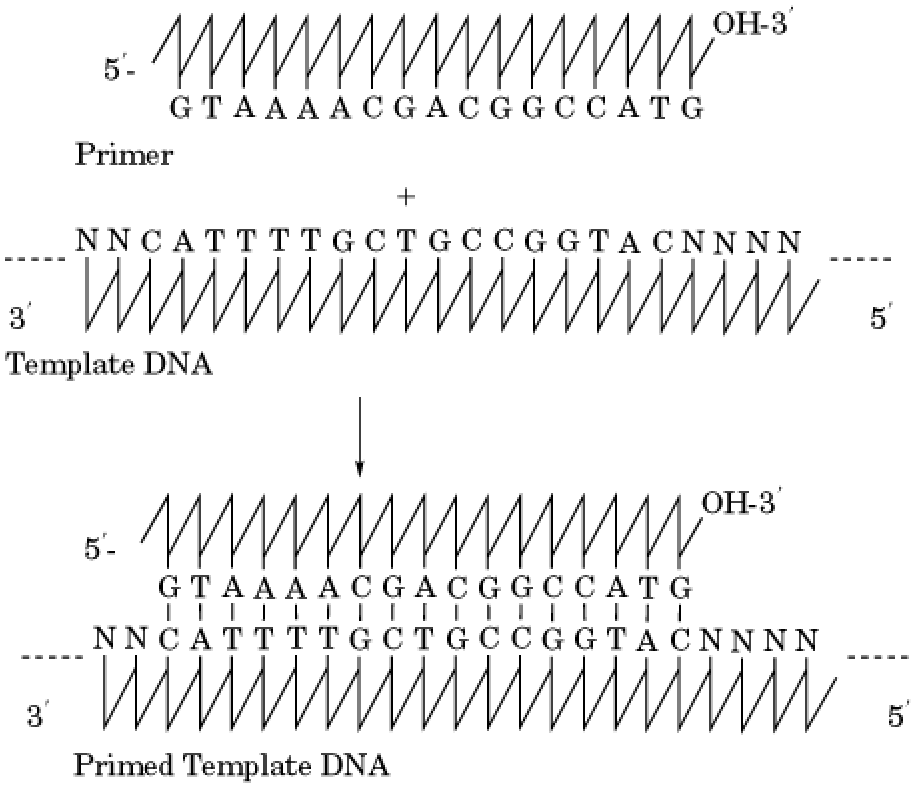
The chain-termination method of DNA sequencing was first described by Sanger in 1977. This method involves synthesizing a DNA strand by a **DNA polymerase** *in vitro*. Synthesis is initiated at only one site, where a primer anneals to the template. The growing chain is terminated by incorporating a 2′,3′-dideoxynucleoside triphosphate (ddNTP) that does not support continued DNA synthesis (hence the name chain termination).

DNA polymerases initiate synthesis only at the 3′-end of a primer annealed to a DNA template. For most sequencing applications, the primer is a short synthetic oligonucleotide (18 to 35 nucleotides long) that is complementary in sequence to the template at a unique position adjacent to the region to be sequenced. The primer is hybridized to the template at the appropriate temperature (Fig. 1). Once this duplex is formed, the primer is extended by the DNA polymerase in the presence of the four deoxynucleoside triphosphates (dGTP, dATP, dTTP, and dCTP; dNTP corresponds to any one of the four).

Figure 1. Annealing of primer to template DNA.



Polymerization of the new strand requires a free 3′-hydroxyl group (Fig. 2). As long as dNTPs are incorporated, there is a 3′ hydroxyl group available for continued polymerization of the growing chain (Fig. 3). However, dideoxynucleoside triphosphates (ddNTPs) lack a 3′-hydroxyl group and terminate chain elongation when incorporated into the DNA. Consequently, synthesis, directed by a sample of template DNA that has a unique primer, in the presence of all four deoxy- and one dideoxynucleoside triphosphate yields a population of molecules that have a common 5′-end, plus 3′-ends all of which have the same terminal dideoxynucleotide base, but have a distribution of sizes depending on the site at which the ddNTP is incorporated (Fig. 4). Thus, the size of each fragment is determined by the sequence of the template. Typically, four separate reactions are performed, each with a different ddNTP. The products of the four reactions are analyzed by electrophoresis using a denaturing polyacrylamide gel, which accurately separates the products by size. Because the size of each fragment is determined by the template sequence, this sequence can be determined from the order of the bands on the gel.

