoyl groups; see below) on neighboring residues will facilitate cysteine palmitoylation presumably as

a result of transient anchoring to membranes. These observations suggest that localization of “exposed” cysteine residues close to the bilayer surface, rather than a well-defined sequence motif, is the determinant for palmitoylation (4). S-palmitoylation of cysteine residues in polypeptide-anchored and integral membrane proteins could simply be the accidental result of proximity to the bilayer surface, where palmitoyl CoA and other molecular species of acylCoA are likely to be abundant.

As a consequence of the experimental problems identified above, there is relatively little information on the functional significance of palmitoylation for most proteins. However, site-directed mutagenesis studies, on a small number of proteins that are involved in signal transduction, demonstrated that a palmitoyl group can act as membrane anchor and may play a role in regulating distribution of proteins between membranes and the cytoplasm as well as their association with lipid rafts (6) (for a general discussion of factors that can affect membrane affinity of lipid-anchored proteins, see Membrane Anchors). In some G protein ÿ subunits and src-related tyrosine kinases, it has been shown that palmitoylation of cysteines near the N-terminus is dependent on prior myristoylation of the N-terminal glycine (7-9). Palmitoylation of ÿ subunits can also be increased by receptor activation (10, 11). Similarly, palmitoylation of cysteine residues near the C-terminus of some Ras proteins is dependent on prior farnesylation (see Prenylation). Because farnesyl and myristoyl groups are both relatively weak anchors, the increase in membrane affinity resulting from palmitoylation has a major effect on the amount of these proteins bound to the membrane (12, 13). Furthermore, biophysical studies indicate that addition of palmitate not only increases binding affinity, but also increases the stability of membrane anchoring by reducing the rate of dissociation from the membrane (14, 15). Palmitoylation also occurs on cysteine residues in polypeptide-anchored proteins (eg, the transferrin receptor and CD4; see Table 1) and integral proteins with multiple transmembrane regions (eg, rhodopsin and some types of adrenergic receptor). As expected, preventing palmitoylation of these proteins by mutagenesis of the appropriate cysteine residues has no discernible effect on membrane anchoring. However, cysteine mutagenesis often has no, or relatively subtle, effects on the functional properties of the protein either, and the biological significance of palmitoylation remains uncertain in these cases.

Table 1. Examples of Palmitoylated Proteins

G protein ÿ subunits
Src family tyrosine kinases (e.g. $p59^{fyn}$, $p56^{lck}$ etc.)
GAP-43 (neuromodulin)
H- or N-Ras proteins
G protein-coupled receptors (e.g. rhodopsin, $ÿ_{2A}$, $ÿ_2$–adrenergic receptors etc.)[a]
Transferrin receptor[a]
CD4[a]
Viral envelope proteins[a]
Myelin proteolipid protein[a, b]
Mucus glycoproteins[b]

[a] Integral or polypeptide-anchored proteins.

[b] O-palmitoylation; all other examples are S-palmitoylation.

Papain

Papain is a thiol proteinase that is obtained from the latex of the papaya tree (1) (Fig. 1). It has an essential cysteine residue at its active site that must be in the reduced form in order to be active. For this reason, it is often used in the presence of a reducing agent, such as b-mercaptoethanol or dithiothreitol . Papain has broad specificity and will hydrolyze peptide bonds adjacent to almost any amino acid residue, although it shows a trypsin -like preference for arginine and lysine residues. Its activity is optimal around pH 6. It is inactivated by reagents that react with thiol groups, such as iodoacetate or iodoacetamide, as well as silver and mercuric ions and p-chloromercuribenzoate.

Other inhibitors include leupeptin, a peptide aldehyde that is a general thiol proteinase inhibitor, and E-64, an epoxide compound isolated from *Aspergillus japonicus* (Fig. 2). Leupeptin also inhibits some serine proteinases, whereas E-64 is more specific and has a strong affinity only for thiol proteinases. The epoxide group of the latter forms a thioether with the active site thiol group of the enzyme. It has little reactivity for thiol groups not in active sites.

Figure 1. The three-dimensional structure of the thiol proteinase papain. Only the polypeptide backbone is indicated schematically as a ribbon, with arrows for b-strands and coils for a-helices.

Figure 2. Chemical structure of E-64, an inhibitor of some thiol proteinases. Its chemical name is L-trans-epoxysuccinyl-leucylamide-(4-guanidino)-butane. The epoxy group forms a thioether linkage with the active-site thiol group of papain or cathepsin B.

Papain is used to degrade proteins in the presence of a reducing agent (2). Because it has broad specificity, it can generate many small peptides from a large protein. For this reason, it is usually employed to digest the intermediate-sized peptides that are generated by treating a protein with a proteinase of narrow specificity such as trypsin (see Peptide Mapping). Papain is used commercially in a popular brand of meat tenderizer.

Papovavirus

The virion of the Papovaviridae family of viruses contains a double-stranded circular DNA as the genome, has an icosahedral capsid, and can induce tumors in animals. The name papovavirus is derived from papillomavirus, polyomavirus, and vacuolating virus (the old name of SV40). The particle and genome sizes of papillomaviruses are slightly greater than those of polyomaviruses, measuring 55 nm in diameter instead of 45 nm, and about 8000 base pairs in length instead of about 5000. On this basis, the papovaviruses are divided into two genera, Polyomavirus and Papillomavirus. BKV, JCV, SV40, LPV, murine polyomavirus, hamster polyomavirus, and many others are classified in the former genus.

Papillomaviruses were isolated as agents that induce warts in many animals, including rabbits, goats, cattle, dogs, deer, and so on. Papillomaviruses were also isolated from human warts in late 1970s. Presently, more than 70 viruses are classified as human papillomavirus (HPV). A subgroup of about 20 HPVs has been associated with lesions of the anogenital tract. These HPVs can be further divided into two groups: the low-risk HPV group, including HPV 6 and HPV 11, which are associated with benign lesions, such as condyloma acuminata, and the high-risk group, including HPV16, HPV18, HPV33, and others, which are associated with malignant lesions that can progress to cancer. The high-risk HPV can efficiently immortalize human squamous epithelial cells in vitro and transform established rodent cells. The genes of the high-risk group HPVs that are responsible for the transforming activity are E6 and E7, which are ubiquitously conserved among all papilloma viruses, including those of animal origins. The E7 gene products of the high-risk HPVs bind and inactivate retinoblastoma family proteins more efficiently than those of the low-risk HPVs and HPVs associated with benign skin lesions. This binding is mediated through the amino acid sequence of the E7 gene product, which is commonly detected in the T antigens of SV40 and polyomaviruses. The only E6 gene products of the high-risk groups bind to p53 protein through an interaction with cellular E6-AP protein, and they subsequently cause ubiquitin-mediated protein degradation of the p53 protein. The consequent deregulation of cellular growth control by E6 and E7 genes is considered to be the molecular basis of carcinogenesis by the high-risk HPVs.

Paralogous Genes

Paralogous genes are two or more genes that emerged during evolution from a common ancestral gene by gene duplication within a species. Usually, they acquire different functions; well-known examples are the a and b-hemoglobin polypeptide chains and that of myoglobin. They contrast with orthologous genes, which have not been duplicated within species, but retain the same function and have descended during evolution by the process of speciation only. Both orthologous and paralogous genes are homologous, but a comparison of paralogous genes from different species will not reflect the process of species divergence. Paralogous genes are usually present as members of a gene family within a genome. For more details, see Orthologous Genes.

Parasexual Cycle

The parasexual cycle allows new allele combinations to be formed independently of whether the organism can undergo a sexual cycle and meiosis. The parasexual cycle involves the fusion of haploid nuclei, mitotic recombination, and random chromosome losses. Parasexuality was discovered by Giorgio Pontecorvo (1) and has been demonstrated with several fungi and, in a modified form, with cultured cells of multicellular animals.

The parasexual cycle is sketched in Fig. 1, taking a filamentous Ascomycete as a model. Fusion of haploid cells to form a heterokaryon occurs spontaneously in many fungi in a process called hyphal anastomosis. In many fungi this process occurs with certain pairs of strains said to be vegetatively compatible and fails with others. Compatibility requires the strains to carry certain combinations of alleles at certain genes. Heterokaryons can be prepared in the laboratory by fusion of protoplasts and other techniques in fungi without anastomosis and in many other organisms.

Figure 1. Parasexual cycle in filamentous Ascomycetes. Nuclei are followed from the haploid parents above to the haploid segregants below, through cell fusion, nuclear fusion, and haploidization. Recombinant nuclei are indicated by different shading patterns.

Two haploid nuclei in a heterokaryon may fuse to form a diploid nucleus. This process occurs seldom or not at all in vegetative heterokaryons, although it may be very quick after the fusion of gametes in the sexual cycle. Diploid cells are usually very hard to distinguish from heterokaryotic cells carrying the same genetic markers, but they may be very easily distinguished from haploid cells. In fungi in which all spores are uninucleate, colonies grown from diploid and haploid spores are distinguished easily with the help of appropriate genetic markers.

The diploid nuclei of many fungi are unstable because the loss of one chromosome of each pair is not deleterious. A slow process of haploidization takes place during mitotic growth as random chromosome losses convert the diploid into haploids through intermediates called aneuploids. The resulting haploid nuclei contain random combinations of the chromosomes of the two original haploid nuclei. The frequency of chromosome loss is increased by treatments with benomyl and other agents.

In addition, mitotic recombination occurs sporadically between the duplicated chromosomes of the diploid and the aneuploids and produces new combinations of their genetic markers (see Mitotic Recombination). The chromosomes in the final haploid nuclei are composed of random combinations of chromosome segments from the two original haploid nuclei (Fig. 2).

Figure 2. Chromosome events during the parasexual cycle. The chromosomes are followed from the haploid parents above to the haploid segregants below, through diploidization, mitotic recombination, and chromosome loss.

As a result of the parasexual cycle, genes in different chromosomes exhibit recombination frequencies of 50 % while those that are close to each other in the same chromosome appear more or less tightly linked.

Fusion of cultured cells from different mammals gives rise first to heterokaryons and then to anfiploid nuclei, which contain all the chromosomes of the original cells. Chromosome losses reduce the number of chromosomes in these anfiploids, but not necessarily at random: chromosomes of *Homo sapiens* are lost more frequently than those of *Mus musculus* from their anfiploids. The correlation between the presence or absence of certain genetic markers and certain chromosomes in the segregants is a powerful technique for the quick assignment of genes to chromosomes (see Cell fusion, Hybridomas).

Parsimony

Parsimony is one of the principles of phylogenetic tree reconstruction in which the phylogeny of a group of species or genes is inferred to be the branching pattern that requires the smallest number of evolutionary changes (1). Of course, no one knows whether evolution actually occurred in this way, but the parsimony principle appears to work reasonably well, particularly for comparisons of closely related species or genes, but it tends to lose its effectiveness in comparison to more remotely related species or genes. For the latter comparisons, double mutational changes (due to reverse mutations) have accumulated to such an extent that the parsimony principle cannot detect all changes.

The merit of using the parsimony principle is that we can infer the amino acid or nucleotide sequences of all the intermediate stages in the continuous lineage between the ancestor and the present species. The intermediate stages may be trustworthy, however, only when closely-related genes are compared.

Parthenogenesis

Parthenogenesis is the development of a zygote without fertilization. Parthenogenesis can be induced experimentally by a number of procedures (1), but it occurs naturally in some species. A special case of parthenogenesis is called arrhenotoky. This is the mechanism of sex determination in many insects. Fertilized eggs develop into diploid females, while unfertilized eggs develop parthenogenetically as haploid males. Arrhenotoky occurs in the four insect orders: Hymenoptera, Homoptera, Thysanoptera, and Coleoptera (2). In the Hymenoptera, arrhenotoky is the only mechanism of sex determination.

In addition to arrhenotoky, or male haploidy, another form of parthenogenesis, called thelytoky, in which the unfertilized eggs develop as females. It can be either (a) cyclic, in which parthenogenetic and bisexual generations alternate, or (b) complete (3). Cyclic parthenogenesis is found among some insects, such as aphids (4), and in a few vertebrates (5). Complete parthenogenesis has appeared many times during evolution in a variety of phyla. The phylum Rotifera appears to be entirely parthenogenetic. There are even parthenogenetic species of vertebrates (6).

In arrhenotoky, the unfertilized eggs develop as haploid males, but in thelytoky the unfertilized eggs develop as diploid females (or polyploid females in some cases). In order for the unfertilized haploid eggs to develop as diploids, the genetic content of the cells must be doubled. Because parthenogenesis has arisen independently many times during evolution, this problem has been solved in a variety of ways (7). The failure of the second meiotic division during gametogenesis results in the production of diploid eggs. Meiosis can also proceed normally, with the fusion of two of the meiotic products producing a diploid egg. In other species, haploid eggs are produced, but fusion of haploid nuclei occurs during the early cleavage stages to restore diploidy.

Partial Specific (Or Molar) Volume

The volumes of macromolecules can be determined from their structures in several different ways (see Molecular Surface, Volume; Isoleucine (Ile, I); Accessible Surface). In solution, the volumes relevant to thermodynamics are the partial specific and partial molar volumes. They involve not only the volume of the macromolecule itself, but also the contribution of solute–solvent interactions (hydration). In general, macromolecule solutions are systems with two or more components, containing the macromolecule, water, salts, etc. However, it is more convenient to reduce any such system to a binary one; one component is the solvent, ie water plus salts, etc., the other is the solute, ie a protein. At constant temperature T and pressure P, the total volume V of such a binary solution comprising g_1 grams of solvent and g_2 grams of solute is expressed as follows:

(1)

where v_1 and v_2 are partial specific volumes of solvent and solute, respectively, as defined by

(2)

(3)

These parameters measure the change in volume upon adding further solvent or solute to the aqueous system.

The partial specific volume can be determined experimentally by measuring the densities of the solution containing the macromolecule (in units of g cm^{-3}) as a function of its concentration. A variety of techniques have been used for density measurements: The majority of specific volume data have been obtained by pycnometry and digital densimetry (mechanical oscillator technique). Except for some rare cases, the plot of V vs g_2, which should be a straight line according to Equation (1), is not straight, due to solute–solute interactions. This means that the specific volumes of the solvent and solute are not the same as those of the pure phases of these components in most cases, and it is necessary to measure directly the values of v_1 and v_2. In practice, the apparent specific volume f_2 is defined instead of the partial specific volume, by assuming the specific volume of solvent in the solution to be the same as that of solvent in the pure phase v_1^0

(4)

The relation between apparent and partial specific volumes is as follows:

(5)

From this equation, it is apparent that the apparent and partial specific volumes become equal at infinite dilution (g_2 = 0). Usually, values of v_2 and f_2 at infinite dilution (denoted as v_2^0 and f_2^0) are used as the appropriate quantity for a protein molecule in solution not involved in intermolecular interactions with other protein molecules. When the molecular weight M_2 of a solute is known, the partial and apparent molar volumes V_2 and F_2, respectively, can be calculated using the equations $V_2 = v_2M_2$ and $f_2 = f_2M_2$, respectively.

In two-component solutions, the partial specific volume of folded proteins falls in the range of 0.69 to 0.76 cm^3 g^{-1}, depending on their structure and amino acid composition (see Table 1 of Compressibility). The majority exhibit values in the range of 0.72 to 0.75 cm^3 g^{-1}, which are within the range of the partial specific volumes of amino acids, which range from 0.559 cm^3 g^{-1} for aspartic acid to 0.819 cm^3 g^{-1} for leucine and isoleucine (Table 1). If we assume the additivity principle of volume, the apparent specific volume of a protein may be estimated from its amino acid composition by using the equation $f_2 = \Sigma f_i w_i / \Sigma w_i$, where f_i is the apparent specific volume of the ith amino acid residue (Table 1) and w_i its weight percent (Ref. 1). In spite of a number of simplifications and assumptions, this method yields relatively rather accurate results. It should be noted, however, that the partial specific and apparent volumes are thermodynamic quantities, and changes in the environment (solvent composition, temperature, pressure, etc.) may cause significant changes in this volume.

Table 1. Apparent specific volumes of amino acid residues at 25°C (Ref. 1)

Residue	Apparent specific volume ($cm^3 g^{-1}$)
Ala	0.732
Arg	0.756
Asn	0.610
Asp	0.573
Cys	0.630
Gln	0.667
Glu	0.605
Gly	0.610
His	0.659
Ile	0.876
Leu	0.876
Lys	0.775
Met	0.739
Phe	0.766
Pro	0.748
Ser	0.596
Thr	0.676
Trp	0.728
Tyr	0.703
Val	0.831

The partial specific volume of a protein in water is expressed as the sum of three contributions (Ref. 2): (1) the constitutive volume estimated as the sum of van der Waals volumes of the constitutive atoms (v_c); (2) the volume of the cavities in the molecule due to imperfect atomic packing (v_{cav}); (3) the volume change due to solvation or hydration (Dv_{sol}).

(6)

The value of Dv_{sol} is usually negative, because hydration processes involve the contraction of solvent water. The volume change on transferring a protein from one solvent to another is calculated as the difference in v_2^0 between the two solvents. The volume change due to any conformational change of protein is also defined as the difference in v_2^0. In such a case, v_c does not change, so the observed volume change is ascribed primarily to differences in v_{cav} and Dv_{sol}. In general, processes increasing the solvent accessible surface area, eg, unfolding and dissociation into subunits, are expected to produce negative volume changes due to increased hydration. Most experimental data meet this expectation, but some data show no change or even slightly positive volume changes. It is noteworthy that the volume change observed at a given protein concentration, which is based on $\bar{v}_2$, may differ, even in its sign, from the result obtained at infinite dilution.

The partial specific volume measured at constant molality of the added cosolvent (eg, salts or organic compounds) is a useful quantity, as it is a truly thermodynamic volume. In practice, however, the measurement of this volume often accompanies difficulties in sample preparation, and most experiments (especially ultracentrifugation or small-angle X-ray scattering) are usually done with solutions that have been subjected to dialysis to equilibrium against the solvent. At equilibrium, the chemical potentials of diffusible components are equal on the two sides of a membrane, but the molalities of the components are not necessarily identical mainly due to Donnan effects and preferential binding of solvent components to protein. The apparent isopotential specific volume $\phi_2'^0$, which is measured at constant chemical potential of the solvent components (equilibrium dialysis systems), can be obtained from the density differences between the protein solutions and the dialyzate by the same procedures as used for ϕ_2^0. However, $\phi_2'^0$ is not a partial quantity in the thermodynamic sense, since the molalities of the diffusible components are not held constant, but this specific volume is operationally very useful because it reflects preferential protein–solvent interactions. In a two-component system or a dilute buffer system where Donnan effects and/or preferential solvent interactions are absent, ϕ_2^0 and $\phi_2'^0$ should be identical. In the presence of high concentration of a third component, however, large differences between these two specific volumes occur, as is shown in Table 2. The difference between ϕ_2^0 and $\phi_2'^0$ was derived theoretically by Casassa and Eisenberg (3):

(7)

where $\bar{v}_1$ and $\bar{v}_3$ are partial specific volumes of components 1 (water) and 3 (cosolvent), respectively; ξ_1 and ξ_3 represent preferential interaction parameters in terms of the number of grams of component 1 (or 3) that must be added per gram of component 2 to maintain components 1 and 3 at constant chemical potential. Then, the values ξ_1 and ξ_3 can be calculated with two specific volumes ϕ_2^0 and $\phi_2'^0$, which are usually measured by digital densimetry within an accuracy of ±0.002 $cm^3\,g^{-1}$ at isomolal and isopotential conditions of solvent components (Ref. 4). Positive values of ξ_3 or negative ξ_1 indicate the preferential binding of component 3 to protein; the opposite, negative ξ_3 or positive ξ_1, indicates that water interacts more favorably with the protein, ie, there is preferential hydration (Fig. 1). Whether preferential binding or preferential hydration occurs depends on the affinity of the cosolvent for the protein. As seen in Table 2, preferential hydration is observed for cosolvents having a potential ability to stabilize and crystallize proteins, whereas preferential binding occurs with denaturants. Thermodynamic properties such as solubility (phase separation), stability, and chemical equilibrium are subject to preferential solvent interaction, because it is directly linked to the chemical potential of the protein.

Figure 1. Schematic illustration of solvent component distributions in mixed solvents. (a) Preferential binding: Cosolvent (additive) is present in the solvation shell of protein at a greater local concentration than in the bulk solvent. (b) Preferential hydration: Exclusion of cosolvent from the protein surface results in enrichment of water in the solvation shell. [Taken from G. C. Na and S. N. Timasheff (5).]

Table 2. Apparent specific volumes of proteins and DNA at constant molality and constant chemical potential of various cosolvents (Ref. 6)

Solvent	Temperature (°C)	f_2^0 (cm^3 g^{-1})	f_2^0 c(cm^3 g^{-1})	x_3 (g^{-1})
Chymotrypsinogen A				
30% glycerol, 10 mM HCl	20	0.727	0.745	–0.123
1 M sucrose, 1 mM HCl	20	0.736	0.773	–0.138
10% PEG1000, pH 3	20	0.732	0.743	–0.07
6 M GdmCl	20	0.729	0.712	0.15
8 M urea	20	0.730	0.720	0.08
Bovine serum albumin				
1 M Na_2SO_4, pH 5.6	20	0.735	0.788	–0.074
2 M glucose, pH 6	20	0.727	0.750	
30% glycerol	25	0.729	0.744	–0.101
30% sorbitol	25	0.738	0.761	–0.092

20% propylene glycol, pH 2	25	0.740	0.726	0.211
1 M GdmCl	20	0.735	0.729	0.025
6 M GdmCl	20	0.717	0.724	0.06
DNA (calf thymus)				
0.20 M NaCl (NaDNA)	25	0.503	0.540	
0.20 M CsCl (CsDNA)	25	0.446	0.503	

The specific volumes f_2^0 and f_2^0 of nucleic acids are very small (around 0.5 $cm^3 g^{-1}$) and remarkably influenced by solvent composition (especially salt concentration) because they are polyelectrolytes with high charge densities (Table 2).

Particle Electrophoresis

As a result of the rising interest of molecular biologists in cells and organelles, the analytical separation and the preparative fractionation of those species by electrophoresis becomes increasingly important. Their large size makes gel electrophoresis difficult, as gels with very large pores are required. Specialized electronic devices for their separation on an analytical scale have been developed (1). Common capillary zone electrophoresis instrumentation has also been applied to particles up to 10 µm in diameter (2). Effective resolution of particles on the basis of differences in their size and shape, using solutions of polymers of various types and molecular weights for molecular sieving is possible (3), but the selection of the appropriate polymer is arbitrary at present. The resolving power is best when the particle diameter is less than the effective pore size (or “screening length”) of the polymer network in solution, and the separation of different particles is due to a differential occupation of available spaces in the network. By contrast, resolution is poor when the particle diameter exceeds that pore size, and separation is then due to a differential displacement of the network by the particle.

On preparative scales, separations in free solution are compatible with available instrumentation, such as free-flow electrophoresis apparatus (4) or automated gel electrophoresis apparatus in its preparative mode in conjunction with polymer solutions is feasible (5). In both analytical and preparative electrophoresis, sedimentation of the particles becomes an impediment to electrophoretic resolution only when the particle size surpasses about 8 μm in diameter (2). In those applications, electrophoretic separations in a microgravity environment are feasible (6).

Partition Coefficient

A molecule's partition coefficient is the equilibrium constant for its transfer between two phases that are immiscible (eg, water and cyclohexane). This equilibrium constant is measured by analyzing both phases after equilibrium has been achieved by stirring or shaking, and then dividing the molar concentration in the first phase by the molar concentration in the second. To avoid (or detect) the occurrence of aggregation (eg, formation of dimers) in either phase, the experiment must be carried out at a series of concentrations and the results extrapolated to infinite dilution. Aggregation in either phase is signaled by a tendency of the apparent equilibrium constant to increase in favor of one phase, that in which aggregation is greatest, as the total concentration of solute increases. Such partition coefficients depend on the particular temperature at which they were measured and are used in determining hydrophobicity. See also Transfer Free Energy.

Parvalbumin

Parvalbumin binds calcium with high affinity and appears to be involved in buffering of intracellular Ca^{2+} signals. It is a small protein (10–12 kDa) that is present in muscle, brain, kidney, testis, and adipose tissue. The various parvalbumin proteins can be classified into two evolutionarily distinct groups: the a-lineage and the b-lineage. Both types of proteins have, however, similar structures and functions. Parvalbumins are members of the EF-Hand Motif family of calcium-binding proteins.

1. Biological Function

Parvalbumin was first identified in skeletal muscle cells, and its function is best understood in these cells. For muscle cells to relax after a stimulus, the Ca^{2+} signal must be quenched by active transport of the Ca^{2+} ions into the sarcoplasmic reticulum. Parvalbumin has been implicated in skeletal muscle relaxation after a single twitch, as well as after a tetanic (continuous) contraction, and it may facilitate Ca^{2+} translocation in the sarcoplasm. There is still some controversy, however, over whether parvalbumin can exchange Ca^{2+} and Mg^{2+} ions fast enough to be involved in relaxation after a single twitch.

The function of parvalbumin in other cell types is less clear. It may act as a Ca^{2+} buffer to protect cells from damage due to calcium overload, particularly in the nervous system. It may also play an indirect role in Ca^{2+} signal transduction by affecting the nature of the incoming signal. For instance, it could modulate how quickly the signal builds, or how long the signal lasts. Parvalbumin may also be involved in cell growth and the cell cycle.

Oncomodulin is a b-lineage parvalbumin of particular interest, because it is found in abundance in certain cancer cells. It is normally found only in the preimplantation embryo and in the placenta. The function of this protein is completely unknown. However, its expression is cell cycle-dependent, and oncomodulin antisense oligonucleotides inhibit cell growth when injected into chemically transformed fibroblasts.

2. Ion-Binding Properties

Parvalbumin's two functional EF-hands will bind either Ca^{2+} or Mg^{2+} ions. Two main types of metal-binding loops are found in parvalbumins. The most common is the Ca^{2+}/Mg^{2+} “mixed” binding loop. These sites bind Ca^{2+} with high affinity ($K_{Ca} = 10^7$ to $10^9 M^{-1}$), and Mg^{2+} with moderate affinity ($K_{Mg} = 10^3$–$10^5 M^{-1}$) (1). Binding is competitive, and at basal physiological ion concentrations ($[Ca^{2+}] = 1 - 10 \times 10^{-8}$M; $[Mg^{2+}] = 1 \times 10^{-3}$M), mixed sites are occupied by Mg^{2+}. Exchange between bound Ca^{2+} and Mg^{2+} is slow (2, 3). The second type of binding loop is the Ca^{2+}-specific loop. The Ca^{2+} affinity of these sites is lower than in mixed sites ($K_{Ca} = 10^5 - 10^7 M^{-1}$), and the Mg^{2+} affinity is significantly reduced ($K_{Mg} = 10^1 - 10^2 M^{-1}$) (4). These sites are metal-free under basal physiological conditions, and can therefore bind Ca^{2+} quickly. Oncomodulin is the only member of the parvalbumin subfamily that has a Ca^{2+}-specific site paired with a mixed site.

3. Structure

Parvalbumins are the only known members of the EF-hand family with three such motifs (a prototypical functional domain is composed of only two). However, the N-terminal EF-hand of parvalbumin does not bind Ca^{2+} and is therefore considered to be a nonfunctional ancestral site. The protein is largely helical, with six alpha-helices, labeled A through F. The functional calcium-binding loops occur between helices C and D and between helices E and F. The loop between helices A and B is shorter than the functional loops (10 residues rather than 12), and as mentioned above, does not bind metal ions.

Parvalbumin was the first EF-hand protein whose high resolution three-dimensional structure was determined (5). To date, all the known parvalbumin structures have metal bound. Structures of parvalbumin bound to both Ca^{2+} and Mg^{2+} are available (6-13). The overall structure of the protein is very similar irrespective of which ion is bound. The two a-helices flanking each functional binding loop (the C/D pair and the E/F pair) are nearly perpendicular to each other, while the A and B helices, which flank the non-functional binding site, are nearly antiparallel (Fig. 1). However, there are some differences between the binding loops with bound Ca^{2+} and those occupied by Mg^{2+}, particularly in the position of the highly conserved glutamic acid residue that is the final residue of the binding loop. In parvalbumin and all other EF-hand calcium-binding proteins studied to date, this glutamic acid is a bidentate calcium ligand. In the Mg^{2+}-bound parvalbumin structures, this glutamic acid is a monodentate ligand (14). This difference reflects the preference of the Mg^{2+} ion for six ligands, whereas the Ca^{2+} ion can accommodate seven or even eight ligands. The apo structure is of questionable physiological importance, since almost all parvalbumin binding loops are occupied by Mg^{2+} under basal physiological conditions. NMR studies indicate, however, that apo-parvalbumin has a structure very similar to that seen for the ion-bound states (15). This is consistent with its proposed role as a calcium buffer, which requires high Ca^{2+} affinity but not the conformational change associated with the transduction of a calcium signal into a mechanical or metabolic response (see Calmodulin).

Pathogenesis In Fungi

1. Pathogenesis and Virulence

To understand how a given organism is able to infect its host, it is important to determine which aspect(s) of the biology of the fungus differs from nonpathogenic fungi. According to Bulmer and Fromtling, "Pathogenicity is the capacity of an organism to damage, ie, to produce disease in another animal or plant" (1). This property is the result of a direct interaction between the pathogen and the host. In many ways, pathogenicity and virulence are very broadly defined terms. If one considers all the possible gene products required for growth on or within a host, those that contribute to disease symptoms and host-range specificity, and those that govern their regulation, then we may be considering hundreds (or thousands) of potential components. Furthermore, the ability of an organism to adapt quickly to new environmental challenges is itself likely to be an effective virulence mechanism, in that it enables the pathogen to take advantage of new opportunities.

One of the most cited examples of virulence in the fungal world is the ability to switch morphological forms. While some fungi are pathogenic as yeast or conidial forms [eg, Histoplasma capsulatum, Coccidioides immitis, and Blastomyces dermatitidis and Coccidioides immitis (2–4)], numerous correlations between hyphal growth and pathogenicity have been cited for many of the fungal pathogens. In fact, mutants incapable of switching to hyphal growth are often revealed as nonpathogenic: cpg-1 deletions in C. parasitica (5), deletions of fuz7 in U. maydis (6), or cph1/efg1 homozygous deletions in C. albicans (7). The ability to switch morphological forms is referred to as dimorphism and is governed by a number of external factors including nitrogen, pH, temperature, and intracellular biochemical pathways (eg, level of cAMP) (8). Similarly, correlations between a strain's ability to myceliate and its virulence (defined by the LD50, lethal dose to obtain 50% killing of the host) have also been cited as strong virulence factors.

Pathogen-produced products which contribute in some way to either the establishment or continuation of the disease process have also been cited as virulence factors. Historically, secretion of degradative enzymes such as elastase and certain proteinases (9, 10) have been cited as potential virulence factors using a variety of methods to correlate disease progression with levels of expression. Paracoccidioides brasiliensis has been shown to alter its level of virulence with the production of a-1,3 glucan, suggesting that this polymer may act as a protective layer (11). Genes that contribute to adherence of the fungus to its host have also been regarded as virulence factors (12). Numerous genetic mutants or strain isolates have been analyzed in in vivo experiments to identify underlying gene products causing changes in pathogenicity. In fungus–plant interactions, the pathogen may produce a substance that specifically detoxifies plant-secreted antifungal compounds. For example, G. graminis deletion mutants have been generated that are relatively resistant to the production of avenacin by oat roots but retain full pathogenicity to wheat, which does not synthesize saponins (13); isolates of Nectria haematococca are similarly able to detoxify the pea phytoalexin, pisatin, using a cytochrome P450 mechanism (14). Furthermore, the biosynthetic pathway leading to melanin production in M. grisea correlates with altered virulence in this fungus; strains with reduced melanin content are less virulent (15). In some instances, these factors are reported to increase the pathogen's ability to penetrate host tissue (as in the case of melanin or proteinase production), while in others they may simply contribute to the overall fitness of the organism in vivo. For example, some auxotrophies are known to decrease virulence in vivo but play little or no role in vitro. Mutations in the URA3 and ADE2 genes of C. albicans and C. neoformans attenuate virulence in vivo (16, 17).

Alternatively, pathogen-induced factors that result in direct attacks upon the host are also known. The best-characterized system of host-selective toxin production by a plant fungus is in Cochliobolus. Different species of this genus are known to produce plant-specific toxins: T-toxin, HC-toxin, and victorin, of which only HC-toxin production has been deleted and shown to be nonpathogenic on maize (reviewed in Ref. 18).

One area in which there is sparse molecular information, but a great deal of inferential information, is in the interactions between the host immune system and pathogen. Research directed toward understanding the role of the unique polysaccharide capsule of Cryptococcus neoformans pathogenicity has uncovered a large difference in ability to phagocytose capsulized versus acapsular C. neoformans mutants in vitro, although it is not yet clear whether the ability to engulf a cell correlates with killing (4). Additionally, macrophages appear to recognize and engulf wild-type, single, and double mutants of the MAPK pathway in C. albicans equally well; however, only wild-type strains were able to switch morphologies, adding further support that dimorphism plays a significant role in virulence in this organism (7). It is tempting to speculate that in the chs3 C. albicans cell wall mutant, prolonged survival in vivo (19) had more to do with a change in its interaction with the host immune system than with any other factor. If, in fact, the host defense system plays a more significant role in disease progression than has been realized, it will be interesting to determine whether factors such as increased lipid content cited as a virulence factors in strains of Coccidioides immitis, Histoplasma capsulatum, and Blastomyces dermatidtidis (1, 20) is a result of an alteration in the interaction rather than a simple defense on the part of the fungus.

2. Signal Transduction and Pathogenesis

Signal transduction pathways play an important role in the cellular biology of all eukaryotic organisms, including fungi. The ability of a pathogen to receive signals from its environment and transmit those signals intracellularly to alter development or enable biochemical pathways so as best to take advantage of those changes has been recognized as a significant partner in pathogenesis of the organism. Some of the pathways have been carefully worked out in S. cerevisiae and S. pombe with regard to cell cycle, filamentation, stress, and the pheromone response. It appears that the molecules required to relay a signal from the external environment to the appropriate transcription factors within the nuclei of many of the filamentous fungi are highly homologous to those described in other organisms. Some of the molecules have been identified and isolated on the basis of sequence homology, and some by complementation or the use of similar screens. While the precise targets of many of these molecules have yet to be discovered, it is becoming clearer that many of the pathways in yeast are similarly conserved in more distantly related organisms.

Virulence and signal transduction pathways are inescapably intertwined in the biology of fungi and their pathogens. In the filamentous fungi, signal transduction pathways have been identified that regulate conidiation in *A. nidulans*, virulence in *C. albicans*, *C. parasitica*, *U. maydis*, and *M. grisea*, and mating. While only a few of the components have been identified in the filamentous fungi to date, there is much anticipation that most, if not all, of the players will eventually be isolated and characterized. Although their exact developmental pathways may be very different in the different fungi, it is important to keep in mind the similarities in order to appreciate the conservation of function across the biological world.

2.1. MAP Kinase Pathway

Signal transduction involves the activation of a receptor molecule at the surface of a cell, which transmits the signal inward toward associated proteins at the cytoplasmic interface of the plasma membrane. Changes in these proteins are relayed via a small number of known pathways (either by a cascade of kinases or by the release of a second messenger), which in turn activate a number of protein targets, some of which are themselves transcriptional activators. Subsequent alterations in transcription of whole sets of genes then reprogram the cell's "transcriptome," resulting in a particular cellular response to the initial signal. That signal may be any of a number of ligands that tells the cell something about its external environment: for example, nutritional availability, osmolarity, presence of compatible mating partners, or light. In one common pathway observed in all eukaryotes, a heterotrimeric G protein activates a mitogen-activated protein (MAP) kinase module that results in the further activation of target proteins, among which is a transcription factor. In some cells, multiple MAPK signaling pathways can be operating simultaneously, altering the organisms' transcriptome moment-by-moment. A MAP kinase pathway influence on pathogenicity has been shown for the corn smut, *U. maydis*, in which tumor production and completion of the sexual cycle is dependent upon successful compatible mating (21). Appressorium formation and pathogenic growth of *M. grisea in planta* also require a functional MAP kinase pathway (22). Because the components of these pathways are so highly conserved, one of the central questions that remains unanswered is how specificity is achieved and how that affects the pathogenicity of the organism.

2.2. Cyclic AMP Pathway

A second common pathway that impinges upon pathogenicity is the cyclic AMP-mediated pathway, which begins with a plasma membrane-bound sensor molecule (none of which has been isolated for the filamentous fungi to date). Upon a functional receptor–ligand interaction, a signal is transmitted to a heterotrimeric GTP-binding protein, possibly through a conformational change in the membrane protein. Second messenger cyclic AMP (cAMP) is produced via adenylate cyclase, which then alters the activity of cAMP-dependent protein kinase A (PKA) by binding to the regulatory subunit of PKA. This releases the catalytic subunits, which continue to activate downstream targets (including transcriptional regulatory proteins). A few components of this pathway have been identified in filamentous fungi. Mutants in *uac1* (adenylyl cyclase of *U. maydis*) have been shown to be defective in their ability to switch from budding to filamentous growth and, in addition, were unable to cause disease on corn (reviewed in (Ref. 23)); disruption of *adr1* (catalytic subunit of PKA) results in nonpathogenesis, whereas inactivation of *uka1* (catalytic subunit of PKA) has apparently little or no effect on growth, morphology, or pathogenesis. Disruption of *fil1* (G a subunit of *U. hordei*) also prevented normal hyphal to bud switching. Interestingly, of the four G a proteins isolated from *U. maydis*, only one, *gpa3*, was shown to be required for pathogenic development, disruption of the other three displayed no obvious phenotypes. Furthermore, *gpa3* mutants were unable to respond to pheromone signals strongly suggesting that a single G a subunit may play a role in multiple signaling pathways as has been observed in *S. cerevisiae* and *C. albicans*. Mutants disrupted in the catalytic subunit of *M. grisea* (CPKA) were shown to be unable to form appressoria on artificial surfaces, and they were also unable to infect rice unless exogenous cAMP was administered (23).

3. Strategies to Identify Virulence Factors

3.1. Gene Knockouts

There are a number of molecular genetic strategies that can be used to identify genes responsible for virulence in fungi (24). In a standard experiment, genetic manipulations are made such that the chromosomal copy of a gene in question is replaced by a marker gene. The growth rate of these strains is then compared to the normal wild-type strain and subsequently tested *in vivo* to determine the potential of the “knocked out” gene to cause disease. Proper controls wherein additional strains containing the chromosomal knockout, but also harboring a transformant carrying a reintroduced wild-type copy of the gene, or a heterozygote, is also compared in order to ensure that the effects observed are due to the presence or absence of a specific gene product and not some other underlying mechanism. It should be noted that due to the frequency of ectopic integration in filamentous fungi, these experiments may be difficult to interpret. They have been successfully accomplished for a wide variety of gene products in the dimorphic fungus, *C. albicans*. Using a modification of the original “ura-blaster” strategy (25), it is possible to knockout both copies of a given gene in this perpetually diploid organism. Genes in cell wall biosynthesis, signal transduction, and so on, have been identified as involved in virulence in such tests (7, 19, 26). This directed approach to virulence determination has also been successful in *A. nidulans* (27), *Gaeumannomyces graminis* (28), and *C. neoformans* (29), for example. Using this approach, there is the potential to knockout each gene in a given organism systematically and test its pathogenicity *in vivo*.

3.2. Gene Transfer

Virulence factors have also be identified by their ability to confer pathogenicity upon a related species or strain that was previously nonpathogenic. In this approach, a library is constructed and transformed into a nonpathogenic organism. Entire library pools are then tested for changes in related events that are suspected of having influences upon pathogenicity (adherence properties, toxin production, proteinase activity, etc.), and gene products are identified and then retested for altered virulence relative to the existing host strain. This approach has been successful in identifying a gene conferring adhesion properties from *C. albicans* to *S. cerevisiae* (30).

3.3. Gene Expression

This may be accomplished in a number of different ways. First is to identify all the genes expressed during an infection, by complementary DNA cloning, differential display analysis, or promoter fusions (all of which are technically feasible in the filamentous fungi). The idea is that crucial genes will be expressed sometime during or immediately prior to the establishment of an infection. These genes can then be further screened for their role in virulence, using a variety of knockout or deletion strategies. The *MPG1* protein of *M. grisea* was identified using this approach and confirmed to be important in the development of fungal infection structures (31). Using a differential display approach, two genes from *U. maydis* (32) and six genes from *C. albicans* have been identified that are differentially induced during infection (33). As additional sequence information becomes available for other fungal genomes, the use of promoter fusions as an approach will probably become somewhat more popular. Following the initial identification of clones that express a viable fusion, sequence analysis of the upstream sequences encoding the fusion will reveal the target gene. Conceivably, libraries in which the reporter proteins are cell surface-directed will aid in the initial identification of positive clones in this type of model.

One of the most fascinating stories concerning pathogenicity in fungal biology involves the interaction between *Cryphonectria parasitica* (chestnut blight fungus) and a hypovirus. These fungi, which have wreaked havoc upon the chestnut forests of the northeastern United States, are themselves infection-susceptible to a hypovirus that causes reduced virulence of the fungus for the plant. In addition to causing reduced virulence, the virus causes altered colony morphology, reduced pigmentation, and attenuated asexual sporulation. Differential display analysis of infected and noninfected isolates identified a candidate gene, *cpg1* whose reduced expression in infected isolates appears to correlate with pathogenicity (5, 34).

3.4. Mutagenesis

Historically, a traditional genetic approach in which mutations are isolated and further characterized has proven beneficial in the understanding of pathogenesis of fungi. One of the more recent strategies to understanding and defining virulence factors has come from alterations in transposon-mediated mutagenesis screens. Transposons are relatively small fragments of DNA that are capable of recombining nearly randomly into different sites within a single genome. They have proven useful in creating large number of "insertional" mutant libraries that are easily screened for loss-of-function phenotypes. Unfortunately, filamentous fungi appear to lack such elements. However, restriction enzyme-mediated integration (REMI) has been be used to create insertional mutants in filamentous fungi. Pathogenicity genes were identified for Cochliobolus heterostrophus (35) and Ustilago maydis (36) using REMI.

A modification of this method, called signature-tagged mutagenesis, has been used successfully in bacterial pathogenesis to identify insertional mutants that fail to grow in vivo (37). In this method, every insertional mutant carries with a unique oligomer tag that identifies it from all other mutants. After inoculating a mouse and recovering all survivors, DNA is prepared and hybridized to colony blots of the original input pool. Mutants not surviving are not recovered and are easily identified as not hybridizing. Identification of the gene into which the insertional tag is present is performed by sequencing. One of the only drawbacks to this approach is that only nonessential genes may be recovered, because insertions into essential genes are by definition lethal in culture.

3.5. Use of In Vivo Models

The use of in vivo models to confirm the role of individual genes in virulence is an important aspect of this field. However, it is important to recognize the difference between the establishment of infection and the maintenance of infection. Both are clearly critical factors in host–pathogen interactions, yet targets should be different, though somewhat overlapping. Second, the size of the inoculum is a well-established variable in disease models. It is not inconceivable that certain genes play a more significant role at low inocula in certain situations while other virulence genes are turned on under conditions of high inocula. Third, it is important to remember that virulence is multifactorial and results from a balance between the pathogen and the host immune system. Comparisons across different fungal backgrounds or different host models should proceed with caution.

4. Fungal Virulence Genes as Targets for Antifungal Therapy

It is not enough that we understand how an organism grows and develops or produces disease; it is our ability to use this information to circumvent those processes that will enable humanity to control and manage diseases produced by microorganisms. Compounds aimed toward inhibiting functions of known or suspected virulence factors have been suggested as likely to be effective in reducing disease even though many of the virulence genes identified to date have been shown to be nonessential for growth and reproduction of the organism in vitro. A compound directed toward such a nonessential target would likely prevent fungal growth until the compound were either removed or inactivated. In clinical situations where prophylaxis is appropriate, a reduction in anticipated fungal pathogen virulence could significantly influence patient outcome, because the disease will not likely gain entry initially. Unfortunately, the human patient population that often contracts fungal diseases is often immune-debilitated. From an agricultural view, inhibition of fungal growth will probably lead to increased production over a short season, making these attractive targets. Another consideration in choosing virulence factors as targets is the likelihood that parallel and/or redundant pathways may exist. With all of this, virulence genes are important to consider as potential drug targets.

Strategies for identifying fungal virulence genes as potential targets for drug development and/or vaccine development include many of the cloning strategies identified earlier. Furthermore, the use of bioinformatics and genome sequencing has made it possible to identify potential candidates based on previously known motifs, which may then be tested in vivo for specific disease.

Patterson Map

Patterson maps give structural information in X-ray crystallography, even if the phases of the reflections are not known (see Phase Problem). With the Patterson function $P(uvw)$, a vector map is calculated. Vectors between atoms in the real structure show up as vectors from the origin to maxima in the Patterson map (Fig. 1). The size and shape of the unit cell in this map is identical to the crystal unit cell.

(1)

where u, v, and w are relative coordinates in the Patterson cell; h, k, and ℓ are the indices of the reflections; V is the volume of the unit cell; and is the amplitude of the structure factor of reflection $h\,k\,\ell$. Calculation of the Patterson function from Eq. 1 does not require knowledge of the phase angles of the reflections and can always be calculated from the experimental diffraction data because, apart from correction factors, , where $I(h\,k\,\ell)$ is the intensity of reflection $hk\ell$.

Figure 1. Example of a simple Patterson map. (a) A two-dimensional unit cell with three atoms. (b) The corresponding

For very simple chemical compounds, it is possible to derive the real structure from the Patterson map. A protein Patterson map, however, has too many overlapping vectors to extract any structural information. However, protein Patterson maps are extremely useful for understanding the molecular replacement technique. They are also employed in isomorphous replacement to locate the attached heavy atoms. The difference between the amplitudes of the reflections for the native and heavy atom crystals is used in the calculation, to produce a difference Patterson map. Such a map should result only from the heavy atoms, and it should be interpretable because the number of heavy atoms attached is usually small and therefore they form a simple structure.

Pax Genes

Nine Pax genes have been isolated from vertebrates through sequence homology to a region in the

Drosophila gene *paired*, which codes for a DNA-binding domain. This domain of 126–amino acid residues is highly conserved and is known as the paired box. Binding sites for Pax proteins have been found in the promoter regions of genes coding for proteins as functionally varied as other transcription factors, crystallins, receptors, peptide hormones and cell adhesion proteins. Pax proteins are expressed in restricted regions during embryonic development. Pax genes are subdivided on the basis of the presence or absence of two further conserved sequences: a paired-type homeobox and an octapeptide coding region. These elements are keys to the functions of Pax proteins in morphogenetic processes such as (1) establishing the competence of tissues to particular developmental fates, (2) commitment of cells to particular developmental fates, and (3) the regionalization of the central nervous system.

1. Structure and Biological Activity of Pax Proteins

1.1. Classes of Pax Proteins

Pax proteins are transcription factors that regulate gene transcription. All nine Pax proteins contain the paired box, a 136–amino acid residue domain with DNA-binding activity that has sequence similarity to a domain found in the Drosophila protein paired (1) (reviewed in (2)). As well as the paired domain, Pax proteins also carry one or both of two other conserved domains: the paired-type homeodomain and the octapeptide sequence (Fig. 1). The presence or absence of these other conserved domains is used to classify the Pax proteins into four groups (Fig. 1). The amino acid sequences of the conserved domains of a Pax protein are more similar to those within the same class than those of Pax proteins from different classes (2). Additionally, when Pax proteins have similar functions in a particular tissue, for example, Pax-2 and Pax-5 in the midbrain/hindbrain boundary, they come from the same class.

Figure 1. Structure of Pax proteins.

1.2. Pax Proteins Directly Regulate the Expression of Many Types of Genes

Pax proteins regulate gene transcription by binding to specific sequences in the enhancer and promoter regions upstream of the coding regions of the gene. This results in the initiation of transcription, which subsequently results in synthesis of the protein. The paired domain binds to DNA; thus it is crucial to the regulation of gene transcription. Changes to the amino acid sequence in this domain have been demonstrated to strongly inhibit the binding of Pax proteins to DNA (3, 4). The specific DNA sequences that Pax proteins bind to have been found in the enhancer and promoter regions of genes coding for many classes of proteins (Table 1). This is consistent with the fact that Pax genes are important regulators of organogenesis in the developing embryo.

Table 1. Types of Genes Whose Expression is Regulated by Pax Proteins

Gene	Protein Product Type	Promoter Bound By	Reference
En1	Transcription Factor	Pax-2, -5, -8	(105)
En2	Transcription Factor	Pax-2, -5, -8	(105)
Crystallin (various)	Structural Protein	Pax-6	(106)
NCAM	Cell Adhesion Protein	Pax-6	(107)
Insulin	Peptide Hormone	Pax-6	(69)
Glucagon	Peptide Hormone	Pax-6	(69)
Thyroperoxidase	Enzyme	Pax-8	(84)
IgH	Immunoglobulin Subunit	Pax-5	(79)
CD19	Receptor	Pax-5	(76)
c-met	Receptor	Pax-3	(60)
p53	Cell Cycle/Apoptosis Regulator	Pax-5	(101)

2. Developing Processes Regulated by Pax Proteins

Pax proteins have important roles in regulating organogenesis, commitment of cells to particular developmental pathways, and the regionalization of the central nervous system (summarized in Table 2). Pax proteins help mediate these processes by (1) enabling an embryonic tissue to be competent to interact with other tissues, (2) conferring regional identity to a portion of tissue that later forms a new embryonic structure, (3) commitment of cells to a lineage with a particular differentiation pathway, (4) maintenance of boundaries between regions that have separate developmental fates, and (5) conferring multipotency to precursor cells (15, 85).

Table 2. Summary of Pax Gene Null Mutation Phenotypes in Mouse Mutants

Gene	Null Mutation	Heterozygous Phenotype	Homozygous Phenotype	Reference
Pax-1	Undulated, targeted	Normal	Hypoplasia of vertebral bodies and discs	(52, 53, 108)
Pax-2	KrD, targeted	Small kidneys, optic coloboma	No kidneys or genital tracts, optic oloboma	(25, 26, 28, 30, 31, 73)
Pax-3	Splotch	Lack of pigmentation	No limb muscle, neural crest derivatives absent or hypoplasic, persistent truncus arteriosus	(45, 58-64, 22-60, 62, 109, 110)
Pax-4	Targeted	Normal		(66)
Pax-5	Targeted	Normal	No B cells, cerebellar and inferior colliculous defects	(26-28, 77, 78)
Pax-6	Sey, Sey[Neu], rSey, targeted	Microphthalmia, corneal and iris defects	No eyes or olfactory bulbs, forebrain and motorneuron/interneuron specification defects	(7-9, 14, 15, 30, 31, 35-38, 47, 67)
Pax-7	Targeted	Normal	No muscle satellite cells, maxillary process, nasal capsule	(22, 46, 85)
Pax-8	Targeted	Normal	Absence of thyroid	(83)
Pax-9	Targeted	Normal	Absence of teeth	(55, 81)
Pax-2/Pax-5	Double homozygous	—	Absence of isthmic organizer, cerebellum and inferior colliculus	(26, 28)
Pax-3/Pax-7	Double homozygous	—	Neuronal specification defects (somitic derivatives not reported)	(22)
Pax-1/Pax-9	Compound heterozygous, double homozygous	—	Absence of vertebral bodies and discs, teeth	(51)

The roles of Pax proteins in these processes have been studied in mice having natural or targeted mutation of the Pax genes (Table 2). One property of Pax genes is that, for some developmental processes, two fully functional copies of the genes are required for normal differentiation of the tissue. Thus, developmental abnormalities in kidney, optic nerve, eye and pigmentation are found in mice heterozygous for mutations in particular Pax genes. These defects are broadly consistent with human syndromes in which one copy of the corresponding PAX genes are mutated. This characteristic, known as haploinsufficiency, results in autosomal-dominant phenotypes that are not the result of novel gene function but, rather, the consequence of depleted levels of functional protein. Increased levels of Pax protein can also alter developmental fate; extra Pax-6 genes results in developmental defects of the eye (5).

2.1. Pax-6 is Necessary for Early Eye Development

The embryonic eye is formed from an extension of the developing forebrain known as the optic vesicle, which is the precursor tissue for the retina, and a portion of the ectoderm, the lens ectoderm, that overlies this optic vesicle (reviewed in (6)). A crucial early process of eye development is the induction of the lens ectoderm by the optic vesicle to form firstly the lens placode, then a vesicle and finally the mature lens. In animals homozygous for the natural Pax-6 null mutations Sey (7-9), Sey^{Neu} (9) and rat rSey (10), lens development fails to occur. Pax-6 is expressed in the presumptive lens ectoderm and in the induced lens placode (11, 12). This pattern of expression strongly suggested that Pax-6 proteins is part of the mechanism that allows the ectoderm to respond to a lens induction signal from the optic vesicle. This notion was supported by explant recombination experiments between homozygous rSey and wild-type tissue which showed that the homozygous ectoderm failed to respond to optic vesicle interactions but that homozygous mutant optic vesicle could still induce lens ectoderm (13). A conclusive study of this interaction employed conditional knockout in mice to specifically ablate functional Pax-6 genes in the lens while leaving fully functional Pax-6 in the optic vesicle and other tissues (14). Lens ectoderm with no functional Pax-6 underwent an initial response resulting in increased expression of the transcription factor Sox-2, then its development arrested. Although optic vesicle development is arrested in the natural Pax-6 mutants, optic vesicles in the conditional knockout mice underwent development to form not one but several retinas. Thus, the optic vesicle is also required for correct placement of the retina, but not further development of the retina.

Development of the optic vesicle into the retina is characterized by the sequential generation of mature retinal cell types from stem cells in the original neuroectodermal layer (reviewed in (6)). An important feature of this process is the prevention of differentiation of all the stem cells into differentiated cells, so that a stem cell population is retained for the generation of later appearing cell types. However, specific ablation of Pax-6 in the retina by conditional knockout, results in all the stem cells of the retina differentiating into the first cell type to appear, the amacrine cells, and the consequent arrest of further retinal development (15). Thus, Pax-6 is necessary for maintenance of this stem cell population.

2.2. Pax Proteins and Patterning the Central Nervous System

Pax proteins are one of many classes of regulator proteins that control the generation of neural tissue. They are part of the mechanism that specify certain neuronal populations. Moreover, some structures in the CNS require Pax proteins for their survival. Pax proteins also modulate the extracellular environment of certain structures resulting in well-demarcated boundaries with neighboring tissues.

The neural tube and hindbrain exhibit particularly striking patterns of Pax gene expression. Pax-6 is expressed in most of the neural tube but is missing in the most dorsal and ventral margins (11, 16). Pax-3 and Pax-7 are expressed in the dorsal neural tube (17, 18). Combinations of transcriptional regulators including the Pax proteins are specified in individual cells on the basis of positional information provided by opposing concentration gradients of secreted peptide factors (reviewed in (19)). Sonic hedgehog, is secreted from the ventral margin of the neural tube, known as the floorplate, and from the notochord while BMP proteins diffuse from the dorsal margin of the neural tube (the roofplate) and the overlying ectoderm is the second group of signals. Additionally, transcriptional regulator expression can be modulated by other transcriptional regulators. Gain or loss of function for individual transcriptional regulators can change the specification of restricted neuronal types. Deletion of functional Pax-6, which is normally expressed in the middle of the neural tube, results in the respecification of the motor neurons supplying the hypoglossal nerve and some ventral interneurons (16, 20). Inappropriate expression of Pax-6 in the ventral neural tube respecifies a population of Nkx-2.2-expressing neurons by repressing expression of the transcriptional regulator (21). Loss of functional Pax-3 and Pax-7 genes results in one population of neurons inappropriately expressing the transcriptional regulator En-1 and the respecification of some ventral commisure neurons to other fates (22). Ectopic expression of Pax-3 in the ventral neural tube prevents the formation of the floorplate (23).

Pax-2 and Pax-5 are required for the maintenance of the isthmic organizer, which forms the boundary between the midbrain and hindbrain. This structure is required for the development of the inferior colliculus and the cerebellum (reviewed in (24)). Development of regions of the optic tectum and cerebellum were hypoplasic in both Pax-2 (25, 26) and Pax-5 null (27) mutant homozygous mouse embryos. These results suggested that Pax-2 and Pax-5 had similar, but not redundant, functions in the maintenance of the isthmic organizer. Generation of Pax-2/Pax-5 double null mutant homozygotes led to the complete absence of isthmic organizer, colliculus and cerebellum (26, 28, 29) and the extension of tissues adjoining these missing structures into the consequent space.

Pax proteins have an instructive role in the establishment of the boundary between the developing optic nerve tract and the retina. Both these structures form from the optic vesicle. The more medial portion, the optic stalk, is the optic nerve tract anlage and the more lateral, the optic cup, forms the retina. The developing optic nerve tract is characterized by expression of Pax-2 (25, 30). Absence of functional Pax-2, results in the extension of Pax-6 expression into the more medial portion of the optic vesicle and ultimately the generation of retinal epithelial cells (25, 30, 31). When functional Pax-6 is missing, the Pax-2 expression domain is shifted into the lateral optic vesicle (30). Furthermore, binding of Pax-6 protein to the Pax-2 promoter represses transactivation and binding of Pax-2 protein to Pax-6 promoter also represses transactivation (30).

In the forebrain, Pax-6 has been shown to establish the correct boundaries between the structures in the forebrain and between the forebrain and midbrain. In Pax-6 null mutant homozygotes, the caudal forebrain develops markers characteristic of the midbrain (32-34). The dorso-anterior aspect of the forebrain, the telencephalon, develops into the cerebral cortex and the striatum. Lack of functional Pax-6 leads to alterations in its boundary with the thalamus (35), defects in the developing cortical-striatal boundary (36, 37) and altered radial glia differentiation (38). The telencephalon phenotype is, in part, a function of modulation of the levels of the extracellular matrix proteins R-cadherin and tenascin (36) resulting in the loss of a well demarcated boundary with neighboring tissues.

2.3. Pax Genes Regulate Migration of Neural Crest Cells

The neural crest lays a crucial role in vertebrate development. Structures derived from neural crest cells include many peripheral neurons, including those in the spinal ganglia (dorsal root, sensory and autonomic), some of the bones of the skull, elements of the inner ear, cardiovascular structures and melanocytes (the pigmented cells) (reviewed in (39)). Neural crest cells migrate from the dorsal region of the neural tube and brain vesicles just after the fusion of their neural folds. This migratory process is influenced by three Pax proteins: Pax-3, Pax-6 and Pax-7. The migration of neural crest cells is blocked at thoracic and lumbar levels in homozygous splotch Pax-3 null mutant embryos and is severely impaired in cervical regions (40-42). This results in small or absent spinal ganglia, deficient ensheathing of peripheral nerves and the absence of melanocytes (43). Lack of neural crest migration into cardiac tissue results in the failure of the separation of the aorta and the pulmonary artery into two separate blood vessels (44, 45). Pax-7 and Pax-6 play similar roles to Pax-3 in the generation of more anterior neural crest-derived craniofacial structures. The maxillary process and nasal capsule are missing in Pax-7 null homozygotes (46) and Pax-6 null allele homozygotes lack lateral nasal processes (47).

2.4. Pax-1 and Pax-9 and Vertebral Body Formation

The vertebral column is derived from the sclerotome compartment of somites (48). Pax-1 and Pax-9 are expressed in the sclerotomes of the differentiated somites (1, 49), as a result of sonic hedgehog protein signaling from the notochord and the neural tube (50). Some Pax-1 expressing cells then migrate ventromedially to surround the notochord and differentiate to form the vertebral bodies and intervertebral discs (1, 49). The cells fated to form the vertebral bodies condense to form cartilage in a process known as chondrogenesis as evidenced by Sox-9 and collagen II expression (51). It is the fate of this cell population that Pax-1 and Pax-9 regulate. Mouse embryos homozygous for the natural null Pax-1 mutation undulated (52, 53) and the targeted Pax-1 null allele (54) exhibit vertebral body hypoplasia and fusions due to inhibited chondrogenesis and agenesis of the intervertebral discs. Hypoplasia is particularly pronounced in the posterior portion of each vertebra, and heterozygotes for Pax-1 null alleles have hypoplasic cervical and lumbar vertebrae (54). When embryos are homozygous for targeted null alleles of both Pax-1 and Pax-9, chondrogenesis does not occur because decreased proliferation and increased apoptosis leads to the disappearance of the vertebral body fated cell population (51). However, homozygotes for the Pax-9 targeted null allele have a normal vertebral column (55). These studies show that Pax-1 and Pax-9 have partially redundant roles in the vertebral bodies, but that Pax-1 acts uniquely in intervertebral disc formation and in normal chondrogenesis of the posterior of each vertebra.

2.5. Pax-3 Requirement for the Migration of Limb Muscle Precursor Cells

The skeletal muscles of the trunk and limbs are derived from the dermomyotome of the somatic mesoderm (reviewed in (48)). The myotome, which develops from the dermomyotome, forms the muscles of the back and ribcage. Precursors of limb muscle migrate from the leading lateral edge of the dermomyotome into the developing limb bud and coalesce into dorsal and ventral premuscle masses. These premuscle masses then form mature musculature. Both Pax-3 (56, 57) and Pax-7 (18, 46) are expressed in the dermomyotome with Pax-3 expressed more strongly in the lateral portion and Pax-7 in the medial portion. Loss of functional Pax-3 results in the failure of limb muscle precursors to make the transition from epithelium to mesenchyme and migrate into the limb (58, 59). This failure in migration is due in part because Pax-3 transactivation is required for the expression of the SF/HGF receptor c-met (60-62). SF/HGF protein is expressed in the limb buds and limb muscle precursor cells do not migrate in embryos homozygous for the null allele for c-met (63). Additionally, apoptotic cells are seen in the somites of mice homozygous for the Pax-3 null allele splotch at the developmental stages that limb muscle precursors emigrate from the somite (64).

2.6. Pax-4 and Pax-6 Mediate Endocrine Cell Specification in the Pancreas

The endocrine cell populations of the pancreas are found in the Islets of Langerhans (reviewed in (65)). The a, b, d and PP cell lineages synthesize glucagon, insulin, somatostatin and pancreatic polypetide, respectively. Pax-4 is expressed in the b (insulin-producing) and d (somatostatin-producing) cells (66), and Pax-6 is expressed in all four lineages (67). Inactivation of both copies of the Pax-4 gene resulted in the failure of insulin- and somatostatin-producing cell populations to differentiate and resulted in increased numbers of glucagons-producing cells (66). The latter finding is consistent with the discovery that Pax-4 protein binding to the enhancer of the glucagon gene represses transcription (68). Pax-6 homozygous null mutants lack glucagon-expressing cells and fail to form islets of Langerhans (67, 69). Moreover, Pax-6 protein transactivates the glucagon and insulin promoters and also binds to the somatostatin promoter (69). In embryos lacking both functional Pax-4 and Pax-6 genes, endocrine pancreatic cells fail to develop altogether (67). Hence the actions of Pax-4 and Pax-6 are required to generate the full complement of endocrine pancreas cell types from a single endocrine pancreatic progenitor population.

2.7. Pax-2 is Required for Mesenchymal-to-Epithelial Transitions in the Urogenital System

The development of the definitive kidney commences when a mesenchymal structure, known as the metanephric mesenchyme, induces the ureter to bud out from the caudal Wolffian duct (reviewed in (70)). Contact by the ureter induces the metanephric mesenchyme to differentiate into the glomerulae which are the proximal and distal tubular epithelial structures seen in the nephrons of the kidney. The metanephric mesenchyme expresses Pax-2 (71, 72). Pax-2 is necessary to allow the metanephric mesenchyme to undergo mesenchymal-to-epithelial transitions since mice that are homozygous for either the targeted Pax-2 null mutation (73) or the natural KrD mutation (31). Moreover, genital structures of epithelial morphology such as the vas deferens and seminal vesicles in the male and the uterus and vagina in the female are also missing in mice homozygous for these mutations. Pax-2's role in kidney formation is dosage dependent, kidneys in heterozygous mice are hypoplasic.

2.8. Pax-5 and the B-Cell Lineage

The B-cell lineage is one of the two cell types that mediate the immune response. Pax-5 is expressed in B cells until terminal differentiation (74) (reviewed in (75)). In Pax-5 null allele homozygotes, differentiation is arrested at a very early stage prior to the initiation of expression of the early marker, CD19 (27). In fact, the CD19 gene's promoter contains Pax-5 binding sites (76). However, the Pax-5 (-/-) pre B cells can populate the thymus when injected into Rag-2 (-/-) mutants (77), and can be diverted to other fates in vitro (78). Pax-5 is thus required for the generation and maintenance of an immature B-cell population. The finding that Pax-5 represses expression from the Immunoglobulin Heavy Chain gene (IgH) enhancer (79) suggests that downregulation of Pax-5 expression may be an important part of terminal differentiation.

2.9. Roles of Pax Proteins in Other Tissues

Pax genes have been found, from developmental defects observed in null-mutant homozygote embryos, to participate in the regulation of other developmental processes that are less studied. Nevertheless, the roles Pax genes play here are similar to the others described above.

Pax-1 and Pax-9 are required for full development of tissues derived from the third and fourth pair of pharyngeal pouches such as the thymus, parathyroid gland and the ultimobranchial bodies. These structures are completely missing from Pax-9 null allele homozygotes (55) and mice with no functional Pax-1 have a reduced thymus with 50 to 80% fewer T-cells (80).

Pax-9 plays a crucial role in the generation of teeth at the tooth germ stage. It is expressed at discrete sites in the mesenchyme along the developing mandible due to inductive signaling by FGF-8 and antagonistic signaling by BMP-2 and -4 (81). Only Pax-9 expressing portions of the mesenchyme can initiate tooth formation (81) in an in vitro assay; its absence in Pax-9 null mutant homozygotes prevents further development of tooth primordia (55).

The thyroid gland is formed from two cell populations: endodermal cells that express Pax-8 and pharyngeal-derived mesenchymal cells that form the parathyroid (82). Ablation of functional Pax-8 prevents the endodermal cells participating in thyroid development resulting in thyroid agenesis (83). Moreover, Pax-8 protein can transactivate the promoters of thyroglobulin and thyroperoxidase (84).

The olfactory bulbs differentiate from the nasal placode, which is induced in a Pax-6 dependent process. These structures are missing in Pax-6 null allele homozygotes (79, 47).

Finally, satellite cells are missing in the muscle tissue of Pax-7 null mutant homozygotes (85). However, the muscle stem cell population is unaffected.

3. Pax Genes and Human Disease

3.1. Human Syndromes Resulting from Mutation of Pax Genes

PAX gene mutations have been implicated in a number of syndromes over the last decade. The symptoms of these conditions are broadly consistent with the observations in heterozygous null mutant mice.

Two syndromes are known to result from mutations at the Pax-6 locus: Aniridia and Peter's anomaly. Aniridia is a syndrome in which the iris fails to develop fully (86-88). This is consistent with the iris malformations in heterozygous Sey mice (7, 8). Significantly, the posterior layer of the iris is derived from the optic cup, which expresses Pax-6. Peter's anomaly is a defect in the formation of the cornea that renders it opaque (89). The cornea develops from ectodermal tissue that expresses Pax-6 and forms over the lens after its formation.

The symptoms of Waardenburg's Syndrome 1 are pigmentation defects and hearing loss, which occurs as a result of PAX-3 mutation (90, 91). These defects occur as a result of the impaired migration or differentiation of neural crest cells, which give rise to structures of the inner ear and to the melanocytes. Sufferers of this syndrome are deaf, however mice heterozygous for the Splotch null mutation of Pax-3 are not (91).

In humans, disruption of PAX-2 function leads to optic nerve colobomass, renal hypoplasia and vesicouretal reflux (92, 93). This syndrome is consistent with the optic nerve and kidney phenotypes in mice heterozygous for the targeted Pax-2 null mutation (73).

3.2. Pax Genes and Cancer

Transcription factors that are inappropriately expressed or mutated play a significant role in tumorigenesis. Some studies have identified PAX genes as tumor promoters in certain cancers. The potential for PAX genes to promote neoplasia was shown in a study where Pax-1, -2, -3 and -6 transformed 3T3 cells could form tumors when injected subcutaneously into nude mice (94). Moreover, the cells transformed in focus assays.

Chromosome translocations leading to fused genes that contain some PAX sequences is one way by which PAX genes may promote tumorigenesis. Rhabdomyosarcomas are soft-tissue tumors with a muscle morphology found in the young. Characteristic of this sarcoma is a translocation from chromosome 13 to the PAX-3 locus in chromosome 2 GALILI (95). This results in a fusion of sequences of a forkhead-class gene to the homeobox of PAX-3, which expresses a chimeric protein that can transactivate gene expression at PAX-3 binding sites in their enhancers (96) (97)s. More recently a PAX-7 to forkhead translocation was isolated from a rhabdomyosarcoma (98). The effect of a translocation like this may put expression of the chimeric gene under a different, looser regulation. Alternatively, the resultant fusion proteins may simply have better transactivator potential than their parent proteins. A recent study found that the PAX-3/forkhead fusion protein was unresponsive to the PAX-3 repressor protein, hDaxx (99).

In other cases, the genetic lesion does not change the coding sequences of the PAX gene but only the promoter-enhancer region. An example of this is the translocation of the Em enhancer of the IgH gene to the PAX-5 locus in diffuse large-cell lymphomas (100). PAX-5 has been shown to directly repress the transcription of p53 (101) whose protein is crucial for initiation of apoptosis and cell cycle control. Another is the elevated PAX-2 and PAX-8 expression in Wilm's tumor (102-104).

4. Conclusion

Over the last twelve years, the Pax genes have been identified, their patterns of expression characterized, and many of their functions analyzed. Functional analyses have been helped by the fortuitous discovery of natural Pax rodent and zebrafish mutants, which complemented the targeted mutational studies. All Pax genes display restricted patterns of expression in both neural and nonneural structures. Some Pax genes have similar functional roles in the development of certain tissues. The best example of this is Pax-2 and Pax-5 in the morphogenesis of the midbrain-hindbrain boundary. Pax protein functions in some morphogenetic processes are sensitive to gene dosage, and the malformations seen in heterozygous mouse mutants and in the corresponding human syndromes resulting from mutation of the cognate PAX gene are strikingly similar. Thus haploinsufficiency is a conserved feature of Pax function in different species.

Pax proteins play important roles in certain morphogenetic processes. One of these is in conferring competence to respond to inductive influences. Examples include the competence of ectodermal tissue to be induced to form lens or nasal placode tissue, metanephric mesenchyme to form kidney epithelial structures, and the competence of dermomyotome cells to form a migratory myogenic cell type. Pax proteins also function in cell specification, examples being the B cells, pancreatic endocrine cells, the neural e developing crest, and certain neuronal cell types. In these cases, Pax proteins also help to mediate the survival of these cell types, since null mutations of Pax genes also lead to the disappearance of the cell types.

Studies in coming years will identify more structures whose genesis requires the actions of Pax genes particularly in the developing brain. Studies will also focus on Pax protein interactions with other nuclear proteins in forming transcriptional complexes, which is poorly characterized at present. Yet other studies will investigate the control of the expression of Pax genes.

Pedigree

A pedigree is a family tree, a graphical presentation of biological descent (Fig. 1). Each generation is represented in a separate row. Males are presented by squares and females are represented by circles; alternative respective symbols are ♂, representing the shield and spear of Mars, and ♀, the mirror of Venus. Horizontal lines join parents and sets of sibs; vertical lines indicate descent. Sibs are ordered according to birth from left to right. Double horizontal lines call attention to parents that are closely related (inbreeding); sometimes they are used to join monozygotic twins as well. Filled, colored, or shaded symbols indicate affected individuals in pedigrees that represent the inheritance of certain traits; partly modified symbols indicate unaffected heterozygous carriers. Several sibs can be pooled together by indicating their number within a single symbol. A pedigree may be described in words, but this is usually impractical.

Figure 1. Conventional symbols used in the representation of pedigrees.

In the analysis of pedigrees, attention must be given to inconstant phenotypes due to effects of the environment or the rest of the genotype of the affected individuals on the expression of the allele. Some alleles are unstable and change from one generation to the next (see Trinucleotide Repeats). Because of the small size of human families, linkage has to be deduced from the pooled results of many groups of sibs (see Lod scores).

PEG (Polyethylene Glycol)

PEG is a polyether polymer commonly used to induce the precipitation or crystallization of macromolecules and viruses. In spite of its name, polyethylene glycol, it has hydroxyl groups only at each end of the polymeric chain:

Except for these ends, the polymer is essentially nonpolar. The ether oxygen atom is only slightly polar and hydrogen bonds with water just sufficiently to make PEG water-soluble. PEG is produced by the simple polymerization of ethylene oxide,

and is available in different lengths, whose molecular weights vary from 200 to 20,000, depending on the polymerization process. The average number of monomers in each molecule may be estimated by dividing the molecular weight of the polymer by 44, the molecular weight of the monomer.

PEG precipitates proteins because it is a large, water-soluble polymer that is excluded from the surfaces of macromolecules simply because of its large physical size, a phenomenon known as steric exclusion (see Excluded Volume). A large polymer cannot penetrate the interior of a folded protein or other macromolecule, so it is effectively excluded from a shell around the macromolecule. The thickness of the shell is defined by the center of the polymer at its point of closest approach to the macromolecule. The presence of the polymer in effect increases the concentration of the macromolecule because the macromolecule is excluded from the volume of the solution occupied by the polymer. When the solubility limit of the macromolecule is reached, it precipitates or crystallizes.

Water molecules are smaller and penetrate within this shell of solvent around the macromolecule from which PEG is excluded. As a result, a zone enriched in water is formed around the protein molecule. The end result is preferential hydration of the macromolecule and preferential exclusion of the polymer (1). Solely on this basis, PEG would be expected to stabilize the folded conformation of the macromolecule (see Stabilization And Destabilization By Co-Solvents). However, PEG is a relatively nonpolar molecule that interacts favorably with the nonpolar surfaces exposed when a macromolecule unfolds, and the net effect is that PEG destabilizes folded proteins (1, 2).

Penicillin

The penicillins are antibacterial agents belonging to the group known as the b-lactam antibiotics. Penicillin was first discovered about 70 years ago by Alexander Fleming as a metabolic by-product of the fungus Penicillium notatum (1). Since then, other fungi have been shown to produce several different structural types of penicillins. All penicillins share a common bicyclic nucleus that is composed of fused b-lactam and thiazolidine rings (Fig. 1). This compound, known as 6-aminopenicillanic acid, is a cyclic peptide formed by the condensation of L-cysteine and D-valine. An important structural feature of the penicillins is the acyl side-chain attached to 6-aminopenicillanic acid (represented by R in Fig. 1). The different members of the penicillin family are distinguished by their acyl side chains, some examples of which are shown in Figure 1b. The derivatives known as penicillin G and penicillin V are natural penicillins, namely, fungal metabolites. The medical application of penicillin in the 1940s highlighted the birth of the antibiotic era, and subsequent misuse of this and other antibiotics has led to the current drug resistance crisis (2) (see Antibiotic Resistance).

Figure 1. (a) The structure of the penicillin nucleus; R represents a hydrogen atom in the case of 6-aminopenicillanic acid. (b) Examples of acyl side chains of natural and semisynthetic pencillins.

Comparative studies indicated that the structure of the acyl side chain significantly influenced the antibacterial spectra and physical properties of penicillin. The development of semisynthetic penicillins was an important event in penicillin development. Nayler (3) has presented a historical account of the discovery of semisynthetic penicillins. Semisynthetic antimicrobial agents are derivatives of a natural product that have been deliberately modified chemically. In the case of the semisynthetic penicillins, the natural product is the penicillin nucleus, 6-aminopenicillanic acid. The discovery of methods to produce large amounts of 6-aminopenicillanic acid in the late 1950s was the pivotal event that led to the development of semisynthetic penicillins. The subsequent synthetic chemical acylation of 6-aminopenicillanic acid gave rise to numerous new penicillins with novel properties, and this approach was essential to keep up with the growing demands to solve problems faced by medical applications. For example (see Fig. 1), this technology gave rise to agents that exhibited broad-spectrum antibacterial activity (eg, ampicillin and carbenicillin), agents that could be administered orally (eg, ampicillin), and agents that were resistant to the action of b-lactamase (eg, methicillin).

Penicillin inhibits the synthesis of the bacterial cell wall polymer known as peptidoglycan or murein. This topic has been reviewed recently by Höltje (4, 5). Peptidoglycan is a single large macromolecule that completely envelopes bacterial cells. It represents an exoskeleton that supports the underlying cytoplasmic membrane. In this regard, it serves an absolutely essential function in preventing osmotic lysis of the bacterial cells. The actual targets of penicillin are membrane-bound enzymes, known as penicillin-binding proteins (PBPs), that catalyze the transpeptidation reaction in the final stage of peptidoglycan polymerization. Transpeptidation creates crosslinkages between adjacent peptide chains in the peptidoglycan polymer. The amide group in the b-lactam ring of penicillin represents a structural analogue of the D-alanyl-D-alanine peptide bond involved in the transpeptidation reaction. Penicillin is a suicide substrate for PBPs, and the interaction of penicillin with its PBP target results in the formation of a stable penicilloylated enzyme derivative. For details of the mechanism of action of penicillin, see Penicillin-Binding Proteins (see Fig. 1 of that article).

Penicillin is bactericidal. The lethal effect of penicillin treatment is normally associated with bacterial cell lysis (4, 5). This lysis is catalyzed by one or more bacterial enzymes known as peptidoglycan hydrolases. These enzymes cleave chemical bonds in peptidoglycan. Their normal physiological functions are poorly understood. It is believed that the activities of at least some of these hydrolases create openings in the completely closed peptidoglycan molecule, to permit the insertion of new subunits during the growth of bacterial cells. The terminal stage of peptidoglycan synthesis is consequently proposed to be a coordinated process catalyzed by two classes of enzymes: the PBPs and the peptidoglycan hydrolases. These enzymes are further proposed to form a multienzyme complex. Therefore, bacteria are killed by penicillin in a two-step process. In the first step, penicillin inhibits activities of the PBPs involved in peptidoglycan polymerization. In the second step, the peptidoglycan hydrolases become uncoupled from the peptidoglycan biosynthetic process and cause lysis of the bacteria.

It has long been recognized that penicillin kills only actively growing bacteria (6). More recent studies have confirmed that the bactericidal effect of penicillin is directly dependent on the bacterial growth rate (7). The first application of penicillin in genetics was based on this concept. Lederberg and Zinder (8) and Davis (9) independently developed a technique, known as penicillin selection, for the isolation of auxotrophic mutants of *Escherichia coli*. The procedure involves inoculating a sample of *E. coli* containing rare auxotrophic mutants into a minimal medium lacking the nutritional factor(s) required by the mutants. Only the wild-type cells in the population are capable of growing in this medium, and the majority of these are subsequently killed by the addition of a lethal dose of penicillin. The auxotrophic mutants are tolerant to penicillin and are readily recovered by screening the survivors of the penicillin treatment.

The basis for the pencillin tolerance of amino acid–deprived cells has been investigated. Amino acid deprivation of *E. coli* results in the coordinate inhibition of a variety of metabolic activities in a phenomenon that has been called the "stringent response" (10) (see Stringent Control). The stringent response is probably a strategy to restrict energy consumption in an effort to promote the survival of bacteria during periods of starvation. Amino acid–deprived *E. coli* accumulate a novel nucleotide, guanosine 3′,5′-bispyrophosphate (ppGpp), which is believed to mediate the stringent response. Membrane phospholipid synthesis, cell wall peptidoglycan synthesis, and penicillin-induced lysis are among the many metabolic activities that are inhibited during the stringent response (11, 12). Moreover, the activities of the membrane peptidoglycan polymerases and peptidoglycan hydrolases have been shown to be dependent on ongoing phospholipid synthesis. Therefore, the inhibition of phospholipid synthesis by ppGpp results in the inhibition of the membrane-associated reactions in peptidoglycan metabolism and is the direct cause of the penicillin tolerance of starved *E. coli*.

The concept of penicillin selection can be applied more broadly. It can be used in any situation where it is possible to design culture conditions that do not permit the growth of the cells to be selected. For example, penicillin selection can be used to select cells that have been spontaneously cured of transposon insertions. Therefore, cured cells can be selected from a population of cells that carry the transposon Tn5 (which encodes kanamycin resistance) by growing the culture in a medium containing both kanamycin and ampicillin. The ampicillin will kill only those cells that carry Tn5, and cured cells can be isolated by screening the surviving population.

Genetic elements encoding b-lactamases (see Penicillin-Binding Proteins) are currently widely employed as selective markers in molecular biological applications. Consequently, penicillin derivatives, especially ampicillin, are among the most common chemicals encountered in a molecular biology laboratory. Penicillin selection is attractive because these antibiotics are relatively inexpensive and are highly effective because of their bactericidal action. In medical applications, penicillin derivatives are considered to be of low toxicity. They are allergenic, however, and the development of either immediate or delayed hypersensitivities are the most frequent and serious problems associated with penicillin therapy. It is notable that anaphylaxis to penicillin has been reported after nontherapeutic exposure (13). It is therefore conceivable that exposure to penicillin in the laboratory could result in hypersensitive reactions in sensitized individuals, and those who are known to be allergic to penicillin should be alerted to this possibility.

Penicillin-Binding Proteins

The concept of antibiosis originated with Ehrlich and the sulfa drugs. It was firmly established by Fleming, Florey, and Chain, who discovered the use of penicillin. The chemical structure of penicillin has some remarkable features: its β-lactam amide bond is equivalent to a peptide bond extending between two carbon atoms that have the D configuration (see Stereochemistry), in the a position to a free carboxyl group . Penicillin kills bacteria because it inactivates specialized acyl serine transferases that are involved in the assembly and metabolism of the cell-wall peptidoglycan. It immobilizes the catalytic center in the form of a stable serine ester-linked penicilloyl enzyme derivative (Fig. 1). Variants of penicillin, such as ampicillin, also exist.

Figure 1. The structure of penicillin and its reaction with the active-site serine residue of acyl-serine transferases. The re
of the reaction is shown at left, and the resulting penicilloyl enzyme is shown at right. If the penicilloyl enzyme is stable,
enzyme is a penicillin-binding protein. Alternatively, if the penicilloyl enzyme is hydrolyzed rapidly, the enzyme is a b-

The bacterial cell-wall peptidoglycan is a covalently closed, net-like polymer (1). Linear glycan strands are made up of alternating b-1,4-linked units of N-acetylglucosamine and N-acetylmuramic acid. The carboxyl groups of the N-acetylmuramic acid residues are amide linked to the amino terminal L-alanine residues of peptide units L-alanyl-g-D-glutamyl-L-diaminoacyl-D-alanine. Neighboring peptide-substituted glycan strands are crosslinked by peptide bridges that extend from the D-alanine at the carboxyl end of one peptide to the side-chain amino group of the diamino acid residue of another peptide. The nature of the diamino acid residue and the composition of the peptide bridge vary according to the bacterial species.

In Escherichia coli, the diamino acid residue is meso-diaminopimelic acid, and the peptide bridges are direct D-alanyl-(D)-meso-diaminopimelic acid bonds. The immediate biosynthetic precursor of the cell-wall peptidoglycan is lipid II (2), in which a disaccharide peptide unit is linked to a $C_{55}H_{89}$ undecaprenyl lipid carrier via a pyrophosphate bridge involving C_1 of N-acetylmuramic acid, and the peptide borne by N-acetylmuramic acid is a pentapeptide that terminates with a D-alanyl-D-alanine sequence. From this precursor, glycosyltransferases catalyze glycan chain elongation by displacement of the pyrophosphate linked to C1 of N-acetylmuramic acid by the 4-hydroxyl group of N-acetylglucosamine. Then acyl serine transferases catalyze peptidoglycan crosslinking at the expense of the D-alanyl-D-alanine bond of the pentapeptide units. This reaction proceeds via formation of a peptidyl (L-alanyl-g-D-glutamyl-L-diaminoacyl-D-alanyl) enzyme intermediate linked as an ester to a serine residue at the active site, with the concomitant release of the carboxy terminal D-alanine residue of the pentapeptide. It is achieved by the transfer of the peptidyl moiety to the side-chain amino group of the diamino acid residue of another peptide. Because the reaction involves breaking a D-alanyl-D-alanine bond, the acyl serine transferases are classified as DD-transpeptidases.

Acyl serine transferases are also involved in the control of the extent of peptidoglycan crosslinking. DD-carboxypeptidases hydrolyze the D-alanyl-D-alanine peptide bonds of pentapeptide units by transferring the peptidyl moiety of the acyl-enzyme intermediate to water. DD-endopeptidases hydrolyze the interpeptide bonds, which in some bacteria extend between two D centers in a position to a free carboxylate, as, for example, the D-alanyl-(D)meso-diaminopimelic acid bonds in the E. coli peptidoglycan.

Penicillin has similarities to the above substrates and is a suicide substrate of the DD-(trans, carboxy, endo)peptidases. These DD-peptidases attack and rupture the b-lactam amide bond of penicillin but produce a serine ester-linked penicilloyl enzyme that is almost completely inert and inactive. The catalytic center turns over very slowly—one time or less per hour—and the inactivated enzymes are detectable as penicillin-binding proteins (PBPs).

In some cases, proteins acquired the ability to catalyze the hydrolysis of the serine ester-linked penicilloyl enzyme, which resulted in a remarkable defensive mechanism by producing enzymes, (the b-lactamases), with the ability to hydrolyze penicillin and other b-lactam antibiotics. On good b-lactam substrates, the catalytic center of these b-lactamases can turn over 1000 times or more per second.

The DD-peptidases and serine b-lactamases form a superfamily of penicilloyl serine transferases (3). They are an exemplary model of molecular evolution. Numerous changes in their amino acid sequences, and gene fusion with the genes for several polypeptides of different origins, resulted in a prolific expansion of groups, classes, and subclasses of these enzymes, with multiple personalities. They share structural motifs. Some have similar enzymatic activity but varying substrate specificities. Others catalyze distinct reactions and fulfill different functions.

1. Protein Structure

The DD-peptidases and b-lactamases presumably diverged from a common ancestor while retaining the same basic protein structure (4). Similarities in their overall amino acid sequences are almost nonexistent, but folding invariably brings three common motifs of the polypeptide chains close to each other in the tertiary structure, forming the catalytic center at the boundary between an all-a domain and an a/b domain, which consists of a five-stranded beta-sheet covered by alpha-helices on both faces. With “x” denoting a variable amino acid residue, motif 1 has the sequence -Ser-x-x-Lys- (where Ser is the active-site serine), is at the amino end of an a-helix, and occupies a central position in the cavity. Motif 2 has the consensus sequence [Ser/Tyr]-x-[Asn/Asp/Cys] and is on a loop between two a-helices on one side of the cavity. Motif 3 has the sequence [Lys/His]-[Thr/Ser]-Gly and is on the innermost strand of the b-sheet on the other side of the cavity. The relative positions of these three motifs are well conserved in the various proteins.

2. Penicillin targets in *Escherichia coli*

E. coli possesses nine PBPs. PBPs 4, 5, 6, and 7 are monofunctional DD-carboxypeptidases that are not essential for viability. PBPs 1a, 1b, 1c, 2, and 3 are multidomain proteins (3) in which a transmembrane spanner is linked to the amino end of a non-penicillin-binding (n-PB) module that is linked to the amino end of an acyl serine transferase, penicillin-binding (PB) module. The two modules comprise a single polypeptide chain that folds on the exterior of the plasma membrane (Fig. 2). There are two classes: A and B (see text below).

Figure 2. Design and membrane topology of multimodular penicillin-binding proteins (PBPs) of class A and class B. Indicated are the five motifs of the n-PB modules of class A PBPs ƒ, the three motifs of the n-PB modules of class B PBPs ○ , and the intermodule junction sites D. For more details on the class-specific motifs, see text. The PB modules bear the characteristic motifs of the penicilloyl serine transferase superfamily. Some PBPs have inserts and N- and C-terminal extensions, which are not shown.

PBP1a and PBP1b of class A (850 and 844 amino acid residues, respectively) combine the transglycosylase (n-PB module) and the DD-transpeptidase (PB module) activities that are required for peptidoglycan assembly. Each catalyzes the conversion of lipid II into polymeric peptidoglycan in in vitro assays (5). Loss of either PBP1a or PBP1b is tolerated, but loss of both is fatal (6). Under these extreme conditions, PBP1c (770 amino acid residues) does not rescue *E. coli* from death.

PBP2 and PBP3 of class B (633 and 588 amino acid residues, respectively) are inert on lipid II (7). They combine in a single polypeptide chain a cell cycle (n-PB) module and an acyl serine transferase (PB) module. Both modules are essential, and loss of neither PBP2 nor PBP3 is tolerated. The genes for PBP2, the DD-carboxypeptidase PBP5, and the integral membrane protein RodA cluster at the 14-min region of the chromosome; these proteins prescribe traits as complex as cell-wall expansion and cell-shape maintenance (8). PBP3, MraW, FtsL, FtsQ, FtsA, the cytoskeletal FtsZ, and FtsW (an analog of RodA)—the encoding genes of which cluster at the 2-min region of the chromosome—prescribe traits as complex as septum formation (9).

3. The Multimodular PBP Family

Sixty-three multimodular PBPs of various bacterial species (10) comprise two classes, A and B, with distinct amino acid sequence signatures in their n-PB modules but conserved motifs in their acyl serine transferase-PB modules. The junction sites between the n-PB and PB modules usually have the carboxy terminal sequence Asp-x-x-x-Gln (Fig. 2). There is a clustering into several subclasses of A and B, corresponding to Gram-negative and Gram-positive bacteria.

Based on these observations, the cores of the n-PB modules (n-PB cores) of the multimodular PBPs start at the amino end of the first motif and terminate at the intermodule junction site. The cores of the associated PB modules (PB cores) start about 70 residues N-terminal of the Ser-x-x-Lys motif—at the carboxy end of the intermodule junction site (where insertions occasionally occur), and they terminate about 70 residues C-terminal of the Lys-[Thr/Ser]-Gly motif; PBPs also have C-terminal extensions. In *E. coli* PBP1b, motif 3 of the PB core has the sequence Lys-Thr-Gly at residues 698–700, residues 762–780 are essential, but residues 781–844 are dispensable (11). (In *Streptococcus pneumoniae* PBP2x (the structure of which is known at low resolution [(12)]), motif 3 of the PB core has the sequence Lys-Ser-Gly at residues 547–549, and residues Ser617–Asp750 form a carboxy terminal module with its own fold.

The multimodular PBPs are fully integrated hybrids. In contrast to the monofunctional PBPs, which are autonomous folding entities, the PB modules of multimodular PBPs have lost the ability to fold by themselves (13-15). They require the assistance of the associated n-PB modules, which implies precise and specific module-module interactions. Correct folding (in terms of penicillin binding) of the associated n-PB and PB modules of *E. coli* PBP3 is independent of the transmembrane spanner (13). In contrast, the cell septation activity of *E. coli* PBP3 is dependent on the membrane-anchor module, indicating that the membrane anchor and its cytosolic tail have more sophisticated functions than that of a simple anchoring device (16).

4. Evolution of Multimodular Class A PBPs

The n-PB cores of the class A PBPs form a continuum of homologous sequences, and they have an extended amino acid sequence signature in the form of five motifs, indicative of conserved transglycosylase activity. In *E. coli* PBP1a, motif 1 starts at residue 86 with the sequence Glu-Asp-Ser-Arg-Phe-x-Glu-His-x-Gly, motif 2 starts at residue 117 with the sequence Gly-Ala-Ser-Thr-Ile-Thr-Gln-Gln, motif 3 starts at residue 139 with the sequence Arg-Lys-x-x-Glu, motif 4 starts at residue 156 with the sequence Lys-x-Glu-Ile-Leu-x-Gly-Tyr-x-Asn, motif 5 starts are residue 221 with the sequence Arg-Arg-x-x-x-Val-Leu-, and Gly284 is at the amino end of the intermodule junction site. Residues Glu86 of motif 1 and Glu143 of motif 3 are almost certainly important components of the transglycosylase catalytic center.

The associated PB cores of the class A PBPs of Gram-negative bacteria cluster into two subclasses: A1 (prototype: *E. coli* PBP1a) and A2 (prototype: *E. coli* PBP1b), which form a supercluster. Those of Gram-positive bacteria cluster into three subclasses: A3 (prototype: *S. pneumoniae* PBP1a), A4 (prototype: *S. pneumoniae* PBP2a), and A5 (prototype: *S. pneumoniae* PBP1b).

Although performing the same transglycosylase-transpeptidase activities, PBPs of subclasses A1 and A2 in Gram-negative bacteria and PBPs of subclasses A3, A4, and A5 in Gram-positive bacteria are almost certainly paralogous. They prescribe distinct, subtle traits in peptidoglycan assembly in these two groups of bacteria that sometimes are difficult to detect.

5. Evolution of Multimodular Class B PBP

The class B PBPs evolved differently than did class A PBPs (10). The n-PB and PB cores underwent adaptive evolution in such a concerted manner that, in Gram-negative bacteria, an n-PB core of subclass B2 (prototype *E. coli* PBP2) or B3 (prototype *E. coli* PBP3) is linked to a PB core of subclass B2 or B3, respectively. In Gram-positive bacteria, an n-PB core of subclass B1 (prototype: *Enterococcus faecium* PBP3), B4 (prototype *S. pneumoniae* PBP2x), or B5 (prototype *S. pneumoniae* PBP2b) is linked to a PB core of subclass B1, B4, and B5, respectively.

This unique combination of the n-PB and PB cores indicates that they have different functions in cell morphogenesis (n-PB module) and peptidoglycan crosslinking (PB-module). The Gram-negative PBPs of subclasses B2 and B3 are paralogous, and the Gram-positive PBPs of subclasses B1, B4, and B5 are also paralogous. In contrast, the Gram-negative PBPs of subclasses B2 or B3 may be orthologous to the Gram-positive PBPs of subclass B5 or B4, respectively.

The Gram-positive PBPs of subclass B1 have no equivalent in the Gram-negative bacteria. They are endowed with unique properties, and they represent an important mechanism of resistance to penicillin. These PBPs have a very low affinity for the drug. They allow the strains that (over) produce them to grow in the presence of penicillin at concentrations sufficient to inactivate the PB modules of all the other PBPs of class A and class B. To all appearances, they are able to perform the basic functions required for cell-wall peptidoglycan assembly in a cell cycle-dependent fashion in conjunction (presumably) with the transglycosylase-n-PB module of class A PBPs (or with monofunctional transglycosylases).

The question of how the class B PBPs function in cell morphogenesis is still open. Yet the unique amino acid sequences of their n-PB modules (10) and the three-dimensional structure of *S. pneumoniae* PBP2x (12) are worthy of reflection. The n-PB cores of all class B PBPs have three conserved motifs. In *S. pneumoniae* PBP2x, motif 1 starts at residue 76 and has the sequence Arg-Gly-x-x-x-Asp-Arg-Asn-Gly, motif 2 starts at residue 186 and has the sequence Arg-x-Tyr-Pro-x-Gly, motif 3 starts at residue 215 and has the sequence Gly-x-x-Gly-x-Glu-x-x-x-Asn, and Gly258 is the amino end of the intermodule junction site. The n-PB module of PBP2x is shaped like a pair of sugar tongs; motifs 1, 2, 3 and the amino half of the intermodule junction site are located in the head of the sugar tongs (which fits into a noncatalytic groove of the PB module), and the long polypeptide stretch that extends between motifs 1 and 2 is well exposed at the surface of the protein.

Other class B PBPs probably adopt the same basic folded structure but with subclass- and species-specific variations. The acyl serine transferase-PB module of class B PBPs probably prescribes traits related to peptidoglycan crosslinking, and this activity might be regulated by the associated n-PB module itself, in conjunction with other components of the morphogenetic networks.

6. Penicillin-Oriented Evolution

Evolution is occurring before our eyes. The massive use of b-lactam antibiotics functions to fuel the emergence of b-lactamases of widely varying specificities by the alteration of a limited number of amino acid residues in the wild-type enzymes (17). Oriented evolution also results in the spread of low-affinity PBPs of subclass B1 among enterococcal and staphylococcal pathogens (18, 19). Strains close to the squirrel *Staphylococcus sciuri* might be the source of the PBP2a-encoding gene in human MRSA (methicillin-resistant *S. aureus*) strains (20). Multimodular PBPs also evolve into variants having a decreased affinity for the drug. Penicillin-resistant *S. pneumoniae* strains possess PBPs that are reduced-affinity variants of PBP1a of subclass A3, PBP2x of subclass B4, and PBP2b of subclass B5 (21). These altered PBPs are the products of mosaic genes in which sensitive sequence blocks are replaced by homologous, resistant blocks from related, naturally penicillin-resistant species by transformation and recombination events (22). The origin of the foreign DNA sequences is unknown, but several sources are probably involved.

7. Penicillin Sensory Transducers

BlaR is a bipartite protein involved in the inducibility of b-lactamase synthesis in *Bacillus licheniformis* (23). An amino terminal module is embedded in the plasma membrane via a four-helix bundle. Loops connecting the transmembrane segments are exposed to the outer and inner faces of the membrane, respectively; the carboxy end of the fourth transmembrane segment is fused to an extracellular penicilloyl serine transferase module. This module possesses the three typical motifs described earlier (Ser402-x-x-Lys, Tyr476-x-Asn, and Lys539-Thr-Gly), and it shares 32% identity with the Oxa-2 class D b-lactamase.

As an independent entity, the penicilloyl serine transferase module of BlaR is a high-affinity PBP. As a component of the full-size BlaR, it adopts a different conformation, and reception of the penicillin-induced signal does not involve penicilloylation of the active-site Ser402. These properties suggest that a class D b-lactamase acquired a new property—penicillin binding—via local structural changes. Fusion of this PBP to another polypeptide then resulted in a hybrid that performs another function: gene regulation.

Signal emission in the cytosol is probably mediated by the intracellular loop that connects transmembrane segments 3 and 4. This loop has no recognizable site of methylation/demethylation and no recognizable site that could be associated with a histidine kinase, but it possesses the His-Glu-Leu-Tyr-His consensus sequence of a neutral zinc peptidase (see Metalloproteinases). This putative peptidase might adopt an active conformation in response to the signal transmitted via the four a-helix bundle. Following this hypothesis, BlaR would be another example of control of gene activity via proteolytic degradation of key regulatory proteins.

Penicillin receptors similar to the *B. licheniformis* BlaR are involved in the inducibility of the synthesis of b-lactamase and low-affinity PBP2a of subclass B1 in *S. aureus* (24). Gram-negative bacteria have developed a different mechanism: b-lactamase synthesis is the result of the b-lactam-induced, peptidoglycan hydrolase-mediated derailment of the peptidoglycan recycling process (25).

Pepsin, Pepsinogen

Pepsin is a carboxyl proteinase that is secreted from the chief (or peptic) cells that are part of the oxyntic glands, located on the lining of the stomach (1). It is synthesized as a 42.5-kDa zymogen precursor, pepsinogen, which is stored in the chief cells and released in response to neural and hormonal signals activated by eating. Once pepsinogen enters the acidic environment of the stomach, it undergoes a change in conformation that exposes its active site. This allows pepsinogen to catalyze the hydrolysis of the peptide bond between residues 16 and 17 of its own polypeptide chain. Subsequently, residues 17 to 44 are also removed proteolytically, and the resultant 35-kDa protein is pepsin. It is active at acidic pH and has broad specificity, with preference for hydrolysis of peptide bonds involving tryptophan, phenylalanine, leucine, and methionine residues, especially when they are adjacent to other hydrophobic amino acids. It is often used to digest proteins under acidic conditions in order to obtain peptides linked by disulfide bonds. Disulfide rearrangement, which can sometimes occur at neutral or alkaline pH, is minimized at acidic pH. Pepsinogen is stable at neutral pH and becomes activated at acidic pH, whereas pepsin is stable at acid pH but becomes inactivated at neutral pH.

Pepsin is inhibited by pepstatin, p-bromophenacyl bromide, diazoketones, and various epoxides. It has been reported that pepsin can catalyze transpeptidation reactions, which could, in principle, cause confusion when trying to sequence proteins. This has not been a major problem in practice, however.

Pepstatin

This naturally occurring peptide analogue was discovered by screening culture filtrates of the mold actinomyces for inhibitors of the proteolytic enzyme pepsin (1). It also inhibits other carboxyl proteinases, but not serine, thiol, or metalloproteinases. Its chemical structure is: isovaleryl-valyl-valyl-statine-alanyl-statine [where statine is the unusual residue (3S,4S)-4-amino-3-hydroxy-6-methylheptanoic acid] (Fig. 1, see top of next page). Analogues of pepstatin (also called pepstatin A) have been obtained from *Streptomyces* strains with variable inhibitory properties toward different carboxyl proteinases, and a range of synthetic pepstatins have been prepared that have quite remarkable affinities for specific carboxyl proteinases (2). Pepstatin is often used to prevent unwanted proteolysis when isolating proteins under acidic conditions. It is effective at a concentration of about 1 mg/mL.

Peptidases

Peptidases are enzymes that catalyze the hydrolysis of peptide bonds—that is, the -CONH- bonds that link amino acids in peptides, polypeptides, and proteins. According to the Enzyme Commission of the International Union of Biochemistry and Molecular Biology, they are Class 3, subgroup 4 (peptide hydrolase) enzymes (E.C. 3.4). Some peptidases only act on small substrates—di-, tri-, or oligopeptides—while others act preferentially on protein substrates. The latter are more properly referred to as proteinases (also known as proteases, proteolytic enzymes). Some peptidases cleave peptide bonds involving the amino acids at either the beginning or end, i.e., the amino terminal (N-terminal) or carboxy terminal (C-terminal)—of a peptide chain. They are therefore called exopeptidases and, depending on their particular specificity, are either aminopeptidases or carboxypeptidases. Other peptidases cleave internal bonds in a polypeptide chain and are called endopeptidases. Most peptidases are relatively specific and will only act at peptide bonds in which a particular amino acid or type of amino acid (acidic, basic, neutral, hydrophobic, etc.) contributes either the -CO or -NH group. Some have broad specificity, especially when acting on unfolded, denatured proteins, but they can be highly specific or not active at all with folded, native proteins.

Figure 1. Chemical structure of pepstatin [isovaleryl-valyl-valyl-(3S,4S)-4-amino-3-hydroxy-6-methylheptanoyl-alanyl-amino-3-hydroxy-6-methylheptanoic acid], a transition-state analogue inhibitor of certain carboxyl proteinases, such as cathepsin D, and many microbial carboxyl proteinases. Because its structure resembles the tetrahedral intermediate that of substrate hydrolysis, it forms a tightly bound complex with the active site of each of these enzymes. See Pepstatin, previ

Peptidases have myriad functions. They activate or inactivate peptide hormones; they degrade dietary proteins and peptides; they participate in structural growth and remodeling by degrading collagen and other structural proteins; they protect against infectious agents; and they induce blood clotting. They regulate blood pressure, play an important role in fertilization, and control the cell cycle. They are ubiquitous and enormously diverse. As might be expected, inappropriate peptidase activity could have devastating consequences, so there are numerous peptidase inhibitors and other biological means of curtailing peptidase activity (see Proteinase Inhibitors).

While all peptidases catalyze peptide bond hydrolysis, they do not all do this the same way. In order to act under various conditions, four different mechanisms have evolved, and peptidases are classified as carboxyl proteinase, thiol proteinase, serine proteinase, and metalloproteinase, depending on the particular mechanism they employ. Even within these classes, there are many thematic variations such that it seems that there are almost as many peptidases as there are peptides.

Peptidases have a host of commercially significant uses ranging from “clot busters” (both in blood vessels and in drain pipes) to meat tenderizers. Peptidase inhibitors represent a multibillion dollar pharmaceutical market where they are important in controlling high blood pressure, as well as preventing the progress of acquired immune deficiency syndrome (AIDS).

Peptide

Peptides, sometimes referred to as oligopeptides, are oligomers in which the repeating units are amino acids. Peptides have a defined sequence of amino acids that are linked together by formation of peptide bonds. In contrast to polypeptides and proteins, peptides consist of a small number of amino acids. The distinction between a peptide and a polypeptide is somewhat arbitrary, but generally a peptide has between 2 and 50 amino acid residues. A peptide of two amino acids may be more specifically referred to as a dipeptide, three repeating units as a tripeptide, four repeating units as a tetrapeptide, and so on.

Most peptides are unstructured, described as having a random coil conformation, but others have highly ordered secondary and tertiary structure similar to that observed in larger proteins. The more structured peptides often incorporate disulfide bonds. Many peptides have important biological functions. For example, the pentapeptide leucine-enkephalin (Fig. 1) is a neurotransmitter with opiate-like activity; the hormone insulin is formed from two disulfide cross-linked peptide chains;

and the major toxins from venomous spiders and cone shells are disulfide-rich peptides (Fig. 2). Naturally occurring peptides are usually produced by hydrolysis or cleavage of precursor proteins, through the action of peptidases or proteinases.

Figure 1. Chemical structure of the pentapeptide Leu-enkephalin, which has the sequence Tyr–Gly–Gly–Phe–Leu.

Figure 2. Schematic representation of the structure of the 16-residue a-conotoxin PnIA (1), showing the backbone and disulfides. The two turns of a-helix are depicted as a coil. The two disulfide bonds are shown in ball-and-stick representation. This figure was generated using Molscript (2) and Raster3d (3, 4).

Peptide Antibiotic Biosynthesis

Peptide antibiotics include a variety of peptide structures with diverse biological properties (1). Historically, the first antibacterial compounds identified were peptides (penicillin, gramicidin, tyrocidine). New such peptides have been characterized steadily, including actinomycin (antitumor); cyclosporin (immunosuppressant); destruxin (insecticide); ferrichrome (siderophore); pepstatin, antipain, and bestatin (proteinase inhibitors); microcystin (phosphatase inhibitor); and defensin and magainin (anti-infectives).

Their biosynthesis may occur either (i) on ribosomes by direct transcription, translation, and post-translational processing of peptide antibiotic genes (see Protein biosynthesis)—for example, nisin—or (ii) without ribosomes but on a multienzyme system, using the thiotemplate mechanism. The structural complexity of peptide antibiotics ranges from modified amino acids to polypeptide chains of up to 50 amino acid residues (2). Ribosomal systems can incorporate only the L isomer of the 20 normal amino acids, plus selenocysteine, while there are no such limitations to the nonribosomal systems, which can use hydroxy acids, fatty acids, and amines. Nevertheless, peptides of ribosomal origin are known to include D amino acid residues, cyclic side chains, and disulfide bonds. All nonribosomal peptides also originate from linear precursors, but a variety of types of cyclization are known. Identification of the biosynthetic origin is crucial for subsequent genetic analysis, and the structural properties of compounds arising from the two types of pathway are compared in Table 1.

Table 1. Structural Features of Peptide Antibiotics of Ribosomal and Nonribosomal Origin

Feature	Ribosomal Path	Nonribosomal Path
Size (amino acids)	No size limitation	2 to about 50, 4 to 10 dominating
amino acid constituents	21 protein amino acids and modified amino acids	Various types of amino acids modified amino acids including 2-, 3-, and 4-amino compounds (more than 300 known)
D-Amino acids	Not more than one, epimerized post-translationally	Often several, either incorporated directly, or epimerized during synthesis
Non-amino acid constituents	Acyl residues, amines originating from decarboxylation	Various acyl residues, including aromatic acids, hydroxy acids
Cyclic structures	Rare; frequent disulfide cycles, thioether cycles	More frequent than linear structures, various peptide bond cyclizations, but also lactones
Modifications	Hydroxylation,	N-Methylation,

	dehydration (Ser, Thr), side-chain cyclization (Cys to thiazoles, Thr to oxazoles, Glu to pyroGlu)	hydroxylation, side-chain cyclization (Cys to thiazole), glycosylation, side-chain crosslinking (aromatic rings)
Unusual constituents	Not known	Urea type of peptide bond, phospho-amino acids, amino-modified fatty-acid-derived components (lipopeptides), mixed polyketide structures
Biosynthesis	Gene can be identified; consider splicing, processing, and posttranslational modification; often prepropeptides detected	Nonribosomal enzyme systems present; peptide families are frequent in the same or related organisms, biosynthesis of rare precursors needed
Sources	Various animals and plants, sometimes bacteria	Mainly bacteria and lower fungi, occasionally plants and insects

1. Ribosomal Biosynthesis

Peptide antibiotics that are synthesized initially on ribosomes comprise a rapidly expanding field of research (3, 4). The compounds synthesized in this way range from linear polypeptide chains to compact multicyclic peptides with several disulfide bonds or thioether linkages (lantibiotics). Their genes are usually isolated by reverse genetics, and they usually reside within gene clusters, together with genetic information for their post-translational modification and export, and for resistance of the host to their actions. Genes for typical animal peptides, like defensins, are present in multiple copies with minor differences in sequence (5). The signals for their targeting and processing are critical for their functions in innate immunity. A peptide from the venom from the spider Agelenopsis aperta is activated by epimerization of a specific residue (6).

Internal cyclizations other than disulfide bond formation have been restricted to bacterial sources, and the enzymes involved in formation of thiazolines (microcin B) and lantibiotic ethers (dehydration of serine and threonine residues to dehydroalanine and dihydrobutryine, respectively, followed by addition of the thiol group of cysteine) are being characterized (7). The post-translational modification of these antibiotics takes place on a membrane-attached multienzyme complex, which also facilitates their export and their role in intercellular communication.

2. Synthesis by Peptide Synthetases

The biosynthesis of peptide antibiotics by nonribosomal systems, on peptide synthetases, requires a considerable amount of information, and these multienzyme complexes are among the largest protein structures known, with masses up to 1700 kDa, corresponding to a 45.5 kbp open reading frame, to synthesize cyclosporin (see Gene Structure). Synthesis of each amino acid residue of such a peptide antibiotic requires a minimum of three catalytic domains: (i) the activating adenylate domain, (ii) the carrier protein, and (iii) the condensing domain, which collectively are referred to as a module (see Thiotemplate Mechanism Of Peptide Antibiotic Synthesis). The nonribosomal code for the amino acid sequence of the peptide is determined by the substrate specificity of the activating domain. Selection and activation of the appropriate amino acid is followed by its attachment as a thioester to the 4′-phosphopantetheine prosthetic group attached to the adjacent carrier domain (8), it is then linked covalently to the next amino acid, on the adjacent module. The thioester intermediates may be subjected to various modifications, such as epimerization, N-methylation, and hydroxylation, catalyzed by additional domains introduced into the module structure. The intermediates in the reaction are covalently attached to the peptide synthetase, and only the final product is released. Examples of known peptide synthetases are compiled in Table 2.

Table 2. Nonribosomal Peptide Synthetase Systems

Peptide	Organism	Structural Type[a]	Gene Cloned	Enzymology
		Linear		
Bacilysin	Bacillus subtilis	P-2-M	(+)	(+)

Tolaasin	Pseudomonas tolaasii	R-P-18-L-5	(+)	–

[a] The abbreviations used are: P, peptide; C, cyclopeptide; L, lactone; E, ester; R, acyl; M, modified. The structural types are defined by the number of amino-, imino-, or hydroxy acids in the precursor chain. The ring sizes of cyclic structures are indicated in the number following C, L, or E, defining the type of ring closure. The abbreviations used for unusual amino acids and other compounds are listed in the abbreviations footnote on the first page.

Current applications of such enzyme systems are the enzymatic synthesis of peptide analogues, taking advantage of the relatively low stringency of the nonribosomal code—this is, the specificities of the peptide synthetases (9). Efforts are being made to alter the modular construction of peptide synthetases so as to generate new enzyme systems capable of synthesizing novel peptides.

Peptide Bond

The peptide bond is the chemical link that connects amino acids to form the polypeptide chains of peptides and proteins. The repeating units of these linear polymers, the 20 amino acids, are naturally occurring chemical entities comprising an amino group, a carboxyl group, a hydrogen, and a side chain of variable chemistry. These four groups are connected to a central carbon atom, denoted C_a (or C_{alpha}) (Fig. 1). Peptide bonds are formed by condensation of the carboxyl group of one amino acid with the amino group of another amino acid, giving rise to a dipeptide. Repeated condensation of amino acids produces tripeptides, tetrapeptides, and so on. Proteins can incorporate many thousands of peptide-linked amino acids.

Figure 1. General scheme for formation of a dipeptide XY from two amino acids, X and Y, by reaction of the carboxyl group of amino acid X with the amino group of amino acid Y. The R group attached to C_a is variable, depending on the type of amino acid (R_x and R_y). The peptide bond of the dipeptide product is boxed, and its partial double bond character is depicted.

In vivo, peptide bond condensation occurs at the C-terminus of the growing polypeptide chain to produce proteins having specific sequences defined in the genetic code. This reaction is catalyzed in a process called translation, by enzymes of the cell's protein biosynthesis machinery. Synthetic peptides and proteins can also be produced by chemical peptide synthesis. In contrast to *in vivo* protein biosynthesis, solid-phase synthesis usually occurs by condensation of amino acids to the N-terminus of the growing polypeptide chain. Peptide bonds can be broken down, or hydrolyzed, by enzymes such as peptidases and proteinases.

Each peptide unit in a polypeptide chain has three chemical bonds. The central peptide bond is not freely rotatable, because it has partial double bond character (Fig. 1). This imposes planarity on the peptide bond, so that only two discrete conformations are available. These two conformations, defined by the angle w (Fig. 2), are called the cis and trans configurations. Of these two, the trans configuration is energetically preferred, and is much more commonly observed, unless the following residue is proline (see Cis/Trans Isomerization).

Figure 2. Section of a polypeptide structure showing two peptide bonds (–CONH–) and one amino acid residue (–NH–C_a(R)(H)–CO–). The dihedral angles w, f, and y of the peptide backbone are labeled.

The single bonds on either side of the peptide bond are rotatable. The angle around the N–C_a bond of a peptide is called phi (f), and the angle of the C_a–**C** bond is called psi (y). Certain combinations of f and y, defined as the "allowed" regions of a f/y or Ramachandran Plot, are preferred and energetically favored over others. The allowed f/y angles define the conformations of regular secondary structure such as a-helix or b-strand that are stabilized by backbone hydrogen bonds between peptide bond units.

Peptide Hormones

The first identified peptide hormone, secretin, was found in 1902 by Baylis and Starling. They discovered that the bioactive compound stimulated the secretion of saliva, and thus they named the factor secretin. Because the compound was produced by one tissue and transported by the blood to a distant organ, where it stimulated the saliva secretion, it was called a hormone based on the Greek word hormao, which means "to stimulate". Since then it has been found that many physiological functions in the body are controlled by such communication with the endocrine and neural systems (1). That is, the regulation, integration, or coordination of various metabolic activities and bodily functions of tissues and organs involve the synthesis of low concentrations (micromolar to picomolar) of biochemical signals or messengers that can be disseminated and transported throughout the organism, to effect the required changes through receptors at distant target cells. Such regulation of function also requires that the production of the hormone be self-limiting; consequently, it requires both negative and positive feedback loops and interactive modulation of G-coupled systems (see GTP-Binding Proteins) of neurotransmitter (see Neuropeptides) systems to affect functional balance, or homeostasis. Through modulation, downregulation, desensitization, upregulation, and receptor cross-talk, hormones in some cases interact with the central nervous system (CNS) to influence neuronal function, to alter behavior, and to control other hormones. In other cases, one function can be influenced by several different hormones. All operate primarily under the hierarchical control of the central nervous, endocrine, and immune systems. Although hormones were originally defined as material that is secreted by endocrine glands, the term is now often applied to hormones that are expressed in other tissues or are formed from precursors located in other tissues. For example, angiotensin, which maintains the water and electrolyte balance and controls blood pressure, is produced by converting angiotensinogen in the blood with renin secreted by the juxtaglomerular cells in the kidney.

1. Biosynthesis, Secretion, and Interaction with Receptors

A peptide hormone is first synthesized on the ribosome as a pre-pro-hormone following transcription and translation of the genetic information (2) of the messenger RNA. This precursor of high molecular weight contains an N-terminal signal peptide, which guides the protein to the rough endoplasmic reticulum (ER), where the signal peptide is removed proteolytically by a signal peptidase, in a form of co-translational processing. The pro-hormone, or hormone precursor (see Polyproteins), that is produced usually does not possess much biological activity. Most pro-hormones and pro-neuropeptides contain within their polypeptide chains several smaller peptides with various biological activities. These pro-hormones normally undergo posttranslational processing, protein folding, disulfide bond formation, or chemical modification, such as N-glycosylation, O-glycosylation, acetylation, or amidination, when they are processed through the Golgi apparatus. The pro-hormones undergo specific proteolytic cleavage by endoproteinases or processing enzymes and then are sorted (3) into secretory granules. The polypeptide hormone is stored in the secretory vesicles and, in some cases, may undergo further processing by enzymes.

Almost all of the cleavage sites in the precursor protein contain a dibasic sequence, Lys–Arg or Arg–Arg, that is recognized by the processing enzymes. The Kex-2 proteinase of yeast, kexin, was the first enzyme found to cleave at Lys–Arg and Arg–Arg sequences. Subsequent use of the kex-2 gene as a probe (see Probe Hybridization) led to the cloning of similar gene products from mammalian cells (4). Investigations demonstrated that these convertases, which cleave at the C-terminal side of Lys–Arg and Arg–Arg sequences, play an important physiological role. Differential processing of a single precursor protein in two different tissues can now be explained by the presence or relative concentrations of different posttranslational enzymes in tissues. For example, pro-opiomelanocortin (POMC) is differentially processed in the anterior and intermediary pituitaries (5). In the anterior and intermediary pituitary, ACTH and b-LPH are the predominant products because PC-1/3 (pro-protein convertase) is most prevalent. In the intermediary pituitary, however, alpha-melanocyte-stimulating hormone (a-MSH), corticotropin-like intermediary peptide (CLIP), and b-endorphin are secreted because PC-2 is more prevalent there (see Fig. 1).

Figure 1. Processing of the pro-opiomelanocortin (POMC) to produce ACTH (adrenocorticotropic hormone), B-LPH (b-lipotropin), A-MSH (a-melanocyte stimulating hormone), CLIP (corticotropin-like intermediary peptide), g-LPH, and b-endorphin. The pro-protein convertase PC-1 / 3 carries out the initial cleavages in the anterior and intermediary pituitary, whereas convertase PC-2 is present primarily in the intermediary pituitary.

The hormone within the secretory vesicles is released from the vesicles by exocytosis upon stimulation by extracellular signals provided by neurotransmitters or other hormones, wherupon the hormone is transported by the blood or extracellular fluid to the target cells. Once a hormone is secreted, it usually binds to a specific plasma protein carrier, which prolongs its half-life because the complex reduces the rate of hormone destruction by plasma proteinases.

The release of the peptide is normally controlled by a feedback mechanism. In the case of ACTH, for example, the secretion of corticoid is stimulated by ACTH, but on the other hand, corticoid suppresses CRF and ACTH secretion from hypothalamus. In turn, ACTH suppresses CRF secretion.

The type of endocrine hormone secretion is classified by the distance between the cells that secrete the peptide and its target cells. Classically, endocrine hormones act at a distant target, while paracrines act upon nearby cells, and an autocrine acts upon the cell that secreted it. Many hormones often function in all three ways, however, making such distinctions difficult. Hormones secreted by neural cells and neurons are called neuroendocrines.

When the hormone reaches its target cell, it binds to its specific receptor in the cell membrane. Each receptor is a membrane protein complex and consists of three domains, (1) extracellular, (2) transmembrane, and (3) intracellular domains. The tertiary structure of the receptor is essential for specific binding of the ligand. This interaction induces structural changes in the receptor that result in activation of an intracellular enzyme that generates a transient increase in concentration of a signaling compound (see Signal Transduction), such as cyclic AMP (cAMP), cyclic GMP (cGMP), diacylglycerol (DAG), or inositol triphosphate, IP_3. The elevated concentration of these second messengers and of the phosphorylated forms of proteins triggers the appropriate metabolic response. Proteins are phosphorylated on serine, threonine, or tyrosine residues by cAMP-dependent protein kinase (PKA), DAG-activated protein kinase C (PKC), or tyrosine kinases.

Many hormone receptors have a common structure in which the single polypeptide chain passes back and forth through the membrane seven times, forming seven transmembrane alpha-helices. For these receptors, the hormone-binding signal is transmitted or transduced to the interior of the cell by binding the receptor-ligand complex to a series of G-proteins (see Heterotrimeric G Proteins). G-proteins bind GDP or GTP. When G-proteins bind to their receptors, GTP exchanges with GDP bound to the a-subunit of the G-protein. The Ga–GTP complex binds adenylate cyclase, activating the enzyme. The activation of adenylate cyclase produces cAMP in the cytosol and leads to the activation of PKA and the phosphorylation of enzymes. Many classes of G-proteins exist, such as G_s and G_i, stimulatory and inhibitory G-proteins, respectively. A second class of G-protein coupled-receptor synthesizes DAG and IP3 as second messengers. The hormone-receptor complex interacts with G-proteins, and this is followed by the G-protein activation of phospholipase C-g (PLCg). PLCg hydrolyzes phosphatidylinositol bisphosphate to IP3 and DAG. IP3 binds to the endoplasmic reticulum and opens the calcium channels so that stored calcium flows into the cytosol and activates enzymes. On the other hand, the DAG binds and activates PKC and also opens calcium channels. PKC phosphorylates serine and threonine residues, thereby modulating the catalytic effect of the corresponding enzymes.

One receptor, that of ANF (atrial natriuretic factor), is coupled to the production of cGMP by guanylate cyclase. Another ANF receptor lacks guanylate cyclase activity and is thought to play a role in the clearance of ANF. Yet another type of receptor is the heterotetrameric insulin receptor. It is composed of two a- and two b-subunits. The a-subunits protrude outside the membrane and contain the binding sites, while the b-subunits penetrate through the membrane in a single transmembrane a-helix and contain tyrosine-kinase activity. When insulin binds to the receptor, intramolecular phosphorylations are triggered, and this autophosphorylation enhances its ability to phosphorylate enzymes that induce the physiological response (Fig. 2). (see also Heterotrimeric G Proteins).

Figure 2. General mechanism of action of peptide hormones that bind to receptors and thereby alter the activity of adenylate cyclase through heterotrimeric G-proteins. The peptide hormone binds to the extracellular part of the receptor embedded in the plasma membrane. This is transmitted to the abg heterotrimeric G-protein, which dissociates in the Gbg-dimer and the Ga subunit, which binds to adenylate cyclase and alters its activity accordingly.

2. Methods of Isolation and Structure Determination

The structure of a peptide hormone was first demonstrated by de Vigneaud in 1953, when he determined the structure of oxytocin and confirmed it by total chemical synthesis. In 1954, the structure of insulin was determined by Sanger. The chemical structure of secretin was not determined until 1966, 60 years after its initial discovery. Because peptide hormones exist in such small concentrations, it was difficult then to isolate, purify, and analyze them. Subsequent development of better detection methods with higher sensitivities, such as radioimmunoassay (RIA), made possible the rapid isolation and structure determination of a large number of peptide hormones and neuropeptides. Later gene cloning provided the sequence of the complementary DNA of hormone precursors by using a DNA probe (see Probe Hybridization) based on the known peptide sequence. This also provides the structure of previously undetected protein isoforms. For example, in the case of endothelin-1 (ET-1), which had been isolated from cultured endothelium cells of blood vessels, screening of the human chromosomal DNA library revealed the existence of genes for three isoforms: ET-1, ET-2, and ET-3. Each isoform consists of 21 amino acid residues, and they have high sequence homology. Another method of detecting new peptide hormones is by screening the DNA sequence of the precursor protein. In this case, another new peptide hormone that is linked in the precursor molecule can be detected. In the precursor of glucagon, two amino acid sequences that resemble glucagon were found, GLP-1 and GLP-2. Another example is the case of calcitonin gene-related peptide (CGRP), which stimulates the formation of cAMP. Analysis of the gene of the precursor protein of calcitonin (CT), which modulates serum calcium concentrations, revealed that the CT gene consists of five introns and six exons. As a consequence of alternative splicing of the RNA transcripts (see Transcription), the mRNA for the CT precursor is found in the thyroid but the mRNA for CGRP is formed in the nervous system.

As a result of the progress in gene technology, the chemical structures of a large number of hormone receptors have now been determined. Most of their intrinsic ligands also have been identified. However, there are still receptors for which no ligands are known. New techniques are being developed to search for new bioactive peptides that serve as ligands for such orphan receptors. In 1998 (6), a prolactin-releasing factor or peptide was found in the search for the ligand for one such orphan receptor that is expressed in the human pituitary. The 31-residue peptide stimulates the pituitary to release prolactin.

3. Synthesis and Conformational Analysis

After the isolation and structure determination of a peptide hormone has been achieved, the peptide is often chemically synthesized to confirm the structure. With the synthesized material, structure-activity relationships can be explored to design drugs for treating individuals with peptide-hormone deficiencies or with malfunctioning peptides. The technique of combinatorial chemistry has recently made it possible to synthesize millions of compounds and to screen them for activity rapidly and efficiently (7). In addition, gene technology has provided a means of producing human peptide sequences, such as insulin, in *Escherichia coli*, yeast, or other expression systems. This has afforded the opportunity to produce peptide hormones and receptors that are uniformly labeled with ^{13}C and ^{15}N isotopes for nuclear magnetic resonance (NMR) analysis. These labeled compounds can then be used to investigate the interaction between ligand and receptor, as well as to study the conformational changes that occur upon binding. Consequently, the ongoing study of the tertiary structures by NMR and X-ray crystallography is now providing more details regarding the mechanisms of hormonal action.

Peptide Libraries

Peptide libraries were first introduced during the mid-1980s as a means to elucidate the details of antibody–antigen recognition (1, 2). Prior to that time, epitope mapping required fragmentation analysis, either at the protein or DNA level, which was a laborious and time-consuming process. Geysen et al. (1) demonstrated that synthetic peptide libraries could be prepared and screened by enzyme-linked immunosorbent assay (ELISA) to elucidate antibody–epitope recognition to the resolution of a single amino acid residue. This was the first case in which a problem in molecular recognition was elucidated using a synthetic library and is often cited as a critical development in the emergence of combinatorial libraries.