Figure 2. Biochemistry of chain elongation. In the presence of dNTPs, DNA polymerase catalyzes the condensation of deoxynucleoside triphosphate at the 3′-end of a primed template, releasing pyrophosphate.

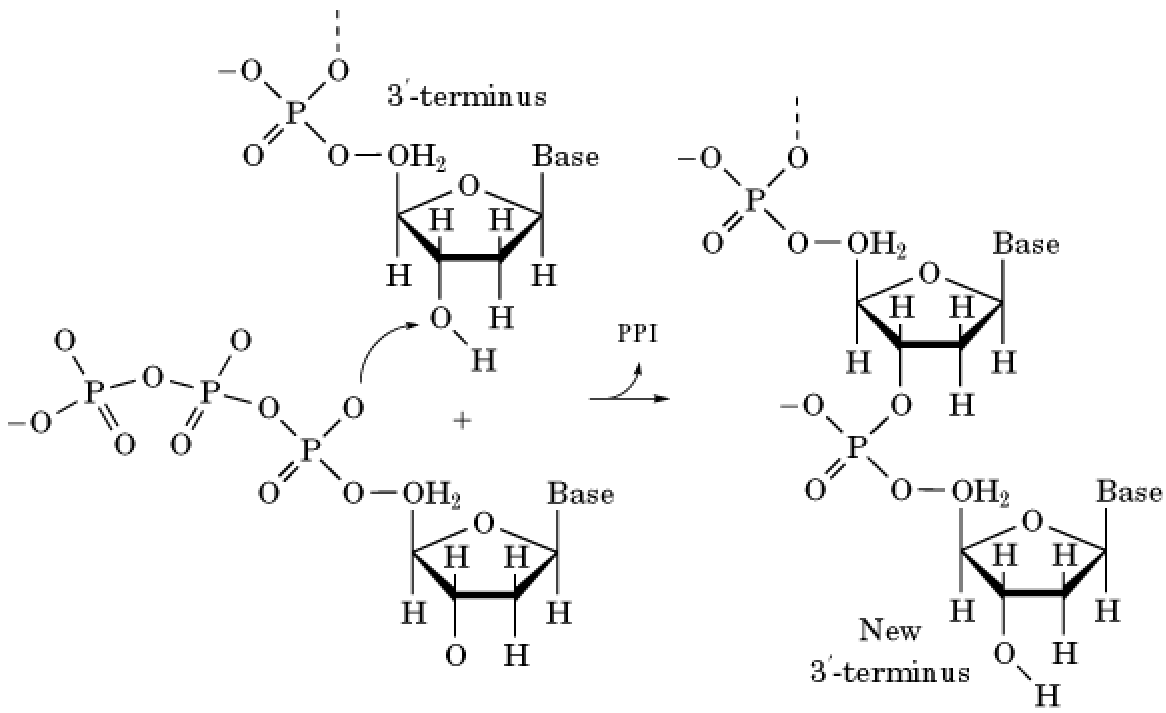


Figure 3. Chain elongation by DNA polymerase. As long as dNTPs are incorporated, there is a free 3′-hydroxyl group available for continued polymerization of the growing chain.