The first generation of synthetic peptide libraries was limited in size to a few hundred peptides, due to the need for each library member to be prepared as a discrete compound. However, the combination of mixture-synthesis techniques (1-4), reliable strategies for identifying active species from complex mixtures (3, 4), and advances in peptide sequencing methods quickly led to the routine preparation and screening of libraries containing millions of distinct peptide sequences. Several reports of ten-residue peptide libraries containing more than 10^{12} peptides have even appeared (5, 6). When coupled with an increasing availability of unnatural amino acid building blocks, peptide libraries of this scale and complexity became valuable tools for identifying novel peptide agents for a wide range of applications (eg, see Refs 7 and 8). Soluble and solid-phase peptide libraries continue to find applications in the identification of antigenic determinants. In addition, they have been used to identify receptor ligands (5, 9-14), inhibitors of enzymatic activity (15), and novel antibacterial agents (3, 7, 14). Many of these applications have employed standard assay formats (eg, soluble activity or binding assays), requiring complex deconvolution or iterative synthesis and screening cycles to identify the active species from complex synthetic pools (see Combinatorial Synthesis).

Split synthesis methods for preparing one-bead, one-compound (OBOC) peptide libraries have overcome many of the limitations of standard assay formats and pooling strategies. Because each bead carries a single compound in amounts approaching several nanomoles, assays can be performed directly on the resin beads that detect interactions of bead-linked compound with a soluble target. A typical assay utilizes ELISA methodologies to indicate beads bearing compounds that interact with the target (16). Positive beads may be selected manually, or more sophisticated instrumentation may be employed to detect and isolate active beads (17). Alternatively, the OBOC format is amenable to off-bead assays through the use of cleavable linkers inserted between the peptide and the solid-phase support (18, 19). In an off-bead assay, the peptide is released from the resin bead, but proximity to the bead is maintained through use of a diffusion-limiting matrix or a positional array. For example, distribution of the library and a test cell line within a soft agar matrix, followed by partial peptide release, leads to the formation of locally high concentrations of peptide in the agar surrounding each bead. Zones of reduced cell growth (or another reporting mechanism such as color change) surrounding single beads are used to identify peptides having the desired activity. Beads producing a zone of activity are removed and analyzed by standard Edman Degradation or mass spectrometric analysis to determine the sequences of the active peptides. This approach has been used for identifying peptide ligands for G-protein-coupled receptors (20), as well as cytotoxic peptides that may have application as anticancer agents (19). This represents but a few examples of the unique screening methods that have been developed using peptide chemistry coupled with the OBOC library format. Other notable examples include the use of a fluorescence-activated cell sorter (FACS) (17) (see Flow Cytometry) to identify active beads, as well as direct visualization of cancer cells binding to peptides on beads (21).

The initial excitement surrounding synthetic peptide libraries has been tempered in recent years. Peptides are linear, highly flexible polymers with fixed side-chain spacing. In contrast, most proteins adopt complex three-dimensional structure that place active chemical groups in positions that cannot be approximated by linear peptides. As a result, many targets fail to yield hits from short peptide libraries. The introduction of constraints into the peptide chain, including cyclization or use of domain scaffolds with defined structural propensities (Fig. 1a), may increase the success rate for some targets. In addition, altering the polymer backbone can change the spacing of the side chains (22-25). Although unnatural amino acids can be used to shift the side-chain spacing (eg, b-amino acids), the problems enumerated above associated with a linear and flexible polymer remain. A wide range of peptidomimetics that employ novel backbones have emerged to address this issue (Fig. 1b) (26-28). Such compounds also address a second major criticism of peptides: They are ill-suited for in vivo applications due to poor pharmacokinetic properties. By utilizing building blocks with physicochemical properties compatible with uptake and absorption, peptidomimetics have moved a step closer to lead compounds for drug discovery. The true utility of peptidomimetics for drug discovery remains unknown, but their potential for use as research tools is high.

Figure 1. Structural aspects of peptide libraries. a) Illustration of one structural bias, a b-turn (top), that can be introduced in a peptide library, and two approaches for creating libraries based on this structural scaffold. They are cyclization (bottom left) and the use of constrained dipeptide surrogates (bottom right). b) Examples of various peptidomimetics.

Peptide Mapping

Peptide mapping allows rapid overall evaluation of a protein's primary structure from limited analysis of the peptides produced by proteolysis. Only a single amino acid difference between two peptides caused by mutation or posttranslational modification alters the physical properties of the peptide in which that difference occurs. So peptide mapping is a very sensitive way of detecting differences between closely related proteins. The peptides produced by a specific proteinase are separated into a pattern ("peptide map"), and the maps of related proteins are compared. Single differences, such as the Glu/Val difference between normal/sickle cell hemoglobins that was early recognized by peptide mapping (1) or the relationships between isozymes are found rapidly (2). Subsequent refinements in the methods and resolution of mapping produced excellent one- and two-dimensional (2-D) techniques that have been reviewed (3) and much used. The classical peptide mapping methods of two-dimensional fingerprinting and Cleveland maps are described in those articles. These classical approaches are still practical when the amounts of protein are sufficient, but molecular biology now centers on different approaches.

One extension increases the sensitivity, as required by present-day and future needs, to evaluate proteins available only in very small amounts. This has become possible by modern separation techniques, such as capillary HPLC (4), capillary electrophoresis (5), and high-resolution two-dimensional gel electrophoresis (6, 7). A further extension is to rely on mass spectrometry, using laser desorption instruments, triple quadrupoles, ion-trap devices, or other techniques, and perform the mapping, detection, and analysis in one step. In this manner, using entire peptide mixtures or preselected fragments, direct determination of the total masses of peptide fragments from a protein gives a unique "fingerprint" and is expected soon to be the mapping method of general choice. Combined with databases of peptides from all known proteins, it allows direct identification of any protein that has been characterized from the same or a closely related source (8-10). Then, mass spectrometric peptide mapping and simultaneous data bank screening will constitute a powerful technique as a descendant of the classical peptide mapping idea. In the near future, when crucial genomes are completely sequenced, the work remaining will center on identifying of each gene product and on proteome analysis to correlate gene expression with predicted protein structures stored in data banks.

1. Liquid chromatography

When reverse-phase HPLC was introduced in the mid-1970s, column chromatographic methods largely replaced paper and thin-layer plate separations. Further miniaturization and additional separation techniques have since continuously altered the separation methods (4), but the principle of peptide mapping by comparing efficient separations of peptides remains. In many cases, the resolution now is so high that complex peptide mixtures are separated completely by single-column chromatographic steps, thereby reintroducing one-step mapping methods. Instruments are also so reproducible that repeated runs, even at different times, are virtually identical, thereby introducing mapping comparisons on the same instrument on different occasions. The principle of peptide mapping has gained further momentum, which is expected to continue in present and future stages of proteome research with all of its gene product characterizations.

The principle is still to compare two or more expressed proteins by suitable proteolytic digests, followed by identical instrument runs, and subsequently evaluating all peak positions and heights of the resulting patterns. The era of peptide mapping has moved from spots or bands on solid supports and multiple but simultaneous separations to peak positions on microcolumns after successive separations. In addition to detecting structural differences, many other applications of this technique are now in use, for example, epitope mapping, determination of glycosylation, phosphorylation, or oxidation sites, and assignment of disulfide bonds. Peptide mapping is used extensively for quality control and characterization of recombinant DNA -derived products.

The major advantages in using microcolumn methods for peptide mapping are speed (often minutes), sensitivity (femtomole amounts, even with detection by UV absorbance), and ease of recovery for further characterization by amino acid analysis, Edman Degradation, and mass spectrometry. Several high-performance separation media have been developed that allow rapid HPLC resolution of peptides and proteins. The classical silica-based stationary phase HPLC column has been used extensively for nearly twenty years in numerous applications, and alternative materials, such as divinylbenzene cross-linked polystyrene (11), have since emerged. Frequently, the stationary phase is packed in microbore columns with a narrow inner diameter (on the order of 1 to 2 mm), with low flow rates (down to 40 µL/min), small elution volumes (40 to 60 µL), better detector response (5- to 20-fold higher) than conventional HPLC columns, and requiring only picomole quantities of protein. However, the current trend is toward further miniaturization and smaller inner diameters, leading to still lower detection limits, but also toward implementation of powerful detection techniques, such as Z-shaped flow cells for efficient UV absorbance, laser-induced fluorescence, electrochemical detection, and mass spectrometry.

Capillary reverse-phase HPLC is conducted with column inner diameters of between 350 and 75 µm and at flow rates of 4 to 0.2 µL/min. The low flow rates necessitate special technical solutions for recovering separated peptides. Such a system has recently been developed [MicroBlotter (12, 13)] for subpicomole peptide mapping after digestion of proteins in gels (14, 15) or on membranes after blotting (16) and for isolating peptides for microsequence analysis. The capillary outlet intermittently touches a strip of poly(vinylidene difluoride) (PVDF) membrane while moving along the strip. After sample collection, the PVDF strip is aligned with the chromatogram to excise spots that correspond to peptide candidates for structural analysis.

The protein to be analyzed is still digested with trypsin, Lys-C proteinase, or another suitable proteolytic enzyme. Protocols for microdigestion in small volumes (1 to 10 µL) and for recovering peptides from small samples (a few picomoles or less) have been developed (17). After digestion, the proteolytic peptides are derivatized with fluorescent tags (18) for detection. Generally, however, separation problems may arise from precolumn derivatization, and the digest is often injected directly onto the column after adjusting the pH to that of the mobile phase at the start of chromatographing. The most widely used solvent systems still consist of gradients of acetonitrile (often 0 to 60%, v/v) in aqueous trifluoroacetic acid (TFA) (often 0.1% v/v), but several other chromatographic solvents have also been suggested, for example, heptafluorobutyric acid instead of TFA, hydrochloric acid, sodium phosphate buffer at acidic or neutral pH, and ammonium bicarbonate, ammonium acetate, triethylammonium phosphate, or 1.0% sodium chloride at neutral pH. The most common detection technique is still UV absorbance, normally at both 214 and 280 nm, the latter for identification of peptides that contain tryptophan and tyrosine residues. Alkylation of cysteine with [^{14}C]- iodoacetic acid or 4-vinylpyridine is common to prevent disulfide formation and peptide aggregation and to promote convenient detection of cysteine-containing peptides in the resulting map. A practical example of capillary HPLC peptide mapping (Fig. 1) illustrates how in *vivo* oxidation of a recombinant protein hormone after intravenous administration is detected (17)

Figure 1. Capillary HPLC tryptic peptide maps of recombinant human growth hormone (lower profile) and of the same protein recovered from rat serum taken 15 (middle profile) and 45 (upper profile) min after an intravenous dose of the preparation. Arrows link methionine-containing peptides (right in each pair) with their corresponding oxidized forms (left in each pair), showing the increase in oxidized form with time *in vivo*. The peptides were separated with a 320 μm×15cm reverse-phase (C_{18}) column. From Ref. 17 with permission.

2. Capillary electrophoresis

Capillary electrophoresis in different separation modes, often capillary zone electrophoresis (CZE), provides a further powerful approach to peptide mapping (19), that has high sensitivity (low femtomole level) and short separation time (minutes). More than 10^6 theoretical plates are achieved and used to generate reproducible peptide patterns suitable for mapping experiments (Fig. 2). Capillary electrophoresis is also a suitable complement to reverse-phase HPLC for identifying peptides because the separation mechanism is different, based on mass-to-charge ratio and hydrophobic interaction, respectively. Consequently, peptide fragments not resolved by reverse-phase HPLC are often completely resolved by CZE. Similarly, reverse-phase HPLC may resolve peptides not separable by CZE (21).

Figure 2. Peptide mapping of a fraction from a brain extract by capillary electrophoresis, to illustrate reproducibility with time and use of mapping for peptide identification. The separation in (*a*) reveals that the fraction contains a mixture of short peptides, the one at the arrow is suspected to be a neuroactive peptide, Gly-Pro-Glu. After adding of the corresponding synthetic peptide, reanalysis in (*b*) reveals that the synthetic peptide (arrow) comigrates with the

biological peptide component. Considering that the time between separations (a and b) is >2 weeks, the repetitive pattern confirms the reproducibility of the system on a sensitive scale (0.1 to 2 pmol analyzed). From Ref. 20 with permission.

Fused silica capillaries that have charged surfaces in which electroendosmosis takes place are commonly employed, typically with inner diameters of 20 to 200 µm and lengths of 20 to 100 cm. Small inner diameters are best suited for peptide mapping because the more narrow the capillary, the better the resolution. For peptide separations, sodium phosphate buffer, pH 2.5, is a good electrolyte that allows sensitive detection at short wavelengths (190–200 nm) because of its high UV transparency. Including short-chain, ion-pairing reagents (hexanesulfonic or heptanesulfonic acid) in the buffer improves resolution, in particular of hydrophobic peptides, and has been tested in peptide mapping (Fig. 3). The voltages applied range from 5 to 30 kV, and electric field strengths range from 200 to 500 V/cm. Separations are influenced by a combination of electrophoretic mobility and electroendosmosis. CZE can be used preparatively, and the components separated in the peptide map can be further characterized by amino acid analysis, Edman degradation, or mass spectrometry (5, 23). In particular, electrospray mass spectrometry has gained recent popularity as an on-line detection technique with simultaneous tandem mass spectrometric capability for peptide structure information at the low femtomole level (24–26).

Figure 3. Tryptic peptide mapping of recombinant human erythropoietin in phosphate buffer, pH 2.5, with 100 mM heptanesulfonic acid by capillary electrophoresis. The maps from two different expression systems are shown, the upper without glycosylation (*E. coli*), the lower with (Chinese Hamster Ovary cells) but subsequently treated with N-glycanase. Although 16 peaks have identical migrations, indicating identical primary gene products, peaks a–f differ and can be attributed to differences at specific sites in the eukaryotic form. From Ref. 22 with permission.

3. Mass spectrometry

Protein fingerprinting by determining the masses of all the peptides generated by proteolysis of polypeptide chains separated by gel electrophoresis has recently emerged as an extremely powerful tool for protein identification. It combines sensitivity and high throughput (8). Complex protein mixtures of crude cell lysates can be separated with 2-D gel electrophoresis systems (27). For identification, the amount of protein in many 2-D gel spots is well below 1 picomole and thus too small for the commonly used sequencer technology, but it is accessible to recently developed sequencer instruments (down to 100 femtomole by cartridge miniaturization and capillary HPLC for phenylthiohydantoin detection; see Edman Degradation) using matrix-assisted laser desorption/ionization (MALDI) (28) or electrospray (29) mass spectrometry, recently extended by nanoelectrospray ionization (30, 31). As a consequence, a novel type of “peptide mapping” of proteins has emerged, using their fragment masses and efficient algorithms to search peptide-mass databases, which permits structural assignment, protein identification, and determination of minor differences (32-34).

As in traditional peptide mapping, the first step in this procedure is proteolytic cleavage of the protein (commonly, still with trypsin), either in solution, in a gel (14, 15), or on a membrane after blotting on nitrocellulose or PVDF membranes (16). The MALDI mass analysis and the database search are highly automated (35), which increases the throughput and makes multiple protein identifications efficient (Fig. 4). If the protein is still unknown after the database search, the peptides are further analyzed by tandem mass spectrometry (36, 37). Using the nanoelectrospray ion source, sequence stretches up to 16 residues obtained from as little as 5 ng of protein digested with trypsin in a gel have been reported (10).

Figure 4. Peptide mapping by automated MALDI mass spectrometry and database searching after in-gel digestion with trypsin of a yeast protein recovered from a 2-D gel system. Ion signals whose measured masses match the

calculated masses of protonated tryptic peptides are indicated with circles. Sequence coverage is greater than 70%. Terminal Arg (R) and Lys (K) sequence tags are marked by arrows. Also shown is a magnification of one of the tryptic peptide peaks that reveals the resolution of molecules containing different natural isotopes. From Ref. 35 with permission.)

4. Conclusion

Peptide mapping, complemented with Edman degradation and mass spectrometry, involves principles from the 1950s and earlier. But they have survived in the newest phases of modern molecular biology and now position themselves at the front of developments by providing rapid and sensitive identification of minor differences among related, alternatively synthesized, and posttranslationally modified gene products at femtomole and soon attomole levels.

Peptide Nucleic Acids

Peptide nucleic acids (PNA) are DNA mimics in which the phosphoribose backbone of DNA has been substituted by a pseudopeptide backbone to which the normal nucleobases are tethered. An 8-mer thymine oligoamide was first described in 1991. The name PNA was coined when it was demonstrated that this molecule forms a triple helix with a polyadenine DNA strand and that a PNA of mixed sequence that contains all four DNA bases forms duplexes with DNA and RNA that obey the Watson–Crick basepair rules. In 1994, it was reported that two PNAs that have complementary base sequences hybridize into a double-helical structure. PNA has attracted great attention within medicinal chemistry and molecular biology, and also in fields, such as organic and physical chemistry because of its interesting chemical and physical properties. Because it binds efficiently and sequence-specifically to single-stranded RNA and DNA and, under certain conditions, also to double-stranded DNA, PNA has great potential for diagnostic and pharmaceutical applications.

1. Chemistry and Synthesis

The backbone of PNA is based on 2-aminoethylglycine linkages that mimic the normal phosphodiester backbone of DNA (1). A methylene carbonyl linker connects the standard nucleotide bases to this backbone at the amino nitrogens (Fig. 1). This chemistry has some interesting consequences. In contrast to DNA or phosphorothioate oligonucleotides, PNA is a nonionic molecule. In addition, it is achiral, which avoids diastereomeric structures and the need to develop stereoselective synthesis reactions. Schemes for protecting reactive groups on the PNA monomers are based on either Boc or Fmoc chemistry (see Peptide Synthesis). In both cases, oligomers can be assembled using established, solid-phase peptide synthesis procedures and a (methylbenzhydryl) amine polystyrene resin as solid support (2). PNA oligomers are cleaved from the support by treatment with either anhydrous hydrogen fluoride or trifluoromethanesulfonic acid, as in traditional peptide chemistry, followed by purification using HPLC. Modifications of PNA are obtained by coupling amino acids during solid-phase synthesis or by attaching other compounds that contain a carboxylic acid group to the exposed N-terminal amino group. The ease with which PNAs are modified should facilitate optimization of specific functional requirements.

2. Physical-Chemical Properties

PNA has proven very potent as a DNA mimic capable of participating in both duplex and triplex formation. Moreover, it displays various interesting properties beyond those of natural DNA.

2.1. PNA-DNA/RNA Duplexes

The properties of PNA-DNA duplexes have been extensively investigated using the mixed-sequence pentadecamer H-TGTACGTCACAACTA-NH_2 (3). This PNA oligomer forms a duplex with complementary DNA that is antiparallel, has the amino-terminus of PNA facing the 3' end of DNA, and has a T_m (melting temperature) of 70°C. The corresponding DNA-DNA complex has a T_m of only 53°C. PNA also binds to the parallel, complementary, DNA target, although it has lower affinity (T_m = 56°C). The preference for antiparallel orientation is a general feature of mixed-sequence PNA-DNA duplexes. Kinetic binding studies have shown that antiparallel PNA-DNA duplex formation is very fast, faster than formation of a corresponding DNA-DNA duplex, whereas considerably slower kinetics were observed for formation of parallel PNA-DNA complexes (4). The thermal stability of PNA-RNA duplexes is generally higher than that of PNA-DNA duplexes, and the rate of association between PNA and RNA is somewhat faster than that between PNA and DNA.

The greater thermal stability of PNA-DNA/RNA duplexes compared to the corresponding DNA-DNA duplexes is predominantly ascribed to the lack of electrostatic repulsions between the two strands. This hypothesis is based on the observation that PNA-DNA and DNA-DNA duplexes have equal thermal stability (melting temperatures) at ionic strengths above 1 M Na^+. As expected, the stability of PNA-DNA hybrids is little affected by changes in ionic strength, except in the limit of low ionic strength, where the stability increases. The higher stability of PNA-DNA compared with DNA-DNA duplexes at low ionic strength is due to a more favorable entropy change linked to duplex formation, which is attributed to a release of counterions from the DNA polyanion as PNA binds (5).

The sequence-specificity of PNA binding to nucleic acids is manifested in the considerably lower stabilities of heteroduplexes that contain mismatches. The effect of base-pair mismatches in the middle of a pentadecamer PNA-DNA duplex revealed decreases in T_m of 8 to 20°C for single mismatches (3). Similar decreases in T_m were observed in PNA-RNA for the corresponding mismatches. Thus, the sequence discrimination of a PNA oligomer is equal to, or even better than, that of a DNA oligomer.

2.2. $(PNA)_2$-DNA Triplexes

Homopyrimidine PNA or PNA oligomers that have a high pyrimidine content bind complementary purine DNA by forming $(PNA)_2$-DNA triplexes (6), virtually without forming of any duplex. Monophasic, well-defined melting curves are obtained for these very stable complexes (T_m > 70°C for decamer PNAs), where the binding is most probably governed by standard Watson–Crick and Hoogsteen base pairing. Triplex formation involving cytosine in the homopyrimidine PNA is pH-dependent (lower pH increases hybrid stability), as expected if C^+GC triplets with one cytosine protonated are being formed. It is interesting to note that experiments still indicate a $(PNA)_2$-DNA stoichiometry even at pH 9, where cytosine is not expected to be protonated. This suggests that only a single hydrogen bond of cytosine is sufficient or that its pK_a is drastically changed.

2.3. Binding to Double-Stranded DNA: Strand Invasion

The high stability of $(PNA)_2$-DNA triplexes enables the PNA to dissociate double-stranded DNA (dsDNA). For example, homopyrimidine PNA oligomers displace the pyrimidine strand of dsDNA at the target site and form a $(PNA)_2$-DNA triplex with the DNA homopurine target. The expelled DNA pyrimidine strand forms a single-stranded loop (Fig. 2). PNA-DNA complexes formed by strand invasion are characterized by high thermodynamic stability and high specificity, which seems contradictory. The strand invasion reaction, however, is kinetically controlled, which allows screening by the PNA for the target sequence, without becoming trapped in thermodynamically stable but incorrectly matched complexes. Although restricted to low ionic strength, this is an interesting binding property of PNA that is being pursued extensively, and several applications have been demonstrated.

Figure 2. Schematic general model of the possible mechanisms of PNA_2-DNA triplex formation by strand invasion of a DNA duplex.

The mechanism of formation of strand-displacement complex involving a PNA(pyrimidine)$_2$-DNA (purine) triplex has been investigated by gel retardation assay using DNA restriction fragments that contain single PNA targets (7). The reaction obeys pseudo-first-order kinetics, and a single mismatch in a 10mer PNA reduces the binding rate constants by more than a factor of 100. For the polynucleotide system poly(dA):poly(dT) and PNA-thymine oligomers, the PNA binding reaction was studied in real time by circular dichroic (CD) spectroscopy (8). This revealed somewhat complex reaction kinetics and also demonstrated the presence of at least one intermediate species. The rate-limiting step is a transient opening of a few base pairs in the DNA duplex (as reflected by the size of the activation barrier). Quite remarkably, the reaction is second-order in PNA concentration, indicating that both PNA strands are involved in the precursor complex. Possibly, the two PNAs are associated loosely with the DNA duplex before the base-pair opening step. Interestingly, intercalators bound to the starting duplex DNA increase the PNA binding rate, even at higher salt concentration, presumably by facilitating initiation of PNA invasion at the intercalation site. Even if the formation of strand-displacement complexes is highly dependent on the ionic strength, complexes formed at low ionic strength are generally stable kinetically at salt concentrations up to 0.5 M NaCl.

PNA targeted to dsDNA sequences other than purine-rich stretches was recently investigated, but such complexes have reduced stability (9). With purine-rich PNA sequences, duplexes formed by the invasion into dsDNA at a complementary pyrimidine target (making a PNA-DNA duplex) have been detected by CD spectroscopy, and by a gel electrophoretic mobility-shift assay. Somewhat surprisingly, cytosine-rich and alternating thymine-cytosine PNA oligomers bind to their corresponding duplex DNA sequence of intact dsDNA by forming PNA-$(DNA)_2$ triplexes. The pH-dependence indicates that this probably involves Hoogsteen base pairing. These recent findings suggest that there are vast possibilities for using PNA to target a variety of base sequences of dsDNA, although more studies are necessary to assess the details of the various binding mechanisms.

2.4. PNA-PNA Duplexes and PNA-PNA-PNA Triplexes

Complementary PNA decamers that contain all four nucleobases form stable antiparallel duplexes very high in thermal stability (PNA–PNA T_m = 67°C; PNA–DNA T_m = 51°C, DNA–DNA T_m = 33.5°C for identical decamer sequences) that have a high sequence specificity that demonstrates Watson–Crick base pairing (10). As observed for PNA-DNA duplexes, the antiparallel PNA-PNA orientation is preferred, although the parallel PNA-PNA complex is still considerably stable (T_m = 47°C. Moreover, a PNA$_3$ triplex that has two pyrimidine decamers and one purine decamer was detected by optical spectroscopy and mass spectrometry, and the CD spectrum indicates a helical structure similar to (DNA)$_3$ and (PNA)$_2$-DNA triplexes (11).

The base pairing in PNA-PNA duplex formation occurs rapidly on a subsecond timescale. Once formed, some PNA-PNA duplexes undergo a conformational transition (10). Although PNA in complexes with DNA or RNA adopts right-handed helical structures as a result of the hybridization, PNA-PNA duplexes, which are devoid of intrinsic chiral constituents, are believed to exist as a racemic mixture of right- and left-handed helices. However, the attachment of a chiral amino acid to the C-terminus of one strand can induce inversion into one predominating helical sense among the PNA-PNA duplexes, which was detectable as a slowly growing CD signal upon mixing. Such a chiral bias depends on the PNA sequence at the C-terminus (a G-C base pair is preferred) and on the nature of the terminal chiral amino acid. The D and L forms of amino acids give rise to mirror image CD spectra of PNA (Fig. 3a), indicating that helices of opposite handedness are formed, The nature of the side chain (hydrophobic or hydrophilic) also decides the preferred helical sense. Helix reorganization occurs on a timescale of minutes at room temperature and exhibits first-order kinetics. The reaction shows a high entropic activation barrier, as would be expected for a transition from one helical sense to another. PNA-PNA duplex helicity that originates from a chiral amino acid at the PNA terminus can propagate about 10 base pairs (chiral persistence length,) or approximately one helical turn.

Figure 3. CD-spectra of GTAGATCACT·AGTGATCTAC duplexes. (a) PNA-PNA duplex with terminal D-lysine (light gray) and L-lysine (dark gray). (b) PNA-DNA antiparallel (light gray), PNA-RNA antiparallel (dark gray), and PNA-DNA parallel ( ). (c) PNA-PNA (light gray) and DNA-DNA (dark gray).

3. Structure of PNA Complexes

The unique chemical and physical properties of PNA have inspired investigations of structural details of PNA-nucleic acid hybrids by various techniques, including NMR, X-ray crystallography, CD, and linear dichroic (LD) spectroscopy.

3.1. Dichroic Spectroscopy of PNA-DNA Hybrids

The CD of PNA-DNA and PNA-RNA duplexes provided the first indications of the overall base-pair geometry in these complexes (3). The CD spectra of DNA-DNA, antiparallel PNA-DNA, and antiparallel PNA-RNA duplexes are all similar, suggesting that PNA participates in forming right-handed helices that have base-pair geometry not much different from that found in B-DNA or A-DNA helices (Fig. 3b). In contrast, the spectra of parallel PNA-DNA and PNA-RNA complexes deviate more from the DNA-DNA spectrum, suggesting different base stacking (Fig. 3b).

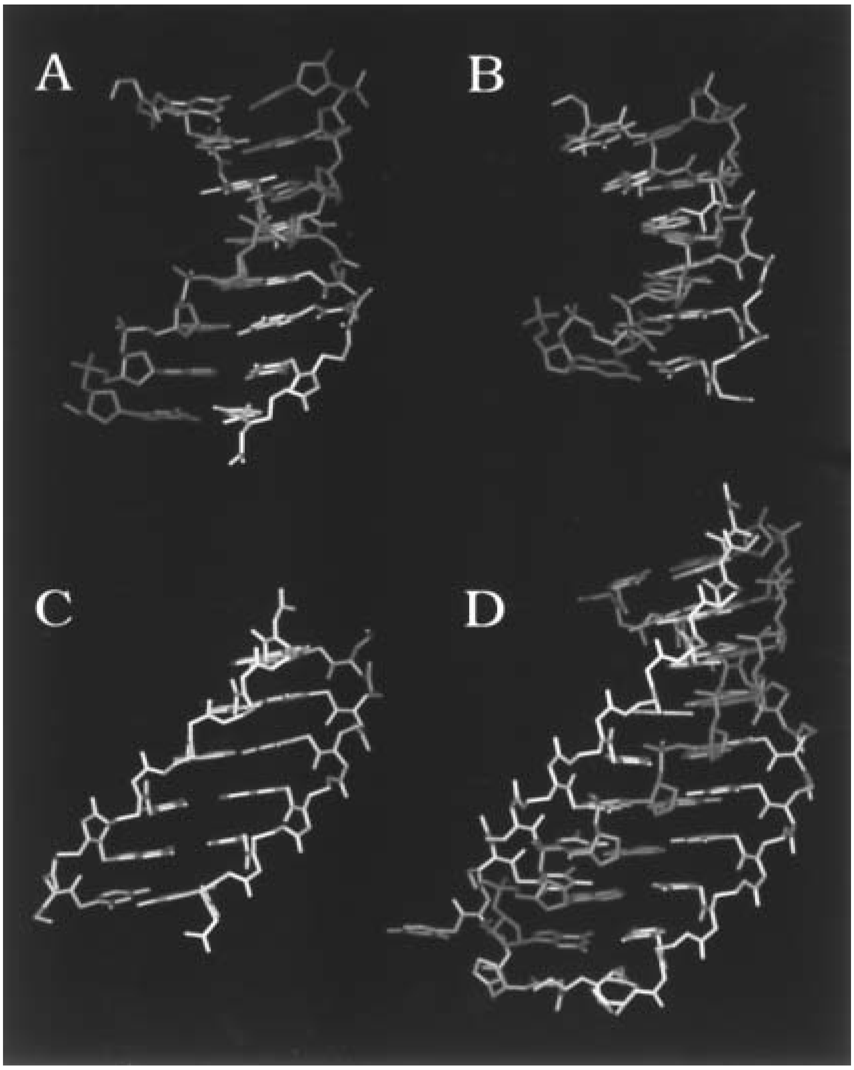
Earlier, LD and CD showed that PNA-T_8 with poly(dA) forms a right-handed PNA_2-DNA triplex, in which the base triplets are arranged with their planes approximately perpendicular to the helix axis, similar to the standard poly$(dT)_2$-poly(dA) triplex (6). Further, the PNA_2-DNA triplex has a remarkably rigid structure, indicating efficient stacking interactions. The high thermal stability of $(PNA)_2$-DNA triplexes is expected because of the absence of interstrand repulsions, and it is assisted by hydrophobic and dipolar interactions, and possibly also by intrabackbone hydrogen bonds (see later). Titration experiments with PNA-T_8 added to poly(dA) show by LD and CD that no duplex stretches are present at subsaturation ratios but that segments of $(PNA)_2$-DNA triplexes are distributed evenly on the poly(dA) strand separated by flexible single-stranded regions. Only close to the saturation point, 2:1 PNA to DNA bases, does the complex become rigid due to complete formation of triplex and stacking between each PNA triplex segment.

A helical structure of PNA-PNA complexes has also been suggested. The CD spectrum of PNA-PNA resembles that of the corresponding DNA-DNA duplex (Fig. 3c) in shape and amplitude, so it is inferred that the structures similar in their base-stacking interactions and degree of organization (10).

3.2. NMR and X-Ray Crystal Structures of PNA-Containing Complexes

Three-dimensional molecular structures have recently been reported for several PNA complexes (Fig. 4). The structures of PNA-RNA hexamer (12) and PNA-DNA octamer (13) duplexes have been determined by NMR. The structures of a nonamer $(PNA)_2$-DNA (14) triplex and a hexamer PNA-PNA (15) duplex were determined by X-ray crystallography. Some general conclusions can be drawn from these structures. It is clear from the heteroduplexes, that binding of PNA still allows the backbone of the nucleic acid partner to retain a nearly "normal" conformation. The RNA strand in the RNA-PNA duplex, has approximately an A-conformation with C3′-endosugar puckering, whereas the DNA in the PNA-DNA duplex is closer to B-form with C2′-endosugar puckering (see DNA Structure). It is striking, however, that the base-pair positions in both duplexes are more A-like in their helical displacement, but, in contrast to a canonical A-form helix, are more perpendicular to the helical axis. The two duplexes also show a larger pitch—about 13 base-pairs for the PNA-DNA duplex—than the usual 10 to 11 base pairs observed in nucleic acid duplexes.

Figure 4. Structures of PNA duplexes and triplexes. (A) and (B). Solution structures of PNA-DNA octamer duplex (A) and PNA-RNA hexamer duplex (B). (C) and (D). X-ray crystallographic structures of a PNA-PNA duplex (C) and of PNA_2-DNA nonamer triplex (D). Figure kindly provided by Dr. Scott Carter.



The crystal structure of the $(PNA)_2$-DNA triplex reveals hydrogen bonds between phosphate groups of the DNA backbone and amide protons in the PNA backbone of the Hoogsteen strand. These contacts could be important for the ability of homopyrimidine PNA oligomers to form very stable triplexes with complementary oligonucleotides. Moreover, the two PNA strands in the triplex structure are nearly identical and resemble the PNA strand in the PNA-DNA duplex. Both the $(PNA)_2$-DNA triplex and especially the PNA-PNA duplex show very wide (26 Å and 28 Å, respectively) helices with a large pitch (16 and 18 bases per turn in the triplex and duplex, respectively), strongly suggesting that this latter type of helix is the natural conformation of helices that have PNA backbones. It is further notable that the base pairs in the PNA-PNA duplex exhibits interbase-pair stacking overlaps close to A-form. Thus, it is clear that PNA helices have a structure of their own that resembles, but is also distinctly different from, known nucleic acid helices.

4. Structure–Activity Studies

Because PNA has demonstrated unique hybridization properties toward complementary oligonucleotides, it has been of the utmost interest to understand what structural elements are responsible for its behavior. Furthermore, it is important to know what kind of chemical modifications can be accomplished and accommodated while retaining binding to DNA and RNA.

A large number of studies on backbone-modified PNAs show that any minor deviations from the original aminoethylglycine backbone can be tolerated. Extensions in any of the three possible linking directions impair stability of its complexes, and the restricted flexibility imposed by the secondary amido group in the nucleobase linker is also necessary because reducting this to a tertiary amine is deleterious to the hybridization potency (16). Isomerization to the retroinverse structure, which essentially moves a methylene group from the ethylene to the glycine moiety, also results in PNAs of low hybridization efficiency. However, there is much freedom in the way substituents may be placed in the a-position of the glycine moiety of the PNA backbone. Backbones based on natural amino acids other than glycine result in fair to good DNA mimicking properties. Even cyclic substituents, such as cyclohexyl substitution at the aminoethyl linker, are acceptable, provided the right stereoisomer is chosen. By using PNA monomers that have incorporated natural amino acids, chemical functionality can be introduced into the backbone and the physical properties of the PNAs, such as hydrophilicity, hydrophobicity, ionic character, etc. might be finely tuned and controlled. It is believed that this greatly facilitates the optimization of pharmacokinetic behavior, for example (see later).

PNA-DNA chimeras are potentially interesting because they may allow DNA-recognizing enzymes (such as ribonuclease H and DNA polymerase) to interact with the DNA part, while the PNA part would provide high binding affinity and specificity. For this purpose, a linker is necessary that connects the two oligomers to allow stacking between the neighboring bases in the PNA and DNA parts of the chimera. Successful reports describe the synthesis of PNA-DNA chimeras of both DNA-3′-N-PNA and DNA-5′-C-PNA type junctions (17). Such chimeras hybridize to complementary oligonucleotides less efficiently than pure PNAs, but they are able to activate ribonuclease H.

5. A Possible Genetic Drug?

The potential use of PNA as an antisense or antigene drug for sequence-specific modulation of gene expression has bright prospects. Oligonucleotide analogs can be designed to recognize and hybridize to complementary sequences in a particular messenger RNA and thereby inhibit its translation (see also Antisense Oligonucleotides). Alternatively, oligonucleotides can be targeted to dsDNA and interfere there with transcription of a particular gene (the antigene strategy). These two approaches are depicted in Figure 5. In vitro assays examining the effect of PNA on DNA replication, transcription, and translation all look quite promising. The sequence specificity is high, and the biological stability of PNA is sufficient (18). Drawbacks include the poor cellular uptake of PNA and the sensitivity of strand invasion complexes to salt concentrations, which must be addressed before general applications can be developed. Moreover, the pharmacological properties of PNAs have not yet been thoroughly investigated.

Figure 5. Principles of the antisense and antigene gene-targeting strategies. In normal cells (a), DNA is transcribed into which then is translated into protein. When the cells are treated with an antisense oligomer (b), hybridization to a sequence specific mRNA inhibits expression of the protein at the level of translation. Treatment of the cells with an antigene oligo complementary to a sequence in the DNA leads to inhibition of transcription of the gene into mRNA.

5.1. Transcription Arrest by PNA

When targeting genomic DNA by the antigene strategy, inhibition should in theory be obtained by the formation of just one PNA-DNA complex in each haploid genome. Because pyrimidine PNAs form extremely stable, strand-invasion complexes upon binding to dsDNA, they should be excellent antigene agents (18). It has been shown that such complexes indeed arrest transcription by both prokaryotic and eukaryotic RNA polymerases in vitro. PNA bound to the promoter clearly blocks the access of the polymerase protein to the DNA, whereas PNA bound within the coding region of a gene sterically blocks polymerase progression (Fig. 6a). In therapeutic applications, several issues are, however, still unclear. First, to bind dsDNA, a polypurine target must be present in the gene of interest. This, of course, limits the number of possible targets. Second, and this could be more serious, the formation of strand-displacement complexes occurs very slowly at physiological salt concentration. Modifications of PNA by intercalators or positively charged lysine residues may, however, improve the binding rates. Furthermore, chemically linking the end of the Watson–Crick and Hoogsteen PNA strands to each other or incorporating pH-independent pseudoisocytosines into the Hoogsteen strand can increase the association rates with dsDNA. It was found that binding of PNA to supercoiled plasmid DNA is much faster than to linear DNA, indicating that the DNA topology is an important parameter for the rate of binding. Because transcriptionally active chromosomal DNA is usually negatively supercoiled, this could be of relevance for PNA binding in vivo. It has also been shown that binding of PNA to dsDNA is enhanced when the DNA is being transcribed, probably because of partly ssDNA in the transcription bubble.

Figure 6. Translational arrest and transcriptional inhibition. (a) Translation initiation is blocked by either a duplex- or a triplex-forming PNA, whereas a triplex-forming PNA is required for translation elongation arrest of the ribosome. (b) Transcriptional inhibition is accomplished by homopyrimidine PNAs that form invasion triplexes either at the promoter or the coding region of the gene.

5.2. PNA as an Artificial Promoter

Even though not considered an antigene effect, the ability of PNA to activate transcription is worth mentioning in this context. The resemblance between PNA strand invasion hybrids and transcriptional initiation complexes allows transcription to start on the looped-out strand of the PNA-DNA complex. Experiments with *Escherichia coli* RNA polymerase show that the looped-out DNA strand acts as a template, and the length of the resulting transcripts corresponds exactly to run-off transcripts initiated at the bound PNA. Such a “PNAmoter” is very strong and might have the potential to activate genes *in vivo*, provided that strand invasion is accessible inside cells. As mentioned, PNA also arrests transcription, but the two processes differ as to the size of the displacement loop. Although arrest works for decamer targets, transcriptional initiation requires a larger loop.

5.3. Translational Arrest by PNA

Because PNA-RNA complexes are not recognized by ribonuclease H, PNA-mediated antisense effects depend on mechanisms involving steric blocking of RNA processing, transport into the cytoplasm, or translation. Studies performed in vitro show that translational initiation is blocked by a PNA that forms either a duplex (mixed sequence) or a triplex (pyrimidine-rich), whereas arrest of translational elongation by the ribosome requires a triplex-forming homopyrimidine PNA (Fig. 6). Antisense properties in a cellular context have been possible to assess by microinjection of PNA directly into cultured cells (circumventing the cellular uptake problem), and sequence-specific effects have been confirmed (18).

Bacteria have attracted relatively little attention as targets for antisense agents. However, the demonstration of gene- and sequence-specific antisense inhibition by PNA in *E. coli* opens possibilities for antisense antibacterial drugs and gene-function analysis in bacteria (19). In view of the resistance to current antibiotics displayed by an increasing number of strains of pathogenic bacteria, the possibility of novel antibiotics seems especially important.

5.4. Delivery and Biological Stability of PNA

The prospect of using PNA as a genetic drug makes sense only if PNA is delivered efficiently to cells and distributed so that it interacts with the target mRNA or DNA. Studies conducted with cells in culture indicate that PNA uptake is slow and that PNA ends up in endosomal compartments (18). Using a liposome system as an in vitro cell model, the PNA penetration properties based on passive diffusion have been investigated in detail and are slow (requiring days) (20). Therefore, PNA molecules need to be modified somehow, either by conjugation to ligands so that active receptor-mediated cellular uptake channels might be exploited or by attachment to moieties that make them attracted to the membrane, so that the local concentration of PNA near or within the cell membranes increases. It has been found that a PNA conjugated to an antibody for transferrin transports across the blood-brain barrier, possibly via the transferrin receptor (21). Most other DNA analogs also show poor uptake properties, similar to those observed with PNA. It is always important, however, to extend uptake studies to *in vivo* situations. Surprisingly, phosphorothioate oligonucleotides, which are taken up only inefficiently in cell culture, have favorable pharmacokinetic behavior in animal models (18).

Agreeing with its chemical remoteness to natural nucleic acids or peptides, PNA exhibits resistance to degradation by cellular nucleases and proteinases and remains intact when incubated in serum or cellular extracts. Thus, PNA has ample biological stability for drug development. Furthermore, no signs of general toxicity by PNA have been observed thus far.

6. PNA as a Diagnostic Tool

An increasing number of applications have been described that confirm the potential for PNAs to facilitate the development of novel methodologies in molecular biology, diagnostics, and related fields. A few of these applications are described here.

6.1. PNA-Directed PCR Clamping

The high stability and sequence selectivity of PNA-DNA complexes have been exploited in analyzing single base-pair mutations in DNA by employing PCR amplification (22). PNA directed toward the primer binding site, the region adjacent to the primer site, or toward the middle of the PCR region, decreases amplification because PNA cannot function as a primer for DNA polymerase. The most efficient and discriminative clamping was observed, as might have been expected, with homopyrimidine PNA decamers. Formation of such PNA_2-DNA triplexes inhibit the polymerase at any PNA binding site. With this technique, a single mismatch in the primer site is detectable.

6.2. PNA and S1 Nuclease as Artificial Restriction Enzymes

PNAS in combination with S1 nuclease have been used as “artificial restriction enzymes” (23). Hybridization of a homopyrimidine PNA oligomer to the complementary target on dsDNA leads to strand displacement of the noncomplementary DNA strand. Upon treatment with nuclease S1, the single-stranded DNA is cut into well-defined fragments. The binding of two PNA molecules to two adjacent targets on the same or opposite DNA strands led to an opening of the entire region, including the intervening base pairs, and thereby provided an accessible substrate for the nuclease and considerably increased the sensitivity to cleavage.

6.3. PNA-Mediated Nucleic Acid Purification

PNA oligomers that carry six histidine residues can be used to purify target nucleic acids by nickel affinity chromatography (24). Moreover, PNAs linked to biotin in combination and streptavidin-coated magnetic beads can be used to purify genomic DNA of *Chlamydia trachomatis* directly from urine samples. This “purification by hybridization” approach offers a number of advantages over traditional purification methods. One drawback, however, is that it requires knowledge of a target sequence and a dedicated capture oligomer must be synthesized for each different target nucleic acid. Short pyrimidine PNAs form unprecedently stable triplexes with complementary nucleic acids. Because being short means that their target sequence is prevalent in large nucleic acids, such short PNAs can be used as generic capture probes to purify large nucleic acids. It has been shown that a biotin-tagged PNA-thymine heptamer purifies human genomic DNA efficiently from whole blood by a simple and rapid procedure.

7. Mimic of DNA

Studies of PNA and its complexes with nucleic acids add new perspectives to our understanding of

DNA and also RNA. The base-pair stacking in the PNA-DNA and PNA-RNA duplexes is similar to that of the pure nucleic acid duplexes, showing that neither the absence of backbone charge nor absence of chirality in one of the strands markedly affects the helical stacking. Thus, the helicity can be considered a result of the stacking interaction (mainly dipolar interactions between the nucleobases) in combination with strains from the backbone, rather than arising from phosphate–phosphate repulsion that strives to increase the separation of negative charges along the backbone. An important manifestation of the preferred helical structure is also the helical stacking in PNA-PNA duplexes (10, 11). It is speculated that the helical shape of nucleic acids was selected in evolution because it allows better exposure of signature features of the bases on the helical surface without loss in secondary structure stability and thereby facilitates protein recognition.

The structural similarity between PNA-DNA and DNA-DNA duplexes offers the opportunity to investigate the forces responsible for binding different ligands to dsDNA (25). Assuming that the main binding forces can be divided into electrostatic interactions and hydrophobic contributions, the effect of replacing the negatively charged DNA backbone with a neutral peptide backbone could help assess the role of the phosphate groups in binding a given ligand. Typical molecules that intercalate or bind to grooves exhibit strongly reduced affinities for PNA-DNA complexes. None of the intercalators studied exhibited any significant binding, whereas classical minor groove binders bind weakly to PNA-DNA complexes. No simple ligand has been found that binds to PNA-PNA duplexes. These findings illustrate the importance of electrostatic attractions for ligand binding to DNA.

8. PNA and Prebiotic Chemistry

Identifying the first genetic molecule could provide the key to understanding the origin of life. The difficulties in spontaneously forming nucleotides under prebiotic conditions might be used to argue that nucleic acids (DNA or RNA) were not the first genetic materials on the primitive earth. Therefore, it has been proposed that one or more genetic systems composed of simpler monomers may have preceded the RNA world, an era in which RNA molecules would have acted as both the genetic material and the catalyst. Then, genetic takeover would have allowed the development of RNA-controlled life. PNA is an example of an oligomer that could have preceded RNA because it is simpler than RNA but exhibits all of the important properties of nucleic acids with respect to information storage. PNA oligomers can act as templates for polymerizing of the complementary activated RNA mononucleotides, and an RNA oligonucleotide template facilitates the synthesis of complementary PNA strands. These experiments suggest that transitions between different genetic systems may occur without loss of information. A continuous transition from one genetic system to another is possible only if it is possible to form chimeras, that is, mixed molecules that contain building blocks of both systems. In fact, template-directed formation of PNA-DNA chimeras has been demonstrated (26).

PNA is attractive as a primordial macromolecule because it is simple and stable, but, not least, also because PNA is achiral. Introducing and maintaining homochirality on the primitive earth is often considered a crucial issue. How would the first RNA and DNA molecules (which are chiral) have formed from a random racemic mixture of chemically related subunits, including all the possible optical isomers? One possibility is that some physical selection mechanism resulted in forming a chiral environment before the origin of life, or, which may be more likely, that a general chiral bias was active during evolution and led to a final complete selection of handedness (27). Because homochirality is required for the function of enzymes and nucleic acids, an adaptive process might have selected for homochirality at some stage in prebiotic chemical evolution. The discovery of PNA-PNA helices with the handedness determined by a terminal chiral seed suggests that a molecular precursor of RNA could have provided a mechanism for chiral amplification (28).

9. Concluding Remarks

The development of PNA has had implications for many areas of DNA chemistry, biology, and technology, ranging from basic molecular recognition, self-assembly, chiral induction, and genetic therapeutic drugs, to our understanding of the structure and function of Nature's genetic material, DNA, and speculation on its prebiotic predecessors and origin. Even some novel materials have their origin in PNA (29). Therefore, PNA should be viewed as a DNA mimic and also as a structural and self-recognizing system in its own right.

Peptide Synthesis

The chemical synthesis of small proteins has only recently become feasible with reliability. Progress in this field has depended on the development of the solid phase procedure and the automated synthesizer by Merrifield to reduce the labor and errors associated with repetitive manual procedures. Difficulties in generating pure peptides arose from accumulated byproducts resulting from synthetic difficulties in chain assembly and deprotection of side-chain functionality. Advances in analytical and purification technologies have provided tools for addressing these problems. A variety of strategies have been developed to overcome the synthetic difficulties, and several laboratories have invested sufficiently in the optimization of the technology to produce synthetic small proteins of sufficient purity as to remove any doubts regarding their biological effects (1).

One of the first examples where a small synthetic protein had a major impact on a biological problem of clinical significance was the development of human immunodeficiency virus (HIV) proteinase inhibitors. Although the gene sequence for the 99-residue protein which dimerized to give the active proteinase, was identified when the DNA sequence of the gene for HIV was determined, cloning and expressing of HIV proteinase proved to be exceptionally difficult for pharmaceutical groups, even for those with records of considerable previous success in biotechnology. Synthetic HIV proteinase, a 99-residue homodimer prepared in the laboratory of Stephen Kent (2), was used in the initial determination of HIV proteinase specificity and inhibitor screening. The availability of this synthetic protein certainly expedited the development of HIV proteinase inhibitors used for the treatment of acquired immune deficiency syndrome (AIDS). This example and others would argue that chemical synthesis of small proteins may be more rapid than cloning and expression for some proteins, and it can provide ready access to sufficient quantities (hundreds of milligrams) of protein for screening or biophysical studies. In fact, the first X-ray crystallography structure (3) of HIV proteinase complexed with an inhibitor, MVT-101, used synthetic HIV proteinase and set the record for the largest synthetic molecule whose structure was confirmed by crystallography.

1. Solution Versus Solid Phase

Traditional approaches to peptide synthesis were based on solution methods using convergent synthetic schemes, with isolation and characterization of each intermediate. This provided well-defined products with confidence in their final structures, but at the price of increased labor and losses at each synthetic step in separating product from reagents and byproducts. Until recently, the synthesis of small proteins (60 to 100 residues) has been dominated by fragment condensation in solution with maximal protection of side chains. The desired protein sequence is divided into peptide segments of about 10 residues, which is about the maximum length of peptide readily prepared by stepwise addition in solution. After each reaction, the product is isolated and fully characterized before proceeding with the next reaction. Once the set of fragments has been prepared, they are combined pairwise to generate segments of approximately 20 residues. These are then combined pairwise to generate fragments of approximately 40 residues, and this fragment condensation continues until the desired sequence is obtained. The protecting groups on side chains are then removed to give the fully unprotected peptide chain, which is allowed to fold, resulting in the desired protein. First, the 80-residue protein is divided into eight 10-residue segments that are prepared by stepwise elongation requiring nine coupling and nine deprotection steps, with isolation of each intermediate to give a completely protected fragment with both amino and carboxyl termini protected. Depending on the role of the segment, either its N- or C-terminus is deprotected and reacted with its adjacent fragment. This process is continued until the entire protein is assembled, deprotected, purified, and allowed to fold.

The solid-phase approach utilizes a polymeric protecting group that allows the use of excess reagents to force reactions to near completion by the mass action law and trivial isolation of polymeric product by filtration and washing. Intermediates are not isolated, and purity of the final product depends on complete reaction at each synthetic step and minimization of side reactions during the buildup of the oligomeric peptide and subsequent removal from the polymer with deprotection, to give the desired product. The advent of high-performance liquid chromatography (HPLC) with more sophisticated techniques such as nuclear magnetic resonance (NMR), capillary electrophoresis, and mass spectrometry for purification and characterization of the intermediates and final products allows routine synthesis of peptides in the 50- to 100-residue range. Because of the difficulties in purification of larger peptides and small proteins with only minor differences in structure from byproducts, the unambiguous synthesis of larger peptides and small proteins is best accomplished by assembly of fragments that have been purified and fully characterized. This prevents accumulation of side products with only minor structural differences that can be difficult to remove in the final mixture. Initially, chain assembly was relatively easy to optimize, and the majority of undesirable side products in the final cleavage were due to incomplete deprotection of side chains. Considerable effort over two decades was devoted to understanding the sequence-dependent problems leading to truncated sequences or those missing a residue, but these efforts were hampered by the polymeric support itself, which limited application of the normal methods for characterizing intermediates. This effort has led to the current state of the technology, in which average reaction yields are estimated to be greater than 99.5%. Such yields are essential if multiple sequential chemical reactions are performed without isolation and purification of intermediate products.

Automation of the solid-phase reaction was initiated almost immediately once a viable synthetic scheme for peptides was evolved, and the first automated synthesizer was announced by Merrifield and Stewart in 1965 (4). Continuous development of synthesizers and the associated chemistry allows the automated addition of 75 residues per day to a growing peptide chain (5). In many cases, the repetitive yields are sufficiently high that useful products can be isolated from the synthetic mixture by HPLC when small proteins are prepared. If one desires to be more confident that the observed properties are uniquely determined by the targeted sequence, then a more conservative approach utilizing fragment condensation is still required.

Illustrative are the solid-phase protocols for the two strategies (Boc and Fmoc) commonly used for the synthesis of peptides. The Boc strategy (Fig. 1) is often combined with a 1% to 2% cross-linked polystyrene support and a benzyl ester linkage to the polymer, requiring strong acid such as hydrogen fluoride for deprotection. The procedure favored by most synthetic laboratories uses an acid-labile linkage similar to the p-methoxybenzyl ester linkage of the Wang resin and a base-labile amino protecting group, the fluorenylmethyloxycarbonyl (Fmoc), on the added amino acids (Fig. 2). One can use side-chain protection with similar acid lability to the Wang linkage to give free peptide upon cleavage, or use more stable side-chain protection to give the protected peptide for fragment condensation after purification and characterization. In the latter case, a final deprotection with strong acid such as HF is required.

2. Orthogonal and Selective Protection

Because many of the 20 common amino acids have side chains containing chemically reactive groups (carboxyl, hydroxyl, imidazole, indole, phenol, amine, guanidinium) which could compete for selective peptide bond formation, they must be protected temporarily during assembly to make sure that only the desired a-amino and a-carboxyl groups react to join the protected amino acid to the growing peptide chain with the desired linkage. It is essential that these side-chain protecting groups are stable (orthogonal) to the conditions used for removal of the amino protecting group (Fig. 3) in chain elongation and yet be readily removable at the end of the synthesis. Much effort has been expended developing compatible sets of protecting groups for the 20 naturally occurring amino acids. The peptide chain is routinely assembled stepwise from the C- to N-terminus because one can best preserve the chiral integrity of the component amino acids by activating the carboxyl group of a urethane-protected amino acid [ROCO-, where R = t-butyl (Boc), R = benzyl (Z), and R = fluorenylmethyl (Fmoc)] for coupling with the N-terminal amine of the growing peptide chain. After the addition of a protected amino acid, the a-amino protecting group must be removed in order to provide the amine nucleophile for the next reaction. This must be accomplished while retaining the side-chain protecting groups of the growing peptide chain. This leads to the concept of orthogonal protection, in which the a-amino group is protected with a group that can be removed selectively by a mechanism that does not affect the side-chain protecting groups. A common example in solid-phase synthesis would be the use of the Fmoc group, which can be removed repetitively from the a-amino groups under basic conditions, and the use of acid-labile protecting groups, such as Boc or OtBu, on the side chains that must remain throughout chain elongation. If one attempts to couple a peptide to another peptide by activation of the carboxyl group of one of the two, the chiral integrity of the amino acid whose carboxyl group is activated (which is analogous to coupling an acetyl amino acid, which can form a cyclic intermediate, leading to rapid exchange and inversion of the alpha carbon) is often compromised by racemization, consequently, a mixture of peptides with R and S configurations at the activated amino acid results. This leads to the use of special procedures for coupling peptides, as well as a strong priority to favor glycine or proline as the C-terminal residues in fragment coupling, due to their resistance to racemization. Chemical or enzymatic ligation of peptide fragments offers an alternative approach to simple chemical activation of the C-terminal carboxyl group of one fragment and nucleophilic attack by the N-terminal amino group of the other fragment.

Figure 3. Urethane protecting groups for amino groups in common usage. Boc, t-butyloxycarbony; Z, carbobenzoxy (or benzyloxycarbonyl); Fmoc, fluorenylmethyloxycarbonyl.

3. Coupling Reagents

The choice of one of the numerous reagents to activate the carboxyl group for nucleophilic attack by the amine function, to produce the peptide bond, depends on numerous factors. When coupling peptide fragments, reagents that minimize racemization are preferred; a traditional favorite in solution chemistry for coupling fragments has been the azide group. A common procedure is activation by a combination of a diimide, such as 1,3-diisopropylcarbodiimide (DIC) or 1,3-dicyclohexylcarbodiimide (DCCI), with hydroxybenzotriazole (HOBt), or through the use of an activated derivative of HOBt, such as TBTU, to generate the activated HOBt ester in situ. Incorporation of multiple sequential sterically hindered amino acids (valine, isoleucine, aminoisobutyric acid, etc.) often require the use of special coupling reagents, such as acid fluorides, HATU, etc.) to provide reasonable reaction rates and efficient coupling yields.

4. Minimal Versus Maximal Protection

In order to get selectivity in the reaction, all reactive groups except the two that are desired to react can be protected transiently with chemically labile protecting groups. This is referred to as maximal protection and would be preferred, except for incomplete removal and side reactions associated with deprotection of the fully protected peptide product containing a heterogeneous set of protecting groups. In solid-phase synthesis, assembly of the correct sequence is often quite facile, but incomplete removal of the protecting groups can lead to an intractable mixture. By careful control of reaction conditions (aqueous, pH, etc.), one can eliminate some of the side-chain protection to minimize problems associated with protecting group removal. This is referred to as minimal protection and is preferred if selective acylation of the amino terminus by the carboxyl of the N-terminal peptide can be achieved.

5. Chemical Ligation

Certain groups of chemical functionality have exceptional affinities for selective reaction, particularly in the formation of small rings. Recent developments have led to the synthesis of large peptide fragments by solid-phase synthesis, removal from the polymeric support and of most, if not all, side-chain protecting groups, and then selective coupling of the unprotected fragments based on chemical ligation. The most developed strategy for this approach is the use of an N-terminal cysteine residue with a special reactive C-terminal group on the other peptide. This approach was initially conceived by Kemp in his thiol capture strategy (7) and was reduced to a practically successful general approach by the groups of Kent (8-10) and Tam (11-13). For illustrative purposes, the native chemical ligation procedure of Dawson et al. (9) is described (Fig. 4), because it seems to have had the most practical impact. In this case, solid-phase synthesis is used to prepare two unprotected peptide segments that are combined in aqueous solution. The C-terminal fragment contains an N-terminal cysteine residue, and the C-terminal peptide fragment is prepared as the thioester. The thioester is displaced by the thiolate anion of a Cys residue. If the Cys is N-terminal, an acyl migration through formation of a five-membered ring occurs to generate the desired stable amide bond. If the sulfur atom of a Cys residue within the peptide chain is involved, then the thioether formed is capable of being displaced by other thiols, until the fragment migrates to the N-terminal Cys, when the stable rearrangement can occur. An alternative strategy, using an N-terminal b-bromoalanine of fragment two and the C-terminal thioester of fragment one to give the same covalent thioester intermediate by thioesterification, has been explored by Tam et al. (12)

Figure 4. Native chemical ligation of two unprotected peptide fragment using thiol–thioester exchange with ligation at the N-terminal cysteine residue (9).

While many proteins contain cysteine residues, and some have them optimally spaced for fragment assembly, many do not, and one of the research goals in this area is the extension of these concepts to allow coupling at residues other than the N-terminus of cysteine residues. Some success has been achieved with ligation at X–Gly and Gly–X sites (14), as well as at X–His sites (15). Another development that bodes well for the chemical synthesis of larger proteins is the adaptation of chemical ligation to solid-phase using agarose as the polymeric support. This should allow repetitive ligation of smaller fragments to generate the larger protein stepwise on the polymer.

6. Applications

One might question why one would want to prepare small proteins when one can easily express the genetic message in a variety of biological systems, including eukaryotic systems that include post-translational modification. Limitations of normal expression systems to the 20 common amino acids restricts chemical modification of the parent protein for a variety of biophysical and pharmaceutical applications. Incorporation via molecular biology of novel amino acids as spectroscopic probes, or to introduce conformational constraints, is feasible using the suppressor mutation approach pioneered by the Schultz group (16-18). In this case, however, steric limitations of the protein biosynthetic machinery preclude the use of certain unusual amino acids or constrained dipeptides (19), which are readily accessible via organic synthesis. The quantities of protein obtained by this approach are generally small, requiring assay methods (enzymatic or spectroscopic) that are sensitive as well as specific.

6.1. Peptide Libraries

The explosion of combinatorial chemistry in the pharmaceutical industry as a paradigm for drug discovery was foreshadowed in the use of peptide libraries by Geysen (20) to map peptide epitopes or antigenic sites on proteins. Numerous strategies (21-23) to synthesize mixtures of thousands to millions of peptides and allow selection of those with the desired activities (24) have developed over the past 20 years. Combinatorial synthesis of individual compounds for assay has developed rapidly, because it eliminates the problem of deconvolution of the mixture to identify the individual compound responsible for the observed activity. It also simplifies the pharmacological evaluation of compounds, due to concerns over synergy or the inhibition of activity that is potentially possible in the bioassay of mixtures. Nevertheless, the most effective strategy for lead generation and optimization will be determined by the cost and efficiency of the biological screen versus that of synthesis.

Peptidyl Prolyl Cis/Trans Isomerases

Only a few cis/trans isomerizations are catalyzed by enzymes. Most of these enzymes catalyze isomerization of C=C double bonds. However, the highly abundant and ubiquitously distributed peptidyl prolyl cis/trans isomerases (PPIases) have evolved to accelerate the rotation about a formal single bond. They catalyze the cis/trans isomerization of imide peptidyl-proline bonds and are inactive toward the -CONH- peptide moiety. In enzyme nomenclature, PPIases are classified under EC number 5.2.1.8.

Initially, PPIases were identified in the cytosol of kidney cells from their ability to accelerate the cis to trans isomerization of chromogenic tetrapeptides of the type succinyl-Ala-Xaa-Pro-Phe-4-nitroanilides (where Xaa is any natural amino acid) by an assay that utilizes the conformational specificity of chymotrypsin (1). Briefly, in this cis/trans assay, the trans prolyl bond isomer of the substrate succinyl-Ala-Ala-Pro-Phe-4-nitroanilide (about 92% of the total) is cleaved completely at the anilide bond in a few seconds when high concentrations (≫ mM) of the proteinase are used. The remaining cis isomer of the peptide (8%) is resistant to chymotrypsin until it undergoes cis to trans isomerization. When monitored by the absorbance of the released product (4-nitroaniline), the isomerization is the rate-limiting step for proteolyzing the cis isomers indirectly. It can be quantified as a first-order reaction with a half-time of about 90 s at 10°C. This kinetic phase, which is equivalent to a quasi-irreversible cis to trans isomerization, has an accelerated rate in the presence of catalytic amounts of a PPIase. The calculated rate constants depend linearly on the PPIase concentration. This assay could not demonstrate catalysis in both directions, but this was possible with NMR (2, 3). The standard assay was greatly improved by dissolving the assay peptides in LiCl/trifluoroethanol to increase the fraction of cis isomer (4).

PPIases were initially anticipated to be fold/rearrangement catalysts for proteins bearing cis prolyl bonds in the native state because the slow trans to cis interconversion following protein synthesis on the ribosome will seriously limit the rate of in vivo protein folding. Indeed, PPIases increase the rate of the slow kinetic phases in vitro refolding of many denatured proteins known to be limited in rate by prolyl isomerization. In support of a physiological role in protein folding, the involvement of a PPIase in triple-helix formation in type I procollagen was shown in chick embryo fibroblasts in cellulo (5). However, the biological functions of PPIases are not yet well understood, and they may have more general roles than affecting only de novo protein folding.

According to our current knowledge, the enzyme class of PPIases comprises three families with unrelated amino acid sequences: cyclophilins (abbreviated Cyp), FK506-binding proteins (abbreviated FKBP), and parvulins. An additional subfamily, the prokaryotic trigger factors, exhibits weak sequence similarity to FKBP proteins but lacks FK506-binding ability (6). The amino acid sequences of several dozen different PPIases are known, encompassing molecular masses from 10.1 kDa (92 amino acids in length) for E. coli parvulin (7) to 158 kDa for the NK-TR1 cyclophilin of human, large granular lymphocytes (8). Typically, Escherichia coli cells harbor two cyclophilins, four FKBP-like PPIases, the archetype of parvulins, along with the SurA protein containing two parvulin domains, and the ribosome-bound trigger factor. Among the 470 predicted coding regions in the free-living bacterium Mycoplasma genitalium, which has the smallest known genome of any free living organism, a trigger factor homologue is the sole PPIase present (9).

Members of the PPIase families resemble perfectly evolved enzymes for catalytic efficiency (10). For oligopeptide substrates, both the Michaelis constant, K_m, and the turnover number, k_{cat}, are large and yield values of k_{cat}/K_m of up to $>10^7\ M^{-1}\ s^{-1}$. These bimolecular rate constants approach the diffusion-controlled limits for enzyme reactions (see Enzymes). With $k_{cat}/K_m = 1.1 \times 10^6\ M^{-1}\ s^{-1}$, the *E. coli* trigger factor catalyzing refolding of a denatured ribonuclease T1 variant exemplifies a particularly efficient catalysis in protein folding (11). This efficacy results from having extended secondary binding sites to bind the unfolded protein substrate favorably. These subsites encompass the two protein domains flanking the central PPIase domain of the enzyme. Many of the PPIase enzymes are specific only for certain amino acid residues flanking the proline in the primary structure, but this is less important with the cyclophilins. Conversely, a hydrophobic side chain of the amino acid preceding the proline enhances catalysis by FKBPs.

PPIases applied in catalytic amounts cannot alter the *cis/trans* equilibrium of the substrates, as expected. When protein refolding is hindered by misfolding and protein aggregation, an increase of the yield of native protein is not obtained by supplementing the refolding buffer with a PPIase. Thus, an important aspect of chaperones is missing in PPIases (12).

Immunosuppressive compounds, like cyclosporin A, FK506 and rapamycin, bind tightly to the respective active site of cyclophilins and FKBPs and inhibit their enzymatic activities reversibly and competitively and have inhibition constants in the picomolar to micromolar range. Cross-inhibition of the different classes does not occur. At the present time, no specific reversible inhibitors for parvulins and trigger factors have been reported.

Definitive identification of the natural substrates of PPI-ases has not been reported yet. Nevertheless, a number of binding proteins, which may include the putative cellular substrates, were identified by chemical cross-linking, affinity chromatography, the yeast two-hybrid screen, and by co-purification. For example, the nuclear parvulin-like PPIase Pin1 has affinity for NIMA protein kinase in the two-hybrid system. The catalytic activity of this isomerase is involved in cell-cycle control in eukaryotes (13). For the trigger factor family, association with nascent chains derived from secreted and cytosolic proteins and specific affinity for the 50S subunit of the *E. coli* ribosome are indicated by cross-linking and fractionation of enzyme activity (6, 14, 15). On the other hand, the same PPIase has been detected as an indispensable component of the heterooligomeric complex of the chaperone GroEL with the degradable fusion protein CRAG. This system has been used to determine the requirements for rapid degradation of abnormal, misfolded proteins by the proteinase ClpP in *E. coli* cells (16). When a trace of copurifying protein of the ryanodine receptor was analyzed, it became obvious that intracellular calcium release channels on the endoplasmic or sarcoplasmic reticulum (ryanodine receptor, RyR) and the inositol 1,4,5-triphosphate receptor constitute heterooligomeric complexes of the type $((RyR)_4(FKBP12)_4)$ with either cytosolic FKBP12 or FKBP12.6 (17, 18). A dysfunctional state, associated with the impairment of the receptor-mediated Ca^{2+} retardation of the channel, arises from inhibiting PPIase activity with both FK506 and rapamycin (19). Furthermore, FKBPs and cyclophilins in the range of 40 to 60 kDa were found as components of the unactivated steroid receptor complex, associated with the hsp90 component of the receptor (20). Interestingly, two members of different families of proteins that assist protein folding, an enzyme and a chaperone, coexist as binding partners in this receptor complex.

Peptidyl Transferase

Peptidyl transferase is an integral part of the large subunit of ribosomes and catalyzes peptide-bond formation in the elongation step of translation during protein biosynthesis. Peptide-bond formation involves an acyl group O-to-N migration and converts an ester to an amide. Peptidyl-transfer RNA in the P site is the ester bond of high energy content that donates its peptidyl group to the amino group of aminoacyl-tRNA bound in the A site of the ribosome. The peptidyl transferase reaction is often measured by the puromycin reaction, in which puromycin acts as the acceptor substrate to form peptidyl-puromycin. In bacteria, peptidyl transferase activity can be detected in the 50 S ribosomal subunit, and several ribosomal proteins are thought to play a role in the activity. The primary activity of peptidyl transfer, however, is a ribozyme activity encoded in the 23 S rRNA. The peptidyl transferase activity of *Escherichia coli* and *Thermus aquaticus* ribosomes are resistant to conventional protein extraction procedures (1), and the formation of a G-C pair between G2252 in the conserved hairpin loop of *E. coli* 23 S rRNA and C74 in the 3 terminal region of tRNA is a prerequisite for the peptidyl transfer reaction. These findings suggest that not all the large subunit proteins are necessarily required for peptidyl transferase activity. It has been shown recently that *E. coli* 23 S rRNA synthesized by *in vitro* transcription with T7 RNA polymerase exhibits the primary peptidyl transfer activity in the absence of any ribosomal proteins *in vitro*, and that the truncated domain V transcript alone has this activity (2).

Peptidyl transferase is also involved in the termination reaction of protein synthesis and hydrolyzes the ester bond between the peptide chain and tRNA at the P site of the ribosome (see Release Factor). Peptidyl transferase is inhibited by various antibiotics, such as chloramphenicol, lincomycin, carbomycin (prokaryotes), and cycloheximide (eukaryotes).

Perinuclear Space

The perinuclear space is the lumenal space between the inner and outer nuclear envelope bilayers that separate the nucleus from the cytoplasm. The width of the space is between 100 Å and 500 Å. Because the outer nuclear membrane is continuous with the endoplasmic reticulum, the perinuclear space is continuous with the lumen of the endoplasmic reticulum.

Permissive Condition

The condition under which a conditional lethal mutant grows is called the permissive condition, in contrast to the nonpermissive condition or restrictive condition, which restricts growth (see Conditional Lethal Mutations).

Peroxidase

Peroxidases occur throughout the biosphere and catalyze the oxidation of various substrates at the expense of peroxide. Peroxidases are involved in plant growth hormone metabolism, the production of thyroxine, neutrophil-mediated detoxification reactions, prostaglandin biosynthesis, and lignin degradation, to name a few. Although peroxidases are found in plants, animals, and microorganisms, the most thoroughly understood are the nonmammalian heme-containing peroxidases. They all are single polypeptide chains in the range of 30 to 40 kDa and contain a single ferric protoporphyrin IX as the prosthetic group. Based on sequence analysis and now X-ray crystallographic structures, the nonmammalian peroxidases have been divided into three classes (1): intercellular (Class I), extracellular fungal (Class II), and extracellular plant peroxidases (Class III). The extracellular enzymes are glycosylated, and in the case of Class III enzymes there often are many isozymes with varying degrees of glycosylation. The extracellular peroxidases contain two calcium-binding sites and at least four disulfide bonds, presumably for the additional stability required of secreted enzymes.

Now a wealth of structural information is available about peroxidases because of recent crystal structure determinations. Coupled with the cloning and expression of several peroxidases in recombinant systems, this has opened the way for using protein engineering methods to study structure–function relationships.

1. Catalytic Cycle

The overall peroxidase cycle occurs in three distinct steps:

(1)

(2)

(3)

where P is the enzyme porphyrin whose heme iron is indicated, and S is the substrate. In Step 1, the peroxide removes two electrons from the enzyme to give what is called Compound I. In doing so, the peroxide O–O bond is broken, produces water, and the second peroxide-derived oxygen atom remains coordinated to the iron. One electron is removed from the iron to give the oxy-ferryl intermediate (Fe^{4+} = O), and a second electron is removed from the porphyrin to give a porphyrin p cation radical. In some peroxidases, an amino acid side chain is oxidized to a radical rather than the porphyrin. Normally, the formation of Compound I is quite easy to follow because the resting enzyme is red/brown in color, whereas Compound I is green. In Step 2, the porphyrin radical is reduced, producing a substrate radical, S·. Because of porphyrin reduction, Compound II is no longer green, but red. Finally in Step 3, Compound II is reduced by a second substrate molecule. In plant peroxidases, the substrates are normally small aromatic molecules. Once substrate radicals form, they dimerize or disproportionate in nonezymatic reactions.

2. Three-Dimensional Structures

From 1980 to 1993, only one nonmammalian heme peroxidase crystal structure was known, cytochrome c peroxidase. Since then an additional six structures have been determined (2), and there may well be more on the way. Representative examples of Class I, II, and III peroxidases are shown in Fig. 1. The sequence identity can be as low as 15% between peroxidases, yet the crystal structures have a similar fold independent of sequence homology or phylogenetic origin. This underscores the important "rule" in structural biology that tertiary structure is far more conserved than primary structure. All of the various peroxidases consist of a core of 10 alpha helices, two of which, the B and F helices, sandwich the heme plane. The various peroxidases differ in structure primarily on the surface. For example, Class III peroxidases have two additional a-helices on the surface (F′ and F″), whereas cytochrome c peroxidase has a beta-sheet structure. It is thought that these additional helices in the Class III enzymes may play a role in substrate binding.

Figure 1. Representative crystal structures from each of the three primary classes of nonmammalian heme peroxidases: (CCP, cytochrome c peroxidase); Class II (LIP, lignin peroxidase); Class III (PNP, peanut peroxidase). The a-helices are as labeled cylinders, and the beta structure as shaded ribbons.

3. Active-Site Structures

Not surprisingly, the active sites of heme peroxidases are highly conserved (Fig. 2). The proximal pocket contains the His residue coordinated to the heme iron. This His ligand donates a hydrogen bond to the conserved Asp residue. It is thought that this interaction imparts a greater imidazolate character to the His ligand, resulting in extra negative charge on the His residue that stabilizes the Fe^{3+} state of the heme. This is one reason that peroxidases exhibit a lower redox potential in the Fe^{3+}/Fe^{2+} couple than the globins, even though the globins and peroxidases both use a His ligand. Directly adjacent to the His ligand, Most peroxidases have an aromatic residue stacked parallel to and in contact with the His ligand. This residue is Phe in most peroxidases, but Trp in the two known Class I peroxidase structures. For the class I peroxidases, the Trp indole ring N atom donates a hydrogen bond to the conserved proximal Asp residue (Fig. 2).

Figure 2. The active site structure of ascorbate peroxidase, a representative example of a nonmammalian heme peroxidase.

The B helix provides key catalytic residues on the opposite, distal side of the heme. It is thought that the distal His and Arg residue operate in concert to help cleave the peroxide O–O bond. Stacked parallel to the distal heme surface is a conserved aromatic residue, which is Phe in the known crystal structures, except for the Class I peroxidases, which use Trp.

4. Catalytic Mechanism

Most of the effort in understanding the peroxidase mechanism has centered on the formation of Compound I. It is thought that the distal His and Arg residues operate in concert to ensure that the peroxide O–O bond is cleaved heterolytically (3; Fig. 3). The distal His operates as an acid/base catalyst by removing a proton from the incoming peroxide and delivering it to the peroxide O2 atom. As shown in Fig. 3, the distal His donates a hydrogen bond to an invariant Asn residue, which ensures that the Nd2 of the distal His is free to accept a proton from the incoming peroxide. The Arg residue may help to stabilize a developing negative charge on the leaving O2 atom. The net result is heterolytic fission of the peroxide O–O bond. This leaves behind an “oxene” O atom that contains only six valent electrons, a potent oxidant. The oxene center removes one electron from the iron atom, to give Fe^{4+} and one from a neighboring organic group, normally the porphyrin. The crystal structure of Compound I (4) shows that the distal Arg residue swings in to hydrogen-bond with the iron-linked oxygen atom. This may account in part for the stability of the $Fe^{4+} = O$ center in Compound I.

Figure 3. The catalytic mechanism of Compound I formation.

The formation of Compound I is stoichiometric and has a second-order rate constant of between 10^7 and 10^8 M^{-1} s^{-1} for most heme peroxidases. Site-directed mutagenesis has been used to probe this mechanism by amino acid substitution of key catalytic groups in the active site. Changing the distal His to Leu (6) lowers the rate of Compound I formation by 10^5, demonstrating that the distal His is indeed a critical residue. Somewhat surprisingly, the nature of the proximal ligand is not important for Compound I formation because a Gln that replaces the proximal His residue affects only the stability of Compound I and not the rate of formation (6).

5. Enzyme Substrate Complexes

All of the known heme peroxidase structures show that one heme edge is accessible to small aromatic molecules that are typical peroxidase substrates. It is generally thought that small substrates interact at this site and deliver electrons directly to the heme, resulting in reduction of the Compound I porphyrin radical or Compound II $Fe^{4+}=O$ center. Nevertheless, there is no direct structural evidence for this view. To date, only the structures of two heme peroxidase-substrate complexes are known. Manganese peroxidase oxidizes Mn^{2+} to Mn^{3+}, and the Mn^{3+} operates in a complex with dicarboxylic acids as a diffusible oxidant of lignin. The crystal structure of manganese peroxidase (7) shows that Mn^{2+} coordinates with protein carboxylates and one heme propionate. Cytochrome c peroxidase is unusual among the known heme peroxidase structures because its substrate is another protein, cytochrome c. The crystal structure of the cytochrome c peroxidase–cytochrome c complex (8) has provided important insights into the nature of interprotein electron transfer reactions.

6. Heme Halo Peroxidases

The crystal structure of one heme halide peroxidase is known (9). Chloroperoxidase (CPO) is secreted by the mold *Caldariomyces fumago* where it functions to chlorinate 1,3-cyclopentanedione to the natural product 2,2-dichloro-1,3-cyclopentanediol (caldariomycin). The catalytic cycle of CPO is similar to other heme peroxidases. However, in CPO the oxidizing power of Compound I is used to oxidize Cl^- ions to HOCl, and then the HOCl operates as an organic chlorinating agent. Traditional heme peroxidases cannot catalyze this reaction probably because the redox potential of Cl^- is too high. However, CPO operates at very low pH (3) where the redox potential and hence the reactivity of Compound I may be significantly increased over other peroxidases that operate closer to physiological pH.

CPO consists of a single 30-kDa polypeptide chain, one heme group, and one disulfide bond. The crystal structure shows at least 14 different sites of glycosylation. The fold is unlike that of other heme peroxidases, and the proximal ligand is a Cys residue not His. This is very similar to cytochromes P450, which also use a Cys ligand. As a result, CPO shares spectral features characteristic of P450s. The most significant is the 450-nm band in the visible absorption spectrum when the enzyme is reduced in the presence of carbon monoxide to give the Fe^{2+}–CO complex.

6.1. Reactions Catalyzed by Chloroperoxidase

CPO is one of the most diverse of the known heme enzymes. In addition to operating as a chloroperoxidase, CPO exhibits activities characteristic of traditional heme peroxidases, catalase, and cytochrome P450s:

Halogenation (normal function)	$RH + H_2O_2 + Cl^- + H^+ \rightarrow R\text{-}Cl + 2H_2O$
Dehydrogenation (heme peroxidases)	$2RH + H_2O_2 \rightarrow R\text{-}R + 2H_2O$
H_2O_2 decomposition (catalase)	$2H_2O_2 \rightarrow O_2 + 2H_2O$
Oxygen insertion (P450)	$R + H_2O_2 \rightarrow R\text{-}O + H_2O$

Sulfoxidation and epoxidation reactions catalyzed by CPO proceed with a high degree of enantioselectivity (10, 11). Even the typical peroxidase dehydrogenation reactions proceed with enantioselectivity, something other peroxidases cannot do. The CPO crystal structure provides some insights into these unusual functional properties. Although CPO is a helical protein, the overall fold is unique not the typical peroxidase fold. In addition, the heme is accessible from the top distal surface, not the heme edge. Bracketing the distal heme pocket near the $Fe^{4+}=O$ center are two key

Phe residues and other hydrophobic groups that form a shallow pocket that is the most probable site for substrate binding (Fig. 4). The asymmetrical nature of this pocket can account for the observed enantioselectivity.

Figure 4. The active site structure of chloroperoxidase. Glu183 most likely serves the same acid/base catalytic role as the distal His in traditional heme peroxidases. The two Phe residues shown help form the substrate binding site that enables this enzyme to catalyze enantioselective sulfoxidation, epoxidation, and electron transfer reactions.

Like other peroxidases, CPO forms Compound I with an Fe^{4+}=O center and porphyrin radical. The catalytic groups, however, are quite different in CPO. Directly adjacent to the peroxide binding site, CPO has a Glu residue rather than His, and there is no active-site Arg in CPO.

7. Other Heme Peroxidases

Although the nonmammalian heme peroxidases have received most of the attention, the heme-containing peroxidases are very diverse. Mammals produce well-known peroxidases like myeloperoxidase, lactoperoxidase, and thyroid peroxidase. Although these peroxidases contain heme and have active sites similar to the nonmammalian heme peroxidases, these enzymes are larger and have different three-dimensional structures (12). The best understood is myeloperoxidase. The function of myeloperoxidase in white blood cells and the related eosinophil peroxidase is to oxidize halides and thiocyanate ions to produce HOCl, HOBr, and HOSCN, which are potent antipathogen oxidizing agents. The marine worm *Amphitrite ornata* produces a dehalogenating heme-containing peroxidase (13). *Mycobacterium tuberculosis*, the causative agent in tuberculosis, produces a heme catalase/peroxidase that metabolizes the most widely used antituberculosis drug, isoniazid. Strains resistant to isoniazid have a point mutation in the catalase/peroxidase, which implicates the peroxidase as a drug activator (14). Other bacteria, such as *Pseudomonas aeruginosa*, produce a cytochrome c peroxidase that contains two heme groups (15).

8. NonHeme Peroxidases

A number of peroxidases do not have heme as the prosthetic group. The fungus Curvularia inaequalis produces a chloroperoxidase that utilizes vanadium (VO_3) as a cofactor (16). Vanadium bromoperoxidases are also well known in algae (17). NADH peroxidase uses a flavin (18), and glutathione peroxidase is unique in utilizing an essential selenocysteine residue at the active site to oxidize glutathione and reduce hydroperoxides (19). There also are peroxidases that contain no metal center or other cofactors, such as the haloperoxidase of Pseudomonas pyrrocinia (20). In many of these, a detailed understanding is just developing based on recent advances in cloning and expression of these unusual and interesting peroxidases.

Pertussis Toxin

Among the several virulence factors implicated in the pathogenesis of whooping cough, a major role is played by pertussis toxin (PT), which is also a major determinant in the development of antipertussis protective antibodies (1). PT is active on a variety of cells and causes a wide range of effects, due to the ADP-ribosylation of different trimeric cytosolic G proteins involved in cell signal transduction (2).

PT is composed of five different subunits: S1 (21 kDa) is the catalytic part, and S2, S3, two copies of S4, and S5 form the cell-binding pentamer B. Despite the heterogeneity of the components of B and lack of an appreciable primary structure similarity, the overall structural organization of PT is closely similar to those of other oligomeric toxins having B units (3-7). The B pentamer is disk-shaped, and its subunits fold in six antiparallel strands with a-helices lining the central pore (6). S2 and S3 possess additional domains with a lectin-like fold, which were suggested to determine the different sugar-binding properties of PT being different from those of cholera toxin and enterotoxins (6). In fact, PT binds to glycoproteins, such as fetuin , having an Asn-linked branched mannose core with terminal N-acetylglucosamine (8).

At variance from cholera toxin, the carboxyl terminus of S1 enters the B oligomer central pore only halfway, and there are fewer protein–protein contacts (4, 6). The similarity with cholera toxin is very high in the active site, with overlapping glutamate and tyrosine residues essential for activity. His35 occupies a central position in the NAD-binding cavity of PT, as is also the case with the active sites of diphtheria toxin and exotoxin A from *Pseudomonas*. Little information is available on the internalization of PT or the mechanism of membrane translocation of S1 (8). That the structural and functional organization of PT is similar to that of cholera toxin, entertotoxins, and shiga toxins suggests there are further similarities in their mode of cell penetration.

Reduction of the S1 subunit in the presence of detergents frees an ADP-ribosyltransferase activity specifically directed toward the a subunit of several trimeric G proteins. At variance from cholera toxin and entertotoxin, PT catalyzes the ADP-ribosylation of a cysteine residue present in a Xaa-Cys-Gly-Leu-Xaa motif contained in the carboxyl-terminal part of the a subunit of several trimeric G proteins, including G_i, G_o, and G_{gust} G_s has a tyrosine residue in the position of the cysteine and is not modified by PT. Another difference from cholera toxin is that the S1 enzymic activity is greatly enhanced by ATP and other adenine nucleotides (9). The result of the S1-catalyzed ADP-ribosylation of G_i and G_t is different from the cholera toxin or entertotoxin modification of G_s because the carboxyl-terminal cysteine residue of G_i and G_t is centered in the area of interaction between the G protein and plasma membrane receptor. As a consequence, the inhibitory physiological effects normally mediated by these G proteins are not transmitted. The PT oligomer B has biological functions independent of the ADP-ribosyltransferase activity, such as that of inducing the proliferation of T lymphocytes (10).

Pest Regions

One of several features of proteins that have been proposed lead to their rapid protein degradation is the presence of so-called PEST regions, protein domains that are enriched in proline, glutamic acid, serine, and threonine residues. These regions were first described by Rechsteiner and co-workers in the mid-1980s after searching for structural features of proteins that correlate with short half-lives. They developed a computer-based algorithm rating the presence of at least one P, E, S, or T residue in a hydrophilic stretch of at least 12 amino-acid residues and flanked by a positively charged residue. Consequently, PEST regions do not represent a specific sequence per se, but they are instead a general feature of the relevant protein domains. Less than 10% of mammalian proteins of known amino acid sequence have such PEST regions, but a high percentage of short-lived proteins do. In some cases, proteins become more stable after removal of their PEST regions, and a few examples have been shown where transplantation of PEST regions into long-lived proteins causes their rate of degradation to be increased.

The mechanism by which PEST sequences may influence degradative rates has remained elusive. Some PEST-containing proteins are degraded by proteasomes in a ubiquitin-dependent manner, and they require different E2 and E3 enzymes (see Ubiquitin). On the other hand, PEST regions may simply correlate with rapid hydrolysis because they often contain consensus sequences for known protein kinases, and phosphorylation often signals ubiquitin conjugation and degradation. Also, proline-rich hydrophilic domains are likely to exist as unfolded loops on the surface of protein structures and to be more susceptible to interactions with molecular chaperones, kinases, and other proteinases. Theories involving degradation by calpains and proline endopeptidase have, however, proved false.

Phage Display Libraries

Phage display libraries are a variant of expression libraries in which cloned DNA inserts are expressed as polypeptide fusion proteins with bacteriophage capsid proteins, so that the foreign proteins are "displayed" on the exterior of the modified virus particle (Fig. 1) (1-3). Because the virus also contains a DNA genome, a physical linkage is maintained between the displayed peptide and its encoding DNA sequence. This linkage is the core of the power of phage display. Although the displayed proteins behave in many respects as soluble factors, they remain associated with their DNA code as part of an infectious particle. Thus, even trace amounts of display phages with desired activity can be amplified by infection, and the active peptide sequences can be decoded by DNA sequencing.

Figure 1. Schematic illustration of phage display. A double-stranded copy of the phage genome is cleaved enzymatically, and foreign DNA is inserted in-frame into a capsid gene. After introduction of recombinant phage DNA into bacterial cells, novel fusion phage are generated with foreign peptides displayed as capsid fusion proteins on the phage surface.

Several different bacterial viruses have been modified to serve as phage display vectors. By far the most common type of vector is derived from the filamentous Ff bacteriophage (4). The popularity of this virus is due first to the fact that it packages a relatively small single-stranded DNA genome, providing some advantages in mutagenesis and DNA sequencing, and second to the robust technologies that have been developed for display of both short peptides and larger proteins. Other viruses that have been adapted for phage display include lambda phage and T4 phage. Future directions in this field will likely include vector construction using human enteric bacteriophages for the purpose of mucosal vaccine development. In addition, certain human viruses could conceivably be modified as viral display vectors for human gene therapy applications.

Filamentous phage display vectors fall into two categories. First are the phage vectors, which accommodate foreign DNA fused to one of several capsid genes within the phage genome. Phage vectors are adequate for peptide display, but larger polypeptide–capsid fusion proteins tend to interfere with phage assembly or infectivity. This interference can be tolerated if the phage can incorporate a preponderance of normal capsid proteins, with only a small proportion of fusion capsid proteins present. Such a situation occurs in the second category of vectors, called “phagemids,” in which the foreign DNA and the capsid gene are both cloned into a special type of plasmid containing the phage DNA-packaging signal. Foreign DNA is thus cloned as a gene fusion with the phagemid capsid protein. A phagemid is not infectious by itself, but in the presence of a “helper” phage the phagemid DNA can be packaged into an infectious virus particle that displays a mixture of normal and fusion capsid proteins. Using phage and phagemid vectors, a great number of foreign sequences have been expressed as viral capsid fusion proteins, including peptides, antibodies, enzymes, DNA-binding proteins, RNA-binding proteins, and regulatory proteins (reviewed in Ref. 4). Furthermore, any of these proteins can be diversified to form combinatorial phage display libraries, which can then be screened to identify novel proteins with desirable properties.

Phage display screening is a robust technology that typically operates through affinity selection of phage-encoded molecules that interact with target proteins (1). A phage display library typically expresses billions of different peptides or polypeptides. The active minority of the library can be fractionated from the noninteracting majority by affinity partitioning over a solid-phase target. Phages that bind are then readily eluted and amplified by infection of a suitable bacterial host, and further rounds of selection can be performed. This iterative selection process provides a powerful means to obtain specific peptide aptamers, as well as sequence–activity relationship (SAR) data for any target of interest.

Phage display has proven to be a powerful means of obtaining functional probes to study any target of interest. Thus, peptide aptamers can be used to characterize target function in much the same way that antibodies have been used historically to detect, trap, and inhibit their targets. However, unlike animal-based antibody technologies, phage display can yield peptide or antibody functional probes without requiring immunogenicity or immunization by the target. Furthermore, the complexity of modern phage display libraries exceeds the genetically encoded complexity of the immune system. Thus, phage display technologies are likely to continue to find increasing applications throughout the biological and medical sciences.

Phagocytosis

Phagocytosis is the ability of a cell to internalize large particles, as exemplified by the feeding of phagocytic amoebae, which is one type of endocytosis. Phagocytosis is initiated by the binding of large extracellular particles (eg, bacteria) to specific cell-surface receptors, either directly or indirectly. Indirect recognition involves host-derived opsins, such as antibody or complement fragments, that coat the particles and serve as ligands for some phagocytic receptors. The best-characterized opsins are antibodies that bind to surface antigens on infectious microorganisms and form an antibody coat in which the tail region of each antibody molecule (the Fc region) is exposed. Binding of the antibody-coated particles to specific Fc receptors on phagocytic cells initiates phagocytosis. Ligands for other receptors, including complement receptors (see Complement System), integrins, cell-surface lectins, and certain glycosylphosphatidylinositol (GPI)-anchored proteins [eg, CD14 (1)], also activate phagocytosis.

A common feature of the phagocytic events mediated by these various receptors is that particle internalization depends on the polymerization of actin. Activated cell-surface receptors transmit signals to the cytoplasm that induce actin polymerization (2, 3). During Fc receptor-mediated phagocytosis at least, these activation signals involve the small GTP-binding proteins Rac/Rho/CDC42 and tyrosine kinases. The localized polymerization of actin at the site of particle attachment to the cell pushes plasma membrane around the particle, allowing further opsin-receptor interactions (zippering) and the progressive development of the particle within a membrane invagination tightly apposed to the particle surface. When engulfment is completed, the forming phagocytic vesicle, or phagosome, is sealed and detaches from the cell surface.

In most cases the phagosome fuses with resident compartments of the endocytic pathway (endosomes and lysosomes) to acquire the spectrum of hydrolases that digest the phagosome content. The resulting digestion products are transferred to the cytosol and used to synthesize cellular constituents or are secreted from the cell. In multicellular organisms, phagocytosis is primarily associated with defense against infection by ingesting invading microorganisms and the scavenging of senescent, damaged, or apoptotic cells (1) and cellular debris. These functions are generally performed by specialized white blood cells, such as macrophages and neutrophils, that act as “professional” phagocytes. These cells are extremely active. In humans, for example, macrophages remove around 10^{11} senescent red blood cells every day. However, most cells are capable of phagocytosis when challenged with appropriate ligands.

Many invasive bacterial, fungal and protozoan pathogens use phagocytosis to enter cells. Some, such as *Listeria* and *Yersinia*, use cadherins or integrins, respectively, as receptors to initiate endocytic events similar to those described previously. Others, such as *Shigella*, secrete proteins that activate phagocytosis directly. Then the fate of the phagocytic vesicle varies according to the nature of the pathogen internalized. *Listeria*, *Shigella*, and *Trypanosoma cruzi* induce lysis of the phagosome membrane to gain access to the cytoplasm. Other agents (*Legionella*, *Salmonella*, *Mycobacterium avium*) reside and replicate within phagocytic vesicles and produce components that prevent fusion with lysosomes, thus avoiding the hydrolytic consequences of endocytosis, or modify the environment within the phagosome to minimize the effects of the hydrolytic environment (4, 5).

Phalloidin

Phalloidin is a cyclic heptapeptide found in the highly poisonous mushroom *Amanita phalloides*. Phalloidin binds with very high affinity to F-actin and stabilizes these filaments by preventing depolymerization. It contains several uncommon amino acids and is resistant to all proteolytic enzymes tried thus far. While phalloidin has the ability to be highly toxic to a cell due to the changes that it will induce in actin polymerization, it is now known that the toxicity of *Amanita phalloides* is due mainly to the a-and b-amanitins (potent inhibitors of RNA polymerase II), since phalloidin is not absorbed from the gastrointestinal tract (1). Nevertheless, phalloidin has been an extremely important drug in answering structural, biochemical, and cell biological questions about actin.

Phalloidin does not bind to monomeric actin (G-actin), but binds with a 1:1 stoichiometry to protomers within the F-actin filament. This is the opposite mode of binding of DNase I (see DNase 1 Sensitivity), which binds with high affinity to G-actin but not to F-actin. As a result of this selective binding, both may be used to assay the concentrations of G- vs F-actin within a fixed cell. The phalloidin-stabilized filament resists depolymerization that would otherwise be induced by a reduction of the actin concentration, by chaotropic agents, *cytochalasins*, heat denaturation, and proteolysis (2). The critical concentration is the concentration of the monomeric species of actin at which it is in equilibrium with *polymers*, and this is about 10^{-6} M for muscle actin. Phalloidin reduces this critical concentration by a factor of about 25. These properties of phalloidin have made it a very useful tool for labeling actin filaments within a cell (using fluorescent derivatives of phalloidin) and for stabilizing actin filaments used in structural and biophysical studies.

Phase Problem

To determine the structure of a molecule by X-ray crystallography, after collecting and processing the data, the electron density $\rho(x\ y\ z)$ in the crystal unit cell can be calculated at every position $x\ y\ z$

(1)

To use this equation requires that the values of both $F(hk\ell)$ and $a(hk\ell)$ for each reflection $hk\ell$ are known. The $F(hk\ell)$'s are easily found because (apart from corrections) they are proportional to the square root of the measured scattered intensities $I(hk\ell)$. The phase problem is that the phase angles $a(hk\ell)$ are not provided directly by the experimental data. This fundamental problem greatly delayed the use of X-ray crystallography initially, but it is hardly a problem anymore. For small molecules, it has long been solved by direct methods. In the crystallography of macromolecules, several methods exist to determine the phase angles of the reflections:

1. isomorphous replacement
2. molecular replacement
3. MAD (multiple-wavelength anomalous dispersion)

Classical direct methods are applicable to macromolecular crystals only if the protein is small and the X-ray data can be collected to high resolution (1).

Phase Variation, Pili

Certain enterotoxigenic strains of *Escherichia coli* produce pilus-like appendages called colonization factor antigens (CFAs) that are longer than common type I pili. Production of type I pili or CFA is mutually exclusive in these bacteria and thus represents a specialized example of bacterial phase variation. That displayed by type IV pili of *Neisseria gonorrhoeae* is the best-characterized system. The N-terminal domain of *N. gonorrhoeae* pilin is hydrophobic and highly conserved among different variants. Other regions of the pilin molecule, however, known as minicassettes, vary widely in amino acid sequence. There is also wide variation at the DNA level between the various copies of the genes that encode a particular pilin protein. In *N. gonorrhoeae* the expression of the *pilE* gene is controlled at transcription by a two-component regulatory system; this comprises the transcriptional activator PilA and the sensor component PilB, which phosphorylates PilA. If Pil$^+$ and Pil$^-$ respectively represent the phenotypes when functional pili are assembled or not on the bacterial cell surface, then phase variation represents the fluctuation that occurs between Pil$^+$ and Pil$^-$. There are several types of phase variation (1).

1. The first arises because the expressed protein has two possible sites (P^+ and P^S) at which subsequent processing can take place. When cleaved proteolytically at P^+, the pilin protein assembles into normal pili (Pil$^+$). In contrast, when it is cut at P^S it no longer contains the hydrophobic region required for assembly. The protein is secreted and lost from the cell, so there is no pili formation (Pil$^-$).

2. The second type of phase variation is similar to the first in that it again gives rise to a pilin protein that is aberrant and not capable of forming pili *in vivo*. Although the pilin gene is present in multiple copies in the chromosome, generally only one of these has a promoter and is expressed. This gene is designated *pilE*, where *E* represents expression. Those gene copies that are not expressed are termed *pilS*, where *S* represents silent. Both the *pilE* and *pilS* genes contain a number of internal repeated DNA sequences. Homologous recombination, which involves exchanges of the interior regions of the genes, can lead to unequal exchange of DNA because of the repetitive nature of the sequences. As a result, the PilE protein produced may be larger in size than normal. As before, this cannot be processed in such a way that pili formation is possible, hence the phenotype is Pil$^-$.

3. The third mechanism of phase variation concerns the *pilC* gene. The expressed protein PilC, which has been detected by immunoelectron microscopy at the tip of the pili, is an important protein in the assembly and functioning of intact mature pili. Towards the 5′ end of the *pilC* coding sequence there is a long run of G bases. Slipped-strand mispairing during synthesis alters the number of G bases and generates a frameshift mutation. This again gives rise to Pil$^-$ phenotype. Note, however, that pili of normal appearance are produced in this case and that another phase-variable pilus-associated protein replaces PilC in its assembly function, but it lacks the ability to bind to epithelial cells (2). Phase variation probably evolved to allow the bacterium to escape the immune response of its host and to allow it to adapt to new cell types (1).

Phenotypic Lag

After a cell sustains a mutation, there may be a delay of one or more generations before the mutant phenotype is expressed. This delay has two causes. First, a recessive mutation may be complemented by the wild-type allele on another chromosome. In mitotically dividing diploid cells, at least a one-generation delay occurs before the phenotype is expressed. Under most laboratory conditions, haploid organisms also have more than one chromosome per cell and show a lag of one or two generations. Secondly, when a mutation that gives rise to a mutant protein first appears, the cell may have many copies of the wild-type protein. Expression of the mutant phenotype may be delayed until these preexisting proteins are diluted or degraded. A classical example from *Escherichia coli* genetics is resistance to bacteriophage T1. Resistance is conferred by mutations that alter the phage receptor on the cell surface, but several generations are needed before the preexisting sensitive receptors are diluted. Even dominant phenotypes may fail to be expressed until the cellular concentration of the wild-type protein falls. Phenotypic lag complicates the determination of mutation rates from fluctuation tests (1-4).

Phenylalanine (Phe, F)

The amino acid phenylalanine is incorporated into the nascent polypeptide chain during protein biosynthesis in response to two codons—UUU and UUC—and represents approximately 3.9% of the residues of the proteins that have been characterized. The phenylalanyl residue incorporated has a mass of 147.18 Da, a van der Waals volume of 135 Å^3, and an accessible surface area of 218 Å^2. Phe residues are changed infrequently during divergent evolution; they are interchanged in homologous proteins most frequently with tyrosine and leucine residues.

Phe is one of the three amino acids with an aromatic ring in its side chain:

which has absorbance and fluorescence spectral properties that are very useful in quantifying proteins and analyzing their structural properties. The other two—tyrosine and tryptophan—predominate, however, so Phe residues are useful only in their absence. The aromatic ring of Phe residues is comparable chemically to that of benzene or toluene; consequently, it is largely nonpolar (except for the tendency of the electrons of the peripheral H atoms to be drawn into the aromatic ring) and is chemically reactive only under extreme conditions that are not applicable to proteins.

Tyr residues occur primarily within the interiors of folded protein structures, and approximately 50% are totally buried; normally, they are still rotating rapidly by 180° rotations about the C_b–C_g single bond. They tend to occur primarily in alpha-helices, although also in beta-sheets, and they favor the a-helical conformation in model peptides.

Phenylketonuria

The metabolic disorder phenylketonuria (PKU) was first described in 1934 by A. Følling, who was investigating the excretion of ketone bodies in the urine of two mentally retarded children. The reagent in use, acidified $FeCl_3$, typically turns a purple-red color with ketones. The urine of these children turned bright blue-green instead. Examination of additional mentally retarded children uncovered eight more who were similar, both clinically and in their urine reactions. Følling subsequently demonstrated that the responsible urinary constituent was phenylpyruvic acid, thus the name phenylketonuria. In addition to mental retardation, affected children share a number of clinical features, including irritability, seizures, eczema, and a “mousy odor.” They tend to be more lightly pigmented than others in the same family.

The rarity of this disorder in the general population and the occurrence of more than one affected person in a sibship suggested recessive inheritance. The equal occurrence of males and females and the fact that the parents and other relatives were unaffected was consistent with autosomal recessive inheritance.

1. The Biochemistry of PKU

F{ø}lling suggested that patients who have PKU have a block in metabolism of phenylalanine, and in 1947 G.A. Jervis proposed that the metabolic error is in the conversion of phenylalanine to tyrosine. He subsequently proved this hypothesis by showing that liver from a PKU patient cannot make the conversion. Thus, PKU was among the earliest examples of a metabolic error, a term proposed by A.E. Garrod in 1909, and it has served as a model for other metabolic defects.

Phenylalanine is efficiently reabsorbed in the kidneys, leading to maintenance of very high blood levels. In normal persons, the blood phenylalanine is ca. 60 µM. The level in PKU patients can be 40 times higher. This leads to formation and excretion of otherwise rare metabolites of phenylalanine, such as phenylpyruvic acid, phenylacetic acid, and o-hydroxyphenylacetic acid. These metabolites very likely contribute to the clinical features of PKU by interfering with various metabolic and developmental processes.

Phenylalanine hydroxylase (PAH; L-phenylalanine-4-monooxygenase; EC 1.14.16.1) is the enzyme that is ordinarily nonfunctional in PKU. The predicted polypeptide molecular weight is 51,862 daltons, but the enzyme is usually a homotetramer. It catalyzes the oxidation of L-phenylalanine, using tetrahydrobiopterin as a cofactor (Fig. 1). Production of PAH occurs almost entirely in the liver. A large number of PAH alleles are known. Some produce completely inactive PAH; others produce PAH that has reduced or normal activity. Persons whose allelic combinations produce PAH activity <1% of normal have classical PKU. If there is some activity, a mild form of the disorder may result. Heterozygotes, with one normal and one inactive allele, are phenotypically normal even though the total enzymic activity is reduced.

Figure 1. Three enzymes that are important in the conversion of phenylalanine to tyrosine. Additional enzymes and cofactors are required to form BH_4. Reduced activity of phenylalanine hydroxylase (PAH) can result from structural modifications of PAH or from deficiency of BH_4.

2. Treatment of PKU

Humans cannot make phenylalanine or tyrosine and must depend on diet for these two essential amino acids. The phenylalanine content of foods is in excess of body requirements for protein synthesis, and the surplus is metabolized via tyrosine. This suggested the possibility of reducing the accumulation of phenylalanine by reducing the dietary intake. Such efforts, initiated in 1953 by H. Bickel, ultimately proved successful. The low-phenylalanine diet must be introduced soon after birth of an affected infant in order to avoid permanent damage to the developing central nervous system.

With the development of an effective method of treatment, the urgency of neonatal diagnosis became apparent. In the early 1960s, R. Guthrie developed a microbial test using whole blood from a heel stick. This rapid and inexpensive test made large-scale screening possible, and required screening of newborns for elevated blood phenylalanine has become widespread in western countries. Once the central nervous system has matured fully, persons with PKU are somewhat less sensitive to increased blood levels of phenylalanine. This includes not only regulation of protein intake but also avoidance of the artificial sweetener aspartame, which is a dipeptide derivative of aspartic acid and phenylalanine. However, long-term studies have shown benefits of continued treatment of adults.

Although dietary regulation has been highly successful, it is not a perfect treatment. Treated patients show mildly depressed IQ compared to non-PKU controls. One suggested cause is increased dysmyelination with age in the presence of elevated blood phenylalanine. Also, tyrosine is lower in PKU patients, treated or untreated, and this may lead to deficiency of neurotransmitters.

In view of the single gene and its single protein product that are defective in PKU, this disorder would seem a good candidate for gene therapy. It has not been considered a high priority, however, because of the effectiveness of dietary restriction of phenylalanine. When procedures for gene therapy have been sufficiently developed and tested, it is likely that they will be applied to PKU. Introduction of functional PAH genes during the neonatal period should cure the metabolic defect. This, in effect, was the case with one young boy who received a liver transplant for reasons unrelated to his PKU status.

The successful treatment of PKU by diet has led to the problem of maternal PKU, which occurs in successfully treated women who are homozygous for PKU and whose offspring therefore are heterozygous. The developing fetus, although genetically normal (but heterozygous), depends on the mother to regulate blood phenylalanine. The fetus is also highly susceptible to moderate increases in blood phenylalanine. Prior to conception and during pregnancy, a PKU mother must regulate her blood phenylalanine levels rigorously to avoid damage to the fetus. The recommended maximal level is 360 μM.

One consequence of introducing screening was the recognition that some children have levels of phenylalanine that are above normal but that do not reach the levels that lead to pathology and that do not require dietary management. These cases of "hyperphenylalaninemia," defined as plasma levels >120 μM, are often due to homozygosity for PAH alleles that have low but nonzero enzyme activity. In other instances, the hyperphenylalaninemia is transient in neonates and disappears with time.

3. Other Defects That Interfere with Metabolism of Phenylalanine

In rare instances, high levels of blood phenylalanine are due to deficiencies of PAH activity caused by other loci. The cofactor 5,6,7,8-tetrahydrobiopterin (BH_4) is produced from 7,8-dihydrobiopterin (BH_2) by the enzyme dihydropteridine reductase (DHPR). The gene that codes for DHPR is on chromosome 4 at 4p15.31. In one form of PKU, loss of activity of this gene leads to absence of BH_4 and therefore to inactivity of PAH (Fig. 1). Because BH_4 is a cofactor in several other reactions that are important to brain function, dietary management of blood phenylalanine levels does not restore a normal phenotype. Such cases occur in 1 to 2 births per million.

A second rare variant of PKU is due to deficiency of 6-pyruvoyl tetrahydropterin synthase (Fig. 1), one of several enzymes necessary for BH_2 synthesis. This enzyme is coded by a gene on chromosome 11 at 11q22.3-q23.3. As in the case of DHPR deficiency, the neurological effects are not prevented by management of diet.

4. Molecular Genetics of PAH

The gene that codes for PAH is on chromosome 12 at 12q24.1. It is some 90 kb long with 13 exons. The messenger RNA is 2,677 nt long, consisting of 472 nt in the 5′ untranslated region, 1,356 nt (452 codons) in the coding sequence, and 849 nt in the 3′ untranslated region. Exons 1 to 12 are relatively small, varying in size from 57 nt to 197 nt. Exon 13 has 890 nt, of which 41 are coding. Introns vary in size from 1.0 kb to 23.5 kb.

Some 200 distinct mutations associated with PKU have been identified in the PAH gene. There are presumed to be many more that are associated with unrecognized hyperphenylalaninemia or that are normal variants. Some normal variants are known, and in a few instances they are polymorphic. Of the mutations that cause PKU, approximately three-fourths are nucleotide substitutions that lead to amino acid substitutions or premature chain termination. Another 25 or more are nucleotide substitutions that interfere with normal splicing of the RNA transcript. A number of small gene deletions have also been identified. A high frequency of mutations is found in exon 7, thought to be due to ascertainment bias rather than mutational hotspots. Almost any change in amino sequence in this region of the PAH molecule is likely to interfere with function.

A relatively small number of these mutations account for the majority of the cases of PKU, and particular mutations may be prevalent only in a limited population. Because several different mutations may occur with relatively high frequencies in a population, most so-called homozygotes are in fact compound heterozygotes, that is, the two alleles involve different mutations. Both, however, are nonfunctional. Comparison of mutations in European and Asian populations shows quite different spectra, indicating that most of the extant mutations arose after separation of the major races.

5. Population Genetics of PKU

The frequency of patients with PKU varies considerably among populations. In Norway, where PKU was first discovered, the frequency is ca. 1 in 14,000 births. Among Northern Europeans in general, the frequency is ca. 1 in 10,000 births, with a higher incidence of 1/4,500 in Ireland. Among U.S.

whites, the frequency is 1/8,000. The frequency among African-Americans is ca. 1/50,000. The frequency is very low in Ashkenazi Jews and Asians. A frequency of homozygotes of 1/10,000 corresponds to a gene frequency of 0.01 and a frequency of heterozygotes of 2%.

Investigation of PKU has been aided by the discovery of eight polymorphic DNA variants within the PKU gene. These were originally recognized as restriction fragment length polymorphisms, although now PCR is used for some sites. One of the sites involves different numbers of short tandem repeats, providing several alleles. Altogether, there are about 800 possible combinations (haplotypes) of "alleles" at these sites, of which only about 75 have been observed. Within a population, many fewer are observed, and usually only a few reach substantial frequencies.

The study of mutant-allele–haplotype associations in a variety of populations has provided insight into the origin and spread of the genes in historic and prehistoric periods. For example, the mutation R261Q is widespread in Europe but is always associated with haplotype **1**. In general, haplotype 1 has a normal PAH allele. The interpretation is that this particular mutation arose on a haplotype 1 chromosome, and all R261Q mutations are descended from that single mutational event. In contrast, the R408W mutation occurs in northwest Europe on a haplotype 1 background and in eastern Europe on a haplotype 2 background. This suggests that two independent mutations occurred, one in a Celtic population and the other in a Slavic population.

Phosphate Buffers

Phosphate buffers are commonly used in biological work. Phosphoric acid, , has pK_a values of about 2, 7, and 12. All three hydroxyl groups are identical and, indeed, all four oxygen atoms are identical on the NMR time scale as a result of rapid hydronations and dehydronations. Thus, 2 is the pK_a for the first H^+ to dissociate, even though it is coming equally from each of three groups. The next pK_a is raised to 7 because it is much harder for H^+ to dissociate from the charged ion than from the neutral H_3PO_4 molecule and, similarly, for the third pK_a. Hence, the Henderson–Hasselbalch equation for orthophosphate is

(1)

The large separation of the pK_a values means that, for a buffer of $H_2PO_4^-$ and HPO_4^{2-}, the concentrations of H_3PO_4 and PO_4^{3-} are negligible, and the pK_a values of 2 and 12 become irrelevant.

An advantage of phosphate as a buffer is that salts such as NaH_2PO_4 and Na_2HPO_4 are solid and both can be weighed out in the appropriate quantities; hence, the reproducible preparation of phosphate buffers need not involve adjustments of pH. Care must be taken, however, that the salt used, hydrate or anhydrous, does not lose or gain water on storage. Another advantage is that phosphate is transparent in the UV, down to wavelengths at which proteins may be estimated by their peptide bond absorbance, where carboxylate ions also absorb.

The main disadvantage is that with a doubly charged buffering species, the pK_a of 7.2 is three times more sensitive to changes in ionic strength than a buffer with only singly and zero charged components. Another disadvantage is that phosphate can support algal or fungal growth as a nutrient. Phosphate will also sequester and precipitate many cations, especially Ca^{2+} (see Calcium Signaling).

1. Diphosphate (pyrophosphate)

A variant of phosphate buffer is diphosphate (pyrophosphate). The acid, , has two strongly acidic groups, with pK_a values near 2, as with orthophosphate. The groups generated are electron-withdrawing, and so the next group has its pK_a lowered from the 7.2 of orthophosphate to 6.2 (at an ionic strength of 0.1 M; with its more strongly charged ions, the dissociation constants of diphosphate are even more sensitive than orthophosphate to changes in ionic strength). The group, however, is slightly electron-donating, so that the final pK_a is raised to 8.4. Hence, the Henderson–Hasselbalch equation for pyrophosphate in the neutral pH region is

(2)

Diphosphate can be hydrolyzed to orthophosphate, and the equilibrium strongly favors orthophosphate, but diphosphate is stable for long periods of time in neutral and alkaline conditions, even on heating.

Phosphatidylinositol

Phosphatidylinositol, generally abbreviated as PI or PtdIns, is a glycerophospholipid that has myo-inositol (one of nine stereoisomers of hexahydroxycyclohexane) as the polar head group. It is found in the membranes of eukaryotes and some eubacteria. Because of the anionic phosphodiester group, it contributes to the negative charge of the phospholipid bilayer. The free hydroxyl groups of PI can be phosphorylated or glycosylated to produce a wide variety of inositol phospholipids with specific functions. Two distinct types of inositol phospholipid have particularly important functions in eukaryotes that are described in separate entries:

1. Phosphatidylinositol phosphates are key components of several intracellular signaling pathways, either as the intact molecule or after they are cleaved by phospholipase C to 1,2-diacylglycerol and an inositol phosphate

2. Glycosylphosphatidylinositols (GPIs) can be covalently attached to the C-terminus of many proteins and are responsible for anchoring them to the membrane (see Membrane Anchors and GPI Anchor). GPIs may also occur in a “free form” without attached protein. Although the role of these free GPIs in mammalian cells is uncertain, they are an essential part of te protective coat used by many protozoal parasites.

Phosphatidylinositol Kinases

Phosphoinositides serve important functions in controlling the regulation of growth and differentiation in cells, as well as serving as substrates for the generation of inositol trisphosphate, IP_3 (see Inositol Lipids and Phosphates). In response to a variety of growth factors and cytokines, phosphatidylinositol (PI) is phosphorylated sequentially, to form the polyphosphoinositide PI-3,4,5-P_3 (PIP_3). These phosphorylations are catalyzed by the enzyme PI 3-kinase. The lipid products of this enzyme are not substrates for phospholipases, but instead have direct regulatory properties themselves.

PI 3-kinase has a number of domains for protein–protein interactions that contribute to its regulation and localization. The enzyme consists of a catalytic (p110) and regulatory (p85) subunit. p85 has two SH2 domains and one SH3 domain, which play a crucial role in regulation of the activity and targeting of the enzyme. Upon growth factor-receptor activation, p85 is recruited to receptors phosphorylated on tyrosine residues, or their substrates. The occupancy of these SH2 domains in p85 causes activation of the enzyme, while also serving to target it to the plasma membrane, or in some cases to intracellular membranes, where its lipid products can bind to proteins (1).

The generation of 3-phosphoinositides appears to play an important role in signal transduction. Activation of PI 3-kinase is necessary for the full expression of a number of tyrosine kinase receptors, including those for insulin, nerve growth factor, and others (1). Activation of the enzyme has been shown to prevent apoptosis in a number of cell types. Moreover, a retrovirus encoding PI 3-kinase was found to induce hemangiosarcomas in chickens, and mutations in the enzyme were associated with increased life span in *Caenorhabditis elegans*. Many advances in identifying the role of PI 3-kinase have come from the use of pharmacological inhibitors, such as wortmannin (1).

The targets of the lipid products of PI 3-kinase have received a great deal of attention. PI 3-kinase appears to play a universal role in membrane trafficking, perhaps explaining its wide importance in signal transduction. Cell adhesion molecules can also cause its activation, linking these events to changes in the actin cytoskeleton. Although there have been numerous reports on the essential role that PI 3-kinase plays in most aspects of signal transduction, most attention has focused on downstream changes in phosphorylation. There have now been a number of protein kinases that are activated after PI 3-kinase activation. One group belongs to the calcium-independent protein kinase C family members, especially z and q. Additionally, PIP_3 can induce a phosphorylation cascade. This involves the activation of the serine/threonine kinases PDK and Akt, which is also known as protein kinase B (PKB). It is now thought that PIP_3 can bind to the pleckstrin homology (PH) domain of these kinases, effectively recruiting them to the plasma membrane or intracellular membranes for activation. While PDK appears to be controlled mainly by targeting, it can phosphorylate and activate Akt, which in turn can phosphorylate a variety of intracellular substrates, including transcription factors, other kinases, proteins controlling apoptosis, and others (1).

Phosphofructokinase

Phosphofructokinase, or PFK (EC 2.7.1.11), is one of the best characterized allosteric enzymes. It catalyzes the step of glycolysis in which fructose-6-phosphate (FRU-6P) is phosphorylated to fructose-1,6-bisphosphate (FRU-1,6P_2) using either ATP or pyrophosphate (PP_i) as a phosphate donor. This enzyme is present in most types of eukaryotes and eubacteria but occurs rarely in archaebacteria. PFKs from animals, yeast, and most bacteria use ATP as a phosphate donor. Those that use PP_i are found in plants, protozoa, and some bacteria, often in addition to ATP-dependent enzymes. The amino acid sequences of most of the ATP-dependent PFKs are homologous, indicating that they form an evolutionary gene family. This family includes both “small” bacterial enzymes and “large” enzymes from mammals and yeast. It is a good model of enzyme evolution and of the appearance of “new” regulatory functions. PFK in most organisms is a highly regulated enzyme that has several allosteric effectors, and it controls (at least in part) the rate of glycolysis. The PFK from *Escherichia coli* has become a paradigm for the concerted allosteric model (1). X-ray crystallography, site-directed mutagenesis, and enzyme kinetic studies on bacterial ATP-dependent PFKs have also explained their catalytic and regulatory properties in some detail.

1. Isoenzymes

In humans (and probably in other mammals), there are three homologous types of PFK polypeptide chains, the muscle M, liver L, and platelet P isozymes. They are encoded by different genes, located on chromosomes 21, 1, and 10, respectively. All have several introns. The few cases of alternative splicing reported always lead to deletion of one exon and formation of a nonfunctional enzyme. Even though the M, L, and P type proteins are different, they share enough similarities assemble into active, multiple, heterologous oligomers, usually tetramers. The many different PFK isoforms generated in this way have somewhat different catalytic and regulatory properties, such as saturation by ATP and Fru-6P or sensitivity to allosteric effectors (2). Some species, such as *E. coli*, also have other minor proteins with PFK activity, but have unrelated amino acid sequences indicating that they do not belong to the main family of PFKs.

2. Metabolic Role

The reaction catalyzed by PFK, using either ATP or PP_i, is irreversible under physiological conditions. Its complex regulation by adenine nucleotides and by various metabolites indicates that PFK controls the production of cellular energy and the carbon flux between glucose and pyruvate. In several instances, the activity of PFK is coupled to that of pyruvate kinase because Fru-6P, the substrate of PFK, is an allosteric activator of one form of pyruvate kinase. This coupling is stronger in bacteria, where phosphoenolpyruvate (PEP), the substrate of pyruvate kinase, is the allosteric inhibitor of PFK. In some microorganisms (Gram-positive bacteria and mycoplasms, but not *E. coli*), the genetic expression of these two enzymes is coordinated. They catalyze reactions seven steps apart in glycolysis. In these cases, the genes that code for PFK and pyruvate kinase are adjacent on the chromosome and constitute an operon under transcriptional control by the same promoter (3).

The enzymatic (and sometimes genetic) coupling between two enzymes that each catalyze irreversible phosphoryl transfer steps is probably crucial for controlling the glycolytic flux, especially in anaerobes that use glycolytic fermentation as their main energy-producing pathway.

3. Primary Structures and Evolution

Most of the ATP-dependent PFKs, whether from animals, yeasts, or bacteria, have homologous sequences and belong to an evolutionary gene family. The simplest members of this family are bacterial PFKs whose polypeptide chains are about 35 kDa. Mammalian PFKs are approximately twice as large, about 80 kDa, and have an internal sequence repeat. Their N- and C-terminal halves are homologous and both resemble bacterial PFKs. This suggests that they have been produced by tandem gene duplication and fusion (4). All of the important active site residues are conserved in the N-terminal half, indicating a catalytic function, whereas replacement of several crucial residues, notably that of Asp127 by Ser, suggests that the C-terminal half is inactive. Yeast PFK is composed of two types of related chains, a of 108 kDa and b of 105 kDa. Each has a segment homologous to mammalian PFKs and unrelated N- and C-terminal extensions. These chains have formed by duplication of a mammalian-like gene followed by independent acquisition of terminal extensions (Fig. 1). The distribution of residues crucial for catalysis, plus various kinetic studies, suggest that the active site is carried by the N-terminal half of the b-chain and that the a-chain has only a regulatory role. Homologous residues are referred to here by their numbers in the *E. coli* enzyme.

Figure 1. Evolution of PFKs suggested by the comparison of their primary sequences. The unrelated segments are represented by thin lines. Among the homologous segments, those that have retained a catalytic function are open, and those that have lost their catalytic abilities and evolved to acquire a regulatory function are crossed. The special weak crossing on the N-terminal segment of the yeast a chain reflects that the evidence in favor of a pure regulatory role is weaker than for the other eukaryotic PFKs.

PP_i-dependent PFKs are made of two homologous chains, each of which has a segment distantly related to bacterial PFKs. This suggests that all PFKs might derive from the same ancestral protein (Fig. 1). The conservation of critical residues indicates that the catalytic site is on the b-chain and that the a-chain is regulatory.

4. Quaternary Structure

Bacterial and mammalian PFKs are active as tetramers and are inactivated upon dissociation into dimers (see Quaternary Structure). The allosteric inhibition of the PFK from *Thermus thermoaquaticus* by PEP involves such a dissociation. The crystal structures of bacterial PFKs explain why an oligomeric state is required for activity. The Fru-6-P binding site is at the interface between two subunits. The fructose moiety interacts with one subunit and the 6-phosphate group with the other (5). Under some conditions, tetrameric mammalian PFKs associate further into octamers and even more complex structures. They are active, but the role of this aggregation is not clear. PP_i-dependent PFKs also have a tetrameric structure that contains two a- and two b-chains. Yeast PFK is active only as an octamer that has four a- and four b-chains.

5. Catalytic Mechanism of Phosphoryl Transfer

Experiments with chiral (^{16}O, ^{17}O, and ^{18}O)-ATP have shown that transfer of the g-phosphate from ATP to Fru-6P occurs directly within a ternary complex (6) without a phosphoryl–enzyme intermediate. Steady-state kinetics are compatible with a random order of substrate binding, and the pH-dependence of the maximum velocity suggests that $Mg^{2+}\cdot ATP^{4-}$ is the most active ionic form (7).

X-ray crystallography of bacterial PFKs and site-directed mutagenesis suggest that several PFK active site groups are involved in catalyzing phosphoryl transfer (Fig. 2). The deprotonated side chain of Asp127 acts as a base and abstracts a proton from the 1-OH group of Fru-6P so as to increase its nucleophilicity. Mutation of Asp127 to Ser decreases the catalytic rate constant 10^4-fold (8). The transferred phosphoryl group is stabilized by interactions with the magnesium ion, by the positive charge of Arg72, and by a hydrogen bond to Thr125. The deprotonated side chains of Asp103 and Asp129 hold the magnesium ion that contributes electrostatic catalysis. The amide NH of Gly104 makes a hydrogen bond with the bg-oxygen bridge to facilitate cleavage of the O–P bond (5). X-ray crystallography also shows that the active site of *E. coli* PFK takes two conformations, one “open” that binds substrates and releases products and one “closed” in which catalysis occurs (5). Rapid kinetics have shown that conformational changes indeed occur in *E. coli* PFK upon substrate binding (and/or product release) and that these changes are slow enough to be rate-limiting in some conditions for the catalytic cycle (9).

Figure 2. The transition state of the reaction catalyzed by PFK with the main interactions with the active site as suggested by X-ray crystallography (5) and site-directed mutagenesis. The residues shown are conserved in all of the active PFKs except for Thr125, replaced by a serine in eukaryotic PFKs, which conserves an OH group. The partial covalent bonds are indicated by broken lines, and the hydrogen and electrostatic bonds by dotted lines.

6. Purification and assay of activity

Most PFKs are purified by affinity chromatography using a nucleotide analog covalently coupled to a resin. The usual assay measures the formation of Fru-1,6P$_2$ by coupling it to the disappearance of

NADH using aldolase, triosephosphate isomerase, and glycerol-phosphate dehydrogenase (10, 11).

7. Regulation of activity

The catalytic activities of all PFKs are sensitive to pH, ionic strength, divalent metal ions and/or their chelators (the real substrate is the ATP – Mg^{2+} complex), and phosphate, , and K^+ ions (10, 11). In addition, PFKs often have complex regulatory properties, such as sensitivity to allosteric effectors and/or a cooperative saturation by the substrate Fru-6P. Only a few (eg, that from Dictyostelium discoideum) follow Michaelis–Menten kinetics under all conditions studied.