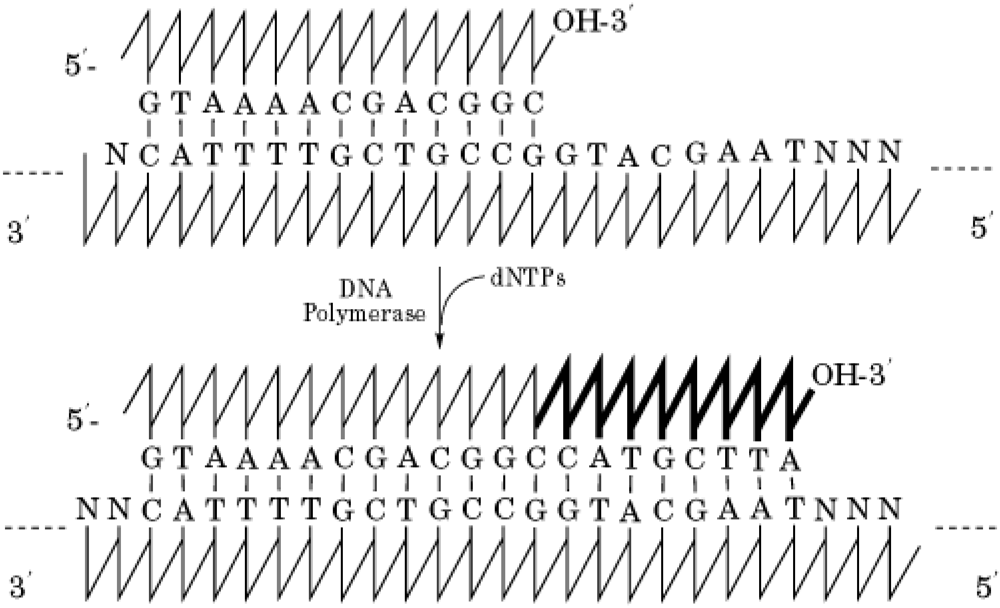

Figure 4. Chain termination. Synthesis from a unique primer in the presence of all four deoxy- and one dideoxynucleoside triphosphate yields a population of molecules with common 5′ ends, but different 3′-ends, depending on the site at which a ddNTP is incorporated.