7.1. Allosteric Effectors

The activities of PFKs are modulated by several allosteric effectors that differ among various organisms (Table 1). Most of these effectors do not modify the maximum velocity, but affect only the saturation by Fru-6P, influencing the cooperativity and/or half-saturating concentration. All PFKs are activated by an increase in levels of ADP and/or AMP, which would express a shortage of cell energy (see Adenylate Charge). In addition, most eukaryotic PFKs are strongly inhibited allosterically by ATP, and show nonhyperbolic ATP saturation. Because of this inhibition by ATP, PFK in the liver is almost inactive with the *in vivo* concentrations of Fru-6P and ATP, and the total PFK activity is much too low to account for the glycolytic flux measured *in vivo*. This discrepancy between the expected and measured glycolytic flux led to the discovery of the most potent allosteric activator of eukaryotic PFKs, Fru-2,6P_2, which relieves allosteric inhibition by ATP (12). The concentration of Fru-2,6P_2 in mammalian cells is controlled by hormones that act on cell metabolism through cAMP and protein kinase A. Fru-2,6P_2 decreases when cAMP increases. This hormonal control of PFK activity via Fru-2,6P_2 regulates the balance between the degradation of glycogen and the synthesis of glucose and/or lipids. Fru-1,6P_2 also activates PFKs, but with a much lower affinity than Fru-2,6P_2 (12).

Table 1. The Main Effects of PFK in Different Organisms

PFKs from	Activation	Inhibition
Bacteria	ADP or GDP[a]	PEP
Mammals[b]	AMP.ADP	Citrate
	Fru-2.6P_2	ATP
Yeast	AMP.ADP	Citrate
	Fru-2.6P_2	ATP

[a] ADP is probably the physiological effector, but GDP has been used to activate bacterial PFKs in many kinetic studies because ADP is also a competitive inhibitor of the substrate ATP.

[b] The three different isotypes of PFK in mammalian cells are sensitive to the same effectors but to varying extents.

Most eukaryotic PFKs are also allosterically inhibited by citrate, the first metabolite in the Krebs cycle. Citrate inhibition is responsible for the “Pasteur effect” in yeast, a decrease of glucose consumption upon shift from anaerobic to aerobic growth. Indeed, the reoxidation of NADH by oxygen via the respiratory chain raises the level of the Krebs cycle intermediates, and the citrate inhibition of PFK decreases the rate of glycolysis.

Bacterial PFKs are insensitive to citrate, but are sensitive to feedback inhibition by PEP, the penultimate end product of glycolysis.

7.2. Appearance of “New” Regulatory Functions upon Evolution of Sites

The variety of allosteric effectors of PFKs can be explained by their evolution. Bacterial PFKs originally possessed an active site that binds both ATP and Fru-6P, plus an effector site that binds ADP or PEP. After the gene duplication and fusion that doubled the polypeptide chain, the active site on the N-terminal half retained its function, whereas that on the C-terminal active site evolved into a regulatory site (Fig. 1). The Fru-6P subsite became the activation site for Fru-2,6P_2 and the ATP subsite became an inhibitory site. Similarly, evolution could have modified an inhibitory site for PEP in bacterial PFKs into one for citrate in eukaryotic PFKs. The evolution from bacterial to eukaryotic PFKs has also created the structural elements needed for communication between the active site and the “new” regulatory sites.

7.3. The Cooperativity of *E. coli* PFK toward Fru-6P and the Concerted Model of Monod, Wyman, and Changeux

The steady-state kinetics of *E. coli* PFK were the first to be analyzed according to the concerted allosteric model. Quantitative agreement between experimental data and predictions from the model was remarkable (1). According to the model, the protein is in equilibrium between two conformational states, R and T. The active R state has a much higher affinity for Fru-6P and for the activator ADP (or GDP), whereas the inactive T state has a much higher affinity for the inhibitor PEP. In the absence of ligand, the equilibrium between the R and T states of free PFK largely favors T, and the a ratio $T_0/R_0 = 4\times10^6$ (1). The simplicity of the concerted model is that a unique transition between the two states R and T is involved in both the cooperativity toward Fru-6P and the influence of allosteric effectors. Some bacterial PFKs show sigmoïdal saturations by Fru-6P only in the presence of the inhibitor PEP, confirming that the transition into an inactive state induced by PEP and the cooperativity toward Fru-6P are related.

The crystal structure of the complex between a bacterial PFK and an analog of the inhibitor PEP shows that the latter is bound to a regulatory site remote from the active site and that the protein has changed its quaternary conformation. The change induced by PEP closes the Fru-6P binding site (13). This is consistent with the observation that PEP inhibits by decreasing PFK's apparent affinity for Fru-6P. Some residues that bind PEP are also involved in binding the allosteric activator ADP when PFK is in its active conformation. The opposite effects of binding activators and inhibitors to a single effector site result because it has two mutually exclusive conformations, that agree with the concerted allosteric model. The quaternary structure of the inactive conformation is less stable, which explains the PEP-induced dissociation of the PFK from *T. thermoaquaticus*

However, the transition between the two states R and T seen by X-ray crystallography cannot explain entirely the cooperativity of *E. coli* PFK toward Fru-6P. In the absence of ligand, free PFK is not in the inactive T_0 state because (1) its crystal structure is that of the R state (14), and (2) it binds Fru-6P with high affinity and without any cooperativity (15). Presteady-state kinetics show that binding substrates and/or effectors to *E. coli* PFK is accompanied by conformational changes within the R state, which are slow enough to be rate-limiting for the catalytic cycle. Thus, the cooperativity of *E. coli* PFK is in part independent of the transition between the crystallographic R and T states and is due to a change in the rate-limiting step from a conformational change at low Fru-6P concentrations to phosphoryl transfer at high Fru-6P (9). Such a kinetic origin of cooperativity explains observations with some mutants that are difficult to fit with the concerted model, such as values of the Hill coefficient larger than the number of Fru-6P binding sites (16) and reversal of the influence of effectors, when PEP becomes an activator (17) and GDP an inhibitor.

7.4. Phosphorylation of Mammalian PFKs by Protein Kinase A

Mammalian PFKs are phosphorylated on specific sites by protein kinase A. This produces changes in kinetic properties and in the tendency to aggregate into octamers, but the physiological role of this phosphorylation is unknown.

Phospholipases

Phospholipases hydrolyze membrane phospholipids (see Lipases). The lipid substrates for these enzymes are usually quite specific. Hormone-regulated phospholipase C (PLC) can hydrolyze a number of membrane phospholipids, including phosphatidylcholine and phosphatidylethanolamine. Phosphatidylinositol (PI) and its phosphorylated derivatives (polyphosphoinositides) are the most common substrates involved in second messenger generation, producing soluble inositol phosphates, such as inositol trisphosphate (IP_3), that are involved in calcium signaling.

Phospholipase D enzymes usually prefer phosphatidylcholine as substrate, generating phosphatidic acid and choline. Phosphatidic acid has been proposed to mediate a variety of biological responses involved in mitogenesis and protein trafficking (1).

The turnover of polyphosphoinositides occurs in a cycle of hydrolysis and resynthesis, called the “PI cycle.” PI is phosphorylated sequentially on the 4 and 5 hydroxyl groups of the inositol ring, to produce PI-4,5-P_2. Upon hormonal activation, PLC subsequently catalyzes the phosphodiesteratic cleavage of this lipid, resulting in the generation of diacylglycerol and IP_3 in the cell. After its degradation, PI can be resynthesized by the phosphorylation of diacylglycerol to PA, via the activity of a diacylglycerol kinase and the subsequent synthesis of PI via PI synthase. Thus, this cycle results in the generation of two potential second messengers, the membrane-associated diacylglycerol, which can activate protein kinase C, as well as IP_3, which can lead to the mobilization of intracellular calcium levels.

Several forms of PI-PLC have been identified (1). These proteins all exhibit an absolute requirement for calcium and are equally capable of hydrolyzing PI and the polyphosphoinositides PIP and PI-4,5-P_2. These proteins exist in three subfamilies, b, g, and d, each with multiple members. They have a number of conserved and divergent domains, reflecting their differential regulation. All three subclasses have a pleckstrin homology (PH) domain, which probably mediates some type of interaction with lipids in the membrane, and an EF-hand motif, presumably involved in calcium binding. Moreover, there are two additional conserved domains, designated X and Y, that contain the catalytic core of the enzyme; there is also a conserved C2 domain, also likely to be required for calcium interaction. PLCg, which is regulated by tyrosine kinase receptors, contains two SH2 domains and one SH3 domain and has been shown to undergo phosphorylation of tyrosine residues. PLCb is responsible for regulation through G-protein-coupled receptors and is generally regulated by a subunits of the Gq family of heterotrimeric G proteins, linked to a subset of such receptors. Additionally, their bg subunits have also been shown to regulate PLCb, although the efficacy of this activation is not comparable to that seen with Gqa. PLCb can also act as an activator of the GTPase activity of Gq, effectively behaving as a GTPase activating protein (GAP).

Phospholipases C

1. Historical Perspective

The phosphatidylinositol (PI)-specific phospholipases C have emerged as key and determining components of the PI cycle of signal transduction. In this pathway, the action of any of several extracellular agents (including hormones, cytokines, neurotransmitters, and xenobiotics) results in activation of PI-specific phospholipases C that cleave phosphatidylinositol bisphosphate (PIP_2) (1-3). This results in the formation of inositol trisphosphate (IP_3) and diacylglycerol (DAG), which act as important second messengers involved in the regulation of calcium signaling and protein kinase C, respectively (Fig. 1).

Figure 1. Regulation and function of the phosphatidylinositol (PI) cycle. The scheme illustrates two mechanisms for

activation of the PI cycle through (1) direct phosphorylation of phospholipase C g by tyrosine kinase receptors, and (2) G proteins in the case of G-protein-coupled receptors. The two products of PIP_2 hydrolysis, IP_3 and diacylglycerol (DAG) function as second messengers in activating calcium release and protein kinase C, respectively. Resynthesis of PIP_2 from DAG completes the PI cycle.

Early insight into the PI cycle came from studies by Hokin and Hokin, who identified turnover of inositol phospholipids in cells stimulated with acetylcholine. Work over the ensuing decades resulted in the delineation of the biochemical components of the PI cycle and the realization of its intimate connection to changes in calcium levels in the cells. Thus, it became appreciated that specific phospholipases of the C type were activated in response to acetylcholine and other hormones. It was also appreciated that PIP_2 was the preferred substrate in this pathway and that this was coupled to changes in calcium homeostasis (3). It was then determined that the IP_3 product of this reaction acted directly on specific receptors internal to the cell to cause changes in the levels of free calcium. Contemporaneously, a direct connection was made between DAG and protein kinase C, demonstrating a second messenger function for DAG (4, 5).

2. Regulation of Phospholipase C

PI-specific phospholipases C have been purified and cloned. They exist as a family of related phospholipases with close similarity in catalytic activity and preference for PIP_2 as a substrate, but with distinct mechanisms of regulation (1). Notably, the two best-studied members of the family, phospholipase Cb and phospholipase Cg, are coupled through distinct mechanisms to two different classes of membrane receptors. G protein–coupled receptors regulate phospholipase Cb through direct activation by hetero-trimeric G proteins. On the other hand, phospholipase Cg is tyrosine phosphorylated (see Phosphorylation, Protein) by transmembrane tyrosine kinase receptors (and also by nonreceptor tyrosine kinases) through interactions with specific SH2 modules in phospholipase Cg that are recognized by specific SH2-binding domains in the tyrosine kinases (Fig. 1).

2.1. Role of Phospholipases C in Signal Transduction and Cell Biology

Given their intimate coupling to two major classes of transmembrane receptors, phospholipases C serve a critical role in allowing the ligands of these receptors to regulate the intracellular levels of calcium and the activity of protein kinase C. This is accomplished by the activity of the two products of the phospholipase C reaction. IP_3 is a hydrophilic and diffusable small molecule that interacts specifically and with high affinity with the IP_3 receptor in the endoplasmic reticulum. This results in release of calcium from stores in the endoplasmic reticulum into the cytosol. In turn, free calcium appears to coordinate a variety of cellular responses through the activation of various enzymes, including protein kinases and phosphodiesterases (see Calcium Signaling). Simultaneously, DAG, which is formed in the membrane, activates several members of the protein kinase C family. Protein kinase C is capable of phosphorylating a variety of substrates that result in the regulation of diverse biological responses. Protein kinase C is also activated potently by phorbol esters, which are plant toxins that cause a myriad of cellular responses, including effects on blood cell activation, cell growth regulation, tumor promotion, memory formation, immune responses, inflammatory reactions, hormone release, and neurotransmission, most likely through activation of protein kinase C (4). Therefore, the two products of the phospholipase C reaction serve as critical second messengers, often acting in synergy to regulate a variety of cellular responses.

Phosphorous Isotopes

Phosphorus is element number 15 in the periodic table and has valence states of 3 or 5 (1). Seventeen isotopes have been identified (2), ranging in atomic mass number from ^{26}P to ^{42}P, most of which have physical half-lives of seconds or milliseconds and do not have important applications. Only one stable isotope of phosphorus is found in nature (^{31}P).

The most important radioactive isotope of phosphorus is ^{32}P (half-life = 14.29 days) (see Radioisotopes). It undergoes beta-minus decay to ^{32}S, which is stable. Phosphorus-32 yields one beta particle per decay, with an energy of 1.71 MeV maximum, 0.695 MeV on average. Another useful radioisotope of phosphorus is ^{33}P (half-life = 25.4days). It yields one beta particle per decay, with an energy of 0.1667 MeV maximum, 0.0486 MeV on average.

Phosphorus-32 is usually prepared in an accelerator by bombarding a stable sulfur target with deuterons according to the reaction $^{34}S(d,a)^{32}P$. It may also be prepared by accelerator deuteron bombardment of ^{31}P according to the reaction $^{31}P(d,p)^{32}P$ or by reactor neutron-activation according to $^{31}P(n,g)^{32}P$. Carrier-free radioisotope is prepared by reactor production according to the reaction $^{32}S(n,p)^{32}P$.

Phosphorus-32 was first made by Fermi in 1934 using neutrons from a radium–beryllium source (3). In 1935, Hevesey made ^{32}P by the same method and studied the metabolism of phosphorus compounds in rats (3). Hevesey also studied blood volume using ^{32}P-labeled red blood cells. When it was found that ^{32}P killed blood cells, Lawrence produced it in a cyclotron and in 1938 was the first to use it as a therapeutic radioisotope for treatment of leukemia in humans (3). Phosphorus-32 is presently used as an effective treatment for polycythemia vera (4, 5), for treatment of painful bone metastases from prostate and other cancers (6), for restenosis stents in treating heart disease, and in colloidal form for direct intratumoral injection, or infusional brachytherapy (7). The systemic use of ^{32}P has been limited by concerns over potential leukemogenic effects.

As a diagnostic agent, ^{32}P has been used to study skeletal growth and bone tumor kinetics. In molecular biology, ^{32}P is used primarily to label nucleic acids, which have one phosphorous atom per nucleotide, and for phosphorylation of proteins. Phosphorus-32 is readily detected by beta-particle liquid scintillation counting, Cerenkov radiation detectors, autoradiography, and fluorography.

Phosphorylase Kinase

Phosphorylase kinase (E.C. 2.7.1.38) catalyzes the phosphorylation of residue Ser14 in relatively inactive glycogen phosphorylase b, converting it to the much more active phosphorylase a. Its discovery in 1955 by Fischer and Krebs, and their later demonstration that the enzyme converting phosphorylase a to b is a protein phosphatase that removed the phosphate, provided a firm basis for further investigation of the first metabolically interconvertible enzyme system to be discovered. These investigators and their colleagues characterized phosphorylase kinase and demonstrated that it was itself activated by phosphorylation by cyclic AMP (cAMP)-dependent protein kinase (cAPK), thus suggesting the famous cascade system for the regulation of glycogen metabolism by hormones. In addition, it was discovered in this same laboratory that Ca^{2+} is required for activity, and later by Drummond et al. that the activation of glycogenolysis is coordinated to muscular contraction by the release of calcium from the endoplasmic reticulum in response to nervous stimulation (see Calcium Signaling). It was not until 1978 that the small calcium-binding protein calmodulin was found to be an integral part of phosphorylase kinase responsible for the allosteric activation by Ca^{2+}. Calmodulin was designated subunit d because three other subunits, the regulatory a and b and the catalytic g, were already known. Each is present in four copies, so the holoenzyme may be represented as $a_4b_4g_4d_4$ with an overall molecular weight of 1.3 million. This enormous protein presents a formidable challenge to investigators, but the subunits have been isolated and their primary sequences determined, while progress is being made on their functions and on the complex regulation of this enzyme. The gene for the catalytic domain of subunit g has been cloned, and the structure of the subunit determined by X-ray crystallography, so the molecular basis of the catalytic activity has been elucidated. The comprehensive review by Picket-Gies and Walsh (1) covers the literature until 1986 and can be used as the essential reference for this article. It is suggested for further reading.

1. Structure and Function

The molecular weights of the subunits have been determined by sequence analyses (2) and are a = 138,422, b = 125,205, g = 44,673, and d = 16,680. Various analyses by electron microscopy of $a_4b_4g_4d_4$ show a bilobed butterfly-like structure that may be cleaved by trypsin into two halves, suggesting that the subunits are arranged as a bridged dimer of octamers ($a_2b_2g_2d_2$), while another study found a “chalice” form. These observations have been reconciled by a three-dimensional model that can account for all views (3). Essentially there are three twofold axes of symmetry relating the four abgd_protomers, resulting in a tetrahedral arrangement. Proteolytic digestion suggests that the b subunits play an essential role in holding the holoenzyme together, but there are additional interactions of other subunits. Lithium bromide causes dissociation into two complexes, agd_and gd;_both of these have activity toward phosphorylase b equal to that of the holoenzyme.

The determination of the amino acid sequences of all four subunits provided valuable insights into their various functions. The g subunit proved to have substantial homology with the catalytic subunit of cAPK. There is an additional C-terminal region (approximately residues 286 to 386) that can be removed by chymotrypsin, to yield a catalytic domain (residues 1 to 285) with full activity and no calmodulin/Ca^{2+} sensitivity. The C-terminal or regulatory domain contains two calmodulin-binding domains, suggesting a double binding mode that accounts for the unusual phenomenon that calmodulin binds to the isolated g subunit in the absence of calcium, becoming subunit d, and suppresses its activity. Troponin C, which is homologous to calmodulin, also binds to the g subunit and may provide a more direct link between the neural activation of skeletal muscle contraction and glycogenolysis. The a and b subunits are highly homologous, suggesting a common ancestral protein. Both have calmodulin-binding domains, but apparently only one extrinsic calmodulin binds per pair of a/b units, known as d subunits, in the intact holoenzyme in the presence of excess calcium, resulting in four d subunits in all. The b subunit contains two sites for phosphorylation by cAPK, on Ser26 and Ser700. The two sites appear to be phosphorylated equally rapidly, and either one results in an increase in activity of the holoenzyme, but a total of only one phosphate per subunit is found. The rate of phosphate incorporation into the b subunit is 5- to 10-fold faster than that into the a subunit and is a prerequisite for the latter, suggesting a conformational change. The a subunit is phosphorylated at Ser1018 by cAPK, with resultant increases in activity. Both the a and b subunits have several sites for autophosphorylation, but the evidence that this phenomenon has significance for *in vivo* regulation is ambiguous.

Kinetics of the phosphorylase kinase reaction were studied using a tetradecapeptide from phosphorylase b (residues 5 to 18) that contained the phosphorylatable Ser14 in order to avoid substrate-directed effects. The kinetic mechanism was found to be rapid equilibrium random Bi–Bi, indicating that either ATP or the protein can bind first and that the phosphoryl transfer step in the ternary complex is rate-limiting. Several studies on the effects of deleting or substituting various amino acid residues of the peptide permit one to conclude that the kinase shows a marked preference for peptides having the natural sequence around Ser14, while the latter is also important because a Thr14 peptide has a very low rate of phosphorylation. Because the first 18 residues of phosphorylase b are disordered, it is not surprising that the corresponding peptide, presumably in a random conformation, should be a good substrate for the kinase. The kinase must, however, recognize more than just the N-terminal peptide, because the intact protein substrate has a K_m at least fivefold lower and a maximum velocity (V_{max}) fivefold greater. Phosphorylase kinase will also phosphorylate Ser7 of glycogen synthase, but this is also the target for other kinases, including cAPK (which does not act on phosphorylase), so the physiological significance of its action on this and several other proteins is not known.

The high-resolution structure of the crystallized catalytic domain of the g subunit has been determined by Johnson et al. (4) and compared to other protein kinases (5). The structure is very similar to that of cAPK and contains the same catalytic residues in equivalent positions. These include Lys57 to interact with the phosphates of ATP and Asp167 to interact with the Mg^{2+} of ATP/Mg^{2+}. An N-terminal lobe, mostly b-sheet, is connected to the a-helical C-terminal lobe by polypeptide chain, allowing opening and closing of the active site cleft between the two lobes. The suggested catalytic mechanism is that Asp149 abstracts a proton from the substrate serine residue and the resultant alcoholate ion attacks the terminal phosphate of ATP. In cAPK, an activation segment has Thr197 phosphate, which interacts with Arg165, next to the catalytic Asp166, and other basic residues, but in phosphorylase kinase this is replaced by Glu182, which forms an ionic link with Arg148 of the catalytic loop and serves the same function of maintaining Asp149 and other catalytic residues in the correct orientation.

2. Regulation

Because so many results from *in vitro* studies may have no physiological significance, only those most likely to apply *in vivo* will be considered here. Because nearly all the phosphorylase and 20% to 40% of the kinase are associated with the glycogen particle in muscle, the kinase action on phosphorylase must occur with the latter bound to glycogen by its catalytic face, leaving the control face with Ser14 exposed to the cytosol (see Glycogen Phosphorylase). It is relevant, then, that glycogen decreases the K_m for phosphorylase b 10-fold; and this is likely to be via conformational changes in the substrate, because glycogen has no effect on phosphorylation of the tetradacapeptide containing residues 5 to 18. The allosteric inhibitor of phosphorylase b, glucose-6-phosphate, also inhibits kinase activity on the protein, but not on the peptide, suggesting augmentation of the metabolite feedback. There is a good correlation between the increase of Ca^{2+} levels due to nervous or electrical stimulation, muscle contraction, and the activation of both phosphorylase kinase and its substrate, and this occurs without changes in either the level of cAMP or the phosphorylation state of the kinase. The molecular basis is the allosteric activation due to binding of Ca^{2+} to the d subunit and, at higher Ca^{2+} levels, of the binding of Ca^{2+}-calmodulin to the a/b_subunits (the d subunits). In contrast, the administration of adrenaline can cause coordinated changes in cAMP levels, activation of cADK and phosphorylase kinase, and formation of phosphorylase a. A point still in contention is whether or not Ca^{2+} is still an obligate requirement for kinase catalysis, as in vitro experiments suggest, but the increased affinity for the metal ion after phosphate incorporation into the b and_a_subunits may allow low endogenous levels to suffice. Heilmeyer (2) summarizes current knowledge of regulation, including a possible role for an allosteric ATP/Mg^{2+} site on the a subunit that may stimulate binding of the same substrate to the g subunit by displacing inhibitory ADP. He suggests that an ancestral gd phosphorylase kinase, responsive only to Ca^{2+}, could not handle all the signals needed to regulate the conversion of phosphorylase b to a. The addition of the two regulatory subunits b and_a permitted regulation by cAMP-dependent phosphorylation, extrinsic calmodulin, and substrate binding (ATP/Mg^{2+}).

Phosphorylation, Protein

Phosphorylation is a common, and usually reversible, post-translational modification of proteins. The amino acid residues that can be phosphorylated are listed in Table 1. Protein phosphorylation is either an intermediate step in the course of an enzymatic reaction or a more durable modification that regulates protein properties. This entry focuses on regulatory protein phosphorylation. In this context, the phosphorylation reaction is catalyzed by protein kinases, which form a specific class of phosphoryl-transferases, generally transferring the phosphoryl group from the g position of ATP (Fig. 1a, see exceptions below) to the side chain of an amino acid residue. The dephosphorylation reaction corresponds to the transfer of the phosphoryl group to a water molecule (ie, the hydrolysis of the phosphoester bond). Both reactions are energetically favorable and occur readily in the presence of the appropriate catalyst, a protein kinase or phosphatase. In a living cell, the level of phosphorylation of a protein is the result of a dynamic equilibrium between its rates of phosphorylation and dephosphorylation. As mentioned above, the phosphoryl donor is usually ATP, in complex with Mg^{2+}. In vitro, for some protein kinases, ATP or Mg^{2+} can be replaced by GTP or Mn^{2+}, respectively. In somewhat artificial conditions (eg, very low levels of ATP and high levels of ADP), protein kinases can catalyze the transfer of phosphoryl group from the phospho-amino acid of a protein to ADP, generating ATP. Although secreted proteins or peptides are known to be phosphorylated, the regulatory phosphorylation reactions that have been well-characterized to date take place within cells.

Figure 1. Major pathways of regulatory protein phosphorylation/dephosphorylation. (a) The most general case, observed in all types of living organisms, corresponds to phosphorylation of serine, threonine, or tyrosine residues by protein kinases using ATP/Mg^{2+} as phosphoryl donor. The dephosphorylation is catalyzed by a protein phosphatase,

usually distinct from the protein kinase. The activity of both the protein kinase and phosphatase can be regulated by intracellular or extracellular stimuli. The phosphorylated or the dephosphorylated forms of the protein substrate, or both, may be responsible for the biological response observed. (b) Although not as common as the previous phosphorylation system, the two-component system is widespread in eubacteria and has also been found in archaebacteria and eukaryotes. A "sensor protein kinase" autophosphorylates histidine residues in response to an environmental stimulus, using ATP/Mg^{2+} as phosphoryl donor. The phosphate is then transferred to an aspartate residue of a "response regulator," which may be located on the same polypeptide chain as the sensor kinase, or on a distinct one. The phosphorylated response regulator triggers the biological response. (c) The third phosphotransferase system has been described in bacteria only. In this system coupled to sugar transport, the phosphoryl group is transferred successively from phosphoenolpyruvate (PEP) to histidine and cysteine residues of several proteins (indicated with roman numerals) and to an incoming sugar. In addition to its function in sugar metabolism, this system has been shown to be coupled to several biological responses. HPr, histidine-containing phosphocarrier protein (see the text for references); Pi, inorganic phosphate; P, phosphate.

Table 1. Amino Acid Residues That Can Be Phosphorylated in Proteins

Acceptor group	Amino acid	Product
Alcohol	Serine, threonine	Phosphoester
Phenol	Tyrosine	Phosphoester
Basic amino acid	Histidine, arginine, lysine	Phosphoramidate
Thiol	Cysteine	Phosphate thioester
Acyl	Aspartate, glutamate	Mixed phosphate-carboxylate acid anhydride

1. Historical Perspective

Regulation by protein phosphorylation was discovered by Edmund Fischer and Edwin Krebs in the course of their studies of glycogen metabolism between 1955 and 1958 (1, 2). It was known from the work of Carl and Gerty Cori that glycogen phosphorylase, the enzyme that degrades glycogen, exists in two forms, an active form (phosphorylase a) and an inactive form (phosphorylase b). Fischer and Krebs showed that the only difference is that phosphorylase a is phosphorylated and they identified phosphorylase kinase, the protein kinase that phosphorylates phosphorylase b on Ser14, transforming it into the active phosphorylase a (Fig. 2). The same authors later showed that cyclic AMP, the intracellular second messenger formed under the action of epinephrine or glucagon, exerts its effects on glycogen catabolism by activating a protein kinase. This protein kinase, cyclic AMP-dependent protein kinase (or protein kinase A, PKA), phosphorylates and activates phosphorylase kinase. In skeletal muscle, they demonstrated that phosphorylase kinase is also activated by Ca^{2+}-calmodulin, allowing the coupling of metabolic events with contraction. Although it was originally thought that these reactions might be specific for the regulation of glycogen, the subsequent work of Paul Greengard and others showed that phosphorylation of proteins accounts for the action of many extracellular signals, and several protein kinases activated by cyclic GMP, Ca^{2+}-calmodulin and Ca^{2+}-lipids were discovered (3-5). During the same period, the protein phosphatases involved in the regulation of glycogen metabolism started to be studied methodically (6). This opened a new field, because it is now apparent that regulation of protein phosphatases is as important as regulation of protein kinases in the control of cell function. Another major step in the study of protein phosphorylation was the discovery of phosphorylated tyrosine residues by Tony Hunter in 1979 (7). Phosphotyrosine raised considerable interest when it was discovered that it is increased in cells transformed by viruses, and that v-src, and v-abl, two major viral oncogenes, are tyrosine kinases. Shortly thereafter, it was shown that growth factor receptors, which are transmembrane proteins, have an intrinsic tyrosine kinase activity associated with their intracellular domain (8) (see Tyrosine Kinase Receptors). This tyrosine kinase activity is stimulated upon binding of the growth factor to the extracellular domain of the receptor. Thus, it became evident that, in spite of its low abundance in normal cells, phosphotyrosine residues are a key step in the control of cell growth and differentiation. More recently, molecular cloning of genes has identified a very large number of protein kinases and phosphatases in all living organisms that have been studied. It is now apparent that protein phosphorylation is a fundamental mechanism of signal transduction used by all cells to regulate the properties of their proteins in response to external or internal clues. The list of fundamental biological processes regulated by protein phosphorylation would be nearly endless, but would include gene expression, energy production and storage, cell division and differentiation, as well as synaptic plasticity in the nervous system, which is thought to underlie learning and memory.

Figure 2. Regulation of glycogen degradation. The main pathways regulating glycogen degradation, the study of which led to the discovery of protein phosphorylation, are illustrated. Glycogen is degraded stepwise by glycogen phosphorylase. Schematically, glycogen phosphorylase exists in either a dephosphorylated inactive form (b) or a phosphorylated active form (a). The transformation of b-form to a-form is catalyzed by phosphorylase kinase. Phosphorylase kinase itself is activated by two independent pathways. In skeletal muscle, Ca^{2+} entering the cell during the action potential binds to calmodulin and activates phosphorylase kinase directly. In addition, phosphorylase kinase is activated by phosphorylation by cAMP-dependent protein kinase (PKA). PKA is directly stimulated by cyclic AMP (cAMP), which is generated in response to the stimulation of adenylyl cyclase by various seven transmembrane-segment G-protein-coupled receptors (e.g. receptors for epinephrine or glucagon). Dephosphorylation and inactivation of glycogen phosphorylase is catalyzed by several enzymes, the study of which led to the description and classification of protein phosphatases. See the text for references. Pi, inorganic phosphate; , phosphatase; ↑, activation.

2. Phosphorylation in Prokaryotes

Studies of protein phosphorylation in prokaryotes initially lagged behind those in eukaryotic cells. However, the paramount role of regulation by protein phosphorylation is now recognized in both Archea and Bacteria (9, 10). Bacteria possess ATP-dependent phosphorylation systems, using protein kinases that have sequence homologies with those of eukaryotes. These protein kinases phosphorylate serine or threonine residues and are, in many cases, regulated by cellular metabolites, rather than by second messengers. An original enzyme of bacteria is isocitrate dehydrogenase kinase/phosphatase of enteric bacteria, which has combined phosphatase and kinase activities located on the same polypeptide chain (11). A second system of protein phosphorylation in eubacteria corresponds to the sensor kinase/response regulator, often termed the two-component system (12). In such systems, a sensor kinase, generally membrane-associated, phosphorylates itself on a histidine residue in response to external stimuli [eg, chemoattractant, nutrient, osmotic pressure, etc. (Fig. 1b)]. The phosphoryl group is then transferred to an aspartic acid residue located on a distinct protein or on the same polypeptide chain, the response regulator, triggering the appropriate biochemical response. This type of signal transduction seems to be evolutionarily very ancient, because it has now been also identified in Eucarya and Archea (10). In the third phosphorylation system, described thus far only in bacteria, the phosphoryl group donated by phosphoenolpyruvate (PEP) is passed down a chain of phosphorylatable proteins (9). Phosphorylation of these proteins occur on histidine and cysteine residues (Fig. 1c). Such PEP-dependent systems are implicated in a wide variety of regulations, including carbohydrate metabolism, transcription, and adenylate cyclase. Protein phosphatases are less well-characterized in prokaryotes. Relatives of the PPP phospho-serine/threonine protein phosphatase gene family have been identified in Archea and in eubacterial bacteriophages (10). Finally, it should be noted that bona fide tyrosine phosphorylation has been demonstrated in bacteria, as well as the presence of potential tyrosine phosphatases that bear a similar sequence signature to that of eukaryotic tyrosine phosphatases in their active site (10).

3. Phosphorylation in Eukaryotes

Regulatory protein phosphorylation in eukaryotes occurs primarily on serine, threonine, and tyrosine residues (Fig. 1a). The great majority of the protein kinases responsible for the phosphorylation of these residues have a conserved catalytic domain that belongs to a single gene family. It has been estimated that more than a thousand different protein kinases can be coded in the genome of higher eukaryotes (13, 14). The genome of *Saccharomyces cerevisiae* contains genes for 113 such conventional protein kinases (15). Interestingly, a number of lipid kinases have a catalytic domain related to that of conventional protein kinases. Some of these enzymes are capable of autophosphorylation; and at least one of them, DNA-PK, is a genuine protein kinase, stimulated by the ends of double-stranded DNA (16). In addition, histidine kinases related to the bacterial two-component system have been identified in several eukaryotes (Fig. 1b). They are, for example, involved in the responses of yeast to osmotic shock (17) and of plants to ethylene (18). An original group of serine kinases related to histidine kinases corresponds to the mitochondrial protein kinase that phosphorylates a-ketoacid dehydrogenases (11).

The catalytic domains of regulatory protein phosphatases in eukaryotes belong to several gene families: Serine/threonine phosphatases belong to two gene families of metal-requiring enzymes, PPP and PPM (19), whereas tyrosine and dual-specificity phosphatases form a superfamily of genes that have a common signature sequence in their active site (Cys–X_5–Arg) and a common catalytic mechanism. These enzymes are grouped in four families: classical phosphotyrosine phosphatases (PTPs), low-molecular-weight PTPs, VH1-like dual-specificity phosphatases, and cdc25-like dual-specificity phosphatases (20).

4. Specificity of Protein Phosphorylation

Protein kinases display a high degree of substrate specificity. First, the vast majority phosphorylate either serine/threonine or tyrosine side chains, whereas only a few kinases have a dual specificity, for both threonine and tyrosine. In addition, protein kinases are highly sensitive to the immediate environment of the phosphorylated residue (21). Thus, specific consensus sequences have been identified for many of them (Table 2). In some cases, the specificity also depends on higher-order determinants, such as interactions between the protein substrate and the protein kinase at sites located at distance from the phosphorylated residue. In living cells, the proximity between the protein kinase and its substrate plays an important role. This is achieved by specific targeting mechanisms, which enrich the kinase concentration at particular sites of the cell (22, 23). There are also a number of scaffolding proteins that associate several enzymes, including kinases and/or phosphatases and their substrates (24). In the case of protein phosphatases, the nature of the sequence surrounding the phospho-amino acid to be dephosphorylated seems generally less critical than in the case of protein kinase, and the role of higher-order determinants, as well as that of targeting processes, appears fundamental (25, 26). It should be pointed out that, with the exception of some monosubstrate systems, there is no perfect match between the substrate specificity of most protein kinases and phosphatases, implying a complex intertwining of the regulation by these enzymes.

Table 2. Examples of Consensus Phosphorylation Sites for Protein Kinase

cAMP-dependent protein kinase	Arg/Lys-Arg-Xxx-Ser*
Ca^{2+}-calmodulin-dependent kinase II	ArgXxxXxxSer*/Thr*
Protein kinase C	Arg/Lys (Xxx)1-2 Ser*/Thr* Xxx-Arg/Lys
Casein kinase 1	Acid-Xxx-Xxx-Ser*
Casein kinase 2	Ser*/Thr* Xxx-Xxx Asp/Glu
MAP-kinases, cyclin-dependent kinases	Ser*/Thr* Pro
EGF-receptor tyrosine kinase	Glu/Asp-Tyr*-Hyd

5. Methods to Study Protein Phosphorylation

5.1. General Methods to Study the State of Phosphorylation of Proteins

(detailed descriptions of methods can be found in Ref. 27-30). The most commonly used approach is metabolic radiolabeling of cells of interest with ^{32}P-orthophosphoric acid (sometimes called "front-phosphorylation"). ^{32}Pi is taken up by cells, incorporated into endogenous ATP (as well as in many other phosphorylated molecules), and used to phosphorylate proteins, lipids, and nucleic acids. Labeled phosphoproteins can be studied by electrophoresis (usually two-dimensional gel electrophoresis) or following immunoprecipitation with specific antibodies. However, proteins are often phosphorylated on several sites, which can have different physiological meanings, and other approaches are required to analyze independently the phosphorylation of each of them (see below). Moreover, the amount of ^{32}P incorporated in a given site does not reflect directly the stoichiometry of phosphorylation of this site, but rather the turnover rate of the phosphoryl group. That is, a site phosphorylated at a high stoichiometry but with a low turnover rate (eg, "constitutive phosphorylation") will appear poorly labeled, whereas a residue phosphorylated at a low stoichiometry, but with a high turnover rate, will appear intensely labeled. The levels of labeling are also dependent on the specific activity of the intracellular ATP pools, which may vary, depending on the cell population or physiological status. Therefore, other methods have been developed to avoid these pitfalls. In "back-phosphorylation" assays, proteins of interest are isolated in conditions in which their phosphorylation state is preserved. They are then phosphorylated stoichiometrically *in vitro* with g^{32}P-ATP and a purified kinase, active on the phosphorylation site of interest. Thus, the higher the level of phosphorylation of the site *in vivo*, the lesser radioactive phosphate is incorporated *in vitro*. The use of this method is limited, however, by the requirement for a highly active purified protein kinase and by its low sensitivity. An alternative approach that is enjoying considerable success is the use of phosphorylation-state-specific antibodies. Some of these antibodies react with a phosphorylated amino acid, almost independently of its sequence environment. For example, antibodies specific for phospho-tyrosine are extremely useful tools in the study of protein tyrosine phosphorylation. Moreover, specific antibodies can be raised against synthetic phosphopeptides encompassing the phosphorylation site of a protein of interest. Such antibodies are specific for a given protein phosphorylated at a particular site, and they provide powerful tools that can be used for immunoblotting, immunocytochemistry, and other approaches.

Phosphoproteins are often studied by one- or two-dimensional electrophoresis. In nondenaturing conditions (eg, isoelectrofocusing), the presence of a phosphorylated residue shifts the electrophoretic mobility of the protein toward a more acidic form. In the presence of SDS, phosphorylation of a protein may have no effect on its electrophoretic mobility, or it may increase its mobility and its apparent size. The slowing of the protein mobility by phosphorylation during SDS-PAGE is often attributed to a decrease in the charge density due to decreased binding of SDS to the phosphorylated protein. In contrast, it is noteworthy that phosphorylation at specific sites may increase the mobility of some rare proteins in SDS-PAGE.

5.2. Methods for Identifying the Phosphorylated Amino Acid(s)

Following prelabeling with ^{32}P or in vitro phosphorylation with g^{32}P-ATP, the nature of the phosphorylated residues can be determined by acid hydrolysis of the peptide bonds and separation of phospho-serine, phospho-threonine, and phospho-tyrosine by thin-layer electrophoresis. Phospho-histidine and phospho-aspartate are extremely acid-labile and cannot be identified by this approach. On the other hand, the resistance of phospho-tyrosine to alkaline pH is used to study this phospho-amino acid preferentially. The phosphopeptides generated by partial proteolysis of a ^{32}P-labeled phosphoprotein with specific endoproteinases can be studied by two-dimensional phosphopeptide maps (usually a combination of thin-layer electrophoresis and chromatography). Such two-dimensional phosphopeptide maps are very useful for comparing the sites phosphorylated on the same protein under various circumstances, in vivo or in vitro. Phosphopeptides can also be separated by high-performance liquid chromatography (HPLC) and, if sufficient amounts of material are recovered, submitted to automatic protein sequencing, allowing the identification of the phosphorylated residue and its surrounding protein sequence. The use of powerful technologies of matrix-assisted laser desorption/ionization (MALDI) mass spectrometry now provides an interesting alternative approach to identify phosphorylation and other post-translational modifications. Site-directed mutagenesis of individual residues (replacement of a "phosphorylatable" residue by a "nonphosphorylatable" one—for example, replacement of a serine or a threonine by alanine, or of a tyrosine by a phenylalanine) is often used to test the phosphorylation of a precise residue. Although this approach is extremely useful, it should be kept in mind that the information obtained is indirect and that such mutations may have consequences on other properties of the protein other than preventing phosphorylation of the mutated residue.

6. Effects of Phosphorylation on the Properties of Proteins

The effects of phosphorylation on the properties of many proteins are known to be functionally important. They include the activation or inhibition of enzymes, the opening or closing of ion channels, the increase or decrease in the activity of transcription factors, the aggregation or disassembly of cytoskeletal components, and many other effects. There are only a few cases, however, in which the precise molecular mechanism by which phosphorylation of a specific residue brings about the functional changes observed is known in detail. The consequences of the phosphorylation of an amino acid residue can be local, or they can be amplified in the three-dimensional protein structure. Phosphorylation can also alter the interactions of a protein with others. A phosphate group being bulky and highly charged (two negative charges at physiological pH), its presence alters dramatically the properties of the amino acid side chain to which it is bound. It is often attempted to mimic the consequence of phosphorylation of a residue by its mutation to a negatively charged amino acid (aspartate or glutamate). In some cases, such mutations reproduce some of the effects of phosphorylation, while they prevent the normal phosphorylation of the corresponding residues. However, the size and the charge of the carboxyl group are less than those of a phosphoryl group, accounting for the many failures of this approach.

6.1. Local Effects of Phosphorylation on the Properties of Proteins

One example of a protein in which phosphorylation modifies dramatically the activity of an enzyme by a local action on the active site is isocitrate dehydrogenase (IDH), an enzyme regulated by phosphorylation in plants and bacteria. In the unphosphorylated state, IDH is active and catalyses the oxidative decarboxylation of isocitrate to a-ketoglutarate, a critical step in the Krebs citric acid cycle. In the presence of high levels of ATP, IDH is switched off by phosphorylation, and citrate is funneled to the glyoxylate cycle, a biosynthetic pathway that allows plants and bacteria to grow on acetate. *Escherichia coli* IDH is phosphorylated on Ser113 by an enzyme that is also able to dephosphorylate the same residue (a tandem kinase/phosphatase; see above). Ser113 is located in the substrate binding site, near the active site of the enzyme (31). Phosphorylation of this serine prevents isocitrate binding by steric hindrance and electrostatic repulsion (Fig. 3a).

Figure 3. Effects of phosphorylation on proteins. (a) Local effects of phosphorylation on isocitrate dehydrogenase (IDH). IDH transforms isocitrate into a-ketoglutarate, with concomitant production of CO_2 and reduction of NAD^+ in NADH. In *E. coli* IDH, phosphorylation of serine-113 in the active site prevents the binding of the substrate and inactivates the enzyme. (b) Allosteric activation of glycogen phosphorylase by phosphorylation. Phosphorylase is a homodimer; phosphorylation of Ser14 in both subunits leads to rearrangement of the amino-terminal region, modification of the subunit interaction, and changes in the tertiary and quaternary structure of the enzyme, making the active site more accessible to the substrate. (c) Regulation of SH2-domain binding by tyrosine phosphorylation. When particular protein sequences are phosphorylated on tyrosine residues, they bind with high affinity to specific SH2 domains. The presence of phosphotyrosine is necessary for the binding, but the specificity of the interaction is achieved by the recognition by the SH2 domain of the residues on the carboxy-terminal side of the phosphorylated tyrosine (Xxx +1, +2, +3). See the text for references. P, phosphate.

Another example of a well-studied local effect of phosphorylation is provided by the structural studies of protein kinases themselves (32). For the protein kinases to be active peptide loop in the vicinity of the active site, termed the activation loop or T loop, must be correctly positioned. In many protein kinases, the correct positioning of the activation loop requires its phosphorylation on one or two residues. Interestingly, in some cases the phosphorylation appears constitutive (eg, protein kinase A), whereas in others (eg, mitogen-activated protein kinases, MAP kinases) the phosphorylation of the activation loop is a fundamental regulatory step, catalyzed by a specific activating protein kinase.

6.2. Effects of Phosphorylation on the Overall Structure of Proteins

Phosphorylation of a single residue can have dramatic consequences on the tertiary structure and quaternary structure of a protein, as demonstrated by the study of the X-ray crystallography structure of glycogen phosphorylase in the phosphorylated and nonphosphorylated states (33). Phosphorylase is a homodimer, and phosphorylation occurs on a serine in the amino-terminal region of each peptide chain (Ser14), located strategically at the subunit interface. Phosphorylation of this serine leads to the reorganization of the amino terminus of each subunit and the modification of its interaction with the other subunit. As a consequence, the enzyme is stabilized in a form in which the active site, located at a distance from the phosphorylated serine, becomes more accessible to the substrate (Fig. 3b). In this case, the effects of phosphorylation on the structure of the enzyme are comparable to those occurring during classical allosteric activation, except that the effects of phosphorylation are due to a covalent modification of the enzyme, and not to ligand binding.

6.3. Effects of Phosphorylation on Protein–Protein Interactions

Protein phosphorylation can have dramatic regulatory effects on protein–protein interactions, as disclosed by the study of protein tyrosine phosphorylation. Indeed, a 100-residue domain first identified in Src, after which it was termed Src-homology 2 (SH2), and then found in many other proteins, was shown to bind specific peptides phosphorylated on tyrosine (34, 35). Phosphorylation of the tyrosine residue is necessary for binding, but the specificity of the interaction is achieved by the recognition of additional residues, located on the carboxy-terminal side of the phosphorylated tyrosine, by the SH2 domain (Fig. 3c). Binding of SH2 domains to specific peptide sequences phosphorylated on tyrosine residues allows the clustering of enzymes directly or via adapter proteins, around activated growth-factors receptors. Such enzymes, including phosphatidylinositol-3-kinase, phospholipase Cγ, or guanine-nucleotide exchange factors, are thus brought into the vicinity of their membrane-associated substrates. SH_2-mediated clustering triggers the cascades of reactions responsible for the effects of growth factors. SH2 domains can also have very different functions, such as maintaining a protein in an inactive state, as in the case of Src-family tyrosine kinases (36, 37). A carboxy-terminal phosphorylated tyrosine is involved in an intramolecular interaction with the SH2 domain, placing the enzyme in a closed conformation unable to reach its substrates. Activation results from dephosphorylation of the carboxy-terminal tyrosine, or by displacement of the SH2 domain by a competing phosphopeptide. Additional domains that interact specifically with phosphorylated proteins have been identified, including PTB domains (phosphotyrosine-binding) (38) and 14–3–3 proteins, whose interaction with their partner proteins appears to require phosphorylation of the latter on a serine residue (39).

7. The Place of Protein Phosphorylation in the Signal Transduction Networks

Many signal transduction systems in cells use several modules whose hierarchical organization allows powerful amplification and precise modulation. Protein phosphorylation is involved in most of these transduction systems, either as an output mechanism, altering the properties of target proteins, or as a module of information processing. Indeed, phosphorylation reactions in cells often occur in cascades in which activation of a first protein kinase phosphorylates and activates a second protein kinase, which, in turn, phosphorylates and activates a third kinase, and so on. This situation may account in part for the very large number of protein kinases, and it apparently has a number of interesting properties (40, 41). First, phosphorylation cascades allow amplification of the signal: One molecule of the first activated kinase can phosphorylate several secondary kinases, which can each phosphorylate several tertiary kinases, and so on. Another property of these cascades is to acquire kinetic properties, such as positive or negative cooperativity, similar to those of allosteric enzymes, even if the kinases composing the cascade themselves follow classical Michaelis–Menten kinetics. Thus, protein kinase cascades can convert graded inputs into switch-like outputs (42). Finally, the kinase cascades provide many levels of regulation and possible cross-talks between different regulatory pathways. Thus, it is likely that the organization of protein kinases in cascades confers strong evolutionary advantages, as attested by the very high degree of conservation of many of these cascades.

8. Examples of Phosphorylation Dysfunction in Human Diseases

As mentioned above, virtually all intracellular biological processes are regulated to some extent by protein phosphorylation. Thus, it is not surprising that dysfunction of these reactions may be responsible for some pathological states, including in humans. Protein kinases and phosphatases regulate cell growth, and a number of mutations leading to the uncontrolled activation of phosphorylation pathways are oncogenic (43, 44). Several oncogenes are tyrosine kinases (eg, v-Src, v-Fyn, v-ErbB, Met) or serine/threonine kinases (eg, Raf1, Mos) that are activated by mutation, whereas it is the loss of function of protein tyrosine and phospholipid phosphatase PTEN that is oncogenic (45). Loss of function of protein kinases is also responsible for various genetic diseases, including immune deficiency by the absence of γ-globulins [mutation of a nonreceptor tyrosine kinase in Bruton's disease (46)], intestinal palsy [mutation of a receptor tyrosine kinase Ret in Hirschprung's disease (47)], or myotonic dystrophy [mutation of a serine/threonine kinase (48)]. Conversely, protein phosphatases are used as weapons by some pathogenic organisms. For example, one of the virulence genes of *Yersinia* bacteria, including the agent of bubonic plague, is a phosphotyrosine phosphatase (49). Some environmental toxins exert their effects by stimulating protein kinases irreversibly (eg, stimulation of protein kinase C by oncogenic phorbol esters) or inhibiting protein phosphatases (inhibition of serine/threonine phosphatases by okadaic acid or microcystins, which are responsible for food poisoning) (50). On the other hand, the immunosuppressant drugs that have allowed the recent progress in organ grafting, cyclosporin A and FK506, act by inhibiting calcineurin, a Ca^{2+}/calmodulin-dependent protein phosphatase (51). Thus, the large number of protein kinases and phosphatases, and their involvement in numerous biological functions, has prompted many investigators to try to develop specific inhibitors or activators of these enzymes as potential therapeutic tools.

Phosphotransferase

Phosphotransferases form a large group of enzymes that are involved with the transfer of a g-phosphoryl group from ATP, or another nucleoside triphosphate, to an acceptor molecule (see Kinase). They are divided into groups according to the identity of the phosphoryl group acceptor. These acceptors can be alcohols and carboxylic acids, as well as nitrogenous and phosphorylated compounds . All phosphotransferases have an essential requirement for a bivalent metal ion (see Metal-Requiring Enzymes).

Photolyase/Photoreactivation

Photoreactivation is the reversal of the effects of ultraviolet (UV) light (200 to 300 nm) by simultaneous or subsequent exposure of the organism to near UV-visible (300 to 500 nm) light (1, 2). Photoreactivation prevents the induction by UV light of growth delay, mutation, and cell death. Although several factors contribute to the phenomenon of photoreactivation, the main mechanism involved is the reversal of UV-induced pyrimidine dimers in DNA by the enzyme called photoreactivating enzyme, or DNA photolyase (3). DNA photolyase is the only known enzyme to employ light energy to catalyze a chemical reaction (3).

The two major lesions induced in DNA by UV light are cyclobutane pyrimidine dimers (Pyr<>Pyr) and [6–4] photoproducts (Pyr[6–4]Pyr) (Fig. 1). There are separate photolyases that are specific for Pyr<>Pyr and for [6–4] photoproducts (4, 5), but no known enzyme can act on both lesions. The structures and reaction mechanisms of the two types of photolyases are similar and may be summarized as follows. Each consists of a single polypeptide chain of 55 to 65 kDa containing a chromophore that acts as a photoantenna (folate or deazaflavin) and a catalytic cofactor ($FADH_2$) (6-9). It binds to the photodamage in DNA in a light-independent manner, producing a relatively stable enzyme-substrate complex. Upon exposure to light, the enzyme breaks the bonds that link the two pyrimidines to one another, generates standard canonical bases as products, and then dissociates from the repaired DNA. In contrast to many other enzymatic reactions that involve electron transfer, catalysis by photolyase involves a cyclic electron transfer and is not a redox reaction, in that upon completion of the enzymatic reaction the redox states of the enzyme and the substrate remain the same (6).

Figure 1. The two major photoproducts produced in DNA by ultraviolet light from (a) thymine dinucleotide: (b) the cyclobutane thymine dimer, and (c) the [6–4] photoproduct. Similar photoproducts arise from other adjacent dipyrimidines in DNA.

1. Evolution

Photolyases are flavoproteins, yet the primary sequences of the apoenzymes do not reveal any obvious homology to the signature sequences found in other flavoproteins (4). Instead, photolyases have remarkable sequence homology to blue-light photoreceptors (10), which regulate circadian rhythms in organisms ranging from mustard to humans (11-13). It appears that the necessity for the flavin cofactor to function from the light-excited state has imposed unique constraints on the flavin binding site of photolyase/blue-light photoreceptor family of proteins, such that the active-site geometry of these proteins is different from all other flavoproteins that carry out catalysis with ground-state flavin.

The distribution of the members of the photolyase/blue-light photoreceptor family in the biological world does not fit a readily defined pattern of evolutionary selection. The coliform bacterium *Escherichia coli* contains photolyase, but the soil bacterium *Bacillus subtilis* does not. The budding yeast *Saccharomyces cerevisiae* has the enzyme, but the fission yeast *S. pombe* does not. *Drosophila melanogaster* possesses cyclobutane pyrimidine dimer photolyase, [6–4] photolyase, and blue-light photoreceptor (14), while humans lack photolyase but express two blue-light photoreceptor proteins. Table 1 shows the expression pattern of this class of proteins in select members of the “three kingdoms of life”: bacteria, archaea, and eukarya. No general rules emerge from this table. The only rules that appear to have arisen from investigations of these groups of proteins are the following. (i) Cyclobutane photolyase has been detected in bacteria, plants, and animals through marsupial animals (15), but it has not been found in placental mammals such as human (16) and mouse. (ii) The [6–4] photolyase has been found in plants, insects (*Drosophila*), and some vertebrates (*Xenopus*, rattlesnake), but not in mammals such as human or mouse, nor in bacteria. (iii) Blue-light photoreceptors have been found in plants (*Arabidopsis*, mustard) and animals (*Drosophila*, human, and mouse), but not in bacteria. (iv) Of all bacterial and eukaryotic viruses investigated, photolyase has, so far, been found only in a grasshopper virus.

Table 1. Distribution of the Photolyase/Blue-Light Photoreceptor Family of Proteins in the Biological World

	Bacteria		Archaea			Eucarya	
	E. coli	B. subtilis	M. thermoauto	M. janaschii	S. cerevisiae	D. melanogaster	H. sapiens

Photolyase	Yes	No	Yes	No	Yes	Yes	No
[6–4] Photolyase	No	No	No	No	No	Yes	No
Cryptochrome	No	No	No	No	No	Yes	Yes

The tissue distribution of photolyase in animals that possess the gene is rather surprising. It is highly expressed in *Drosophila* ovaries, where it is expected to protect germ cells from UV damage. However, it is also expressed in all internal organs of opossum, including high levels of expression in the brain. Considering the nocturnal nature of the opossum, and the low probability even in bright daylight of UV and photoreactivating light penetrating the skull of the opossum, this expression pattern remains enigmatic.

2. Structure

Photolyases consist of a single polypeptide of 500 to 700 amino acid residues and two noncovalently bound cofactors/chromophores. One of the chromophores is always flavin adenine dinucleotide (FAD), and the other is either pterin (methenyltetrahydrofolate in the case of *E. coli* and *S. cerevisiae* photolyases) or deazariboflavin. Deazariboflavin is considered an ancient molecule, and photolyases with this cofactor have been found only in a few organisms that are capable of synthesizing this uncommon cofactor: *Aspergillus nidulans, Streptomyces griseus*, and *M. thermoautotrophicum*. Most other photolyases characterized to date, including those from *E. coli, S. cerevisiae, D. melanogaster*, and marsupials, contain a pterin as the second chromophore. Only two [6–4] photolyases have been characterized in detail, those of *D. melanogaster* and *X. laevis*, and both contain a pterin as the second chromophore (17). Blue-light photoreceptors from mustard, *A. thaliana*, and humans contain FAD and a pterin (11, 12).

The structures of *E. coli* and *A. nidulans* photolyases have been determined (18, 19). Even though the two enzymes are only 39% identical in sequence, they have remarkably similar structures, such that the traces of C^{a} atoms are superimposable. The enzymes consist of two well-defined domains: an *N*-terminal a/b domain, which is connected to the *C*-terminal alpha-helical domain through a long inter-domain loop. The folate or the deazaflavin chromophores are located in a crevice separating the two domains. In the *E. coli* enzyme, the folate is close to the surface of the protein and hence is not tightly bound to the enzyme; furthermore, its orientation is not optimal for energy transfer to the FAD cofactor. In contrast, the deazariboflavin chromophore in *A. nidulans* photolyase is deeply buried between the two domains, and it has a more favorable orientation relative to FAD for efficient energy transfer between the chromophores. Thus even though center-to-center distances between the two chromophores in the two photolyases are about 17 Å, the energy transfer from the second chromophore to FAD is more efficient (97% to 70%) in *A. nidulans* photolyase than in that of *E. coli* (20). The helical domain is made up exclusively of a-helices that are packed in two rather compact clusters. The FAD is buried between these clusters, and the flavin and adenine rings of the cofactor are in the unusual *cis* conformation in both photolyases.

The crystal structures of both enzymes also reveal how they bind to DNA. A plot of the surface potential of the enzyme reveals a longitudinal groove traversing both the a/b and the a-helical domains that is paved with positive charges. At its center is a hole that has the shape and size appropriate for cyclobutane pyrimidine dimer. The bottom of the hole is made up by the flavin ring. These structural features suggest that the DNA is in the positively charged groove through ionic interactions between the DNA backbone and the positive charge of the side chains and that the dimer “flips out” of the duplex into the hole within the enzyme. Following repair, the flipped-out dinucleotide would undergo a conformational change upon transformation of the dimer into two monomers, which would force the bases out of the hole and assist the repaired DNA to dissociate from the enzyme. Biochemical data indicate that [6–4] photolyase also employs a "flip-out" mode of complex formation during catalysis.

3. Reaction Mechanism

Photolyase works by the classical Michaelis–Menten kinetic mechanism; that is, the enzyme and substrate form a noncovalent complex that is converted to an enzyme–product complex after catalysis and eventually dissociates to yield product and free enzyme. The light-dependence of this catalysis step is unique to photolyase.

3.1. Binding

Photolyase, unlike some other high-specificity DNA-binding proteins, does not rely on diffusion along the linear DNA molecule to recognize its substrate. Similarly, the enzyme, in contrast to most proteins that bind to DNA in a sequence-specific manner and hence require double-stranded DNA, binds to its cognate lesions in single- and double-stranded DNA with almost equal affinities (2, 1). This property of the enzyme, combined with the fact that the enzyme can bind the photoproduct even in a dinucleotide form and repair it with high affinity, are consistent with a model in which the enzyme binds mostly to the backbone of the damaged strand and flips-out the photolesion into the catalytic hole for repair.

3.2. Catalysis

A most extraordinary aspect of catalysis by photolyase is its absolute dependence on light. According to the Woodward–Hoffman rule on symmetry in molecular orbitals, the symmetry of molecular orbitals in a chemical reaction is conserved between reactants and products. A corollary of this rule is that photochemically allowed reactions that proceed from the lowest unoccupied molecular orbitals (LUMO) are thermally forbidden; and conversely, thermally allowed reactions that proceed from the highest-occupied molecular orbitals (HOMO) are photochemically forbidden. In line with these rules, the cyclobutane ring of Pyr<>Pyr is stable at pH 1 and 160 °C for 6 h, but it is reversed to pyrimidine monomers with 240 nm light with a quantum yield of about 1.0. Surprisingly, however, even though photolyase utilizes light energy to catalyze the repair, the reaction is not a photochemical reaction in the strict sense, because it does not involve photoexcitation of the pyrimidine dimer, either directly or indirectly. Consequently, splitting of Pyr<>Pyr by photolyase does not break the rule of conversation of orbital symmetry. The enzyme accomplishes this feat by converting the Pyr<>Pyr into a radical, which then readily proceeds, thermally, to monomers. Light (300 to 500 nm) is used simply to excite the cofactor of the enzyme into a strong reductant capable of donating an electron to the relatively inert Pyr<>Pyr.

Having thus stated the general features of catalysis, the specifics for Pyr<>Pyr photolyase can be summarized as shown in Figure 2. The enzyme binds to its substrate independent of light, and the reaction proceeds upon exposure to light as follows (6). First, a photon is absorbed by the photoantenna (pterin or deazaflavin) to excite the chromophore to the excited singlet state. Second, the photoantenna transfers the energy by dipole–dipole interactions to $FADH^-$ with either 70% (pterin) or 97% (deazaflavin) efficiency. Third, the excited singlet state of $FADH^-$ transfers an electron to Pyr<>Pyr with about 100% efficiency, generating flavin neutral radical and Pyr<>Pyr radical anion. Fourth, the Pyr<>Pyr radical anion splits to pyrimidine monomers, concomitant with electron transfer back to restore the flavin to its catalytically active state. The reaction is a photoinitiated cyclic electron transfer, which results in bond rearrangement without changing the redox status of the reactants.

Figure 2. Photoreactivation photocycle for photolyase. The active site of the enzyme complexed to substrate is shown. (
pterin) absorbs a near-UV photon. (2) The excited singlet-state pterin transfers energy to $FADH^-$ by dipole–dipole inter

FADH⁻ transfers an electron to the thymine dimer (4). The thymine dimer anion radical collapses to two thymines, conc the flavin neutral radical.

The [6–4] photolyase functions in a similar manner (17, 22), with one important exception. Formation of [6–4] photoproduct encompasses joining of C6 of the 5′ base to the C4 of the 3′ base via a sigma bond, accompanied by transfer of the group at the C4 position (–NH or –OH) of the 3′ base to the C5 position of the 5′ base. Thus, simple cleavage of these new bonds would not restore the bases to normal. Hence, before the photoinduced cleavage of these bonds, the enzyme converts the “open form” of [6–4] photoproduct to an oxetane intermediate in which the NH or OH that was transferred to the C5 position of the 5′ base is shared by the C5 of the 5′ base and the C4 of the 3′ base (22). When the oxetane intermediate receives an electron from the active-site flavin, the resulting radical intermediate collapses to the two original bases, with back electron transfer to restore the flavin radical to its catalytically active form (Figure 3).

Figure 3. [6–4] Photolyase photocycle. Upon binding to the enzyme, the open form of the [6–4] photoproduct is conver photocycle proceeds as follows: (1) The photoantenna absorbs a photon and (2) transfers energy to the catalytic cofactor 4] photoproduct; (4) the photoproduct radical splits into two normal bases, concomitant with electron transfer back to th

The blue-light photoreceptors that exhibit 40% to 60% sequence identity to photolyases (10) have absolutely no repair activity (11). They are photoreceptors for regulating plant growth or for photoentrainment of the circadian clock in animals (13). However, the reaction mechanism of these molecules is not known at present.

Photon Correlation Spectroscopy

Dynamic light scattering is a method for measuring the diffusion of macromolecules within a solution due to Brownian motion. It differs from “classical” or “static” light scattering, which permits the measurement of the molecular weight and radius of gyration of macromolecules from the light they scatter at varying scattering angles. Dynamic light scattering measures instead the intensity fluctuations of the scattered light on the timescale of 10^{-3} to 10^{-9} s. The frequencies of these fluctuations depend on how rapidly the molecules are moving by diffusion. These measurements require lasers, which provide light of high intensity, collimation, monochromaticity, and, most importantly, spatial and time coherence; the last attributes mean that the light is emitted from the laser as a continuous wave rather than as short bursts.

The physics underlying dynamic light scattering is complicated (1). In simple terms, the moving macromolecules will Doppler-broaden the otherwise monochromatic incident radiation. The scattered intensity will fluctuate because of beating interference of scattered waves of different, but similar, wavelengths; the situation is analogous to the fluctuations in intensity of a radio channel caused by interference from another radio channel of a very close wavelength. This broadening of the originally monochromatic light is why the technique is often referred to as quasi-elastic light scattering (QLS). The detector sends the intensity signal to a special computer, called an autocorrelator, which compares or correlates the intensity at different times; for this reason, the technique has another term, photon correlation spectroscopy (PCS). How rapidly the intensity fluctuates over short periods of time, or delay times, t, is represented by how a parameter known as the normalized intensity autocorrelation function, $g^{(2)}$ (t), decays as a function of t. The superscript “(2)” is used to indicate that it is an intensity, as opposed to an electric field “(1)” autocorrelation function. Many data sets of $g^{(2)}$(t) as a function of t are accumulated and averaged. The degree of averaging necessary depends on the incident laser intensity and the size and concentration of the scattering macromolecule (at a given concentration; larger molecules scatter more). For globular proteins, sufficient data can usually be acquired within one to several minutes.

Analysis of how the normalized intensity autocorrelation function $g^{(2)}$(t) decays as a function of t can be used to evaluate the translational diffusion coefficient, D_t. For dilute solutions of spherical or near-spherical (ie, globular) macromolecules, the variation of $g^{(2)}$(t) with t can be represented by the simple logarithmic equation

(1)

where the parameter k is known as the Bragg wave vector, whose magnitude is defined by

(2)

where n is the refractive index of the medium, q is the scattering angle, and l is the wavelength of the incident light. Consequently, the value of D_t can be found from a plot of ln[$g^{(2)}$(t) – 1] versus t. Figure 1 illustrates an example for the motility protein dynein.

Figure 1. Dynamic light scattering of a solution of dynein. The channel number is a measure of the delay time, q (see Eq. (1) of the text).

Two important practical conditions need to be noted: (1) the value of D_t is sensitive to the temperature, which needs to be accurately controlled or, at the very least, monitored during the measurement; and (2) the scattering signal is very sensitive to the presence of trace amounts of dust or aggregation products; solutions and the scattering cell or cuvette need to be scrupulously clean and free of particulates. The samples must be filtered and centrifuged and the vessels washed. Special filling devices have been constructed to minimize this dust problem (2).

The value of D_t can be converted to the standard conditions of water at 20.0°C and extrapolated to zero sample concentration (see Diffusion). An additional extrapolation is necessary if the macromolecule is not globular. There is an extra term on the right-hand side of equation 1 that arises from rotational diffusion at finite angles q. This term approaches zero as q does. Therefore, it is necessary to make the measurements of D_t at a number of angles q and to extrapolate to zero angle (or Bragg vector k). The extrapolations to zero sample concentration and to zero angle q (or k) can be performed simultaneously on a biaxial extrapolation plot known as a dynamic Zimm plot (3). If an angular extrapolation is not necessary, a scattering angle of 90° is usually chosen, and fixed-angle instruments are usually set at this angle. At low angles, the problems due to contamination with large particles (see (2) above) are accentuated.

If a sample is heterogeneous, it is possible, at least in principle, to obtain a distribution of diffusion coefficients after various assumptions and mathematical manipulation of the autocorrelation data; these methods have been reviewed (4), and several commercially available computer programs are available. A more simple way of representing heterogeneity is with the polydispersity factor (PF), which is obtained by comparing linear with quadratic or more complex fits of the normalized autocorrelation function decay data (5).

Measurements can be made very rapidly with dynamic light scattering, and it is possible to follow biomolecular assembly–disassembly processes that occur on a timescale of minutes. An example of the swelling of southern bean mosaic virus in response to the removal of bound Ca^{2+} ions is given in Fig. 2 (6).

Figure 2. Following the dynamics of a process using dynamic light scattering: effect of removal of calcium ions (by adding EGTA at 10 min) on the hydrodynamic radius (R_H) of southern bean mosaic virus (adapted from Ref. 6).

Photosynthesis

Photosynthesis is the energy transduction process whereby solar light energy is converted into a chemical form and used for the synthesis of organic molecules. Photosynthesis takes place in higher plants, algae, and certain bacteria. It involves light-induced redox processes in which carbon dioxide becomes reduced. The ability to use water as an electron source distinguishes the oxygenic photosynthetic organisms—eukaryotic plants and algae, plus prokaryotic cyanobacteria and prochlorophytes, from the nonoxygenic photosynthetic bacteria. Photosynthetic organisms evolved more than 3.5 billion years ago, and they are the origin of current biomass, as well as of fossil fuels.

In all types of photosynthetic organisms, the photosynthesis reaction can be divided into two major phases: (1) the light reactions and (2) the carbon fixation reactions (the Calvin cycle). The light reactions lead to the production of ATP and NADH or NADPH. These molecules are required for the subsequent CO_2 fixation and the formation of trioses, glucose, and more complex carbohydrates. The primary energy conversion is driven by redox-active pigment-protein complexes known as photosynthetic reaction centers. Together with light-harvesting complexes and electron transport components, such as cytochromes, iron-sulfur proteins, and quinones, the reaction centers catalyze electron and proton transport across a biological membrane to create a proton motive force. In analogy with the respiratory process in mitochondria and bacteria, this proton motive force drives the synthesis of ATP (adenosine triphosphate) by the enzyme ATP synthase.

In oxygenic photosynthesis, $NADP^+$ is reduced by electron transfer from two reaction centers, photosystem II and photosystem I, which are coupled in series (Fig. 1). The electrons are supplied by photosystem II through its unique ability to oxidize water, leading to release of molecular oxygen. The nonoxygenic photosynthetic bacteria contain only one reaction center and typically use organic or inorganic compounds as reductant to reduce NAD(P). They perform cyclic electron transport to produce ATP. Two groups of reaction centers (type I and type II) are present among the various photosynthetic bacteria and have been shown to be highly analogous to photosystem I and photosystem II of oxygenic photosynthesis, respectively (1).

is plastoquinone in photosystem II and phylloquinone in photosystem I. Fe is a nonheme iron; F_X, F_A, F_B are low potent
centers, and F_D is ferredoxin. $(Mn)_4$ is the cluster of manganese atoms involved in the oxidation of water; Y_Z and Y_D are
tyrosine residues—the former are on the main route of electron transfer. Arrows show electron transfer paths. The two p
are functionally connected by the cytochrome b_6f complex, which oxidizes the reduced quinone (QH_2, plastoquinol) an
copper-containing extrinsic protein, plastocyanin (PC). Because quinones are normally 2 electron/2 proton acceptors, th
cytochrome complex accepts two electrons, one reducing an iron–sulfur center (FeS) and the other reducing a low pote
cytochrome (cyt b). The reduced FeS center donates an electron to cytochrome f (cyt f). The other electron participates in q
dependent cyclic electron transport, involving high and low potential b-type cytochromes, which functions as a proton p
developed from reference 1.

In eukaryotic organisms, photosynthesis occurs in specialized cell organelles (chloroplasts) enclosed by a double outer membrane (envelope) and an internal membrane system (thylakoid membrane). This organelle contains, like mitochondria, its own DNA. The thylakoid membrane harbors the two photosystems, the light-harvesting antenna, electron transport components, and the ATP synthase (CF_0–CF_1). Despite their prokaryotic nature, cyanobacteria have a photosynthetic thylakoid membrane that is differentiated from the plasma membrane. In nonoxygenic photosynthetic bacteria, various forms of invaginations of the cell membrane give rise to so-called chromatophores, to which the photosynthetic light reactions are confined. The reduction of CO_2 and the subsequent enzymatic reactions of the Calvin cycle take place in the cytoplasm of prokaryotic cells or in the soluble stromal compartment of chloroplasts. The photosynthetic apparatus is remarkably adaptable to various stress conditions, in particular to short- and long-term changes in light intensity. Under severe light stress, however, photosystem II can suffer from oxidative damage leading to (photo)inhibition of photosynthesis.

1. Photosynthetic Reaction Centers

Photosynthetic bacteria are rudimentary in a general biological perspective, but they have been extremely useful as simple experimental model organisms to elucidate the structure and function of the photosynthetic light reactions and to understand the evolution of photosynthesis (2). These bacteria can be classified into two major groups based on their types of reaction centers: (1) green-sulfur bacteria (eg, *Chlorobium limicola*) and heliobacteria (eg, *Heliobacterium chlorum*, *Heliobacillus mobilis*) use low potential iron–sulfur clusters as electron acceptors, and their reaction centers are designated FeS type or type I; and (2) purple bacteria (eg, *Rhodobacter sphaeroides*, *Rhodopseudomonas viridis*, *Rhodospirillum rubrum*, *Chromatium vinosum*) and green gliding bacteria (*Chloroflexus aurantiacus*) have type II reaction centers with pheophytin and two quinone molecules as electron acceptors.

X-ray crystallographic, functional, and genetic analyses have revealed that photosystem I and photosystem II of oxygenic photosynthesis are closely related to the bacterial type I and type II reaction centers, respectively (Fig. 1).

The reaction center is the most vital part of the photosynthetic apparatus in which the primary light-induced redox processes take place (1). The type I and II reaction centers have a similar basic architecture, and they function using essentially the same mechanistic principle. Both use a “special pair” of chlorophyll or bacteriochlorophyll molecules as the primary electron donor (P_D) and a (bacterio-) chlorophyll (type I) or a (bacterio-)pheophytin (type II) as primary electron acceptor (P_A). When excited by light, P_D donates an electron to P_A within a few picoseconds, and the radical pair $P^+_D P^-_A$ is formed:

The primary donor and acceptor are arranged in the reaction center in such a way that the primary charge separation occurs across the lipid bilayer of the photosynthetic membrane.

The stability of this primary charge separation is ensured by rapid transfer of the electron from P_A to the secondary electron acceptors, A_1, A_2, and so on and by passing an electron to P^+_D from secondary electron donors, D_1, D_2, and so forth:

In type I reaction centers, A_1 is a quinone, while A_2 is a low potential 4Fe–4 S cluster (F_X). The donors are typically c-type cytochromes or the copper protein plastocyanin (in oxygenic electron transport only) (see Electron Transfer Proteins). In the type II reaction center, quinones constitute both the A_1 (Q_A) and A_2 (Q_B) acceptors. These are normally plastoquinone or, in purple bacteria, ubiquinone. In the bacterial type II centers, **cyt**ochromes are often the electron donors, while in oxygenic photosynthesis the electrons are provided by the unique system of water oxidation. The primary donor of photosystem II (P680) is a powerful oxidant in its P680$^+$ form. In fact, P680$^+$ is the most oxidizing species found in living organisms (E_m = +1.1V), enabling extraction of electrons from water (see Electron Transfer Proteins and Redox Enzymes). Oxidation of water requires the accumulation of four oxidizing equivalents, which are necessary to abstract four reducing equivalents from two water molecules to produce one molecule of dioxygen (O_2). The water-oxidation system involves a cluster of four manganese atoms that are converted to higher valence in a stepwise manner by four separate photochemical events (the S-state cycle) involving P680 and a redox-active tyrosine residue in the reaction center.

1.1. Type II Centers

Determination of the high-resolution three-dimensional structure of the purple bacterial reaction center was a landmark in photosynthesis research (3). The structure revealed an approximately twofold symmetrical relationship of the prosthetic groups (Fig. 1) and the two protein subunits (L and M) that bind them. These two subunits each possess five transmembrane helices and have very similar structures, forming a heterodimeric structure. The two bacteriochlorophylls of the primary electron donor, P_D, form a special pair at the periplasmic side of the chromatophore membrane. Following the structure across the membrane, the next cofactors are two additional bacteriochlorophylls, then two bacteriopheophytins, followed by two quinones in the Q_A and Q_B sites near the cytoplasmic surface. All the duplicated cofactors (Fig. 1) are related by a twofold axis passing through the special pair P_D and a nonheme iron located midway between the two quinones. Notably, despite this approximate twofold symmetry, the electron transfer to Q_B via Q_A occurs exclusively along one branch, while the other branch is inoperational (Fig. 1). It is still not clear whether the bacterial chlorophyll located between the primary donor and the bacteriopheophytin is directly involved in the charge separation process as a redox-active species. The symmetry of the reaction center is broken by the H subunit, which has a single membrane-spanning alpha-helix and a globular domain at the cytoplasmic side of the membrane. Furthermore, there is a four-heme cytochrome present on the periplasmic side in most purple bacteria.

Functional and compositional analyses of oxygenic photosynthesis have revealed that photosystem II carries out electron transfer reactions similar to those occurring in the reaction centers of purple bacteria (3). On the acceptor side, photosystem II has pheophytin and Q_A, Q_B plastoquinone molecules, as well as the nonheme iron (Fig. 1), and electron transfer occurs with similar rate constants. Furthermore, the two protein subunits of the photosystem II reaction center (D_1 and D_2) show homology with the L and M proteins and form a heterodimeric structure similar to the bacterial reaction center. This has been confirmed by the structure of photosystem II obtained at 0.8 nm resolution by electron microscopy. In contrast to the bacterial reaction center, two photosystem II complexes are tightly associated to form a dimeric structure (4).

P680 is probably a dimer of chlorophyll molecules, but the relative orientation of the chromophores and their degree of exciton interaction seem to differ somewhat from the bacterial primary donor. Most significantly, photosystem II differs in its donor properties, allowing the extraction of electrons from water (Fig. 1). Most experimental observations suggest a close association between the active manganese cluster and the reaction center heterodimer.

Despite all the redox components required for the light-induced electron transfer from water to plastoquinone being associated with the D_1/D_2 reaction center heterodimer, photosystem II contains as many as 25 different subunits (1). These are encoded either by chloroplast or nuclear genes designated psbA-X. Closely associated with the reaction center is cytochrome b559, which is not a part of the main electron transfer chain but instead protects against photodamage. Most subunits are integral membrane proteins and span the membrane, but three extrinsic proteins are located at the inner thylakoid surface to stabilize the manganese cluster and to sequester the Ca^{2+} and Cl^- ions that are also required for water oxidation. A peculiar feature of the complex is the relatively large number (up to 10) of small proteins with only one membrane-spanning segment. Two chlorophyll-a-binding proteins, CP47 and CP43, serve as inner light-harvesting antenna closely associated with the reaction center. Each contains 40 chlorophyll-a molecules and possesses 6 transmembrane domains; they are complemented by an outer antenna constructed of various pigment-protein complexes, depending on the taxonomic group (see text below).

1.2. Type I Centers

Of the type I reaction centers, photosystem I is the best characterized, partly due to the 0.4 nm-resolution structure of the complex obtained from a thermophilic cyanobacterium (6). Notably, the basic three-dimensional structural arrangement of photosystem I is the same as for the type II center, despite its different content of redox-active groups. Photosystem I has the twofold symmetry with the axis passing through the chlorophyll-a dimer of the primary donor (P700) and a 4Fe–4 S center (Fig. 1). Two additional pairs of acceptor chlorophyll molecules occur along this axis. A fourth pair of chlorophyll molecules appears to connect those of the reaction center and of the light-harvesting antenna. The photosystem I reaction center is a heterodimer composed of two large reaction center subunits (PsaA and PsaB), each possessing 11 membrane-spanning segments. In contrast to the type II center, the two reaction center subunits also harbor the inner light-harvesting antenna of about 100 chlorophyll-a molecules. The 22 a-helices of the PsaA and PsaB proteins are arranged in such a way that 5 helices from each subunit form a central reaction center portion, in analogy with the D_1/D_2 and L/M heterodimers. The additional 12 a-helices are located on either side of this central portion and harbor the antenna chlorophylls. This arrangement should be compared to the inner chlorophyll-a antenna of photosystem II composed of two distinct proteins, CP47 and CP43, together comprising

12 membrane spanning helices (4).

Photosystem I is also a multisubunit complex of both nuclear and chloroplast genetic origin, with up to 15 different subunits (PsaA- PsaM) (5). PsaC, an extrinsic subunit at the outer stromal surface (Fig. 1), provides ligation for two acceptor FeS clusters (F_A and F_B). There are also subunits providing docking sites for ferredoxin and plastocyanin (see Azurin) at the acceptor and donor sides of the reaction center, respectively. The eukaryotic photosystem is complemented by an outer antenna of chlorophyll a/b -binding proteins (LHCI). In cyanobacteria, but probably not in plants, the photosystem I complex is trimeric.

No structural information is yet available for the nonoxygenic type I reaction centers of green sulfur bacteria or heliobacteria. There is compelling evidence that these photosynthetic bacteria have homodimeric reaction centers despite the same overall arrangement of the redox active groups as in photosystem I. It is therefore assumed that these bacterial reactions centers are evolutionarily more primitive and ancestral to the heterodimeric reaction centers (7, 8).

1.3. Evolutionary Aspects of Photosynthesis

The occurrence of two different but analogous reaction centers, composed of two related, yet distinct protein subunits, provides insight into the evolution of photosynthesis (1, 7, 8). In the beginning, there was probably a primordial reaction center composed of one single subunit (Fig. 2), which may have evolved to a homodimeric structure with both electron transfer branches operational. Then a gene duplication took place in early evolution, the heterodimeric reaction centers were generated by divergent evolution, and one of the electron transfer branches was closed. It is assumed that the ancestral reaction center contained both quinone and iron–sulfur acceptors, but that the latter were lost in the type II centers. Later the two types of reaction centers were linked to pave the way for current oxygenic photosynthesis (Fig. 2). It is not clear when the ability to oxidize water was acquired, but no single type II reaction center able to split water has been identified. The chloroplast of eukaryotic photosynthetic organisms is generally assumed to have its evolutionary origin in symbiotic ancestors of cyanobacteria.

Figure 2. Evolution of photosynthetic reaction centers. A primordial reaction center containing both quinones and Fe-S centers as electron acceptors, evolved into type I and type II centers, where the latter lost their FeS component. Gene duplications and divergence gave rise to homodimeric, finally heterodimeric, reaction centers where only one electron transfer route is operational. In cyanobacteria, the two types of reaction centers merged to pave the way for oxygenic photosynthesis (see Fig. 1). The scheme is developed from References 6 and 7.

2. Light-Harvesting Protein Complexes

The evolution of type I and type II reaction centers has been matched by the development of a multitude of different light-harvesting pigment-protein systems. This enables photosynthetic organisms to use the entire solar spectrum and provides versatility with respect to the surrounding light environment. In bacteria there are typically 40 chlorophyll-containing molecules per reaction center, while in plants this number could be several hundred (2). The correct organization of the various pigments within the antenna systems is crucial in order to ensure efficient energy transfer. Following absorption of a photon by one of the antenna pigments, the excitation moves from pigment to pigment via so-called resonance energy transfer, until being trapped in the reaction center. These ultrafast processes can now be followed by femtosecond (10^{-15} s) flash spectroscopy.

Purple bacteria have two types of light-harvesting protein complexes, designated LHI and LHII (9). They are composed of two small proteins (a and b) that each span the membrane once and bind bacteriochlorophyll a and carotenoids. LH1 is closely associated with the reaction center (L, M, and H subunits). LH2 is located more peripherally and functions as an outer and variable antenna. The structure of LH2 has been determined to high resolution by X-ray crystallography (9). The complex has a donut shape with 9 a-subunits forming a hollow cylinder with 1.8 nm inner and 3.4 nm outer radii. All the pigments are located between these cylinder walls. The bacteriochlorophylls are ligated to histidine residues. Eighteen molecules form an overlapping ring located toward the outer membrane surface, while nine are located more toward the inner portion of the membrane. The latter are perpendicular to the other bacteriochlorophylls and with the bacteriochlorophyll ring parallel to the membrane surface. The carotenoids are arranged in close association with the bacterial chlorophylls. This ring of chlorophylls allows the excitation to become delocalized over a large area, thereby facilitating the energy transfer to LHI, which is likely to have a structure similar to LHII. Purple bacteria can also contain bacteriochlorophyll-*b*, in addition to bacteriochlorophyll-*a*. Typically, purple bacteria can harvest light in a very broad interval of the spectrum, even above 1000 nm.

Green sulfur bacteria have a peculiar antenna system, chlorosomes, which appear as bag-like structures on the inside of the cytoplasmic membrane (2). They contain a complex mixture of bacteriochlorophylls *c*, *d*, and *e* assembled into rod elements approximately 5–10 nm in diameter. Notably, chlorosomes contain very few proteins, and the polymeric structures are maintained primarily by pigment–pigment interactions. A water-soluble baseplate bacteriochlorophyll-*a*-protein complex sandwiched between the chlorosomes and the cytoplasmic membrane provides the link between the chlorosome antenna and the reaction center chlorophylls. Green sulfur bacteria can absorb light up to 850 nm. Heliobacteria do not contain an outer antenna but manage with the inner bacteriochlorophyll *a* antenna of its type I reaction center.

Cyanobacteria use water-soluble protein structures known as phycobilisomes as outer light-harvesting antenna (10). A phycobilisome contains several hundreds of phycobilin pigments (phycocyanin, phycoerythrin, and allophycocyanin) covalently bound to the phycobiliproteins. The organization of a phycobilisome involves rod-like structures composed of 5 to 6 elements that are connected to a tricylindrical core of phycobiliproteins carrying allophycocyanin. The excitation energy migrates, via the core, from the peripheral rod sections to the CP47/CP43 inner chlorophyll-*a* antenna, and finally to the D_1/D_2 reaction center. The phycobilosomes are located at the outer thylakoid membrane surface facing the cytoplasm and connected to photosystem II via nonpigmented linker proteins.

The plant photosystems have chlorophyll *a/b*-binding (CAB) proteins as their outer light-harvesting antenna (10). Altogether there are ten different but related nucleus-encoded CAB proteins: 6 associated with photosystem II and 4 with photosystem I. These are all integral membrane proteins, each with a molecular weight of about 25 kDa and with three transmembrane-spanning regions. The CAB proteins noncovalently bind approximately half of the chlorophyll *a* and all of the chlorophyll-*b*, as well as a majority of the carotenoids. Most attention has been paid to the major CAB protein complex of photosystem II, designated LHCII. It is the most abundant thylakoid protein complex and, apart from a crucial function in light harvesting, is essential for maintaining the thylakoid membrane organization and to adjust the antenna of photosystem II in response to short- and long-term fluctuations in the light environment. LHCII normally exists as a trimer. Each monomer has been estimated to bind up to 14 chlorophyll molecules, one chlorophyll molecule for every 15 amino acids, indicating a very tight packing. The structure of LHCII has been determined to 0.34 nm resolution by electron crystallography (11).

Green algae have basically the same outer light-harvesting antenna as plants. In brown algae, the CAB proteins are homologous to the plant CAB proteins. Interestingly, the CAB proteins are not unique to eukaryotic organisms, since the prokaryotic prochlorophytes have a similar kind of light-harvesting proteins. On the other hand, eukaryotic red algae have no CAB proteins, but phycobilisomes similar to those of cyanobacteria.

The carotenoids of the various light-harvesting complexes and reaction centers not only play a role in light-harvesting but are also essential as protectants against oxidative damages.

3. Electron Transport

3.1. Oxygenic Photosynthesis

Photosystem I and photosystem II are linked in series via plastoquinone, the cytochrome b_6f complex, and plastocyanin (Fig. 1). When the secondary plastoquinone acceptor of photosystem II

(Q_B) has received two electrons, it is protonated and leaves its binding site on the D_1 protein. This Q_B site is the major target for several commercial herbicides, such as atrazine and diuron. The reduced plastoquinone interacts with the Q_0 site of cytochrome b_6f. This cytochrome complex is analogous to the mitochondrial cytochrome bc_1, whose structure has been solved to high resolution. The photosynthetic cytochrome complex contains four redox centers: one heme c (f), two hemes b, and a high potential Rieske 2Fe–2 S cluster. The redox components are ligated to three protein subunits: cytochrome f and cytochrome b_6, which are both plastid-encoded, and the nucleus-encoded Rieske FeS protein. Altogether, the complex contains at least five subunits. It performs quinol oxidation via cytochrome b_6f, involving a so-called Q cycle, which translocates twice the number of protons that could be translocated by the plastoquinone/plastoquinol oxidoreduction alone. The electrons are eventually linked via cytochrome f, the FeS center and plastocyanin to photosystem I, reducing $P700^+$. The final step in noncyclic electron transfer is the reduction of $NADP^+$, which is mediated by ferredoxin and the ferredoxin-$NADP^+$ reductase, a flavoprotein.

Noncyclic electron transport gives rise to proton transport into the inner (lumen) thylakoid compartment, via cytochrome b_6f and the plastoquinone/plastoquinol oxidoreduction (Fig. 1). In addition, protons are translocated into the lumen as a consequence of the oxidation of water. Cyclic electron transfer leading to transmembrane proton transport can occur around photosystem I and cytochrome b_6f, although the precise mechanism is still under debate. The proton motive force created by non-cyclic or cyclic electron transport substantiate the chemiosmotic coupling theory of ATP formation.

3.2. Nonoxygenic Photosynthesis

The simplest form of electron transport occurs in purple bacteria (2). The electrons from the quinol formed at the reaction center are transported back to the primary donor via a cytochrome bc_1 complex and at least one other cytochrome. This light-driven cyclic electron transfer is coupled to ATP production via a proton motive force. Purple bacteria do not possess noncyclic electron transport in the classical sense. A reductant can donate electrons into the quinone pool or to a cytochrome, but these reductants are not sufficiently strong to reduce NAD^+ directly. Instead, this is performed via "reversed" electron transport involving a NADH dehydrogenase enzyme. Some of the energy from the light-mediated cyclic electron transfer is used to drive these reactions.

Photosynthetic bacteria containing type I reaction centers are able to perform non-cyclic electron transport using other compounds as reductants, for example, simple sulfur components (2). The iron-sulfur centers on the acceptor side have redox potentials that are sufficiently low to allow reduction of NAD^+. In addition, sulfur bacteria and heliobacteria can perform cyclic electron transport coupled to ATP formation.

4. Carbon Dioxide Fixation and Photorespiration

The conversion of carbon dioxide to carbohydrates occurs in a cyclic process, called the Calvin cycle or the photosynthetic carbon reduction cycle. These reactions take place in the cytoplasm of prokaryotic cells or in the stroma of chloroplasts, mediated by at least a dozen enzymes. In the first step, ribulose-1,5-bisphosphate (RuBP) reacts with a molecule of carbon dioxide, thereby forming two identical C3 molecules of 3-phosphoglycerate, 3-PGA. This reaction is catalyzed by ribulosebisphosphate carboxylase (Rubisco), which is the most abundant protein on earth, and in eukaryotes consists of eight copies each of a small and a large subunit. In subsequent reactions, 3-PGA is converted into hexose and pentose phosphates, which requires 3 mol of ATP and 2 mol of NADPH per mole of CO_2 fixed. Hexose phosphates are converted to starch or are exported from the chloroplast via the phosphate translocator as triose phosphates. RuBP is regenerated from 3-PGA in reactions requiring further input of NADPH and ATP. The activities of some of the Calvin cycle enzymes are regulated and coupled to the redox state of the electron transport chain via thioredoxin (12).

A proportion of RuBP is oxygenated by Rubisco, which also can function as an oxygenase, in a potentially wasteful reaction (in terms of quantum efficiency of CO_2 fixation), to form phosphoglycolate and 3-phosphoglycerate. This reaction is called photorespiration. The major part of the carbon flow to glycolate is returned, via the photosynthetic carbon oxidation cycle, back into the Calvin cycle. Production of 1 mol of CO_2 results in the net consumption of 7 mol of ATP and 4 mol of NADPH. Although photorespiration lowers the quantum efficiency of CO_2 fixation, it is an important side reaction because it can dissipate excess energy under unfavorable conditions, thereby preventing oxidative damage to the photosynthetic apparatus. In addition, photorespiration provides a link between the carbon and nitrogen cycles and can provide additional ATP to the mitochondria and the cytosol. Under conditions of a short supply of carbon dioxide, such as under conditions of water stress when the leaves close their stomata to reduce water loss or at elevated temperatures, photorespiration is enhanced.

In the so-called C4 plants, photorespiration is strongly reduced (12), and the primary carboxylation reaction is of phosphoenolpyruvate (PEP), involving an enzyme that has a much higher affinity for CO_2 than Rubisco. In this carboxylation reaction, 4-carbon carboxylic acids are formed (hence the name C4 plants) in specialized mesophyll cells and are then transported to the bundle sheath cells. There they are decarboxylated, and the concentrated CO_2 is assimilated into the Calvin cycle via Rubisco. The photorespiration is kept low because of both the elevated CO_2 levels and the very low proportion of oxygen-evolving photosystem II centers in the bundle sheath cells.

5. Thylakoid Membrane Organization

5.1. Thylakoid Membrane Heterogeneity

The thylakoid membrane is a lipid bilayer that is composed mainly of galactolipids with an unusually high level of unsaturation and encloses an aqueous compartment, the lumen. The thylakoid membrane shows a strong lateral heterogeneity (5), in terms of both protein and lipid compositions (Fig. 3). A substantial amount of the membrane is folded into stacks ("grana stacks"), where the outer membrane surfaces are in close contact. The extent of stacking varies greatly with plant species and light conditions. The stacked regions contain mainly photosystem II, whereas the unstacked, stroma-exposed membranes contain photosystem I and the ATP synthase (Fig. 3). The intermediate electron carrier cytochrome b_6f is distributed over both membrane regions. Destacking of the membrane and randomization of the protein complexes occurs when divalent cations (mainly Mg^{2+}) are depleted. In cyanobacteria, there is no thylakoid stacking or lateral segregation between the photosystems.

Figure 3. Schematic model of thylakoid membrane organization and its lateral heterogeneity. The thylakoid membrane is a lipid bilayer that encloses an aqueous compartment, the lumen. The protein and protein complexes within the thylakoid membrane are unequally distributed over the stacked and stroma-exposed membrane regions.

5.2. Biogenesis and Maintenance of the Thylakoid Membrane

Chloroplasts develop from structurally very simple proplastids, which consist of an envelope, a nucleoid with DNA fibrils, a small number of ribosomes, and some flattened thylakoid membrane sacs that appear to be continuous with the inner membrane of the envelope. Development of the proplastid requires light, several chromophores, and multiple nuclear genes, all acting together through several signal transduction chains in a tightly regulated process. When leaves develop in total darkness, so called etioplasts are formed, which contain no chlorophyll and no thylakoid membrane system. These etioplasts consist of lipid-rich cube-like structures called prolamellar bodies, containing mainly the light-regulated enzyme protochlorophyllide reductase and its pigment substrate protochorophyllide. Within a day of illumination of the etioplast, chlorophyll is synthesized and an active thylakoid membrane system is formed.

Biogenesis of the thylakoid membrane system involves the synthesis of at least 70 to 85 proteins of the four main photosynthetic protein complexes (5). Many of these proteins are encoded in the nucleus; after synthesis in the cytosol, they are imported into the chloroplast and targeted and inserted into the thylakoid membrane. To increase targeting efficiency to the chloroplast and to prevent missorting to other organelles, these nucleus-encoded proteins are synthesized with a signal sequence that is recognized by a receptor on the outer envelope surface (13). After nucleotide triphosphate-driven import into the chloroplast, this signal sequence is cleaved off by a stromal peptidase . Targeting to the thylakoid is facilitated by a second signal sequence, or via information within the mature protein. Different pathways for targeting and insertion into the membrane have been found, and a number of structurally important components, such as the Sec machinery and a signal recognition particle (SRP) have been identified (14). It should be noted that most chloroplast-encoded proteins do not contain a signal sequence. The chloroplast-encoded thylakoid proteins are inserted into the membrane either co-translationally or post-translationally, possibly by mechanisms similar to those in *Escherichia coli*. Most proteins that form the central functional core of each photosynthetic complex are chloroplast-encoded, whereas the more peripheral proteins are nuclear-encoded. To achieve the proper stoichiometry of the different proteins, regulation of synthesis takes place at transcriptional, translational, and post-translational levels, via various signal transduction chains and through feedback mechanisms.

The two photosystems and the cytochrome b_6f complex contain in total at least 15 different cofactors and many different pigments. The biosynthesis of these cofactors and pigments is tightly linked to the synthesis and accumulation of the proteins. Very little is understood, however, about the mechanisms of this coordination.

It has become clear that, in addition to the proteins of the photosynthetic complexes, there must be a fairly large number of proteins involved in the biogenesis and maintenance of the complexes.

Several functions must be performed during these processes: synthesis and ligation of cofactors, membrane insertion, folding, and degradation of proteins. Notably, these auxiliary proteins are mostly located in the stroma-exposed thylakoid regions (Fig. 3).

Recently, members of several classes of these enzymes have been discovered, and most of these auxiliary proteins are encoded in the nuclear genome. Some of these genes have an eukaryotic origin, whereas many originate from prokaryotic chloroplast predecessors. Sequencing of various bacterial genomes, such as those of *Synechocystis* 6803 and *E. coli* and the ongoing sequencing of the higher plant genome of *Arabidopsis thaliana* and other plant species, will prove helpful in identification of the components involved in biogenesis of the photosynthetic apparatus.

5.3. Short- and Long-Term Adaptation to the Environment

The photosynthetic apparatus is constantly regulating its activity, in response to both the quantity and the quality of light, as well as the varying demands for metabolic end products of the light and dark reactions (NADPH, ATP, glucose, etc). The two photosystems operate in series but do not have the same action spectrum. Photosystem II can use light at wavelengths below 680 nm, whereas photosystem I can use wavelengths up to 700 nm. Maximal absorption of the outer antenna of photosystem I (LHCI) is 5 nm red-shifted (thus lower energy level) compared to that of photosystem II (LHCII). Thus, changes in color of the light will affect the relative activities of the two photosystems. For optimal quantum use, it is important to balance the activities of the two photosystems, and several short- and long-term adaptive and regulatory processes must occur. The demand for ATP and reducing equivalents by the dark reaction shows several-fold variations on changing environmental conditions, such as cold, heat, or water stress, and also during different stages of plant development (e.g., vegetative growth, senescence).

On a short-term timescale (milliseconds to minutes), light energy can be redistributed via disconnection of the major CAB protein (LHCII) from photosystem II (5). This process is driven by redox-controlled phosphorylation of LHCII. The disconnected LHCII can migrate along the thylakoid membrane to photosystem I and thereby redistribute absorbed light energy. This reversible process is called the *state transition*. Some of the light absorbed by CAB proteins can also be dissipated in the form of heat. This heat dissipation is probably occurring through formation of exciton traps through the reversible conversion of xanthophyll pigments. Furthermore, cyclic electron flow from photosystem I back into the plastoquinone pool could help to balance the activities of the two photosystems and to alter the ATP/NAPDH ratio.

If the short-term adaptations are not sufficient, the quantities of the structural components of the photosynthetic apparatus are changed through the regulated biosynthesis and proteolysis. Various signal transduction chains that respond to different environmental conditions exist to make these dynamic changes possible.

5.4. Light-Induced Stress, Photoinhibition and Repair

If the adaptation and regulatory processes described above are not sufficient, damaging oxidative reactions can occur. Several scavenging mechanisms, such as superoxide dismutases and exciton transfer to carotenoids, are present in the thylakoid to quench toxic oxygen species. The main target for photoinhibitory damage of the photosynthetic apparatus is photosystem II, especially its D_1 reaction center protein. Consequently, the D_1 protein has a much shorter lifetime than any other photosynthetic protein. Photoinactivation of photosystem II function can occur either on its donor side, when electron donation to P680 is limiting, or on its acceptor side, when the quinones become overreduced. Since photosystem II is not functional without the D_1 protein, plants have evolved a very efficient repair mechanism. Two important features of this repair mechanism are (1) a controlled disassembly of photosystem II, to ensure that the other, undamaged, protein subunits of photosystem II are not proteolyzed and can be recycled; and (2) tightly coupled proteolysis and synthesis of the D_1 protein through an as-yet unidentified mechanism.

Photosynthetic Reaction Center

The photosynthetic reaction center is a redox-active complex of pigments and proteins that is the most vital part of the photosynthetic apparatus. All reaction centers have similar basic architectures, and their functions follow essentially the same mechanistic principles. They use a “special pair” of chlorophyll molecules as a primary electron donor (P_D) and a chlorophyll or pheophytin as the primary electron acceptor (P_A). On excitation by light, P_D donates an electron to P_A, and a radical pair is formed. This primary charge separation is stabilized by transfer of the electron to secondary acceptors and by passing an electron from secondary donors. The donors and acceptors are arranged in the reaction center in such a way that the primary charge separation occurs across the lipid bilayer of a photosynthetic membrane. The redox components are ligated to two distinct, but related, membrane-spanning proteins. In oxygenic photosynthesis in plants, algae and cyanobacteria, two reaction centers, photosystem I and photosystem II, are coupled in series. Photosystem I belongs to the type I reaction centers, which contain FeS clusters as electron acceptors and are also found in nonoxygenic green sulfur photosynthetic bacteria. Photosystem II belongs to the type II reaction centers, which contain quinone acceptors and are also present in purple bacteria. The two types of reaction centers are thought to be related evolutionarily. The structures of photosynthetic reaction centers are known primarily through X-ray crystallography, in particular from the elucidation of the reaction center of purple bacteria. See Photosynthesis for further details.

Phylogenetic Tree

A phylogenetic tree is a tree-like presentation of the phylogenetic relationships among species or genes. In particular, a phylogenetic tree can be constructed by using evolutionary distances between amino acid or nucleotide sequences (see Sequence Analysis). The tree obtained by this construction is called a “molecular phylogenetic tree” or simply a “phylogenetic tree.”

The methods for constructing a phylogenetic tree can be separated into two major categories, depending on the target traits. These are character-based methods and distance-based methods (1, 2). For example, the maximum-likelihood (ML) method (3) for constructing a phylogenetic tree is a character-based method, whereas the neighbor-joining (NJ) method (4) is a distance-based method. In most instances, the following procedures are used to construct a phylogenetic tree: First, the nucleotide (or amino acid) sequences to be compared are aligned simultaneously with each other. When the number of sequences to be compared is more than two, the alignment is called a “multiple alignment.” A character-based method, such as the ML method, can then be used immediately. For the distance-based methods, on the other hand, the number of nucleotide or amino acid substitutions is estimated for all possible combinations of sequence pairs. Using the substitution numbers as evolutionary distances, one is able to use distance-based methods, such as the NJ method.

Phylogenetic trees are either rooted and unrooted trees (see Fig. 1). The rooted tree has an ancestral node, but the unrooted tree is just a network without any ancestral node. The ML methods give a rooted tree, whereas the NJ methods produce a network or unrooted tree. It is, however, possible to identify the ancestral node in a phylogenetic tree that has been constructed by the NJ method. If a particular gene sequence is known to be apparently the most remotely related one to other sequences, it is included as an outgroup into a set of sequences to be compared when a phylogenetic tree is constructed. Then, the branching point between the outgroup and all other sequences can be identified as an ancestral point. Note that if the outgroup is related very remotely to other genes, the substitution numbers may not be estimated correctly because of the so-called saturation effect.

Figure 1. Schematic representation of (a) rooted and (b) unrooted phylogenetic trees.

When a phylogenetic tree is constructed by using gene sequences, the tree obtained (the “gene tree”) may be different from the tree of species (the “species tree”) that has been constructed utilizing information other than sequences, such as the fossil record. In particular, if paralogous genes are included in the analysis, the phylogenetic tree will not be the same as the species tree. This is because paralogous genes, by definition, do not follow the speciation process. Thus, special attention to paralogous genes is required when the species tree is inferred from the gene tree. A species tree can be constructed only by comparing orthologous genes.

Phylogeny

Phylogeny is the evolutionary relationship among organisms or genes that takes into account the time and the divergence process from a common ancestor. When evolutionary relationships among organisms are studied by the techniques of molecular biology, the subject and the phylogeny obtained are called “molecular phylogeny” (1). Molecular phylogeny can be studied by immunological methods, protein electrophoresis, DNA-DNA hybridization, and amino acid and nucleotide sequences. For example, the immunological method utilizes the fact that cross-reactions in antibody–antigen interactions are stronger for closely related organisms than for distantly related ones. With this method, however, quantitative analysis has been difficult. Now the numbers of nucleotide or amino acid substitutions are used, as evolutionary distances, primarily to reconstruct the phylogeny of genes or proteins (see Phylogenetic Tree).

Previously in the study of phylogeny, controversy existed between cladistics and phenetics. Cladistics is the study of the pathway of evolution, in which the ancestor–descendant relationship is always discussed with the topology of a rooted phylogenetic tree, called a “cladogram” (see Phylogenetic Tree). On the other hand, phenetics is the study of the relationship among a group of organisms on the basis of the degree of similarity between their molecular, phenotypic, and anatomic traits. A tree-like network presenting phenotypic relationships is called “phenogram.” When a molecular clock exists, it is generally considered that a phenogram and a cladogram at the molecular level become identical to each other.

When the phylogeny of closely related organisms or genes is studied, for example, for individuals or alleles within a given population, it may be better to call it genealogy rather than phylogeny. Molecular genealogy is important for the study of genetic relationships among individuals or their alleles. The coalescence time is the shortest time for individuals or alleles to share the common ancestor in a given genealogy, and this can give us useful information about the time and degree of genetic diversity in the ancestral population (2).

Physarum

The acellular slime mold *Physarum polycephalum* has been studied in the laboratory extensively as a model eukaryotic organism. This soil amoeba has provided insights into many basic cellular functions. It is most famous for its complex developmental and sexual cycle. In the laboratory, it can be maintained in several forms, including a plasmodium that is basically an enormous singe cell containing several thousands of synchronously dividing nuclei. A simplified schematic of its developmental cycle is shown in Figure 1.

Figure 1. Schematic diagram of the *Physarum* developmental cycle.

In conditions that are not limiting in terms of food or moisture, Physarum is usually found in the plasmodium form. When the food supply begins to dwindle, the cell can either migrate to find more or begin the process of sporulation. In early stages of sporulation, cytoplasmic projections are formed that are filled with haploid nuclei. As the process continues, structures called fruiting bodies are constructed, and the nuclei packed in a protective shell and become spores. A mature fruiting body can rupture and spread the spores over the immediate area, where they remain dormant until conditions become right for germination or they get carried to a more favorable place by wind or insects.

When conditions are optimal, the spore germinates, releasing a haploid cell. This amoeba can search for food and can transform into a flagellate swimming form if it encounters water. Interestingly, this transition between the amoeba and myxoflagellate form occurs quickly and does not require additional protein biosynthesis, only rearrangement of existing components. If the amoeba encounters unfavorable conditions, it can change into a dormant and resistant form called a cyst. Amoebae can also mate or fuse with others, and the resulting cell grows into the plasmodium.

The Physarum genome is complex. The nuclei in the plasmodium form are a mixture of haploid and diploid. There has also been reported extrachromosomal linear DNA that can be maintained even upon transformation into yeast cells (1). There appear to be substantial differences between strains and under different growth conditions. One strain was reported to have about 70 chromosomes, containing a total of 1 to 5 × 10^9 base pairs of DNA (2).

A wide variety of genetic tools have been developed for manipulation of Physarum. Mutations can be created, and the resulting phenotypes analyzed in many ways. Extrachromosomal plasmids have been constructed into a family of vectors useful in stable or transient expression of heterologous genes. Multiple selectable markers systems are available, allowing the construction of strains in which complementation can be used to analyze the functions and interactions of proteins. Homologous recombination has been shown to occur, allowing gene knock outs and gene replacements to be made.

Of particular interest in Physarum is a complex system of photoreceptors and signaling that controls the onset of sporulation (3). The naturally synchronous cell cycle of Physarum plasmodium has been especially interesting, because fluctuations of inositol phosphate levels appear to be involved in its control (4).

Studies using the acellular slime mold Physarum polycephalum as a model eukaryotic organism have made contributions to our understanding of basic cell functions. Interesting insights will continue to be made using this social amoeba in the laboratory.

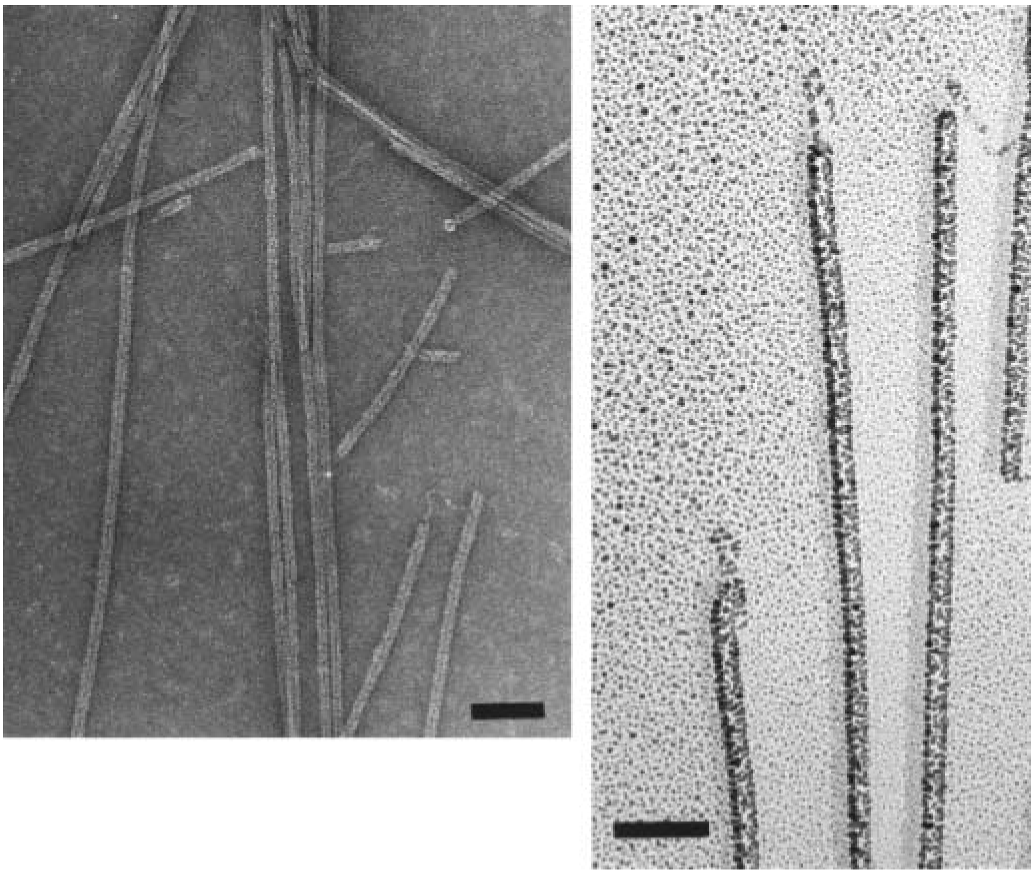
Pili

Adhesion pili are fairly stiff, filamentous structures, typically about 6.8 nm in diameter and about 1 µm in length, that protrude from a bacterium and provide specific attachment sites between the bacterium and some target cell (Fig. 1). The pili (or fimbriae as they are also known) terminate in a flexible fibrillum about 2.5 nm in diameter. The link between the bacterium and the cell is maintained during mechanically challenging situations *in vivo*, but the pili undergo significant structural rearrangement as a consequence. Single-particle reconstruction work has shown that the pilus may unwind without depolymerizing to produce a fibrillum-like structure, thus generating a filament as much as five times its original length whilst maintaining a high degree of structural coherence (1). A wide variety of pili exist *in vivo*, and these include the mannose-binding type I pili of the *Enterobacteriaceae* family and the gonococcal type IV pili. The data suggest that pili from all sources have a conserved structure and a similar morphology.

Figure 1. Electron micrographs of (left) negatively stained and (right) metal-shadowed P pili from *E. coli* that cause pyelonephritis. The 2.5-nm-diameter fibrillum extending from the end of the pilus is clearly shown at right. Bar = 50 nm. (Courtesy of E. Bullitt and L. Makowski.)



P pili, the surface appendages of *Escherichia coli*, have been particularly well characterized by X-ray fiber diffraction, scanning transmission electron microscopy (STEM), and three-dimensional reconstruction methods (1, 2), and for that reason they are described here in more detail. The pilus of diameter 6.8 nm contains approximately 1000 copies of a single protein (PapA) of molecular weight 16.5 kDa (Fig 2). Pili-terminating fibrillae are composed of proteins known as PapE, PapF, and PapK. The former two proteins position PapG at the tip of the fibrillus: PapG is a digalactose-binding molecule and is responsible for binding to the host (1). PapA, PapE, and PapF are similar in sequence, especially at their C-termini where they bind to PapD, the periplasmic molecular chaperone. The crystal structure of PapD (3) reveals a pair of domains, each comprising an antiparallel b-barrel, linked by a hinge region. PapH appears to stabilize the attachment of the pilus to the outer membrane of the bacterium. The assembly of P pili also requires PapC, an outer membrane protein.

Figure 2. Schematic of the position of proteins in P pili. (From Ref. 4, with permission.)

Fiber X-ray diffraction patterns from orientated pili are consistent with a helical structure having about 33 subunits in 10 turns (2). This helix is characterized by an axial repeat of 24.45 nm, a pitch length of 2.445 nm, a rise per subunit of 0.742 nm, and 3.30 subunits per turn. Measurements of the mass-per-unit length determined using STEM were consistent with each subunit comprising a single PapA molecule. Three-dimensional reconstruction methods yielded similar helical parameters based on a structure with 23 subunits in seven turns (axial repeat of 17.43 nm, a pitch length of 2.49 nm, a rise per subunit of 0.758 nm, and 3.28 subunits per turn: Fig. 3). These values are also very similar to those reported for type I pili from E. coli (pitch length 2.32 nm and 3.125 subunits per turn), in which a single pilin (FimA) predominates. This protein has about 25% sequence identity with PapA and would be expected to have a similar three-dimensional conformation. Using rotary shadowing, the handedness of the P pili helix has been determined. The three-start helix with a pitch length of about 9 nm has been visualized directly and is left-handed. Hence, the fundamental one-start helix is right-handed. The pili have an off-centered helical cavity (the radial coordinate of the center of the cavity is about 0.5 nm) with approximate dimensions 2.5 by 1.5 nm (1). Channels emanating out from the cavity link it to the outside of the pilus. The shape of the PapA molecule is not yet known, but it has been suggested that its long axis may lie along the same direction as the one-start helix, thus facilitating a possible structural transition to the more extended helical form arising from the response of the pili to mechanical stress. Bullitt and Makowski (1) have proposed that the relatively stiff pilus can be transformed to a flexible fibrillum if the interactions between the PapA molecules on adjacent turns of the one-start helix are broken and if there is a rotation of the domains along the direction of the one-start helix. PapA, as well as some of the other Pap proteins, would thus be expected to be elongated under these conditions. Because the mass-per-unit-length of a fibrillum is about one-fifth of that of the pilus, it is possible that the pilus could be extended fivefold. As a result, many pili with different lengths would be able to bind the cell simultaneously, thus providing stronger adhesion than if the pili were of fixed length. In that case they would have a greater chance of being broken individually when under shear.

Figure 3. Three-dimensional reconstruction of P pili from electron microscopy and image analysis. P pili are 6.8 nm in diameter and have a helical symmetry with 23 subunits in seven turns. The pitch length of the helix is 2.49 nm, and the axial rise per residue is 0.758 nm. *E. coli* may utilize plastic deformation of P pili to withstand shear forces in the host cell environment, extending the pilus to a thin fibrillum-like structure to maintain attachment to the target cell. Bar = 2.5 nm. (Courtesy of E. Bullitt and L. Makowski.)

Pinocytosis

Pinocytosis is a form of endocytosis that is mediated by several different vesicular mechanisms and is responsible for both receptor-mediated and fluid-phase endocytosis. Clathrin -mediated endocytosis is the best-characterized pinocytic pathway and, in some cell types at least, is the major pathway for pinocytosis.

0.1. Clathrin-Dependent Endocytosis

The uptake of most receptor-bound ligands and extracellular fluid is mediated by endocytic clathrin-coated vesicles, typically 100 to 150 nm in diameter (1). These form constitutively from plasma membrane clathrin-coated pits during most of the cell cycle, but their formation, in common with other membrane trafficking events, does not occur during mitosis. Clathrin-coated vesicle assembly is initiated by the multifunctional AP-2 adaptor protein complex. The recruitment of AP-2 from the cytosol is poorly understood, but it may involve binding to inositol phospholipids and possibly to a polypeptide receptor [two related adaptor complexes, AP-1 and AP-3, are involved in vesicular transport from intracellular compartments (2)]. Membrane-bound AP-2 provides sites for attachment of cytosolic clathrin triskelions, which assemble either as flat lattices or invaginating lattice structures (see Clathrin). Clathrin assembly is required to drive membrane invagination at the cell surface, although local concentrations of specific lipids also contribute to membrane deformation.

AP-2 also provides binding sites for a spectrum of other proteins that are required structurally or catalytically for the formation of coated vesicles. These include amphyphysin, dynamin, EPS-15, synaptojanin, AP180/CALM, and the endophilins (SH3p4, SH3p8, SH3p13) (3). The precise roles of these proteins are still being established. Dynamin is currently the best characterized. This 100-kDa GTPase is recruited to coated pits via the SH3 domain of amphyphysin and is required for pinching off (scission of) invaginated coated vesicles (1). GTP hydrolysis is required for a conformational change in dynamin that leads to fusion of the membrane at the neck of an invaginated vesicle. Cells that express dominant-negative mutant forms of dynamin do not internalize transferrin and other ligands taken up by receptor-mediated endocytosis. Moreover, the Shibire mutant of Drosophila melanogaster has a temperature-sensitive defect in dynamin. At the nonpermissive temperature, Shibire mutants are paralyzed because they cannot recycle clathrin-coated vesicles, which is required to regenerate synaptic vesicles. Dynamin has also been implicated in forming of caveolae and non-clathrin vesicles (4, 5), but these processes are not well understood, and the full extent of dynamin function is still to be clearly established. Rab5 and RabGDI are also required for coated vesicle budding (6), and this may reflect some quality-control mechanism to ensure that endocytic-coated vesicles also include the correct SNARE proteins and allow the subsequent targeting and fusion of the vesicles with early endosomes.

Clathrin-dependent endocytosis is inhibited by treatments that interfere with the functions of the regulatory proteins, such as cytosol acidification, hypertonic medium, or K^+-depletion, or by overexpressing modified forms of key protein components (clathrin hub domains, GTP-bound dynamin, amphyphysin-SH3 domains, Eps15 AP-2-binding domains), all of which act as dominant negatives (7). Under these conditions clathrin-dependent, receptor-mediated endocytosis (e.g., transferrin uptake) is blocked. Although the overexpression, for example, of dominant-negative dynamin blocks clathrin-dependent endocytosis, fluid-phase endocytosis is unaffected or only partially affected, suggesting that there is also a clathrin-independent pathway for constitutive endocytosis. Although this clathrin-independent pathway may be active to some extent under normal conditions (its contribution to total endocytosis may vary in different cell types ranging from <10% in baby hamster kidney cells to 50% in hepatocytes), its activity may be up-regulated when clathrin-dependent endocytosis is effectively blocked (8). The molecular basis of this clathrin-independent pathway is not known, but there are several other pathways that could mediate fluid-phase uptake (see later).

Following endocytosis, clathrin-coated vesicles must be uncoated to allow fusion with early endosomes. Uncoating, which is ATP-dependent and requires the proteins auxilin and hsc70, releases clathrin, AP-2, and the other vesicle components, allowing them to be reused (9).

0.2. Clathrin-Independent Endocytosis

Caveolae, or plasmalemmal vesicles, are flask-shaped (60 to 80 nm in diameter) invaginations seen on the cytoplasmic aspect of the plasma membrane in many cell types. It is believed that they form by the oligomerization of a coat protein, caveolin (VIP-21). The function of caveolae is unclear. In endothelial cells, they mediate transcytosis, but in other cells they may provide an alternative endocytic route, although their net contribution to total endocytosis is likely to be small. Caveolae function in the concentration of a subset of cell-surface proteins, including GPI-anchored molecules, such as the folate receptor, and may internalize these components. Caveolae have also been implicated in the entry of SV40 virus. The caveolar membrane has a characteristic lipid composition distinct from the bulk of the plasma membrane and includes a relatively high cholesterol content. Thus drugs that preferentially bind cholesterol, such as filipin or nystatin, disrupt caveolae structurally and functionally. This distinctive membrane lipid composition also includes a concentration of the ganglioside GM1. GM1 functions as the receptor for cholera toxin and, in keeping with this, the endocytic uptake of cholera toxin is caveolae-mediated. Dynamin (see previous) has also been implicated in the pinching off required to release caveolae into the cytosol, presumably using the same mechanism as in clathrin-mediated endocytosis (4, 5). Caveolae also function in calcium signalling and signal transduction, and purified caveolae contain heterotrimeric G proteins, Src family protein kinases, and protein kinase C. Certain cell types, for example lymphocytes, lack VIP-21/caveolin and identifiable caveolae, suggesting that caveolar function is not essential for cell viability. The fate of internalized caveolae is unclear, and it has been suggested that they may fuse with early endosomes.

Plant Genetic Engineering

Plant genetic engineering is defined as the creation of a complete plant containing a fragment of foreign DNA stably inserted into its nuclear genome. During the last 15 years, the majority of the world's most significant crop plants have been transformed. Apart from a significant impact on plant research in general, the products of transgenic plants are currently entering the marketplace and, indeed in some cases, are achieving market dominance.

Plant transformation relies on inserting foreign DNA into a single plant cell, followed by regenerating that cell into a complete plant. Often this process relies on totipotency, the unique ability of isolated plant cells, when cultured in the presence of plant hormones, to divide to form an undifferentiated callus that, in turn, is induced to form shoots and roots and thus a complete plant. Two general means are available for transferring foreign DNA to plant cells, *Agrobacterium*-mediated transformation and naked DNA uptake.

Agrobacterium is a soil bacterium that contains a tumor-inducing Ti plasmid. During *Agrobacterium*-mediated transformation, a defined fragment of the Ti plasmid, the so-called transferred or T-DNA (see T-Complex, T-DNA, T-Region, T-Strand), is transferred from the bacterium to the infected plant cell and integrated stably into the plant nuclear genome. The T-DNA is delimited by 25-bp imperfect border repeats. Transformation vectors based on the T-DNA have been developed and can be grouped into two types, cointegrative and binary. Cointegrative vectors are based on a Ti plasmid in which the body of the T-DNA within the border sequences has been replaced by a defined sequence of DNA. Foreign DNA contained on an appropriate plasmid is introduced into *Agrobacterium* and integrated into the cointegrative vector by recombination. Binary vectors are based on plasmids stable in both *Escherichia coli* and *Agrobacterium*. They contain T-DNA border sequences between which foreign DNA can be cloned to be transferred to the plant genome. Then, the binary vector is transferred to a host *Agrobacterium* that contains a Ti helper plasmid which contains functions necessary for gene transfer to plant cells, but lacks a T-DNA. Because cointegrative vectors are based on Ti plasmid, they are very stable in *Agrobacterium*, but they can be difficult to work with in practice. On the other hand, binary vectors can be handled with relative ease, although they are unstable in *Agrobacterium* and continued antibiotic resistance selection is required to maintain them (1).

Transformation using *Agrobacterium* requires direct contact between the plant cell and the infecting bacteria. In practice, this is achieved by cocultivation of *Agrobacterium* with isolated plant cells or explants, such as leaves, roots, or tubers. In this case, bacteria are incubated with plant material, and transformation occurs over a period of about two days. Then, the plant material is washed to remove excess bacteria and cultured further to allow plant regeneration (1). Recently, a novel nontissue culture approach of transformation has been described using the model plant Arabidopsis. Here the developing floral buds of intact plants are vacuum infiltrated with the Agrobacterium. The plants are washed, allowed to recover, and selfed. From progeny seeds, transgenic plants can be selected by growth on antibiotics to which resistance is encoded by the foreign DNA contained on the transformation vector (2). It has been generally assumed that Agrobacterium-mediated transformation is limited to the obvious natural hosts of Agrobacterium, the dicotyledonous plants. Recently, however, it has been established that Agrobacterium can be used effectively to create transgenic monocotyledonous plants, such as rice (3).

Naked DNA uptake was developed for two reasons: (1) as a means of transforming plants whose cells, or tissues, are not amenable to culture and to high-frequency Agrobacterium transformation; (2) because of the possibility of using nonspecialized plant transformation vectors in transformation. Naked DNA transformation uses standard bacterial plasmids as vectors. The only requirement is that the plasmid contains a gene linked to a plant-specific promoter that is functional in transgenic plants. Several methods are available to transfer foreign DNA into plants. The two techniques used most frequently with isolated cells, treatment with polyethylene glycol and electric discharge or electroporation (see Transfection), achieve relatively high frequencies of transformation, which generally result in measurable activity of the transferred gene constructs after approximately one day. This allows transient expression assays, for example, to test the expression of specific promoter/gene constructs. Cells transformed in this manner can also be regenerated to intact plants as described previously. Naked DNA can also be introduced into plant cells by particle bombardment. This involves coating gold or tungsten particles with DNA and using a gas or electric discharge to project the particles into target cells. This can be used to study transient expression in intact tissue, but its greatest practical application has been to insert foreign DNA into explants from which shoot or root organogenesis can occur (4).

In both Agrobacterium-mediated transformation and naked DNA uptake, the foreign DNA stably integrates into the nuclear genome of the plant. Agrobacterium-mediated transformation can result in inserting a single unrearranged fragment of DNA that represents the T-DNA. In transgenic cells resulting from naked DNA uptake, however, the DNA might be rearranged and can occur as multimers.

Upon insertion into the genome, a gene linked to a plant-specific promoter is expressed in a pattern determined by that promoter. A variety of reporter genes have been developed to allow direct selection for the growth of transgenic material (for example, resistance to kanamycin, hygromycin, or herbicides) or for screening for expression (for example, histochemical staining with b-glucuronidase or fluorescence resulting from expression of the jellyfish green fluorescent protein). An increasing variety of promoters are available to produce expression in most plant tissues (for example, the 35 S-RNA promoter derived from cauliflower mosaic virus) or expression in a tissue-specific manner (for example, tapetum-specific expression). Recently promoter constructs have been developed so that the expression of specific genes can be induced in defined tissues following the external application of an inducing substance, such as glucocorticoids (5).

Gene expression can also be inactivated in transgenic plants, by the expression of either antisense oligonucleotides (6) or sense constructs of the target gene, a phenomenon known as cosuppression. The exact mechanism by which cosuppression occurs is not known nor is the reason for the instability of transgenic expression that often occurs in some plant lines (7).

In addition to transferring foreign genes to the genomes of plants, transformation in plants can be considered a form of insertional mutagenesis. This is the basis of gene tagging, where a defined sequence of DNA inserts into the genome and knowledge of this sequence allows recovering the flanking plant sequence from mutant genomes by hybridization, PCR, or plasmid rescue. Either transposable elements transferred to a novel plant host or T-DNA can be used in gene tagging. The latter has the advantage of producing single insertions, simplifying genetic analysis, but requires screening large numbers of mutant individuals following a transformation experiment. The transposable element approach has the advantage of using populations of mutant individuals produced by genetic crossing. Each individual contains multiple transposon insertions, thus reducing the number of mutants that need to be screened for a mutant phenotype. The construction of gene tags can vary. For example, at their borders they can contain a reporter gene lacking a promoter, so that expression of the reporter gene occurs only if it is inserted into the genome near a promoter (8, 9). Another example is the use of a tag that contains transcriptional enhancers, so that expression of flanking genes becomes activated following insertion of the tag into the plant genome (10).