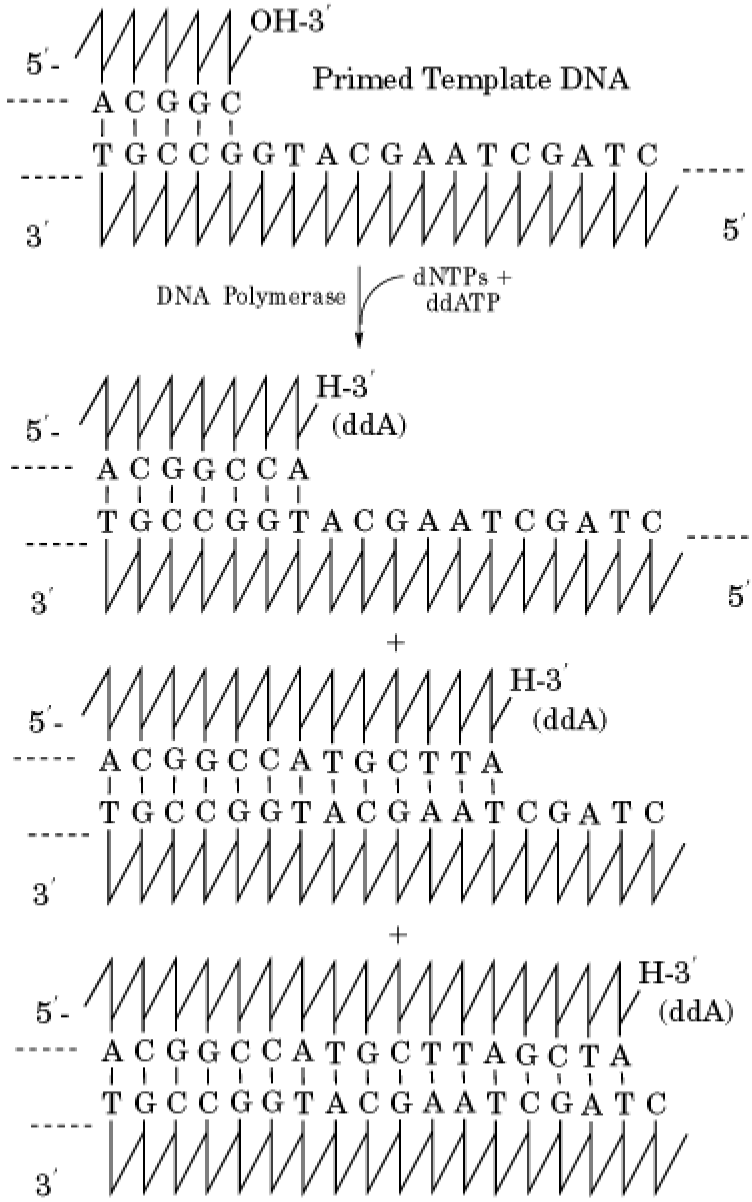

2. Chain Cleavage, Maxam–Gilbert Method

Another general sequencing method, known as the chain-cleavage or Maxam–Gilbert method, has also been used extensively. This method works by a similar method of mapping DNA sequence to DNA size, but does so by degrading existing DNA chains, rather than synthesizing new ones. A sample of purified DNA to be sequenced is first labeled at one end. Then the DNA is subjected to a chemical treatment that breaks each DNA molecule at random, but only at places where one (or a defined subset) of the bases occurs. The result is a population of labeled molecules whose sizes are determined by the sequence. Determination of the sizes on samples cleaved with several sequence-specific cleavage treatments yields complete sequence information. Unfortunately, it is difficult to find chemical cleavage conditions that consistently give unambiguous, clean cleavage products, and few labeling methods can be used that provide labels stable enough for these treatments. For these and other technical reasons, chain-cleavage methods are rarely used today.

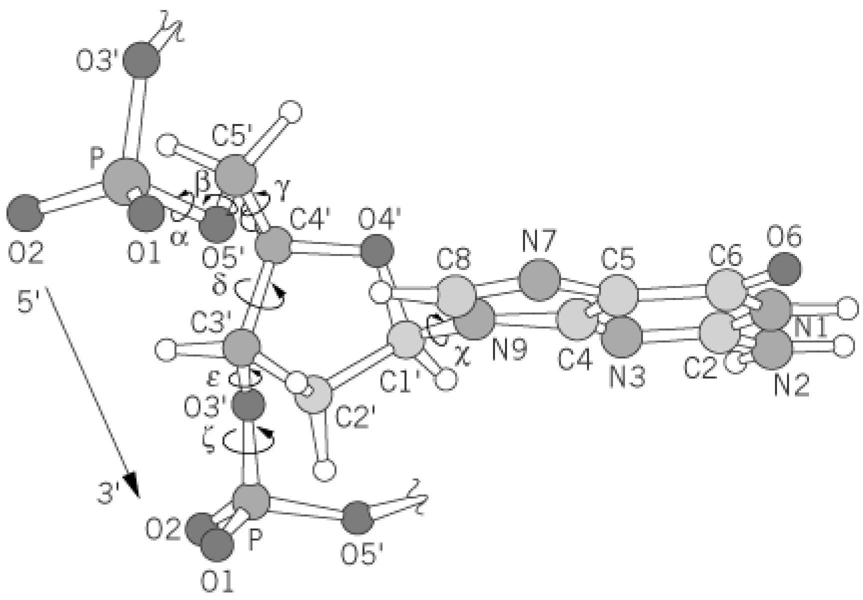
DNA Structure

The central roles of deoxyribonucleic acid (DNA) in life, especially those associated with the storage and transfer of genetic information, are now well established. The discovery of the structure of DNA double helix by Watson and Crick nearly half a century ago ushered the modern biology into a new era and forever changed the landscape of biology. It became clear that the three-dimensional structure of DNA is intimately associated with its function. Recently, the rapid advances in the ability to determine the structures of biological macromolecules has produced a great wealth of information. In the field related to DNA structure, we begin not only to understand the subtle, yet important, sequence-dependent conformation associated with the canonical Watson–Crick DNA double helix, but also to discover new structural forms of DNA and to visualize how DNA interacts with important biomolecules, such as proteins and drugs. A better understanding of the structural basis for the function of DNA will facilitate the rational design of compounds that contribute to improve the quality of life. The out-pouring of the DNA sequence information through various genome projects has made the effort of getting structural information associated with DNA an urgent one.