Plant genetic engineering has had a profound effect on basic plant biology. Transgenic plants have been used to study the mechanism of gene expression and the developmental and biochemical consequences of the expression or inhibition of the expression of various genes (11).

The creation of transgenic plants has begun to have a profound effect on agriculture because of the steady appearance of genetically engineered crop plants. These include plants tolerant of herbicides or resistant to insect predation and viral infection. Interestingly, plants altered in developmental events or biochemical processes have also gained a place in the agronomic marketplace. Possibly the most widely known example of this is the tomato engineered, using antisense technology, so that the polygalacturonidase gene, which is normally involved in the softening of fruit, is not expressed during fruit development. These tomatoes have delayed ripening (12). Another interesting example is the potatoes engineered so that they contain changed starch content and quality for industrial processes (13). The acreage of transgenic crops plants is steadily increasing worldwide (14). This technology is, however, not without its opponents. Concerns have been raised as to transfer of the transgenes from transgenic plants to local plant relatives, increasing the weediness of certain plant species, and the creation of products that may induce unexpected allergies in consumers.

Plant Hormones

Development of higher organisms—plants as well as animals—is largely based on a coordinate division, expansion, and differentiation of cells. This coordination is primarily based on cell-to-cell communication over short and long distances and is orchestrated by messengers of various chemical nature. One class of signaling molecules contains the hormones, characterized by their ability to exert, most often, specific effects over a distance and by their capacity to act at very low concentrations. This entry presents a brief overview of the current state of the art in the field of plant hormones, or phytohormones.

Since the first discovery of phytohormones, approximately 70 years ago, dedicated efforts of plant physiologists and biochemists have produced a wealth of data on their chemical nature, pathways of biosynthesis and metabolism, possible conjugates, transport mechanisms throughout the plant, and physiological functions (1). Studies have been based traditionally on the correlation of the effects observed upon exogenous application of hormones with changes in their endogenous concentration. A major disadvantage of this approach is that it remains uncertain whether the effect reflects the normal physiological role of the hormone. Another problem arises from the fact that the distribution of the growth regulator over the entire plant body is largely unpredictable. Moreover, problems of uptake and rapid metabolism were not uncommon. The use of inhibitors had the additional drawback of potential lack of specificity. In the past decade, our knowledge of the molecular basis of plant hormone biology has made a giant leap forward, mainly owing to molecular genetic studies of mutants in thale cress (*Arabidopsis thaliana* (L.) Heynh.). Molecular techniques have allowed the unraveling of mechanisms by which phytohormones control tissue-specific and developmentally regulated responses. Genetic engineering enables changes in internal concentration or perception of a hormone in a temporally and spatially controlled manner. Moreover, several applications in agriculture and horticulture are being explored (2–4). Introduction of bacterial hormone biosynthesis genes (mainly from *Agrobacterium tumefaciens*) into plants has confirmed much of the classical view of hormone action (5).

Our current understanding of the biosynthesis, perception, signal transduction, control of gene expression, and effects of each class of phytohormones are presented in the separate entries. Six classes of compounds are recognized as true phytohormones: auxins, cytokinins, gibberellins, abscisic acid, ethylene, and brassinosteroids. Other growth regulators, such as polyamines, oligosaccharides, and salicylic and jasmonic acids, also influence plant growth and development. For a description of their effects, see recent reviews (6–8).

It is important to stress that plant hormones do not play exclusive roles in development, but that they instead act coordinately at different stages. The most direct indication for this characteristic is their overlapping physiological roles (1). This cross-talk is most certainly based on molecular interactions between factors regulating signal transduction and feedforward or feedback loops of different hormone pathways. Moreover, environmental cues exert an additional level of control on plant hormone abundance and activity. Thus, hormone signaling pathways are probably integrated with those participating in phototransduction, control of the biological clock, nutrient sensing, and stress (9). Given the redundancy of involvement of signaling intermediates, such as G proteins, phosphorylation cascades, and calcium signaling mechanisms should exist to maintain accuracy of individual signaling chains (10). Much of the specificity might derive from a restricted spatial distribution of signaling components together with their assembly in complexes, called transducons. The latter would consist of a module of receptors, receptor targets, and downstream signaling factors, presumably coupled by 14–3–3 proteins (11). Such scaffolding proteins have been demonstrated in signaling pathways in bacteria and in yeast (12, 13). Interactions between different transduction cascades could be exerted by components that navigate between them—for example, second messengers or mobile protein kinases (14).

With the current progress in sequencing of the genome of Arabidopsis, plus the technical advances that allow rapid map-based cloning, creation of large tagged-mutant collections (15), and production of knockout mutants by homologous recombination (16), it can be predicted that the molecular controls of hormonal pathways and their target genes will be unraveled at a dazzling pace in the next few years. The puzzle of inter- and intracellular hormonal networking will soon come of age.

Plasmalemma

Plasmalemma (plasma+Gr. lemma = pellicle) is a membrane structure that is synonomous with the plasma membrane of cells. There are other usages of the term. In sea urchin eggs, it is the vitelline membrane covering the hyaline plasma layer; upon fertilization the vitelline membrane thickens and becomes the fertilization membrane, which separates from the plasma membrane lying just beneath. In amoeba, it is the outermost membrane, which also contains many filamentous structures. In plants, it is the external membrane of the cytoplasm; under osmotic stress in hypertonic salt solutions, plant cells undergo plasmolysis, where the plasmalemma separates from the cellulose wall of the cell. (See also Membranes.)

Plasminogen

Plasminogen is one of the most abundant zymogens of serine proteinases in mammalian species; it is expressed constitutively in the liver and is present in blood at 200 µg/mL. The activated proteinase, plasmin, is one of the most active, because of its broad substrate specificity. The activation system for plasminogen is therefore a powerful and potentially promiscuous proteolytic system, which consequently has mechanisms for its strict regulation. The most fundamental of these is the ability of plasminogen to bind to various insoluble matrices (ie, fibrin and certain cell-surface components), a process regulating both the activation of plasminogen (see Plasminogen Activators) and the inhibition of plasmin.

The binding properties of plasminogen are mediated by its various kringle domains. Plasminogen is a mosaic protein composed of a 77-residue N-terminal domain, five kringle modules, and the serine proteinase domain. The kringle modules each contain a binding site for lysine or other w-amino carboxylic acids. Kringle 1 binds these ligands with the highest affinity (dissociation constant K_d = 10 µM for 6-aminohexanoic acid) and represents the archetype for this binding site. It contains both anionic and cationic centers, with an intervening hydrophobic depression (1, 2). The cationic center is not present in all kringles, such as kringle 5, and these have a preference for ligands lacking a carboxylate function. Therefore, plasminogen can interact with the side chains of internal lysine residues, as well as those at the C-termini of proteins degraded by proteinases with a specificity for basic residues, including trypsin, or plasmin itself. The latter mechanism may act to amplify the plasminogen activation system.

The gross conformation of plasminogen is dramatically affected by kringle-binding ligands (3). In the absence of such ligands, it adopts a compact conformation, due to poorly understood interactions between the N-terminal domain and the kringle modules. Exogenous kringle-binding ligands disrupt these interactions and cause an extension of the molecule to approximately double its length. This conformational change can also be accomplished by proteolytic removal of the N-terminal peptide, generating Lys78-plasminogen (to discriminate between them, the native molecule is often referred to as Glu1-plasminogen). The conformation of plasminogen has a very marked effect on its activation, with the extended or "open" form being activated at least 10-fold more efficiently. The absolute difference in activation rates may be much larger, as the "closed" form is in equilibrium with the "open" form in the absence of exogenous ligands. Thus the physiologically relevant substrate form of plasminogen is thought to be that bound to various surfaces in the "open" conformation.

Plasmin free in solution is very rapidly inhibited by the serpin α_2-antiplasmin, which is dependent largely on an initial interaction between the C-terminal region of the inhibitor with the lysine-binding site of plasmin kringle 1 (4). Hence, plasmin inhibition is decreased when these sites are occupied by binding to fibrin or cell surfaces (5). Plasmin and plasminogen have moderate affinities for these surfaces (K_d ~1 µM),. with dissociation half-lives of the order of minutes. Thus binding of plasminogen and subsequent dissociation of plasmin, respectively, regulate the activation and inhibition of this proteolytic system.

One final notable feature of plasminogen is its potential to attain proteolytic activity in the absence of the activation cleavage at Arg561–Val562. The non-enzymatic bacterial protein streptokinase binds to the serine proteinase domain of plasminogen and induces a conformational change, with the formation of a functional active site. This has full activity against peptide substrates, but the specificity of the complex against macromolecular substrates is changed from that of plasmin to that of a plasminogen activator. Therefore, "catalytic" amounts of streptokinase can rapidly lead to full activation of plasminogen. Although this property is used clinically to generate plasmin activity *in vivo*, an equivalent endogenous mechanism has not been detected.

Plasminogen Activators

Mammalian species have two plasminogen activators, urokinase- or urinary-type plasminogen activator (uPA) and tissue-type plasminogen activator (tPA), that are the products of separate genes and members of the chymotrypsin family of serine proteinases. Both are mosaic proteins with a modular structure similar to that of the blood coagulation proteinases to which they are closely related [Blood Clotting]. The two plasminogen activators provide an excellent example of the regulatory potential made available by the modular construction of these proteinases. Although catalyzing the same reaction, i.e., specific hydrolysis of Arg560–Val561 of plasminogen, gross differences in the organization of the N-terminal modules of the plasminogen activators, together with subtle differences in the serine proteinase domain, lead to remarkably different functional properties. These are reflected in their biological roles with tPA being predominantly responsible for plasmin-catalyzed fibrin dissolution, whereas uPA is thought to be responsible for generating plasmin activity in the context of extracellular matrix degradation and thus to be involved in tissue remodeling and invasive cell migration (e.g. tumor invasion and metastasis; vascular remodeling) (see Urokinase).

1. tPA

tPA is composed of five independent domains; an N-terminal fibronectin type-I (finger) module, an EGF-like module, two kringle modules and the serine proteinase domain. It is secreted primarily by vascular endothelial cells as a single-chain glycoprotein of 527 residues (M_r 65,000). This single-chain form also undergoes a plasmin-catalyzed “activation” cleavage (Arg275-Ile276) to give a disulfide-bridged two-chain molecule. However, uniquely among the serine proteinases, the catalytic activities of these two forms are very similar. They vary by approximately 10–20–fold in the absence of cofactors, but in the presence of fibrin [see “Fibrinogen”] as a cofactor their activities are essentially indistinguishable. Molecular modeling and mutagenesis studies suggest that the “active zymogen” nature of tPA is largely due to Lys429 (Lys156 in chymotrypsin numbering); in the absence of a proteolytically exposed N-terminal a-amino group at Ile276, it can form a salt-bridge with Asp477, substituting for the interaction between the a-amino group of Ile16 with Asp194 in chymotrypsin (1). The crystal structure of two-chain tPA is compatible with this hypothesis (2).

Fibrin has a dramatic effect on the activities of both forms of tPA. The catalytic efficiency increases up to 1000-fold, as a result of a large reduction in the K_m (Michaelis constant) for plasminogen and a more modest increase in the value of the catalytic rate constant k_{cat} (3). More than one mechanism appears to be responsible for these kinetic effects. Fibrin principally enhances plasminogen activation by provides a template for the coincident binding of enzyme and substrate in a ternary complex. In contrast to the binding of uPA to uPAR, the interactions between tPA and fibrin responsible for this binding are complex and not fully elucidated. The fibronectin type-I and the lysine-binding properties of the second kringle module are involved, with sites in the serine proteinase domain also implicated. Secondary to this template effect, fibrin also appears to induce conformational changes in the serine proteinase domain of single-chain tPA, bringing it to catalytic equivalence with two-chain tPA, and increasing its activity against small peptide substrates. Whether these are direct effects or result from the significant interdomain interactions that exist in tPA is presently undetermined.

In addition to its fibrinolytic role, analysis of tPA$^{-/-}$ knock-out mice has revealed a role for tPA in the brain, in both normal and neurodegenerative situations. The proteolytic activity of tPA is implicated in the plasticity and reorganization of synapses involved in various learning processes, although it is not known whether plasminogen activation is required in these processes or whether tPA acts on other substrates. tPA is also involved in neuronal cell death following excitotoxin stimulation of the hippocampus and in ischemic stroke. The former process is known to require plasminogen activation, with plasmin acting to degrade laminin, an important extracellular matrix component in the central nervous system (4).

Plasmogamy

Plasmogamy occurs when two different cells fuse with each other and the cytoplasm of both is joined. During fertilization , plasmogamy occurs when the sperm has entered the cell membrane of the egg and a male and a female pronucleus develop. However, plasmogamy in animal reproduction is unusual in that the amount of cytoplasm of the two gametes is disparate. The oocyte is one of the biggest cells in the body and contains most of the cytoplasm, whereas the spermatozoon is a very specialized cell that contains only very small amounts.

The length of time it takes the sperm head to fuse with the oocyte cytoplasm depends on the species. In general, fusion takes place during meiosis of the oocyte. These divisions are necessary, as the primordial germ cells remain diploid until ovulation commences at the beginning of puberty under the influence of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). During growth and oogenesis, the oocyte becomes temporarily tetraploid and undergoes two meiotic divisions, resulting in the extrusion of polar bodies. Formation of the first polar body involves a cytoplasmic protrusion at the animal pole. The cytoplasm is not divided equally among the two cells, however, and the polar bodies contain less material than the remaining oocyte. The first polar body in a number of different species appears to be a maturized cell. The second polar body appears after the second meiotic division and contains a variable amount of cytoplasmic contents. In most cases, however, the fate of the polar bodies is a degenerative process. During this stage of fertilization, the formation of crenations along the vegetal pole occurs, along with redistribution of cytoplasmic compounds.

Upon sperm entry, which is the first step that can be considered a unification in which the cytoplasms are joined, a number of events are triggered. Sperm entry itself is mediated by an adhesion protein named fertilin (previously known as PH-30). The a subunit of fertilin is involved in mediating the binding of sperm and egg plasma membranes (1); there is also evidence for adhesive activity of an egg b1 integrin-mediated interaction (2). These gene products are expressed by the ADAM gene family and are processed during sperm maturation (3, 4).

The first measurable event during plasmogamy is a rapid depolarization of the plasma membrane on sperm entry. This process is used in some species to prevent more than one spermatozoon from entering the egg. In sea urchins, eggs with a fertilization potential greater than 0 mV are not polyspermic. Maintaining a potential of +5 mV causes a block of fertilization. If the applied voltage is lowered below 0 mV, fertilization will occur and, if the potential is maintained below –30 mV, the eggs will become polyspermic. These observations indicate that a rapid change in the potential of the plasma membrane is a first reaction of the egg to sperm entry. The change in polarity occurs concomitantly with the influx of calcium (see Calcium Signaling). The release of calcium and of the cortical granules occurs in a sort of wave, starting from the point of sperm entry. Within the cell, the pH is raised, which is assumed to be another factor of egg activation, along with enhancing or initiating protein biosynthesis, DNA replication, messenger RNA polyadenylation, glucose-6-phosphate dehydrogenase activity, potassium conductance, glycogenolysis, and thymidine uptake. These events go together with the pronucleus development and chromatin condensation. The cortical granule reaction does not seem to be affected by the raised pH.

Exocytosis of the cortical granules is another event that occurs during plasmogamy. The contents of the granules trigger the conversion of the ZP2 and ZP3 glycoprotein receptors for sperm to ZP2f and ZP3f, respectively, which are the inactivated forms. In the mouse, rabphilin-3A is involved in the process of calcium-dependent exocytosis on fertilization (5).

There are several explanations for the calcium release mechanism: It can be mediated by inositol triphosphate (IP_3) or be IP_3-independent, or it can be mediated by G-protein or tyrosine kinase-linked enzymes. It has been shown that IP_3 and diacylglycerol are involved in a number of signal transduction processes and that IP_3 is involved in the autocatalytic cycle of calcium release at fertilization (6). These observations have led to the assumption that the sperm induces an initial production of IP_3, but the mechanism of IP_3 generation has not been elucidated. In addition to this theory, the production of IP_3 and diacylglycerol is assumed to be linked to proteins, as their involvement was shown in several species in which G-proteins triggered the formation of IP_3. Up until now, however, no corresponding molecules were found that could support this kind of sperm-induced egg activation. It was also shown, in sea urchins, that ryanodine is able to induce calcium release through ryanodine receptors, which are distantly related to the IP_3 receptors. In experiments with agonists and antagonists of the IP_3 receptor, the involvement of both systems in calcium release was observed. When the IP_3-induced calcium release was blocked, however, other systems were not able to compensate. At this time, it must be assumed that a number of mechanisms act together to induce calcium release, but the main triggering mechanism is still not clear.

Plastocyanin

Plastocyanins belong to the family of cupredoxins [ie, relatively small (~10 kDa, 97–104 amino acid) blue single copper proteins, including azurins] involved in electron transfer (1). They are

DNA to protein, it also plays a vital structural role in many ribonucleoprotein particles and, as is now recognized, can itself have catalytic activity. Whereas in the hypothetical RNA world, RNA would have acted unaided by other macromolecules, RNA almost invariably functions in modern organisms associated with RNA-binding proteins, a wide variety of which have now been identified. Although many RNA-binding proteins are uncharacterized structurally and do not fall into known categories, primary sequence analysis has led to the identification of a number of recurring RNA-binding motifs in functionally diverse RNA-binding proteins (1, 2). Interestingly in most cases, these are structurally and therefore probably evolutionarily distinct from DNA-binding motifs. RNA molecules are classified into various types based on their function or localization, such as transfer RNA (tRNA), messenger RNA (mRNA), ribosomal RNA (rRNA), viral RNA (vRNA), small nuclear RNA (snRNA), and small cytoplasmic RNA (scRNA). Table 1 gives some examples of RNA-binding proteins associated with each form, and Table 2 summarizes with examples the known RNA-binding motifs. Understanding how RNA-binding proteins specifically interact with their target RNA to form functional complexes is a key problem in structural biology, that has ramifications throughout molecular biology from transcription to protein biosynthesis and from replication of viruses to development of embryos and genetic disease.

Table 1. Selected RNA-Binding Proteins, their RNA Targets, and their Functions

RNA	RNA binding proteins	Function
tRNA	tRNA (m^5U54)methyl-transferase	General tRNA modification
	tRNA-guanine transglycosylase	Specific tRNA modification
	aminoacyl-tRNA synthetase	tRNA aminoacylation
	met-tRNAf^{met} formyltransferase	Prokaryote translation initiation
	IF3	Prokaryote translation initiation
	EF-Tu	tRNA transport to ribosome
M1 RNA	C5 protein	Subunit of E. coli Rnase-P endoribonuclease
mRNA/hnRNA	RNA polymerase II	Transcription
	GreA	Transcription termination
	hnRNP proteins	Pre-mRNA binding
	Sex-lethal	Pre-mRNA splicing
	mRNA capping enzyme	5′ capping enzyme
	E. coli RNase III	RNA processing
	ds RNA adenosine deaminase	mRNA editing
	CBP20, CPB80	Nuclear cap-binding protein subunits
	eIF-4F	Cytoplasmic cap binding protein
	Poly-A-polymerase, CStF	3′ poly-adenylation
	Poly-A-binding protein (PABP)	mRNA stability
	aCP-1, aCP-2	a-Globin mRNA stability
	Staufen	mRNA localization

	Endo-, exoribonucleases	mRNA degradation
	IRE-binding protein, E. coli	Translational regulation
	Threonyl-tRNA synthetase, T4 regA	Translational regulation
	Thymidylate synthase	Translational regulation
rRNA	RNA polymerase III	rRNA transcription
	Nucleolin	rRNA processing
	Nucleolar 2′-O-methyltransferase	rRNA modification
	TFIIIa	5s rRNA storage
	Sx, Lx	Small and large subunit ribosomal proteinss
snRNA	B, B′, D1, etc.	Core snRNP proteins (Sm-proteins)s
	U1A, U2B″, etc.	Specific SnRNP proteinss
	Human RNA helicase A	RNA helicases
vRNA	RNA-dependent RNA polymerase	Replications
	Viral nucleocapsid proteins	Assembly, protections
	MS2 coat protein	Viral capsid, translational repressors
	dsRNA-dependent protein kinase	Translation regulations
	Reverse transcriptase	Copying RNA to DNAs
RNA ligase	DNA ligase	Ligating RNAs
	HIV-Tat	Transcriptional activators
scRNA		
SRP RNA	Signal recognition particle proteins	Targeting of secretory proteinss
gRNA	TUTase	mRNA editings

Table 2. Various RNA-Binding Domains and Sequence Motifs[a, b]

Sequence Motif	Representative Proteins and Reference Describing Structure (in parentheses)	Target RNA
RNP domain	U1A spliceosomal protein (7)	U1 snRNA
	(9,10)	U1A protein mRNA
(RNA recognition motif)	U1 70k spliceosomal protein (1,6)	U1 snRNA
	hnRNP protein C (1)	mRNA precursor
		mRNA

	hnRNP protein A1[a]	precursor
	Poly(A)-binding protein (1)	mRNA poly(A) tail
dsRNA-binding motif	*E. coli* RNase III (12)	RNA transcript
	Drosophila Staufen (11)	Maternal bicoid mRNA
KH domain	hnRNP protein K (1)	mRNA precursor
	Fragile X protein (13)	Unknown
	Vigilin (14)	tRNA?
Zn-finger	TFIIIA (18)	5 S rRNA
S1 domain	Polynucelotide phosphorylase (15)	
	Ribosomal protein S1	mRNA
	Initiation factor 1	
Sm domain	Spliceosomal core proteins (2)	snRNAs
OB domain	Class IIb aminoacyl tRNA synthetase (19–21)	tRNA
RGG box	hnRNP proteins (1)	mRNA precursor
Alu binding module	SRP 14 / 9 heterodimer	Alu domain of SRP RNA

[b] M. Görlach, M. Friedrichs, G. Dreyfuss, and L. Mueller (1992) *Biochemistry* **31**, 9254.

Some of the important questions concerning the nature of protein-RNA recognition can be illustrated by considering tRNAs (see Transfer RNA). They function as adaptor molecules that specify amino acid residues corresponding to particular triplet codons. There are 20 aminoacyl-tRNA synthetases, one for each amino acid, and each of these enzymes must specifically recognize and aminoacylate only its cognate tRNA with its cognate amino acid (3, 4). In contrast, the prokaryotic elongation factor Tu (EF-Tu), which introduces aminoacylated tRNA (aa-tRNA) into the A-site of the ribosome, binds to all aa-tRNA (except initiator-Met tRNA and selenocysteinyl-tRNA) and hence must recognize features common to all elongator aa-tRNAs (5). These are two extreme examples of tRNA recognition mechanisms that are essential in maintaining the fidelity and efficiency of protein biosynthesis. The various tRNAs are transcribed as precursor RNA molecules and must be processed correctly by specific nucleases and a surprisingly large number of different base-modifying enzymes to form mature molecules. These modifying enzymes also have diverse specificities. Some recognize almost all tRNA [eg, tRNA (m^5U54)methyltransferase]. Others recognize a subset of tRNA (eg, tRNA-guanine transglycosylase), even a unique tRNA species.

A wide variety of RNA-binding proteins are involved in producing, processing, transporting, translating, and degrading mRNA, the most abundant single-stranded RNA in cells. mRNA in eukaryotes is capped at the 5′ end and polyadenylated at the 3′ end, and introns must be correctly excised by the splicing machinery. Mature mRNAs are transported from the nucleus to the cytoplasm for translation. Gene expression is regulated at the transcriptional level and also at the translational level by a variety of mechanisms mediated by mRNA-binding proteins. The controlled degradation of mRNA is also an important process, involving a complex set of endo- and exonucleases. All of these processes must interact precisely with a large number of specific or nonspecific RNA-binding proteins and enzymes.

RNA is an essential structural and functional component of many ribonucleoproteins (RNP). Assembly of these RNP requires specific recognition of RNA structure and/or base identity by RNP protein subunits. The ribosome itself contains RNA molecules, which are matured by splicing and modifying enzymes in the nucleolus in association with small nuclear RNP (snoRNP). The rRNA may actually play the key catalytic role in peptidyl transfer. Pre-mRNA splicing is a complicated regulated process, involving a number of small nuclear RNPs containing snRNA that form a dynamic complex known as the spliceosome. The substrate of the spliceosome is not naked RNA, but pre-mRNA (also known as heterogeneous nuclear RNA, hnRNA) complexed with various proteins that form particles known as hnRNP. The mammalian signal recognition particle (SRP) is an scRNP consisting of a 300-nucleotide 7 S RNA associated with six protein subunits. It binds to signal peptides at the N-terminal end of secreted proteins as they emerge from the ribosome and directs the nascent-chain/ribosome complex to receptors on the endoplasmic reticulum membrane in eukaryotic cells. Systems homologous to SRPs are found in all living cells. Ribonuclease P, a tRNA-processing endonuclease, is an RNP in which the RNA component plays the catalytic role. Telomerase is a complex enzyme consisting of template RNA and protein subunits that adds multiple repeats of a particular sequence onto the ends of chromosomal DNA. Many viruses contain RNA as their genetic element, and virally-coded RNA-binding proteins play essential roles in the very diverse modes of replication and assembly of viruses.

How do RNA-binding proteins recognize their RNA-binding sites? RNA is distinguished from DNA most readily by the presence of the ribose 2′-OH and because the extended RNA double helix is predominantly in the A-form and has helical parameters significantly different from DNA, which is normally in the B-form. These general features permit nonspecific double-stranded RNA-binding proteins to recognize their correct nucleic acid substrate (eg, dsRNA-dependent protein kinase). On the other hand, specific RNA-binding proteins have more difficulty recognizing undistorted A-form RNA, which is characterized by a deep, narrow major groove and a shallower minor groove. The bases in the major groove are not readily accessible to protein side chains for specific recognition by hydrogen bonding except near the beginning or ends of helices. By contrast, the readily accessible minor groove contains less information for base discrimination. This problem is in reality bypassed by the fact that most cellular RNA is single-stranded, which forms irregular structures comprising short helices resulting from Watson-Crick pairing of short complementary stretches interspersed with hairpins, internal loops, bulges, or pseudoknots. Many RNA-binding proteins specifically recognize irregular RNA structures whose bases are more exposed for hydrogen bonding or stacking interactions with protein side chains. Indeed, the irregularities may be specifically induced or enhanced by the protein/RNA interaction. Some RNA molecules fold further into complex tertiary structures (eg, tRNA) whose unique three-dimensional shape may be sufficient to define specific backbone interactions with an RNA-binding protein (eg, seryl-tRNA synthetase recognizing $tRNA^{Ser}$).

1. Domains and Motifs Found in RNA-Binding Proteins

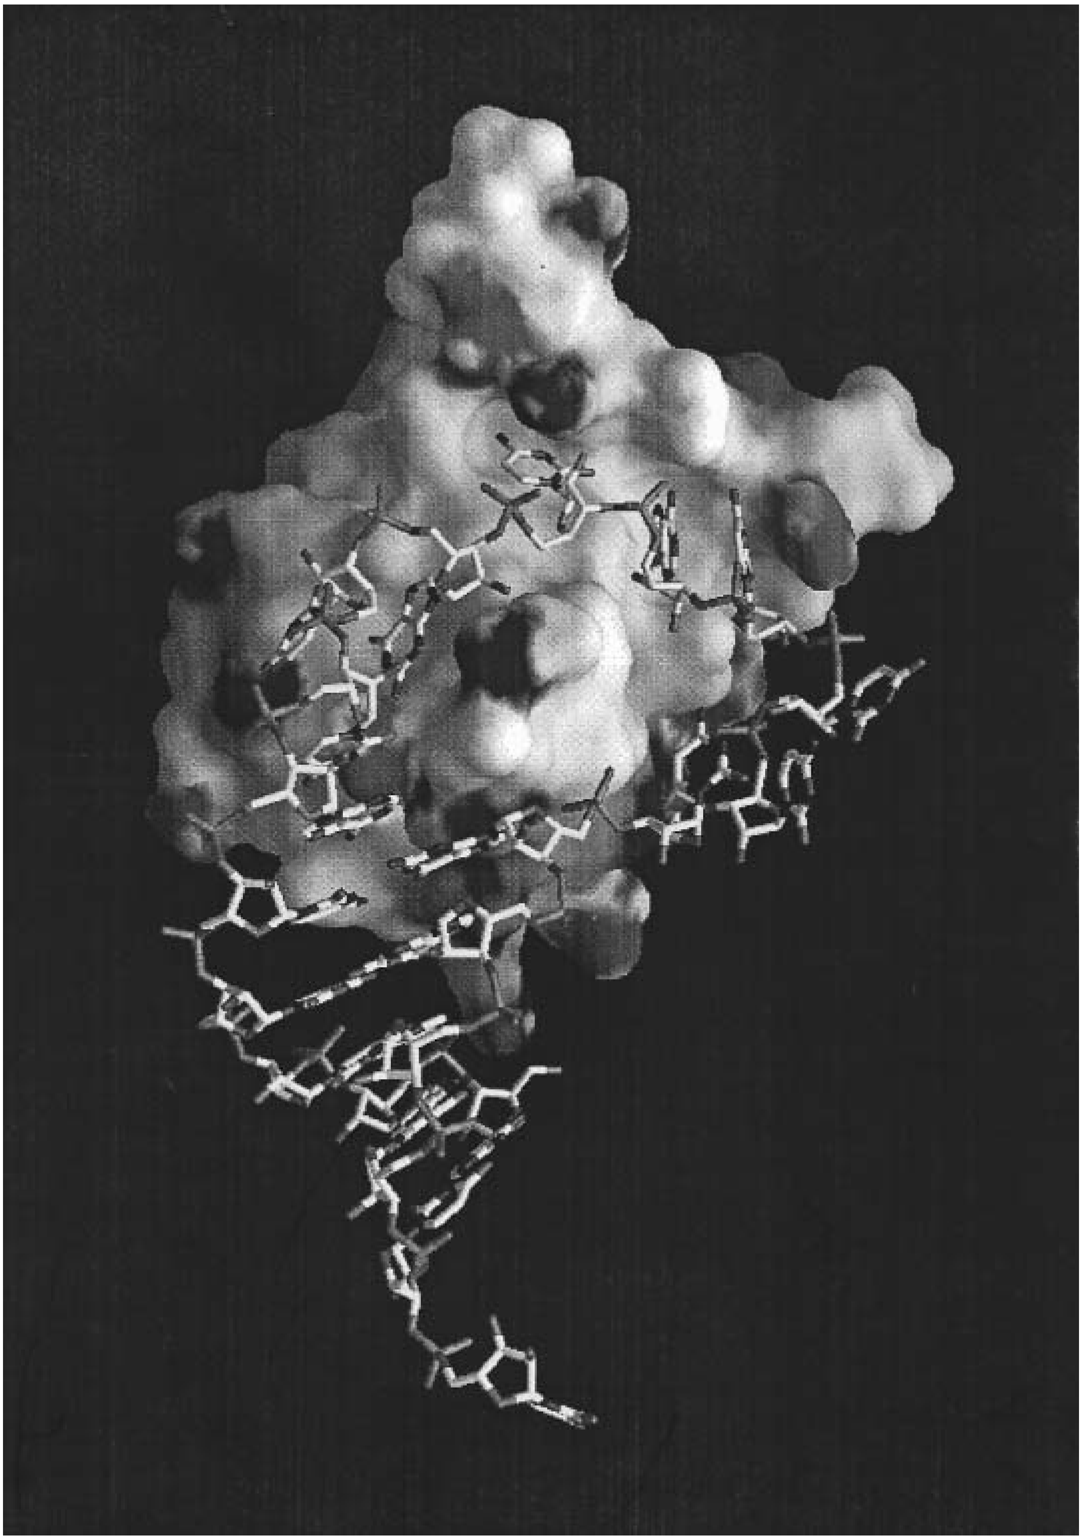
The majority of the known RNA-binding proteins have modular structures that contain an RNA-binding domain combined with other auxiliary domains (1, 2). Four RNA-binding sequence motifs have been found in RNA-binding proteins from diverse species; therefore, it is considered that they arose early in evolution. These correspond to (1) the RNP domain, (2) the KH domain , (3) the dsRNA-binding domain, and (4) the S1 domain. X-ray crystallography has shown or NMR that they contain an a/b fold similar to those found in some ribosomal protein subunits, and it has been suggested that these RNA-binding motifs may have evolved from ribosomal proteins. This might help to explain why RNA-binding domains are generally distinct from DNA-binding domains. Notable exceptions are the zinc finger, OB fold, and homeodomain. It is an interesting observation that many known RNA-binding proteins are all b or a/b proteins that contain an exposed b-sheet. The crystalline structure of the complex between U1A protein and an RNA hairpin discussed later suggests why a b-sheet is a good RNA-binding surface.

1.1. RNP Domain

The RNP domain, also known as RNA recognition motif (RRM) or RNP-consensus sequence (RNP-CS) type RNA-binding domain, is found in more than 200 distinct RNA-binding proteins from diverse species (1, 2, 6). It is also the second most common protein sequence motif in the entire genome of the nematode Caenorhabditis elegans. These facts suggest that this module appeared early in evolution. The RNP domain is about 80 amino acid residues long and contains two highly conserved short sequence motifs called RNP octamer (RNP1) and RNP hexamer (RNP2). Some proteins contain only a single RNP domain, but others contain multiple copies. For example, the protein that binds to the polyadenylate (poly A) tail of mRNA in eukaryotes contains four tandem copies of the RNP domain.

The three-dimensional structure of the RNP domain first determined for U1A spliceosomal protein, indicated that it consists of a four-stranded antiparallel b-sheet flanked on one side by two a-helices. The RNP1 and RNP2 motifs are located in the two middle b-strands of the sheet, and the side chains of the three highly conserved aromatic residues within RNP1 and RNP2 are projected onto the surface of the b-sheet (in U1A one of these residues is replaced by a glutamine) (7). U1A protein is a protein component of U1 snRNP, a large RNA-protein complex involved in pre-mRNA splicing, and binds to an RNA hairpin that contains 10 nucleotides in the loop. The crystal structure of a complex between U1A protein and an RNA hairpin representing its binding site has been determined at 1.9 Å resolution (8). The RNA hairpin loop binds to the surface of the b-sheet as an open structure, and the first seven nucleotides of the loop are fitted into a groove formed on the surface of the b-sheet (Fig. 1). The polypeptide loop between the b2 and b3 strands protrudes through the RNA loop. The bases of the seven nucleotides are splayed, and the protein-RNA contacts are made almost exclusively by RNA bases. These seven bases stack on an adjacent base, a protein side chain, or both and also form an intricate hydrogen-bond network with protein side chains and the amide and carbonyl groups of the protein main chain. U1A protein also binds to the 3′ untranslated region of its own pre-mRNA and prevents its polyadenylation by directly interacting with poly-A polymerase. The binding site contains two internal loops, each with the AUUG(CU)AC heptamer found in U1 snRNA hairpin II (6, 9, 10).

Figure 1. Crystal structure of a complex between U1A spliceosomal protein and its hairpin RNA binding site in U1 snRNA (8). The contact surface of the protein molecule is shown, whereas the RNA is a skeletal model. The AUUGCAC sequence in the ten-nucleotide loop fits into the groove on the surface of the b-sheet and binds tightly through stacking and hydrogen bond interactions with the protein.



1.2. Double-Stranded RNA-Binding Domain (dsRBD)

The dsRBD is a short sequence motif found in multiple copies in RNA-binding proteins from diverse origins including *Escherichia coli*, *Drosophila*, *Xenopus*, and mammals. In the *Drosophila* embryo, Staufen protein binds to maternal bicoid mRNA and plays an important role in establishing the anterior-posterior polarity through mRNA localization (11). *E. coli* ribonuclease III is an important enzyme involved in processing ribosomal and transfer RNA. The dsRBD is also found in adenosine deaminase, which is a key enzyme in RNA Editing, and in the double-stranded RNA-dependent protein kinase, which plays an important role in viral gene expression. The NMR structures of dsRBD from RNase III and Staufen protein show that the module contains a three-stranded antiparallel b-sheet that has two a-helices packed on one side (11, 12). The dsRDB shows strong similarities to the N-terminal domain of *Bacillus stearothermophilus* ribosomal protein S5 at the levels of both amino acid sequence and three-dimensional structure (11). This strongly suggests that dsRBD may have evolved from a ribosomal protein. It is not yet known how this domain binds RNA, but site-directed mutagenesis experiments suggest that loops between b1 and b2 and between b3 and a2 may be involved in RNA-binding. The major groove of dsRNA is narrow and deep, and the bases are not accessible by protein side chains for sequence-specific interactions. It is likely that each dsRBD binds to the minor groove or to the phosphate backbone in the major groove. Biochemical experiments suggest that a set of dsRDB, together with some auxiliary domains, may recognize a structural feature of folded RNA.

1.3. KH Domain

Heterogeneous nuclear ribonucleoprotein (hnRNP) K is one of the nuclear proteins that bind to precursors of mRNA (1). There are three copies of a sequence motif within hnRNP K, and homologous sequences have been found in many proteins from diverse species, from bacteria to man, that interact with RNA. Human Fragile X (FMR1) gene contains two copies of the KH domain. A mutation in one of these is responsible for severe hereditary mental retardation (1, 13). The natural RNA target of the FMR1 gene product has not been identified, but the mutation that causes severe hereditary mental retardation abolishes the binding of poly(U) to the FMR1 protein. This suggests that the ability of FMR1 to bind to RNA is essential for its *in vivo* function. Two proteins that contain three copies of the KH domain are associated with the 3′ untranslated region of a-globin mRNA. These proteins affect the *in vivo* half-life of the a-globin mRNA. Ribosomal protein S3 from *E. coli* and other bacteria contains the KH domain, suggesting that the KH domains found in higher organisms have evolved from a ribosomal protein (1). The NMR structure of the KH domain from human vigilin has an a/b structure that contains a three-stranded b-sheet with three a-helices (14).

1.4. S1 Domain

Ribosomal protein S1 from *Escherichia coli* contains six copies of a short sequence motif of approximately 80 amino acid residues. S1 protein is directly involved in RNA binding because it can be cross-linked to mRNA in the translational initiation complex. The S1 domain has been found in proteins from bacteria and eukaryotes, including polynucleotide phosphorylase, initiation factor 1 (IF1), NusA, ribonucleases II and E from *E. coli*, yeast RNA helicase PRP22, eukaryotic initiation factor eIF2a, and eIF2a kinase inhibitor. An NMR study of the S1 domain of polynucleotide phosphorylase shows that this domain consists of a five-stranded antiparallel b-barrel (15).

1.5. MS2 Bacteriophage Coat Protein

One of the best studied examples of an RNA-binding protein is the MS2 bacteriophage coat protein. The MS2 phage contains a genomic RNA 3569 nucleotides long, packaged into an icosahedral protein shell that consists of 180 copies of the coat protein. A capsid protein dimer binds to an RNA hairpin formed near the ribosome-binding site of the virally encoded replicase gene, thereby inhibiting translation of the replicase mRNA. The interaction also triggers assembly of the coat protein and packaging of the genomic RNA. A synthetic RNA hairpin that represents the binding site was soaked into a crystal of the empty phage particle, and its structure was determined to 2.8 Å resolution (16). The RNA, which contains a tetraloop and a bulged adenosine, binds to the surface of the continuous b-sheet across the dyad axis. The side chain of a tyrosine residue stacks onto a cytidine in the tetraloop, and the bulged adenosine and an adenosine in the tetraloop bind to equivalent sets of residues from each subunit.

1.6. Zinc-Containing RNA-Binding Proteins

Transcription factor IIIA is a transcriptional activator of the 5 S rRNA gene, but it also binds to its gene product 5 S to rRNA, and functions as a storage or transport protein (17). It contains nine zinc fingers, each of which folds into a domain that contains two b-strands and one a-helix stabilized by the coordination of two histidine and two cysteine residues to a zinc ion. Crystallographic analyses of zinc finger proteins in complex with dsDNA show that the a-helix fits into the major groove of the

DNA and forms many sequence-specific contacts with the DNA bases (18). It is believed that 5 S rRNA folds into a branched double helix that contains many bulges which may widen the major groove of RNA to permit entry of the recognition helices. The HIV nucleocapsid protein is another example of a zinc-containing, RNA-binding protein. Others are *E. coli* alanyl-tRNA synthetase and tRNA guanine transglycosylase (28).

1.7. Other RNA-Binding Modules

The bases of the anticodon loops of $tRNA^{Asp}$ and $tRNA^{Lys}$ are splayed over the surface of a b-barrel domain of their cognate tRNA synthetases and are recognized in a sequence specific manner (see later) (19, 20). Many structural homologues of this b-barrel domain, which is known as the OB-fold, have been found in proteins that bind oligonucleotides (both ssRNA and ssDNA) or oligosaccharides (21).

The Sm proteins that form the core of spliceosomal small nuclear ribonucleoprotein particles (snRNP) contain a conserved sequence motif. It is predicted that this domain has an a/b fold, but its structure is yet to be determined (2). Some hnRNP proteins contain multiple repeats of an Arg-Gly-Gly (RGG) sequence that are believed involved in RNA binding (1).

The crystal structure of the SRP 9/14 heterodimer, which binds to the Alu domain of the mammalian signal recognition particle RNA, has been determined. SRP9 and SRP14 are structurally homologous and contain the same a-b-b-b-a fold, related to but distinct from the dsRNA-binding module. The heterodimer has pseudo two-fold symmetry and is saddle-like, comprising a strongly curved six-stranded amphipathic b-sheet. The four helices are packed on the convex side, and the exposed concave surface is lined with positively charged residues.

Both HIV tat and rev proteins bind the TAR and RRE elements, respectively, to their target RNA sequences, by arginine-rich peptides. The solution structure of a 14-residue arginine-rich peptide from BIV tat complexed with BIV TAR has been determined by NMR (26). The peptide forms a b-hairpin that interacts in the RNA major groove.

2. tRNA-Binding Proteins

2.1. Aminoacyl-tRNA Synthetases

The fidelity of protein synthesis depends to a large extent on the extreme specificity with which aminoacyl-tRNA synthetases charge their cognate tRNA with their cognate amino acid. In *E. coli*, there are at least 46 different tRNA molecules that have anticodons which correspond to the various amino acids. The seryl-tRNA synthetase, for example, has to charge the six serine isoacceptors (including one for selenocysteine) selectively and ignore the others. Because tRNA superficially have similar secondary and tertiary structures, what is the molecular basis for the specific recognition between aminoacyl-tRNA synthetases and tRNA? In many cases, extensive biochemical studies have revealed the so-called tRNA identity elements (see Aminoacyl tRNA Synthetases).

A more detailed picture of specific tRNA recognition and catalysis by aminoacyl-tRNA synthetases is emerging from crystallographic studies of aminoacyl tRNA synthetases complexed with various combinations of their three substrates: ATP, cognate amino acid, and cognate tRNA, plus the activated amino acid intermediate, the aminoacyl-adenylate. Now crystal structures are known of 14 of the 20 aminoacyl tRNA synthetases, five of which are in complexes with cognate tRNA (3, 4). The three systems, for which the most extensive structural data exists on protein-tRNA recognition, are the class I glutaminyl system and the class II aspartyl and seryl systems. These show strikingly different modes of specific synthetase-tRNA interaction but share certain general features, including a fairly large synthetase-tRNA interactive interface characterized by (1) nonspecific backbone contacts, often involving basic residues, both of which increase binding affinity and aid correct positioning and orienting the tRNA; (2) discriminatory base-specific interactions restricted to a few regions, principally the anticodon and the acceptor stem. The second general feature is mutual induced fit by which protein-RNA contacts are made as a result of conformational changes in either or both macromolecules. This includes ordering of protein loops and reorienting and stabilizing domains (eg, SerRS), base-pair breaking in the acceptor stem, and 3′-end distortion (eg, tRNA^{Gln}) and destacking of bases in the anticodon loop (eg, tRNA^{Gln}, tRNA^{Asp}).

2.2. Glutaminyl-tRNA Synthetase (GlnRS)

GlnRS is a monomeric class I synthetase whose specificity for tRNA^{Gln} is largely determined by interactions with identity elements in the tRNA acceptor stem and anticodon stem-loop, both of which have severe distortions from the structure found in uncomplexed tRNA. In the E. coli complex, the tRNA anticodon stem is extended from five to seven base pairs by two extra non-Watson–Crick base pairs (23). The three anticodon bases (CUG) are splayed to fit into three separate recognition pockets formed at the interface between distal two b-barrel domains of the protein. In the active site of the synthetase, the tRNA is oriented so that specific interactions can be made within the acceptor stem's minor groove to identity determinants in base pairs 2 and 3. On the other hand, the tRNA 3′-end reaches the catalytic center only by forming an unusual hairpin turn. This conformation requires breaking the first U1-A72 base pair and is stabilized, in part, by a hydrogen bond between the discriminator base G73 and the phosphate of A72.

2.3. Aspartyl-tRNA Synthetase (AspRS)

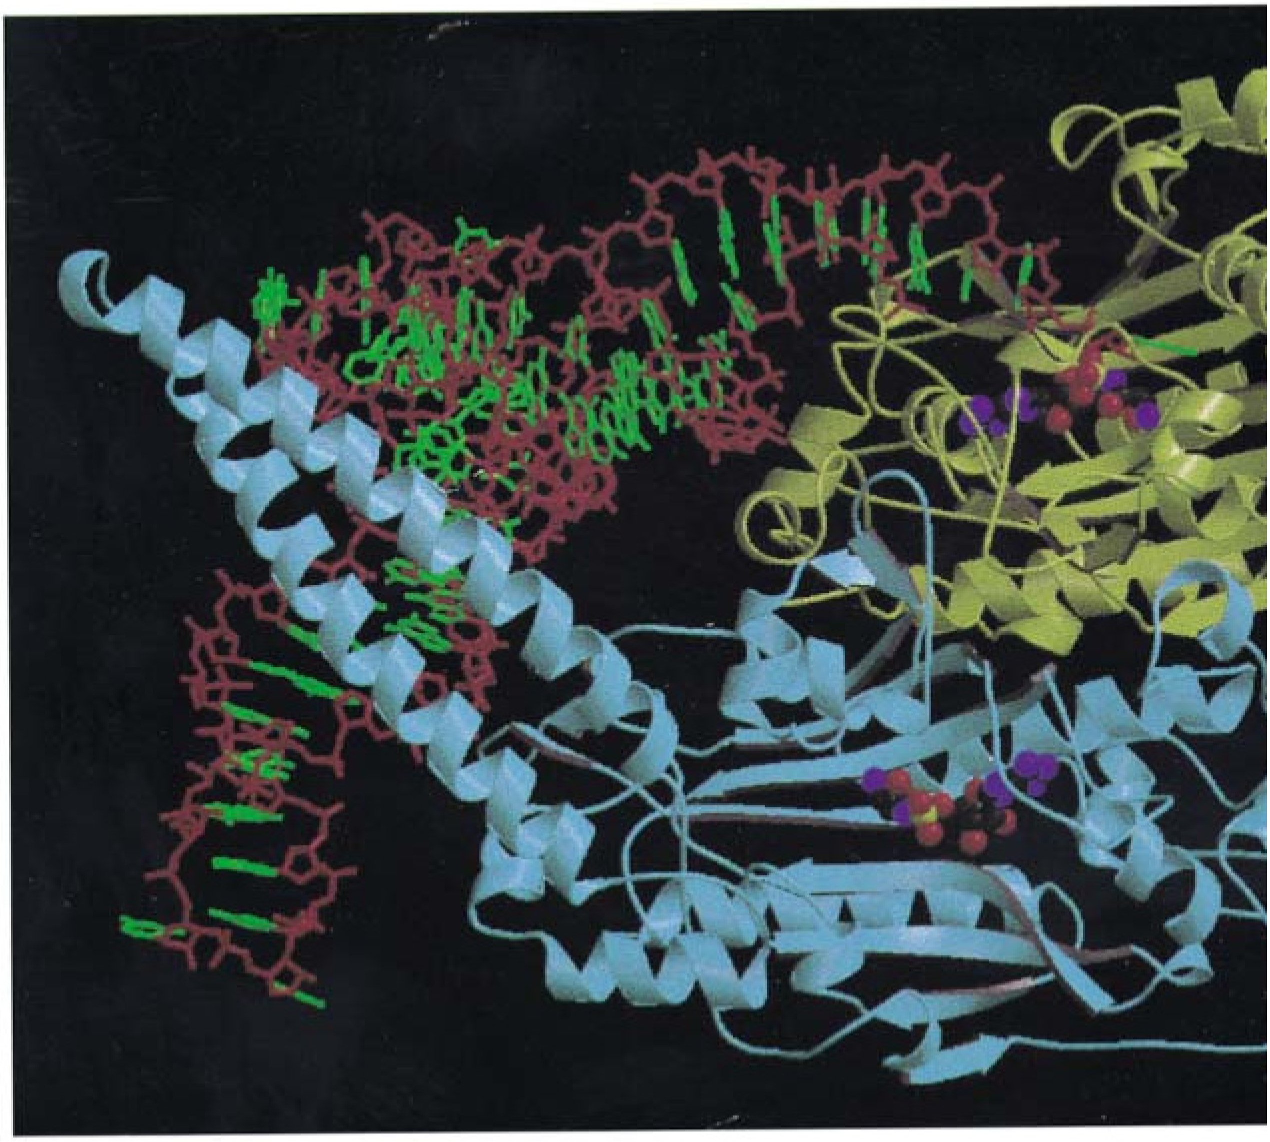
AspRS is a dimeric class IIb synthetase that binds two tRNAs symmetrically, although each tRNA interacts predominantly with only one subunit. In contrast to class I, class II synthetases interact with the acceptor stem of their cognate tRNA from the major groove side (27) by the so-called motif 2 loop, which in yeast AspRS makes base-specific interactions with the discriminator base G73 and base pair U1-A72 (19). The major groove side recognition also means that the single-stranded 3′-end of the tRNA enters the synthetase active site without significant distortion from its normal helical path, again in strong contrast to class I. Anticodon recognition by AspRS is performed by an N-terminal, five-stranded, b-barrel domain (OB fold) (21). The normal compact structure of the free tRNA anticodon loop undergoes a large conformational change, and the five anticodon loop bases are exposed to the exterior. The three anticodon bases (GUC) lie across the b-sheet surface and are recognized by specific hydrogen bonding interactions (19). Recent crystallographic results on another closely related class IIb synthetase complexed with its cognate tRNA, T. thermophilus lysyl-tRNA synthetase, show a very similar interaction between the anticodon of tRNA^{Lys} (CUU) and the N-terminal, b-barrel domain of LysRS (20). Whereas the central U35 interacts identically in the two systems (by stacking with a conserved phenylalanine residue and hydrogen bonding with conserved glutamine and arginine residues), the specificity for base 36 and to a lesser extent for base 34 is idiosyncratic for each synthetase.

2.4. Seryl-tRNA Synthetase (SerRS)

SerRS is also a dimeric class II synthetase, but its mode of tRNA recognition differs significantly from that of AspRS (Fig. 2). SerRS is characterized by a unique 100-residue, N-terminal domain that is folded into a 60 Å long, solvent exposed and flexible, antiparallel coiled coil, known as the helical arm (24, 25). The variety of serine anticodons from two distinct groups means that the serine isoacceptors share no common anticodon base. Thus, the anticodon is not an identity element of tRNA^{Ser}, whereas the long variable arm is, a feature shared only by tRNA^{Leu} and tRNA^{Tyr}. The main features of the recognition of tRNA^{Ser} by T. thermophilus SerRS are (1) the tRNA binds across the two subunits of the dimer; (2) upon tRNA binding the helical arm of the synthetase is stabilized in a new orientation and binds between the TΨC loop and the long, variable arm of the tRNA; (3) contacts with the tRNA long, variable-arm backbone extend until the sixth base pair, explaining the need for a minimum length of the tRNA variable arm; (4) the synthetase makes many backbone contacts, but few base-specific interactions, and is principally recognizing the unique shape of tRNA^{Ser}. The unique shape of tRNA^{Ser} is largely determined by bases 20A and 20B inserted into the D-loop, both of which play novel roles in tertiary interactions in the tRNA core. In particular, the base of G20B is stacked against the first base pair of the long variable arm and thus defines the spatial orientation of the latter; (5) the anticodon stem loop is not in contact with the synthetase; (6)

the motif 2 loop of SerRS (longer than that of AspRS) makes base contacts down to the fourth base pair within the acceptor stem's major groove, but they are, however, only weakly discriminatory (25).

Figure 2. Overall view of the ternary complex of seryl-tRNA synthetase, tRNA^{Ser}(GGA), and a nonhydrolyzable analog monomer 1 is in yellow, and monomer 2 is in blue. Only the backbone and its secondary structure are shown (arrows ar tRNA backbone is in red, and the bases are in green. The tRNA is viewed looking down the anticodon stem, which is no in the figure. The long variable arm of the tRNA crosses the helical arm of monomer 2 perpendicularly and emerges at t the Ser-AMS molecule is represented by spheres. See color insert.



2.5. Elongation Factor EF-Tu

EF-Tu is a G-protein that, in the activated GTP-bound state, binds all aminoacylated elongator tRNA with higher affinity than uncharged tRNA and delivers them to the ribosome. The crystalline structure of the ternary complex of yeast tRNA^{Phe}, T. aquaticus EF-Tu and GDPNP has recently been determined and reveals how activated EF-Tu contacts relatively limited and conserved regions of aa-tRNA (6). The only parts of the aa-tRNA in contact with EF-Tu are the aminoacylated CCA end, the 5′ phosphate, and the T-stem helix. The long stem of the L-shaped tRNA projects away from the protein, so that the entire complex is extremely elongated. The CCA-3' end binds in a cleft between domains 1 and 2 of EF-Tu, and conserved residues from domain 2 interact with the base and phosphate of A76. Main-chain hydrogen bonds from EF-Tu are made to the ester group linking the carboxyl group of the amino acid to the 3'OH of the ribose and to the free amino group of the amino acid. The amino acid itself projects into a pocket formed between domains 1 and 2. The tRNA 5' phosphate is bound by conserved basic residues in helix B of domain 1 and from domain 2. One side of the T-stem helix is packed against a depression between domains 1 and 3. The contacts are made by nonconserved residues from domain 3.

It has been pointed out that the EF-Tu.GTP.tRNA^{Phe} ternary complex extraordinarily similar in shape to that of the elongation factor EF-G.GDP binary complex. This mimicry suggests that the two complexes might bind to the same ribosomal state.

ROESY Spectrum

A conventional nuclear Overhauser effect (NOE) experiment in nuclear magnetic resonance (NMR) spectroscopy involves detection of changes in the intensities of NMR signals associated with a particular spin of the molecule being examined, when other spins are perturbed in some way. The changes in signal intensity are the result of altered populations of nuclear spin energy levels associated with both sets of spins and reflect their physical proximity. There may be magnetic interactions between spins while they are in coherent states and these may lead to changes of signal intensity. This second kind of Overhauser effect is detected in a "rotating frame" NOE (or ROE) experiment. The ROE may be determined in a one-dimensional format or be incorporated into multidimensional experiments. A two-dimensional (2D) ROE experiment is often referred to as ROESY (rotating frame Overhauser effect spectroscopy). In such a 2D experiment, the appearance of a cross peak at the chemical shift coordinate (A, B) requires that there be a ROE between the spins characterized by these chemical shifts (δ_A, δ_B). The power of experiments that produce ROEs or NOEs is that changes in signal strength are strongly dependent on the distance between interacting spins. Thus, the observation of a ROE or NOE provides a constraint that can be used to define the tertiary structure of the macromolecule being studied.

For the standard NOE experiment wherein the detected signal intensity changes arise from alterations of spin energy level populations, the effect is given by

(1)

where $f_I\{S\}$ indicates the NOE on the signal from spin I when there is a perturbation of level populations associated with spin S; I_0 is the normal intensity of the signal for spin I observed from a sample at thermal equilibrium before the analyzing RF pulse, and I_p is the intensity of the same signal when there has been a perturbation of spins S before the analyzing pulse. The value of $f_I\{S\}$ depends on the gyromagnetic ratios of spins I and S, how these spins move in the sample, the strength of the magnetic field used for the NMR experiment, and the details of how the energy level populations associated with spin S are perturbed during the course of an experiment. Values of $f_I\{S\}$ ranging from 0.5 to -1.0 are possible when both I and S are protons. It should be noted that, given the definition of $f_I\{S\}$, some set of experimental conditions may exist for which $f_I\{S\}$ becomes zero. Under these conditions, there is little or no change in signal intensity, even though spins I and S might be very close to each other. These conditions are typically experienced when the mass of the molecule under study is in the range of 500–2000 D.

In contrast, the ROE on signal intensities is always positive for near-neighbor nucleus-nucleus interactions and thus remains detectable under all experimental conditions (1-3). This very significant advantage is countered, however, by the need to correct the experimental data for various artifacts and by the possibility that coherence transfers may produce effects that are unrelated to the ROE. Analysis of ROE data in conjunction with conventional NOE data may provide important insights into existing chemical exchange processes (4). Although most ROESY experiments with biological macromolecules involve interactions between hydrogen ^{1}H atoms, useful heteronuclear ROESY experiments also are feasible (5). The elements of the ROESY experiment can be built into experiments that produce three-dimensional or higher NMR spectra. (See also Nuclear Overhauser Effect (NOE), NOESY Spectrum.)

Rolling Circle DNA Replication

In DNA replication, the DNA polymerase cannot initiate the synthesis of a new DNA strand and must rely on a priming device. In general, an RNA primer is synthesized at or near a replication origin to start synthesis of the leading strand. However, a DNA primer terminus can be generated by a nuclease-generated nick at a specific place in some circular duplex DNA, and replication will then proceed unidirectionally, as shown in Figure 1. This mode of replication is called rolling circle replication and is found for replication of the replicative form (RF) form of bacteriophage single-stranded genomes of Gram-negative bacteria and of the multicopy plasmids of Gram-positive bacteria (see Single-Stranded DNA Replication). Rolling circle replication is also observed in the late stage of the replication of the lambda phage genome and in the process of the conjugative transfer of bacterial plasmids.

Figure 1. Scheme for rolling circle replication (see text for details).

DNA synthesis initiates using the free 3'-OH end at the nick as a primer, and a replication fork proceeds around the template. In the process, the newly synthesized strand displaces the old strand from the template. In the case of replication of the RF form of single-stranded phage genomes and of plasmids of Gram-positive bacteria, the displaced old strand is cleaved off after one round of replication and is converted into the circular, double-stranded form. In contrast, in phage lambda replication, the replication fork proceeds a number of revolutions around the template without cleavage of the displaced strand, and the displaced strand becomes double-stranded as it is peeled off. The linear concatemer thus created is cleaved into one unit length and packaged into the phage particles. In the conjugation process of plasmids, this displaced strand is transferred into the new cell.

The initial nick of rolling circle replication is introduced by an endonuclease specific for each system. The similarity of the amino acid sequences of the initiator endonucleases and of the proteins (known as relaxases) involved in the initiation and termination of conjugative DNA strand transfer clearly indicate that they are evolved from a common ancestor (1, 2).

Rossmann Fold

In the 1970s, Rossman and colleagues (1, 2) identified, analyzed, and characterized the similarity between the protein structures of lactate dehydrogenase and malate dehydrogenase, two enzymes that bind the dinucleotide NAD. Both protein structures incorporate two b–a–b–a–b protein motifs, and each half of the bound dinucleotide binds to one of these units. The b–a–b–a–b structural motif, which forms a parallel b-sheet surrounded by a-helices, is referred to as either a Rossmann fold or a mononucleotide-binding motif.

R_0T Curve

1. DNA–RNA Hybridization

During purification of messenger RNA, its quantity and the extent of purification can be determined by hybridization techniques. This also permits determining the size of the mRNA independently by gel electrophoresis.

Hybridization involves annealing a large excess of RNA with double-stranded DNA previously radiolabeled by nick translation or during its synthesis. Such labeling techniques result in a high specific radioactivity, so the necessary excess of RNA can be obtained easily. Heating double-stranded DNA denatures it to its single-stranded components and slow cooling of these single strands permit renaturation. This technique is used in C_0t curves to characterize DNA samples. Hall and Spiegelman (1) demonstrated that the same experiment can be performed with heat-denatured DNA and the corresponding mRNA, and slow cooling produces DNA–mRNA hybrids that were observed in cesium chloride density gradient centrifugation. When mRNA was heated with genetically unrelated DNA, no hybrid molecules were formed.

1.1. Kinetics of Association

DNA–RNA hybridization is a second-order reaction (see Kinetics). If t is the time, D the concentration of single-stranded DNA in moles of nucleotides/liter, R the concentration of excess mRNA in the same units, and k the rate constant for the reaction, then the equation describing the reaction is the following:

The value of k is expressed in units of .

DNA self-reassociation is avoided by using a low concentration with RNA in excess. Then the RNA hybridizes much faster than the DNA, and its concentration remains practically constant throughout the reaction. The reaction follows pseudo-first order kinetics, and the equation above simplifies to the following:

R_0 is the mRNA concentration at .

By substituting at , the integrated equation becomes

When 50% of the DNA (cDNA) strands have been converted into DNA-RNA hybrids, at D becomes $D_0/2$, and R_0t becomes $R_0t_{1/2}$. This yields

from which the value of k can be derived by

Therefore the velocity of the association reaction is inversely proportional to the value $R_0t_{1/2}$, which itself is directly related to the size of a pure RNA or DNA molecule.

1.2. Determining mRNA size and evaluating a given mRNA in an RNA mixture

Knowing the size a of a given mRNA, the unknown size x of another mRNA is determined by the following equation:

For ovalbumin mRNA, which is 2000 nucleotides long, the $R_0t_{1/2}$ value is $4 \times 10^{-3} M^{-1} s^{-1}$. For prolactin mRNA (900 nucleotides long) the $R_0t_{1/2}$ value is accordingly smaller: $1.8 \times 10^{-3} m^{-1} s^{-1}$ (2).

The values of $R_0t_{1/2}$ allow determining the fraction of a certain mRNA in a mixture by comparing hybridization of the corresponding cDNA with the corresponding “pure” mRNA and with the same mRNA in a mRNA mixture. Because the size of the studied mRNA is constant, its reassociation rate depends only on its concentration in the mixture, according to the equation

The course of hybridization is monitored by determining the number of DNA–RNA hybrids at various reaction times. This is done in two ways (2):

1. by applying the reaction mixture to a chromatography column of hydroxyapatite in 0.05 M phosphate buffer at pH 6.8 and at a temperature of 60°C. The single-stranded DNA elutes with 0.14 M phosphate buffer, whereas the double-stranded DNA–RNA molecules elutes with 0.45 M phosphate buffer.
2. by digestion with S1 nuclease, which digests single-stranded DNA, whereas RNA–DNA hybrids remain unaffected and are precipitated with trichloroacetic acid.

2. Determining the Number of Different Sequences in mRNA Transcribed from a cDNA Library

To judge whether a cDNA library is representative, ie, whether the number of different clones carrying a particular cDNA insert reflects the relative fraction of the corresponding mRNA molecules in the cell from which the library has been prepared, the number of different mRNA sequences in the mRNA population is determined. This is done by hybridizing highly labeled cDNA with an excess of mRNA. The amount of hybridized DNA at any time t is plotted as a function of R_0t. The kinetic curve yields the number of kinetic classes of mRNA molecules and their $R_0t_{1/2}$ values. The values are corrected to obtain the values that would have been obtained if each of the classes had been considered on its own. The values are also corrected for the nonspecific poly-dA sequences in the cDNA from the mRNA poly A tails, which do not contribute to hybridization. Then the corrected $R_0t_{1/2}$ values are used to determine the number of different sequences in each kinetic class by comparing them with the values of mRNA of known complexity ((3),(4)).

Rous Sarcoma Virus (RSV)

Rous sarcoma virus (RSV) was discovered in the extract of chicken sarcoma by Dr. P. Rous in 1911 as the first infectious reagent that causes tumors, and it is now known to be the prototype oncogenic retrovirus (Oncovirinae). It is widely accepted that ALV (avian leukosis virus), a replication-competent retrovirus carrying the genes gag (internal structural proteins), pol (reverse transcriptase and DNA endonuclease) (see HIV (Human Immunodeficiency Virus) and Hepatitis B Virus), and env (envelope glycoproteins), had once picked up a gene present in the chicken chromosome, now designated as cellular src (c-src), during its replication cycle as a rare event. RSV therefore carries an extra gene designated viral src (v-src) (because it is derived from c-src) at the extreme 3′ region of the genome, and it can be expressed from a subgenomic messenger RNA produced by RNA splicing (Fig. 1). By changing from c-src upon its integration into the virus genome and by accumulation of mutations during the subsequent propagation of virus, this virus gene had acquired the ability to cause neoplastic transformation in chickens. High-level expression of c-src, however, does not cause such transformation. The products of both these v-src and c-src genes are now known to be tyrosine-kinases, with molecular weights of 60 kDa, and $p60^{v\text{-}src}$ has much higher kinase activity than does $p60^{c\text{-}src}$.

Figure 1. Proviral DNA structure of Rous sarcoma virus. The line at the top indicates the chromosomal DNA containing proviral DNA. SD, splicing donor site; and SA, splicing acceptor site. Three transcripts are produced from the LTR promoter, as shown below.

This prototype virus, however, is exceptional among RNA tumor viruses in that it is replication-competent. All the other oncogenic retroviruses acquired proto-oncogenes at the expense of a part of their genomes that is essential for virus replication, and they therefore require the association of other replication-competent virus such as ALV (often called helper virus) for their propagation. Because of the advantage of this exceptional genome structure, RSV has been historically used in laboratory for the analysis of neoplastic transformation in cell culture; virus titers, which were originally assayed by sarcoma formation in the injected chicken, are now determined much more easily by formation of a focus (a group of transformed cells) in infected chicken embryo fibroblasts (CEFs). RSV-infected CEF assume refractile morphology and acquire the ability to grow in soft agar (anchorage-independent growth). These phenotypes unique to cellular transformation are maintained even after cell divisions, because the virus genome is also replicated as a proviral DNA that is integrated into the host chromosome.

One of the breakthroughs in oncogene research was the isolation of unique temperature-sensitive mutants of RSV. These mutant RSVs were replication-competent independent of the temperature, but the transformation phenotypes of the infected cells were temperature-dependent. At 37°C, infected cells assume fully transformed morphology, while cells become flatter and assume very similar morphology to that of uninfected CEF at 40°C to 41°C. These observations led to the discovery of oncogenes and revealed the following basic ideas about them:

1. RSV encodes a gene responsible for the initiation of cellular transformation (the oncogene now known to be v-src, described above).
2. The oncogene is not necessary for the viral replication.
3. Continuous function of the oncogene is necessary for the maintenance of cellular transformation. (This observation excluded another hypothesis, the "hit and run theory," in which the virus infection process is supposed to cause irreversible phenotypic changes to the host cells.)

It is also noteworthy that RSV-based avian retrovirus vectors are now widely used as a powerful tool for basic research. By transfecting plasmid DNA carrying a proviral DNA in which the v-src sequence was substituted with an exogenous gene, replication-competent virus vectors expressing the exogenous gene can be recovered from the culture fluid of the transfectants and used to introduce foreign genes into several avian primary cells, embryos, or adults quite efficiently.

S-Adenosyl-L-Methionine

S-Adenosyl-L-methionine (AdoMet), one of nature's most intriguing biological objects, is a sulfonium compound, first described by Cantoni (1), that is synthesized in every cell from L-methionine and adenosine triphosphate (ATP) by methionine adenosyl transferase (MAT).

(1)

MAT catalyzes a most unusual reaction where ATP serves as the donor of its adenosine moiety, while its triphosphate chain is cleaved nonrandomly by the intrinsic triphosphatase activity of MAT itself, with the a and the b phosphates yielding inorganic pyrophosphate (PP_i) and the g phosphate yielding orthophosphate, P_i (2). It is noteworthy that the triphosphatase activity of MAT is stimulated by AdoMet (3). MAT is found in every cell, and the amino acid sequences of enzymes isolated from species that are separated by more than a billion years in evolutionary divergence (see Divergent Evolution), such as *Escherichia coli* (4) and humans (5, 6), exhibit an extraordinary degree of homology.

Elucidation of the structure of AdoMet as a sulfonium compound and clarification of the mechanism of its biosynthesis revealed that, in the reaction catalyzed by MAT, the chemical energy of the pyrophosphate bonds in ATP is utilized for the synthesis of a new class of energy-rich compounds. At physiological pH, the free energy of hydrolysis of a sulfonium compound is equivalent to that of the pyrophosphate bond in ATP (see Adenylate Charge, Free Energy Relationships), and the reaction is essentially irreversible, because it is accompanied by the release of a proton (7).

AdoMet was first identified as the source of methyl groups for biological transmethylation reactions (8), but it was anticipated that the energetic equivalence of the bonds linking the three ligands to the sulfur atom would enable AdoMet to function biologically as a source of either alkyl or adenosyl groups, thereby endowing AdoMet with unique biochemical versatility (9). Experimentally, Tabor et al. (10, 11) made the important discovery that *S*-adenosylpropylamine, a sulfonium compound resulting from the enzymatic decarboxylation of AdoMet (12), can serve as a donor of propylamine in the synthesis of spermidine from putrescine, and of spermine from spermidine (11). AdoMet decarboxylase is particularly interesting from the mechanistic point of view, since it has a covalently bound pyruvate that is required for activity (13). AdoMet decarboxylase and the propylaminetransferases are widely distributed in nature having been found in bacteria, yeast (14), and vertebrates. The synthesis of polyamines is of great biological importance although, quantitatively, it is less significant than biological transmethylation.

The biochemical availability of the groups linked to the sulfonium center of AdoMet was demonstrated by Nishimura et al. (15), who showed that AdoMet can serve as a donor of the aminobutyryl group to S-RNA, and more recently by Knappe (16) and by Reichardt and collaborators, who demonstrated that AdoMet can serve as an adenosine donor (17, 18). Finally Adams and Yang (19, 20) discovered in fruit ripening that AdoMet is cleaved to thiomethyl-adenosine and 1-aminocyclopropane-1-carboxylic acid. This reaction is of great biological significance, in that 1-aminocyclopropane-carboxylic acid is further metabolized to ethylene, a plant hormone that initiates fruit ripening and regulates many aspects of plant growth and development. Thiomethyl-adenosine is cleaved phosphorolytically to adenine and thiomethyl ribose 1-phosphate, in the first step of a salvage pathway that results in the regeneration of methionine (21).

In these reactions, AdoMet functions as a donor of one of the three ligands attached to the sulfonium atom. In addition, it has been shown that its 6 amino group is utilized in the synthesis of 7,8-diaminopelargonic acid, an intermediate in the synthesis of biotin (22). The mechanism of this reaction is entirely unknown, but it demonstrates the biochemical versatility of AdoMet.

In addition, AdoMet plays a role as a positive or as a negative allosteric effector (see Allostery) in the regulation of the key reactions that affect the metabolism of homocysteine. This amino acid can either be remethylated to methionine by 5-methyl-tetrahydrofolate (see Aminopterin, Methotrexate, Trimethoprim, and Folic Acid) or conjugated with serine to yield cystathionine. As an inhibitor of methylene-tetrahydrofolate reductase (23, 24), AdoMet regulates the availability of methyl-tetrahydrofolate, the key intermediate needed for the methylation of homocysteine in the de novo synthesis of methionine, whereas as an allosteric effector of cystathionine synthase (25) AdoMet favors commitment of homocysteine to the transulfuration pathway.

Quantitatively, AdoMet's role of serving as a methyl donor predominates. With the exception of the de novo synthesis of methionine, AdoMet is the sole source of the methyl groups utilized by a myriad of substrate-specific methyltransferases for the synthesis of a great variety of compounds, such as creatine, phospatidylcholine, yeast sterols, plant alkaloids, fungal and bacterial antibiotics, ubiquinone, triterpenes, lignins, and methyl chloride. AdoMet is also the source of the methyl groups required for the post-translational modification of proteins and nucleic acids.

Inversion of configuration at the stereospecific sulfonium center is a constant feature of the enzymatic methyl group transfer reactions (26-29). This indicates that methyltranferases, and by extrapolation alkyltransferases in general, operate by a mechanism involving direct transfer of the methyl, or alkyl, group from the sulfonium atom to the acceptor substrate, thus precluding a methylated intermediate or a ping-pong mechanism (see Enzymes).

S-Adenosyl-L-homocysteine (AdoHcy) is a product (30) and consequently a competitive inhibitor (31, 32), of all the reactions in which AdoMet participates as a methyl donor. AdoHcy also regulates fruit ripening by inhibiting the formation of ethylene (33) from AdoMet. In eukaryotes and most prokaryotes, the only pathway for the further metabolism of AdoHcy is catalyzed by adenosylhomocysteine hydrolase (AdoHcyase), an enzyme that, first shown by de la Haba and Cantoni (34), catalyzes the reversible hydrolysis of AdoHcy to homocysteine and adenosine. The equilibrium of this reaction lies far in the direction of synthesis; physiologically, however, the reaction proceeds in the hydrolytic direction because homocysteine and adenosine are efficiently removed by methionine synthase and by adenosine deaminase, respectively. It was shown by Eloranta (35) that in most tissues the activity of AdoHcyase is 100 to 1000 times greater than the activity of MAT and that consequently the intracellular concentration of AdoHcy is 20 to 100 times smaller than that of AdoMet.

The mechanisms regulating the utilization of AdoMet by many different competing reactions are not well understood. Many methyltransferases have been purified and studied in detail. The kinetics of most are relatively simple, and the physiological activity of these enzymes appears to be related directly to the availability of methyl acceptor substrates, to their affinity (K_m) for AdoMet, and to their inhibition constant (K_i) for AdoHcy. Comparison of these parameters in a number of enzymes revealed that the kinetic features of different methyltransferases can be very different, and they appear to vary independently. This led to the suggestion that the intracellular ratio of AdoMet/AdoHcy, also known as the "methylation ratio," might play a key role in the regulation of AdoMet utilization (36).

The validity of this hypothesis can be explored by modulating experimentally the intracellular AdoMet/AdoHcy ratio. This ratio will decrease whenever inhibition of the enzymes responsible for the removal of adenosine and/or homocysteine shifts the equilibrium of AdoHcyase towards AdoHcy synthesis, or when removal of AdoHcy generated by methyltransfer reactions is prevented by inhibition of AdoHcyase. It is also possible to take advantage of the broad specificity of AdoHcyase for adenosine by supplying adenosine analogs, like 3-deazaadenosine (DZA), that, being adenosine deaminase-resistant, can be converted to 3DZAHcy (37). Modulation of the AdoMet/AdoHcy ratio or the generation of analogues containing groups other than adenosine in response to the administration of various AdoHcyase inhibitors and/or substrates, indicates that in different tissues the physiological responses may be ascribed to the inhibition of specific methyltransferases (38). These results therefore appear to support the hypothesis that the utilization of AdoMet by various competing reactions is regulated by the intracellular AdoMet/AdoHcy ratio. It should be noted, however, that interpretation of these experiments is complex because the accumulation of AdoHcy and/or of other analogues may also result in an increase in the intracellular level of AdoMet, due to feedback inhibition of AdoMet-dependent methyl or alkyl transferases.

Unexpectedly and most importantly, AdoMet has been found to be a safe and effective agent in the treatment of certain forms of clinical depression (39, 40). While it has been clearly established that administration of AdoMet results in a significant increase in the concentration of AdoMet in the cerebrospinal fluid (CSF) (41), it has not been determined whether the therapeutic effects of AdoMet are related to its ability to function as a methyl donor. In the absence of an animal model for depressive disorders, it has unfortunately been possible only to formulate hypotheses to account for the mode of action of AdoMet in such illnesses.

S1 Nuclease

S1 nuclease is a 32-kDa nuclease that is specific for hydrolyzing of single-stranded RNA or DNA molecules into 5′-mononucleotides. It is a zinc-requiring metalloprotein that is inactivated by chelating agents, such as EDTA and citrate, and by phosphate concentrations as low as 10 mM. Its enzyme activity is optimal at pH 4.0 to 4.3, half at pH 4.9, and negligible above pH 6.0. The protein is thermostable (1) and resistant to several denaturing agents, such as urea, SDS, and formamide (2, 3). Digestion of single-stranded DNA is five times more efficient than that of single-stranded RNA, and 75,000 times more efficient than digestion of double-stranded DNA. The low level of cleavage of double-stranded DNA is minimized by increasing the ionic strength to about 0.2 M salt (2, 4-6), whereas it is increased by negative supercoiling of the double-helical DNA, UV irradiation, and depurination (3, 6-9).

Because S1 nuclease does not degrade double-stranded DNA or DNA–RNA hybrids, it is used widely to remove single-stranded regions from such duplexes. It is extremely useful for (1) measuring the extent of specific hybridization between single strands of DNA and/or RNA; (2) probing the existence of duplex DNA regions; (3) removing cohesive, sticky ends generated by restriction enzymes from single-stranded protruding DNA; (4) increasing the specificity of nucleic acid hybridization (10); (5) localizing intron, exon boundaries; (6) isolating of duplex regions in single-stranded viral genomes (11, 12); (7) probing strand breaks in duplex DNA molecules (2, 9, 13); (8) cleaving double-stranded regions that have lower duplex stability (14, 15); (9) localizing inverted repeat sequences (14, 15); (10) introducing deletion mutations at D loops in duplex DNA; and (11) mapping the genomic regions involved in interactions with DNA-binding proteins (16). Its most frequent use in mapping DNA sequences that encode RNA is described further here, because it exemplifies the potential and limits of the technique.

1. Mapping DNA sequences that encode RNA

A method for mapping RNA molecules onto the DNA templates from which they were transcribed was first described by Berk and Sharp (17, 18). The rationale is illustrated in Figure 1. An RNA transcript R is complementary to nucleotides of the coding strand of a DNA, D. Hybridization of the denatured DNA and RNA leads to a hybrid duplex molecule that has single-stranded overhangs. These are removed by digestion with S1 nuclease. The size of the resulting DNA fragment, that is, the value of n, can be determined by subjecting it to electrophoresis on a polyacrylamide gel like those used in DNA sequencing. S1 nuclease does not remove the poly A track or the cap of eukaryotic messenger RNA when they are base-paired, but the 5′-cap structure, it has been thought, sterically hinders S1 digestion of single-stranded mRNA at the phosphodiester bond adjacent to the first nucleotide (19). When mapping is done with an end-labeled probe, one can determine the polarity and the map position of the RNA on the corresponding DNA sequences (19). This strategy is very useful for mapping the 5′-end of mRNA transcripts, thereby identifying promoter sequences (Fig. 2), and mapping the exons in spliced eukaryotic mRNA (Fig. 3).

Figure 1. Rationale for S1-nuclease mapping

Figure 2. Mapping of 5′-proximal promoter sequences. Promoter sequences localized upstream of the 5′ terminus of eukaryotic spliced RNAs can be mapped after hybridization of RNA preparations with a labeled DNA template (corresponding to the coding strand) that contains the putative promoter sequences (as suggested by DNase hypersensitivity, sequence analysis, etc.). In this example, DNA fragment XYZ encodes an RNA complementary to sequence YZ. The promoter sequences are localized in X. The 5′-end of the RNA delineates the X-Y junction. The first step consists of preparing a single-stranded, 5′-labeled DNA probe (XY) that contains the 5′-proximal promoter sequences and does not cover the 3-end of the RNA molecule. This conserves the 5′-labeled end (the dark sphere) after S1 digestion. Then, this DNA strand (top) is hybridized to the mRNA (bottom). The DNA and RNA overhangs are digested by S1 nuclease, and hybridized regions are protected. The S1- digested hybrid is denatured before to analysis by denaturing gel electrophoresis. Only the labeled DNA fragments are visualized by autoradiography. Left lane: control undigested labeled probe (XY); right lane: S1-digested sample in which only the protected Y region of labeled probe is protected. The length of the protected DNA fragment (Y) is smaller than that of the initial probe (XY). The difference in size (X) identifies the starting point (5′-end) of the RNA molecule.

Figure 3. Mapping exon-intron junctions. In this example, a spliced mRNA composed of two exons is hybridized with the complementary, labeled DNA template (coding strand). Following hybridization of complementary sequences, a loop of single-stranded DNA (corresponding to the intron) is generated. Upon incubation of the partial DNA–RNA duplex with S1 nuclease, the free 3′ and 5′ exon-proximal DNA overhangs and the loop are digested. The size of the resulting DNA–RNA hybrid, which contains only exon sequences, is determined by gel electrophoresis in a nondenaturing buffer. Establishing the individual sizes of the two exons requires gel electrophoresis under denaturing conditions to dissociate the hybrid strands. Only the labeled DNA fragments are observed by autoradiography.

Labeling the DNA fragmant

Determining the size of the S1-resistant DNA fragment relies on measuring a difference in size between the initial DNA probe and the protected segment. The DNA is usually detected specifically by autoradiography, which requires that it be radiolabeled and that the label be within the protected segment and survive the S1 nuclease digestion. Cloned DNA fragments are labeled uniformly or specifically at either the 5' or 3' termini. Labeling at the 5' terminus is usually done with polynucleotide kinase in the presence of γ-^{32}P-ATP, whereas 3' labeling is achieved with α^{32}P-nucleoside triphosphates and either the Klenow fragment of Escherichia coli DNA polymerase I, T4 polynucleotide kinase, or nucleotidyl terminal transferase.

2. Preparing single-strand templates

The previous labeling methods label both strands, so it is necessary to purify the labeled coding strand or to use conditions that favor hybridization between the RNA and DNA strands (see later). Generally, the best results are obtained with separated strands. After denaturation, the two strands of a DNA fragment may be separated by electrophoresis in polyacrylamide or agarose gels if they have different base compositions. It is not possible to predict how each strand will migrate, however, so the S1 mapping must be done with each strand. Hybridization of polyUG to the denatured strands may accentuate differences in their electrophoretic mobilities (20, 21). The double-stranded DNA fragment is digested asymmetrically from its two ends, so that the two single strands have different mobilities after denaturation (see Fig. 3). Alternatively, single-stranded DNA may be isolated by cloning in filamentous bacteriophage or plasmid vectors based upon such phage (see DNA Sequencing).

2.1. Use of Double-Stranded DNA Fragments

The rate of hybridization of RNA molecules to single strands of DNA is similar to that of DNA single-strand renaturation (22, 23). Therefore, the rate of hybridization is maximal in the presence of a high salt concentration (1 M NaCl) and a temperature corresponding to the melting temperature (T_m) of 25 to 30°C. In practice, hybridization is often done in the presence of formamide to decrease the T_m and to hybridize at a lower temperature (24, 25). The melting temperature of duplex DNA molecules can be calculated (26) from the base composition, the ionic strength, and the formamide concentration by using the equation

(1)

At high concentrations of formamide (70 to 80%), the T_m of a DNA-DNA duplex is 5 to 10°C lower than the T_m of the corresponding RNA–DNA hybrid (26). Under such conditions, a hybridization temperature between these two T_m values considerably favors association of the RNA with its coding DNA strand. Most RNA–DNA hybridizations are done at temperatures between 40 and 60°C with a buffer that provides constant pH and ionic strength, such as 0.04 M NaCl and 1 mM EDTA. To establish the optimal conditions for hybridization, the T_m of the DNA duplex used should be determined experimentally. Then, hybridization with the RNA is done at a temperature 2 to 4°C higher. The best results are usually obtained when excess DNA is used. Under such conditions, RNA–DNA hybridization is nearly complete in 3 hours with adenovirus 2 DNA (35 kbp) at a concentration of 10 µg/mL (27). Extrapolating, it can be predicted that nearly complete hybridization of a DNA that has n kilobases will be obtained under similar conditions in 3 hours at a DNA concentration of (n/3.5) mg/mL.

In practice, the labeled, double-stranded DNA and the RNA molecule are mixed and reextracted together once. After resuspending the pellet in "double-strand hybridization buffer" of 50 mM PIPES (pH 6.4), 1 mM EDTA, 0.4 M NaCl, 80% formamide, the mixture is incubated at 65°C to denature the nucleic acids. Then, it is transferred to the appropriate temperature for hybridization.

2.2. Use of Single-Stranded DNA Fragments

The probe and the target single-stranded DNA are resuspended in a "single-strand hybridization buffer" of 0.3 M PIPES (pH 6.4), 30 mM EDTA, 2.5 M NaCl, and incubated as before.

Salt Bridge (Salt Linkage, Ionic Bond)

A salt bridge is a pair of ionized groups with opposite charge that are in very close proximity in a macromolecule and contact each other at their van der Waals radii. The ion pair is stabilized by attractive electrostatic interaction and may even have some hydrogen bond character. Intra- and intermolecular salt bridges are frequently observed in proteins (1) and at protein–protein and protein–nucleic acid interfaces (2).

Saltatory DNA Replication

Particles of SV40 virus are produced in permissive simian cells. Infection of nonpermissive rodent cells by SV40 results in integration of the viral genome into the host chromosome. The transformed rodent cells have no free SV40 genomes, but SV40 genomes are produced when these nonpermissive cells are fused with permissive simian cells. The chromosomes from the monkey cells provide replicative functions not present in the rodent cells, making SV40 DNA replication possible in the heterokaryons. Repeated rounds of initiation of DNA replication from the integrated SV40 replication origins result in polytenization of that region (see Polytene Chromosome), which may liberate a linear DNA duplex containing the integrated SV40 genome. The liberated DNA will then recombine with itself to form a circular viral genome. In cell lines with tandem duplications of the integrated SV40 DNA, the efficiency of infectious virus formation is increased because of the terminal duplication of the liberated linear DNA. In the absence of tandem duplication, cyclization by nonhomologous recombination may form mutants with deletion of viral DNA or insertion of host DNA (1).

Salting In, Salting Out

The effect of salts on protein solubility is described by the salting in, salting out effect (1): The dependence of the solubility of a protein on salt concentration is one in which, for any salt, at low salt concentration the solubility of a protein increases; then, after the protein passes a point of maximal solubility, the further addition of salt reduces its solubility (see Precipitation). Typical patterns are shown in Figure 1 (2).

Figure 1. The solubility of carboxyhemoglobin in various electrolytes at 25°C. (Reprinted from (2) with permission of The American Society of Biological Chemists.)

This complex dependence has been decomposed into two contributions (3). At low salt concentration, proteins are salted in; in other words, their solubility increases. For any protein, this is independent of the nature of the salt and is simply the consequence of the fact that proteins carry positively and negatively charged groups on their accessible surface. These are surrounded by an atmosphere of the ions of the salt, which increases the solubility according to the simple Debye–Hückel equation. Thus, if s_s and s_w are the solubilities of the protein in salt solution and pure water, respectively, the salting in is described by the following equation:

(1)

where Z is the net charge of the protein, I its ionic strength, and [illegible] a combination of constants.

At high salt concentration (approximately > 0.5 M), salting in becomes saturated, and the effect of salting out takes over, ie, the protein solubility decreases, following the law that the logarithm of the solubility (S, usually given in units of grams of protein per 1000 cm^3 of solvent) is linear in salt concentration expressed as ionic strength:

(2)

where b and K_s are empirical constants. The parameter K_s, called the salting out constant, is characteristic of the particular salt. The order of salting out effectiveness is close to invariant for most proteins and follows the Hofmeister series (2). The magnitude of K_s is defined by the preferential interaction of the particular salt with the protein, as

(3)

where m_s is the molal concentration of the salt (3). (Salts that induce preferential hydration (negative binding in equilibrium dialysis; see Binding) reduce the solubility of proteins. Conversely, a solvent system that shows preferential binding increases the solubility of proteins.

Salvage Pathways To Nucleotide Biosynthesis

Most nucleotide biosynthesis in most cells occurs via the nearly ubiquitous de novo synthetic pathways, starting from amino acids and their derivatives (see Purine Ribonucleotide Metabolism and Pyrimidine Ribonucleotide Metabolism). However, most cells possess capabilities for taking up nucleosides and nucleobases and converting them to nucleotides. Because these processes involve reutilization of previously synthesized purine and pyrimidine rings, they are called salvage pathways. These pathways are much shorter and simpler than the de novo pathways. On the other hand, there is much more variability from organism to organism, and from tissue to tissue in the same organism, in salvage synthetic capabilities. The metabolic importance of salvage pathways has come to light, first, along with the realization of the serious consequences of hereditary deficiencies in certain salvage enzymes and, second, with the many ways in which salvage pathways are being exploited to create or enhance the effectiveness of chemotherapy against a variety of diseases.

1. Transport of Nucleosides and Nucleobases

Substrates for salvage pathways can come from intracellular nucleic acid degradation (see DNA Degradation In Vivo). For most cells, however, salvage precursors are derived from the extracellular environment. An extreme example is protozoan parasites, which derive all their nucleic acid precursors from salvage substrates in the blood of infected organisms. In fact, these parasites have evolved to the extent that they completely lack de novo pathways and are totally dependent on salvage (1, 2); development of specific salvage inhibitors now constitutes one of the most active research areas of biochemical parasitology.

Nucleosides are hydrophilic molecules and do not readily diffuse through membranes; to an extent, the same is true for nucleobases. Thus, most cells contain specific transporter systems, which take up these molecules by facilitated diffusion (3, 4). In recent years, however, concentrative transport systems have been described, especially for nucleosides. These systems depend on sodium and involve cotransport of the nucleoside with Na^+. Most animal cells contain a broad-specificity nucleoside transporter that functions by facilitated diffusion, the active transport systems being limited primarily to specialized cells, for example, those that take up and use adenosine as a physiological regulator. The nucleobase transport systems are less well characterized, and the question of whether cells contain multiple base transporters or a single broad-specificity transporter has not yet been resolved.

2. Salvage Pathways

Nucleobases are anabolized by phosphoribosyltransferases , which use 5-phosphoribosyl-1-pyrophosphate (PRPP),

while nucleosides are anabolized primarily by kinases

Nucleosides can also be salvaged by a nucleoside phosphorylase followed by a phosphoribosyltransferase.

In principle, this route could be used for nucleotide synthesis, starting with a base, given that nucleoside phosphorylases are readily reversible. However, these enzymes generally act within cells in the direction of nucleoside degradation.

Salvage enzymes vary considerably in tissue distribution and specificity. Mammalian cells salvage purines primarily at the free base level through the action of two phosphoribosyltransferases: hypoxanthine guanine phosphoribosyltransferase (HGPRT), which converts hypoxanthine and guanine to inosinic acid (IMP) and GMP, respectively; and adenine phosphoribosyltransferase (APRT), which specifically converts adenine to AMP. HGPRT is the enzyme missing in cells of males suffering from Lesch–Nyhan syndrome (see Purine Ribonucleotide Metabolism). Pyrimidines, by contrast, are more likely to be salvaged at the nucleoside level. In the de novo pathway, orotic acid is converted to orotidylate by a phosphoribosyltransferase, but comparable pyrimidine salvage enzymes are of extremely limited distribution.

Protozoa that rely on nucleotide salvage pathways, particularly for purines, bear a distinctive set of enzymes— nucleoside hydrolases. These organisms take up purine nucleosides from the blood of infected animals, for example, and then hydrolyze the nucleoside to ribose plus the base; the base is then salvaged by a phosphoribosyltransferase (5). Because the nucleoside hydrolases are quite distinct from known proteins, they are being explored as targets for drugs that would specifically inhibit the growth of an infecting parasite by blocking this salvage route, which is essential for the parasite but not the host.

As discussed more thoroughly below, nucleoside and base analogues are widely used as antiviral, antimicrobial, and anticancer drugs. Because of the interest in developing or improving the effectiveness of drugs that act as DNA synthesis inhibitors, there has been particular emphasis on the deoxyribonucleoside kinases (6). Four such enzymes, with overlapping specificities, are found in human cells. Properties and subcellular distributions of these enzymes are summarized in Table 1. It is of particular interest that deoxycytidine kinase (dCK) is also the principal enzyme for utilization of purine deoxyribonucleosides (the K_m values are much higher for the purines than for deoxycytidine; hence the name of the enzyme).

Table 1. Properties of the Human Deoxyribonucleoside Kinases

Enzyme Cycle Regulation	Natural Substrates	Intracellular Distribution	Cell Cycle Regulation
Deoxycytidine kinase (dCK)	dCyd, dAdo, dGuo	Cytosol	Constitutive
Thymidine kinase 1 (TK1)	dThd, dUrd	Cytosol	S-phase-specific
Thymidine kinase 2 (TK2)	dThd, dUrd, dCyd	Mitochondria	Constitutive
Deoxyguanosine kinase (dGK)	dGuo, dAdo, dIno	Mitochondria[0]	Constitutive

Source: Arnér and Eriksson (6)

A key to understanding some clinical disorders is knowledge of the tissue distribution of salvage enzymes. For example, the immunodeficiency state that results from adenosine deaminase deficiency can be related to this factor (see Purine Ribonucleotide Metabolism). Most or all tissues in an affected individual accumulate adenosine and deoxyadenosine as a result of the genetic block to purine catabolism. Nucleoside salvage enzymes are particularly active in the reticuloendothelial system, where apoptosis leads to degradation and reutilization of cell components, including nucleic acids. Thus, blood cells accumulate excessive amounts of ATP, and in particular, dATP, which interferes with white cell proliferation as part of the immune response, through its inhibition of ribonucleotide reductase.

A salvage enzyme of considerable interest is the family of thymidine kinases specified by herpes viruses. As exemplified by the herpes simplex thymidine kinase, these enzymes have two distinctive properties. First, they are bifunctional enzymes, with thymidylate kinase activity as well. Thus, the enzyme is evidently designed to catalyze two sequential reactions. Second, the nucleoside kinase activity has much broader substrate specificity than most cellular nucleoside kinases. As discussed below, antiviral chemotherapeutic strategies exploit this distinctive property.

3. Salvage Enzymes as Selectable Markers

Because nearly all cells possess de novo nucleotide synthetic capabilities, the salvage enzymes are usually not required for cell viability. In addition, a large number of nucleobase and nucleoside antimetabolites are available, most of them inhibitors of specific enzymes (see Nucleotides, Nucleosides, And Nucleobases). These factors create favorable conditions for the use of salvage enzymes as selectable genetic markers, ie, genetic characteristics that promote the selective survival or growth of desired cell types. For example, the mammalian enzyme encoding HGPRT is widely used as a selectable marker in genetic analysis. 6-Thioguanine is metabolized by HGPRT to give the thiol analogue of inosinic acid, which is toxic. Cells lacking HGPRT can be selected for because they grow in 6-thioguanine-containing medium, while other cells are killed. Hence, one can estimate mutation rates by culturing wild-type cells in the presence of thioguanine and enumerating the cells that grow. Another advantage of this gene for genetic analysis is that it is carried on the X-chromosome. Thus, in male-derived cell lines, only one mutation, rather than two independent events is required to give the resistant phenotype.

A comparable selectable marker is the gene encoding thymidine kinase. 5-Bromodeoxyuridine is anabolized similarly to thymidine;

(1)

However, incorporation of bromodeoxyuridine into DNA is a lethal event. Thus, thymidine kinase deficiency leads to a BrdUrd-resistant phenotype. Because many large DNA viruses encode a thymidine kinase, this is a useful system for manipulating viral genes, for example, the use of vaccinia virus as a vector in the generation of multivalent vaccines (7).

On the other hand, one can select for the presence of active salvage enzymes. The best example is the use of “HAT medium” in somatic cell genetic analysis and in preparing monoclonal antibodies. These techniques involve fusing cells of differing origins and culturing in HAT medium to select for those cells that have undergone fusion. HAT is an acronym for the medium's constituents,— hypoxanthine, aminopterin, and thymidine. Aminopterin inhibits dihydrofolate reductase, blocking the synthesis of tetrahydrofolate needed for de novo synthesis of purine nucleotides and thymidine nucleotides. Thus, cells can grow in HAT medium only if they express active thymidine kinase and HGPRT, for salvage synthesis of thymidine and purine nucleotides, respectively. In monoclonal antibody production, one of the cell lines to be fused lacks thymidine kinase, and the other lacks HGPRT. Thus, only cells resulting from a fusion event have functional copies of both enzymes and can grow.

A final example relates to the use of a selectable marker to force expression of a nonselected marker. For cloning into expression systems in mammalian cells, one often incorporates into the cloning vector the *Escherichia coli xpt* gene, which encodes a distinctive phosphoribosyltransferase that acts on xanthine and guanine. During and after transfection of cells with the recombinant DNA, the cells are cultured in the presence of mycophenolic acid, which blocks de novo guanine nucleotide synthesis by inhibiting IMP dehydrogenase, the enzyme that converts IMP to XMP (which would then be converted to GMP). Thus, the only cells that can grow are those that have taken up and expressed the *xpt* gene, which bypasses this metabolic block. Being carried on the same vector, the gene of interest is also cloned and/or expressed, even though its expression was not directly selected for.

4. Salvage Enzymes and Molecular Pharmacology

A large number of antiviral, antibacterial, antiparasitic, and anticancer drugs act by inhibiting or otherwise manipulating pathways in nucleotide metabolism and thereby interfering with nucleic acid synthesis. Several examples are cited in Nucleotides, nucleosides, and nucleobases. In most cases, the active species is a nucleotide. Because nucleotide molecules are charged, and because specific transport systems for nucleotides don't exist, these molecules penetrate membranes poorly, if at all.

Therefore, in order to generate a therapeutically effective nucleotide intracellularly, its precursor must be administered extracellularly as a nucleobase or nucleoside analogue. Effective use of such drugs demands extensive understanding of salvage pathways in the target cell, subcellular distribution of the enzymes involved, degradative enzymes that might compete with the pathway leading to the desired nucleotide analogue, levels of the target enzyme, and cell-cycle regulation of all the enzymes involved (8).

As an example of the factors involved, consider the fluorinated pyrimidines, 5-fluorouracil (FUra) and 5-fluorodeoxyuridine (FdUrd), analogues used for decades in treating various cancers. It was established in 1958 (9) that these drugs are converted *in vivo* to 5-fluorodeoxyuridine monophosphate (FdUMP), an analogue of deoxyuridine monophosphate, the substrate for thymidylate synthase (Fig. 1; see Deoxyribonucleotide Biosynthesis And Degradation), and that FdUMP is a potent inhibitor of thymidylate synthase and, hence, of DNA replication. Figure 1 shows also the metabolic pathways that both activate these analogues and divert them from their desired endpoint (10). From the figure, one can see that coadministration with FdUrd of a thymidine phosphorylase inhibitor should increase the effectiveness of the analogue by blocking its catabolism. Note that there are multiple routes for activation of FUra; note also that FUra can enter pools of RNA precursors which, in principle, could limit its selectivity by diminishing the specificity of its effect against DNA synthesis. There is evidence, however, that, in some tumors, the effectiveness of FUra actually depends in part on its incorporation into RNA, where it stimulates translational miscoding.

Figure 1. Metabolism of fluorinated pyrimidines by salvage and other enzymes. dR-P is deoxyribose-5-phosphate, dR-1-P deoxyribose-1-phosphate, and R-1-P ribose-1-phosphate. Enzymes are 1, thymidylate synthase; 2, dihydrofolate reductase; 3, serine transhydroxymethylase; 4, thymidine kinase; 5, thymidine phosphorylase; 6, uridine phosphorylase; 7, uridine kinase; 8, uridylate kinase; 9, nucleoside diphosphate kinase; 10, ribonucleoside diphosphate reductase; 11, RNA polymerase.

Sarkosyl

Sodium N-lauroylsarcosine, or Sarkosyl, is a detergent that is structurally related to SDS, except that Sarkosyl has an additional polar and rigid peptide bond linkage within the hydrophobic backbone (Fig. 1). Such rigidity added to the N-terminus of the hydrophobic chain could lead to a decrease in its ability to be inserted freely into hydrophobic membrane bilayers and proteins. This could explain why Sarkosyl is milder than SDS in its ability to denature and disrupt membrane and protein structures. Because of a similar difference in side-chain structure, the bile acid detergent CHAPS is rendered milder than the strongly denaturing sodium cholate, which inactivates integral membrane proteins, such as the serotonin 1A receptor (1). The relatively mild nature of Sarkosyl has been exploited at least in a few cases. Important examples include the purification of Escherichia coli RNA polymerase sigma factors by solubilizing inclusion bodies (2) and the solubilization and purification of the scrapie protein, the prion PrP^{Sc} (3, 4). Although comparison of the structural features of Sarkosyl with those of other detergents suggests that it might be effective in solubilizing functionally active membrane proteins, the major use of Sarkosyl has been to isolate DNA and RNA. The principal reason for this is that Sarkosyl is highly efficient in dissociating nucleosomes and ribosomes (5). The detergent also denatures nucleic acids and inhibits certain enzymes, such as deoxyribonucleases and ribonucleases, which could degrade these molecules.

Figure 1. The structure of Sarkosyl.

Satellite DNA

The regions adjacent to the centromeres in chromosomes of higher eukaryotes are composed of very long blocks of highly repetitive DNA, in which simple sequences are repeated a thousand times or more. Often, these repeated sequences have a base composition very different from that of the remainder of the DNA, so they can be separated from the bulk DNA by cesium chloride density gradient centrifugation of slightly fragmented DNA. For this reason, such DNA is referred to as satellite DNA. The localization of satellite DNA near the centromeres allows localization of the centromeres by *in situ* hybridization and autoradiography in squashed metaphase cells, using radiolabeled RNA copies of the satellite sequence (2).

Different satellites can occur in the same species. For example, *Drosophila virilis* possesses three centromeric satellites (1) whose sequences are highly related. None of these satellite sequences is a pure repeat of the basic consensus sequence. The reason behind the evolution of several sequences is not clear.

Usually, satellite DNA is not transcribed into messenger RNA, as it lacks promoter sites where RNA chains can be initiated. DNA polymerase must recognize the satellite sequences, however, because the DNA from centromeres is replicated at the same rate as the rest of the chromosomal DNA. It is assumed that the satellite sequences bind particular proteins essential for the centromere's function of holding the daughter chromatids together during metaphase, such as playing a role in the assembly of the kinetochores responsible for their attachment to the mitotic spindle or guiding the topoisomerase that eventually separates the sister chromatids (see DNA Topology). Thus satellite sequences are examples of structural rather than genetic regions of DNA.

Satellites

Satellites are subviral agents that depend for their replication on co-infection of a host cell with a helper virus (HV). The nucleotide sequences of the nucleic acids of satellites are substantially different from those of their HV or their hosts, although some satellites may share with their HV short sequences, often at the termini. Thus, satellites are different from defective interfering particles or RNAs, which are wholly derived from the genome of the HV. One chimeric replicon with sequences derived from both a satellite and a HV has been described (1). The relationship between helper virus and satellite is usually specific in that only one HV species, or a group of related species, can sustain the replication of a particular satellite species; on the other hand, a particular HV may sustain the replication of different, unrelated satellites. There is no correlation between the taxonomic relationships of satellites and those of their HVs. Thus, satellitism may have evolved independently several times. The presence of a satellite may modulate the level of accumulation and the pathogenicity of the HV. Because of these properties, satellites can be considered as molecular parasites of their HVs. Satellites are not needed for the normal multiplication of HVs, but there are satellite-like RNA molecules that may be necessary for completion of the HV's life cycle under natural conditions. Examples are the satellite-like single-stranded RNAs associated with groundnut rosette umbravirus or with beet necrotic yellow vein benyvirus, which are needed for transmission of the HV by their respective aphid or fungal vector.

Satellites are a heterogeneous group, rather than a single taxonomic unit. There are satellites that encode proteins that are expressed *in vivo*, and others that are noncoding. When the encoded protein is a structural protein that encapsidates the satellite nucleic acid, the satellite is called a **satellite virus**. Satellite viruses are found as distinct nucleoprotein components in preparations of the HV. The first satellite virus was described in 1962 associated with tobacco necrosis virus (TNV) (2). Satellites that do not encode their structural proteins are called **satellite nucleic acids**. The first satellite nucleic acid was described associated with tobacco ringspot nepovirus in 1969 (3). The different groups of satellite viruses and nucleic acids, and their abbreviations, are listed in Table 1.

Table 1. Satellites and Their Types, with Indication of Size of Nucleic Acid and Accession Number of Typical Sequence Variants[a]

Satellite	Size (nt)	Accession
Viruses		
Subgroup I		
Tobacco necrosis satellite virus (STNV)	1239	J02399
Panicum mosaic satellite virus (SPMV)	826	M17182
St. Augustine decline satellite virus (SSADV)	824	L10083
Tobacco mosaic satellite virus (STMV)	1058	M24782
Maize white line mosaic satellite virus (SMWLMV)	1168	M55012
Subgroup II		
Chronic bee-paralysis associated satellite virus (CPVA)	~ 1100	NR
Nucleic acids		
ssRNA satellites		
Large satRNAs with messenger properties		

Arabis mosaic nepovirus (ArMV) large sat-RNA	1104	D00664
Chicory yellow mottle nepovirus (CYMV) large sat-RNA	1165	D00686
Grapevine bulgarian latent nepovirus (GBLV) sat-RNA	~ 1500	NR
Grapevine fanleaf nepovirus (GFLV) sat-RNA	1114	D00442
Myrobalan latent ringspot nepovirus (MLRV) sat-RNA	~ 1400	NR
Strawberry latent ringspot nepovirus (SLRV) sat-RNA	1118	X69826
Tomato black ring nepovirus (TBRV) sat-RNA	1374	X05689
Bamboo mosaic potexvirus (BaMV) sat-RNA	836	L22762
Small linear satellite RNAs		
Turnip crinkle carmovirus (TCV) sat-RNA	230	X12749
	355[b]	X12750
Cucumber mosaic cucumovirus (CMV) sat-RNA	335	M18872
Peanut stunt cucumovirus (PSV) PSV sat-RNA	393	Z98198
Pea enation mosaic enamovirus (PEMV) sat-RNA	717	U03564
Tobacco necrosis necrovirus (TNV) small sat-RNA	620	NR
Chicory yellow mottle nepovirus (CYMV) small sat-RNA	457	D00721
Artichoke mottled crinkle tombusvirus (AMCV)sat-RNA	~700	NR
Cymbidium ringspot tombusvirus (CyRSV) sat-RNA	619	D0072
Tomato bushy stunt tombusvirus (TBSV) sat-RNA	822	Af022788
Small circular satellite RNAs		
Barley yellow dwarf luteovirus (BYDV) sat-RNA	322	M63666
Arabis mosaic nepovirus (ArMV) small sat-RNA	300	M21212
Tobacco ringspot nepovirus (TRSV) sat-RNA	359	M14879
Lucerne transient streak sobemovirus (LTSV) sat-RNA	324	X01984
Rice yellow mottle sobemovirus (RYMV) sat-RNA	212	AF039909
Solanum nodiflorum mottle sobemovirus (SNMV) sat-RNA	377	J02386
Subterranean clover mottle sobemovirus (SCMV) sat-RNA	332	M33000
Velvet tobacco mottle sobemovirus (VTMoV) sat-RNA	366	J02439
dsRNA satellites		
M satellite of *Saccharomyces cerevisiae* virus L-A	1801	U78817
Satellite of *Trichomonas vaginalis* virus T1	497	U15991
ssDNA satellites		
Tomato leaf curl geminivirus (TLCV) sat-DNA	682	U74627

[a] nt, nucleotides; ss, single-stranded; ds, double-stranded; NR, not reported.

[b] A chimeric replicon with sequences derived from both satellite and helper virus.

1. Satellite viruses

All known satellite viruses have a single-stranded RNA of 800 to 1200 nucleotides. In addition to the open reading frame (ORF) encoding their coat protein, some satellite viruses contain further ORFs; it remains unclear if the encoded products have any role *in vivo* (4). The structure of their isometric, 17-nm diameter particles, built of 60 protein subunits, differs from that of their HV. The particle structures of STNV, STMV and SPMV (see Table 1) have been determined at high resolution by X-ray crystallography (5). In spite of the different structures of the TNV virus particle and of the coat protein of its satellite STNV, both are able to bind specifically to zoospores of the vector fungus *Olpidium brassicae*.

Best-characterized are the satellites of the tobacco necrosis satellite virus (STNV) subgroup. The 1000- to 1200-nucleotide RNA of STNV has no methylated cap structure or genome-linked protein (Vpg protein) at its 5' end. Unlike most plant virus RNAs, it has a phosphorylated 5' terminus. Interference with the accumulation of the TNV has been described for STNV. The particles of STNV may also contain a noncoding satellite RNA of about 620 nucleotides, which depends on TNV for its replication and on STNV for its encapsidation. This is a good example of the complexity of the dependence relationships in satellitism.

Satellite viruses are also found associated with chronic bee-paralysis virus (CPV) (6). Its RNA consists of three species, about 1.1 kb, which can be encapsidated in 17-nm isometric particles built of coat proteins encoded by the satellite or by CPV. The satellite interferes with CPV replication.

2. Satellite nucleic acids

Satellite nucleic acids are single-stranded RNA, single-stranded DNA, or double-stranded RNA satellites associated to viruses of the same type of nucleic acid. Most of the characterized satellites are associated with plant viruses, and most are single-stranded RNA.

2.1. Single-Stranded RNA Satellites

These are classified into three subgroups.

(i) Subgroup I includes satellites with messenger properties. The RNA molecules are between 0.8 and 1.5 kb in size. These satellites encode nonstructural proteins that are expressed *in vivo*. The most studied satellites of this subgroup are those associated with nepoviruses. Large single-strand RNA satellites of nepoviruses have a 3' terminal Poly A sequence and a 5' terminal Vpg protein that, in the analyzed instances, is indistinguishable from that on the HV genome and, therefore, is encoded by it. The encoded nonstructural proteins of different satellite RNAs share some conserved domains, and in some cases have been shown to be needed for replication of the satellite RNA. It may be speculated that these proteins are needed to adapt the virus replication complex to the satellite RNA. For most large satellite RNAs of nepoviruses, effect on the accumulation or pathogenicity of the HV has not been shown. This may depend on the experimental system: the large satellite RNA of ArMV was shown to modulate the symptoms of the HV, depending on the species of host plant. Another satellite RNA in this subgroup has been found associated with bamboo mosaic potexvirus. The encoded nonstructural protein is not essential for satellite replication (7). Interestingly, this protein shares significant sequence similarity with the structural protein of the satellite virus of PMV, suggesting an evolutionary relationship between the satellite virus and the satellite RNA.

(ii) The second subgroup of single-stranded RNA satellites are small, linear RNAs, of less than 800 nucleotides and with no circular forms. Although they may contain potential ORFs, and *in vitro* translation products have been described for some variants of the satellite RNA of CMV, evidence is strong that these molecules are noncoding RNAs. Thus, their biological functions must depend on the RNA structure, which would mediate the direct interaction of the satellite RNA with components of the HV and/or the host plant. Experimental analyses of secondary structure have been done for the satellite RNAs of CMV and TCV, and there is evidence that several have highly-paired secondary structures. This may account for the high survivability of satellite RNAs *in vivo* and *in vitro*, as well as for their high infectivity. Most satellite RNAs in this subgroup modify the symptoms induced by the HV. The most frequent modification is symptom attenuation, but modulation to more severe symptoms (eg intense chlorosis or necrosis) also occurs. Symptom modulation depends on the triple interaction between the strain of satellite RNA, strain of HV, and species or genotype of the host plant. For the satellite RNA of CMV, there has been an extensive analysis of symptom determinants in the satellite RNA. For the satellite RNAs of CMV and TCV, the HV and host determinants have been identified as well. The presence of the satellite RNA often results in depression of the accumulation of the HV, but the relationship between this and the attenuation of symptoms is unclear: depression of HV accumulation also occurs when the interaction between satellite RNA and HV results in symptom exacerbation. Also, for some combinations of satellite RNA and HV, symptom attenuation is not accompanied by a reduction in the accumulation of the HV. The satellite RNA may also interfere with movement of the HV within the infected plant, as shown for the satellite RNA of TCV (8).

(iii) The third subgroup of single-stranded RNA satellites are small circular RNAs. These satellite RNAs actually occur as both circular and linear molecules. The HV may encapsidate circular forms (for sobemoviruses) or linear forms (for nepoviruses and luteoviruses). In both cases, replication is through a rolling circle mechanism (see Rolling Circle DNA Replication). Small circular single-stranded RNA satellites interfere with the accumulation and symptoms induced by the HV. These satellites have been described under the heading Virusoids.

The single-stranded RNA satellites may replicate by different mechanisms than their HV. Thus, the replication machinery of the HV must be adapted to the replication of the satellite RNA. Satellite-encoded factors (for the large, encoding satellites) or unidentified host factors may play a role in modifying the virus replication complex. It is to be noted that for those systems that have been analyzed in detail, the efficiency of satellite RNA replication depends on the HV, as well as on the host plant.

Because of the attenuation of the symptoms of HV, single-stranded RNA satellites have been proposed as efficient agents for the biocontrol of HV-induced plant diseases, both in classical cross-protection programs and by engineering transgenic plants. The high genetic variability of satellite RNAs under experimental and natural conditions, and the possibility of their evolution from attenuating to highly pathogenic types, should be considered when evaluating the potential risks of such control programs.

2.2. Double-Stranded RNA Satellites

Other nucleic acid satellites are the double-stranded RNA satellites associated with viruses in the family *Totiviridae*. Of these, the best studied are the M satellites, which are responsible for the killer phenotype and for immunity to the killer toxin associated with the L-A virus of *Saccharomyces cerevisiae*. The multiplication of the M satellite depends on both the helper virus L-A and on host chromosomal genes.

2.3. Single-Stranded DNA Satellites

A 682-nucleotide, circular, single-stranded DNA satellite has been found associated with tomato leaf curl geminivirus (TLCV). The satellite DNA contains no ORF, is encapsidated in TLCV particles, and is totally dependent for its replication on the replication-associated protein of TLCV. It shows no sequence similarity with the HV DNA, except for a motif that is universally conserved in geminiviruses and involved in single-stranded DNA replication, and for the binding site for the replication-associated protein. At odds with most RNA satellites, this satellite DNA can be supported by distantly related geminiviruses (9).

Satellites have been considered interesting models to approach the analysis of fundamental aspects of virology, such as virus replication, encapsidation, pathogenesis, recombination, and variability. Also, the often complex dependence relationships between satellites and HV pose interesting questions about evolution. Because of this, much research has focused on satellites. Still, major questions remain largely unanswered: (i) how satellites are replicated by the replication machinery of the HV, (ii) how they affect the accumulation (ie, replication and/or movement) of the HV, (iii) how they modify symptoms of the HV, and (iv) what is their origin, evolution, and fate in populations of their HV.

Scalar Coupling

Nuclear magnetic resonance (NMR) spectra of liquid or gaseous samples of a molecule are usually more complex than would be expected based on the number of chemically distinct nuclei in the molecule. The additional complexity (fine structure) in the spectra arises from spin-spin coupling, also called J-coupling, spin-spin splitting, or scalar coupling. The exact resonance frequencies of NMR transitions associated with a particular nucleus depend on the magnetic field at that nucleus, which is the sum of many components. The largest part is provided by the magnetic field of the NMR instrument, as modified by the chemical shift effects of the electrons of the subject molecule and the electrons of surrounding molecules. (See Chemical Shift.) Smaller contributions to the total magnetic field are made by other nuclei in the vicinity of the subject nucleus. Surrounding nuclei are usually “spin 1/2” nuclei and, according to quantum mechanics, these nuclei can have only a “spin-up” or “spin-down” state. Either of these states will potentially contribute to the magnetic field experienced at a neighboring nucleus, with the result that the NMR signals associated with that nucleus may be a collection of signals (a multiplet). Each line of the multiplet represents a particular combination of neighboring nuclear spin orientations. Analysis of multiplet structure can provide important details of a molecule, because scalar coupling effects are dependent on the number and relative orientations of the coupled nuclei. Scalar coupling is a necessary condition for coherence transfer experiments such as correlation spectroscopy (COSY) and total correlation spectorscopy (TOCSY), and it is fundamental to isotope-filtering NMR experiments.

Consider the one-dimensional proton NMR spectrum of N-acetyltryptophan shown in Figure 1. The proton (hydrogen atom) attached to C-4 of the indole ring of this molecule has a shielding parameter that corresponds to 7.53 ppm. The NMR spectrum of proton H-4 is more complicated than would be expected because H-4 feels the orientation of adjacent proton H-5. Two possible orientations exist for H-5, so H-4 experiences two different magnetic fields, and these are represented in the proton NMR spectrum as two signals at slightly different frequencies.

Figure 1. A portion of the proton NMR spectrum of N-acetyltryptophan corresponding to the protons attached to the indole ring, obtained at 500 MHz. (The full spectrum is given in Figure 3 of NMR.) The acetylated amino acid was dissolved in d$_6$-DMSO.

The size of the scalar coupling effect is measured in terms of a parameter called the scalar coupling constant, or spin-spin coupling constant, usually symbolized J and always measured in Hz. Subscripts may follow the J that denote the identities of the spins whose interaction is represented by the coupling constant. A superscript may precede the J that indicates the number of chemical bonds that separate the interacting nuclei. Experiments show that J can be either positive or negative. Not all NMR experiments are sensitive to the sign of J, however, and often only the magnitude of J is discussed. In the case of proton H-4 of N-acetyltryptophan, the spin-spin coupling interaction between H-4 and H-5, represented by the symbol has a value for the coupling constant of about +7Hz.

The value of a spin-coupling constant depends on several factors, including the gyromagnetic ratios of the interacting nuclei and the nature of the chemical bonding between them. The larger the product of the gyromagnetic ratios of the coupling partners, the larger the J_{AB}. A tendency exists for coupling constants to decrease with the number of intervening bonds, that is, $^1J_{AB} > {}^2J_{AB} > {}^3J_{AB}$. $^3J_{AB}$ has an important dependence on the dihedral angle between the first and third covalent bonds, which can be the source of useful stereochemical information. Table 1 indicates the ranges observed for various spin coupling constants between spin 1/2 nuclei that make up biological macromolecules.

Table 1. Typical Values for Coupling Constants, $^{n}J_{AB}$)

Chemical System	J, Hz
	$^{2}J_{HH}$, –15 to –10
(1)	
	$^{3}J_{HH}$, 2 to 12 (depends on dihedral angle)
(2)	
	$^{3}J_{HH}$, 7 to 9 (ortho) $^{4}J_{HH}$, 1.5 to 2.5 (meta) $^{5}J_{HH}$, 0 to 1 (para)
(3)	
^{13}C-H	$^{1}J_{CH}$, 125 to 250 (depends on carbon hybridization)
^{13}C-C-H	$^{2}J_{CH}$, –5 to 5
	$^{1}J_{CC}$, ~55
(4)	
	$^{1}J_{CC}$, 30 to 40
(5)	
^{15}N-H	$^{1}J_{NH}$, 80 to 100
	$^{1}J_{CN}$, ~11

(6)

$^1J_{CN}$, ~15

(7)

A detailed understanding of the spin-spin coupling phenomenon requires a quantum-mechanical treatment. An important result of such an analysis is that J-coupling between nuclei that have the same chemical shift is not observable experimentally in most of the commonly performed NMR experiments with liquids. Thus, the spin coupling constant between two protons of a methyl group, which is a two-bond proton-proton interaction ($^2J_{HH}$), is not observable in a standard one-dimensional proton NMR spectrum.

An observed spin-spin coupling constant of $^nJ_{AB}$ is potentially made up of two types of contributions. Interactions between the A and B nuclei and the electrons that bind A and B to each other and to the remainder of the molecule provide the means whereby the orientation of one nuclear spin is sensed by the other. There are several possible mechanisms by which nuclei-electron interactions can take place; in all cases, the fine structure introduced by them, as reflected by J values, is independent of the laboratory magnetic field used for the NMR experiment (B_o) and, for all practical purposes, independent of the orientation of the molecule being studied in this magnetic field. A direct through-space interaction between spin 1/2 nuclei is also possible. This nuclear dipole–nuclear dipole interaction is strongly dependent on internuclear distance and on orientation of the molecule relative to B_o. Importantly, in samples where sufficient molecular motion exists so that all possible orientations relative to the magnetic field are rapidly sampled, this contribution to spin-spin coupling averages to zero, leaving only the electron-mediated contributions. These are the conditions that normally obtain in nonviscous solutions at magnetic fields less than ~12 T and normal laboratory temperatures. In organized systems (such as liquid crystals) or in very high magnetic fields, sufficient ordering may exist that the dipole-dipole contribution to J is not completely averaged away, and an appreciable structure-dependent contribution to the observed coupling constant through this mechanism will be present.

Often, the multiplet structure produced in an NMR spectrum by J-coupling is undesirable because it provides no useful information. A variety of experimental techniques, generally known as decoupling, can be used to remove the effects of spin-spin coupling from an NMR spectrum. Under decoupling conditions, the spectrum is simplified, perhaps reduced to single peaks at the positions corresponding to the chemical shifts (shielding parameters) of the nuclei being examined. Bear in mind, however, that decoupling methods do not remove spin-spin couplings. These are fundamental aspects of the electronic and geometrical properties of the sample that cannot be removed by external intervention. Only the effects of spin coupling—multiplicity in NMR spectra—are removed by a decoupling procedure. The ^{13}C spectrum shown in Figure 4 of NMR was obtained with proton decoupling. Because proton-^{13}C spin coupling effects are absent from the spectrum, the spectral line positions depend only on the ^{13}C chemical shifts.

Scanning Electron Microscopy

The scanning electron microscope (SEM) has been used for three decades to produce direct, 3-D topographic images of biological samples. Until recently, the resolution in SEM has been too low to directly observe most macromolecules. Advances in specimen preparation, which are sufficient to preserve fine structural details at the molecular level, and instrumentation have extended the possible spatial resolution from 5–10 nm to 2–4 nm. In the SEM, the image is constructed by using a fine electron beam that is raster-scanned over the surface of a specimen. Secondary electrons from the specimen are emitted through excitation caused by primary electrons in the beam striking the specimen. The intensity of the secondary electrons is detected and used to modulate the brightness of another electron beam synchronously scanned over the surface of a cathode ray tube (1). Even though its resolution does not approach that routinely attained in the TEM, the high-resolution SEM (HRSEM) has the advantage of high contrast and high signal-to-noise. However, it must be noted that the SEM provides information only about the surface, whereas the TEM will provide information about the internal structure as well. To increase HRSEM signal yield, enhance contrast, and reduce charging artifacts, coating the specimen with a thin metal layer is performed. However, it is possible to view the fracture surface of a frozen hydrated specimen directly in the SEM without coating the surface with metal (2). For high-resolution work, the metal coat must be thin, with a grain size small enough to reduce decoration artifacts while still producing a high-resolution secondary electron signal.

The preparation of biological specimens can be broadly divided into two methods, chemical and cryo. Though easier to perform, chemical fixation is slower than cryofixation and consideration of pH and osmotic strength must be made. Furthermore, the more widespread adoption of high-pressure freezing to inhibit ice crystal formation has made cryofixation more attractive. One advance that has permitted cryo-HRSEM to characterize biological specimens at near molecular resolution is the employment of an in-lens field emission gun as the source of the electron beam (3). The beam diameter from such a gun is less than 1 nm. However, practical resolution has not achieved this dimension because of the nature of the metal coat and beam damage during observation in the HRSEM. Furthermore, the resolution is limited by the penetration of the electron beam into the specimen, since secondary electrons are emitted from a volume around the site at which the probe meets the specimen. HRSEM can be performed at either low voltage with bulk specimens, or high voltage with thin specimens. The low-voltage electron beam penetrates less deeply into bulk specimens, resulting in the high-contrast signal being generated at only a few nanometers radius from the point of beam impact. Hence, high topographic spatial resolution can be achieved (1). On the other hand, the beam diameter can be made smaller at high voltage, therefore representing a greater potential for high-resolution scanning of thin specimens (4).

HRSEM is being used more often to probe fine details of biological specimens than in the past. Cryo-HRSEM has been used to visualize surface features of reovirus particles (5). It was found that because SEM imaged only the surface of each particle, obscuring of structural detail by the internal structure or by the opposite surface was avoided, an important consideration with large structures such as viruses. Further results with cryo-HRSEM provided evidence that topographical views of actin filaments, microtubules, and clathrin cages could show individual subunits, thus permitting identification by molecular morphology (6). The success in visualizing the 3-D surface architecture of these cytoskeletal elements was attributed to controlled freeze-drying, thin metal coating, cryo-transfer and cryo-observation. In order for SEM visualization to be accomplished, the ice surrounding frozen samples must be removed, either by freeze-drying (ice sublimation in a vacuum) or freeze-substitution (ice dissolved by a chemical solvent), followed by critical point drying. It was found for cytoskeletal structures that freeze-drying provided a superior topography. HRSEM of mitochondria showed a greater variation of cristae morphology than previously recognized and also elucidated how serial-section TEM produced unreliable results because of limited resolution (7).

Scanning Hypothesis

Most cellular messenger RNAs initiate translation via a scanning mechanism in eukaryotes. According to the scanning hypothesis (1), eukaryotic ribosomes bind to the 5′ end of the mRNA and subsequently migrate along the mRNA until they encounter an AUG codon embedded in an appropriate context, whereupon translation initiation occurs. One of the first steps in initiation of translation of most mRNAs in mammalian cells is recognition of the Cap structure and the interaction with it of eIF-4F. At some point in this process, the small ribosomal subunit with associated factors binds to the mRNA and scans to the initiation codon. The scanning model postulates that the 40S ribosomal subunit stops at the first AUG if that codon occurs in a favorable context. But if the first AUG codon occurs in a suboptimal context—for example, in the absence of the critical purine at position –3 or a G at position +4—some 40S subunits will bypass the first AUG and initiate instead at a downstream site. Two independently initiated proteins may thus be produced from one mRNA by context-dependent leaky scanning. Sometimes ribosomal leaky scanning is used for protein expression. For example, translation of the hepatitis B virus pol gene from the viral pre-genome RNA involves such a mechanism (2).

In addition, internal start codons in eukaryotes can be reached by a reinitiation mechanism, originally thought to be the exclusive trait of eubacterial ribosomes. Reinitiation at a downstream codon may be possible when the 5-proximal AUG triplet is followed shortly by a terminator codon and fails to form the proper initiation complex (3).