1. Chemical Structure

DNA is a biological polymer made of the deoxynucleotide building blocks (Fig. 1). Nucleotides, nucleosides, and nucleobases are discussed in that entry. The polynucleotide chain has a directionality due to the specific internucleotide phosphodiester linkage between the O3′ and O5′ atoms from two neighboring deoxyriboses. By convention, a polynucleotide chain is described as going from the 5′ to the 3′ direction. DNA oligonucleotides can now be synthesized routinely for a wide range of applications, including structural studies (see DNA Synthesis). For convenience, DNA oligonucleotides are denoted with their sequence in a form such as d(CGCGAATTCGCG).

Figure 1. The torsion angles (a, b, g, d, ε, z) of a polynucleotide sugar-phosphate backbone and the glycosyl torsion angle c are shown. The diagram show a fragment of B-DNA; therefore the deoxyribose conformation is C2′-*endo*, the glycosyl angle c is *anti*, and the a/z combination is gauche⁻/gauche⁻.



DNA is a polyelectrolyte because of the negative charges associated with the phosphate groups. The negatively charged DNA is neutralized by the positive charges of metal ions, polyamines, or proteins. Metal ions, such as sodium, potassium, or magnesium ions, are used in the screening of the DNA negative charges by interactions with the phosphate oxygen atoms, in enzyme reactions (eg, Mg^{2+} in **DNA polymerase's** function), or in the folding of more complex structures, such the guanine quartet structure.

The sugar–phosphate polynucleotide chain consists of many single bonds around which the attached atoms may rotate. The definition of the torsion angles of the DNA backbone is shown in Figure 1. The deoxyribose ring is nonplanar, and adopts two preferred "puckers," namely, C2′- *endo* and C3′-*endo* conformations. Two parameters, the sugar pseudorotation phase angle and its maximum torsion angle (ie, pseudorotation amplitude), are normally used to describe the puckering modes available in terms of the sugar torsion angles. Two preferred orientations (*anti* or *syn*) of the base with respect to the sugar (as defined by the torsion angle about the C1′━N glycosyl bond c) are found.

DNA predominantly exists as an antiparallel double-stranded helix. The two strands are helically coiled, which maximizes the exposure of the negatively charged sugar–phosphate backbone to water and shields the **hydrophobic** aromatic bases in the middle from water. In the Watson–Crick base pairs of guanine with cytosine (G:C) and adenine with thymine (A:T), the specificity of base pairing is provided by hydrogen bonds. It should be noted that other types of base pairs are also known to exist, and they often are involved in unusual DNA structures.

2. DNA Double Helices

The polymorphism of DNA associated with different helical forms, under the influence of different environmental conditions, has begun to emerge in recent years. Much of the detailed structural information of DNA has been obtained through the high resolution X-ray crystallography analysis and nuclear magnetic resonance (NMR) spectroscopic analysis of DNA oligonucleotides with defined sequences. A survey of the Nucleic Acids Database (site currently unavailable) and their complexes with proteins and drugs indicates that hundreds of crystal structures are available. Additional structures solved by NMR can also be found in the Brookhaven Protein Database (`http://www.pdb.bnl.gov/`). The structural features of the three common types of DNA helices—namely, the B-DNA, A-DNA, and Z-DNA—are illustrated in Figure 2, detailed in Table 1, and described in more detail in the individual entries.

Figure 2. End view and side view of the B-DNA, A-DNA, and Z-DNA helices. Note the decrease in diameter, as well as the relative positions of the base pairs and backbone to the helix axis. See color insert.

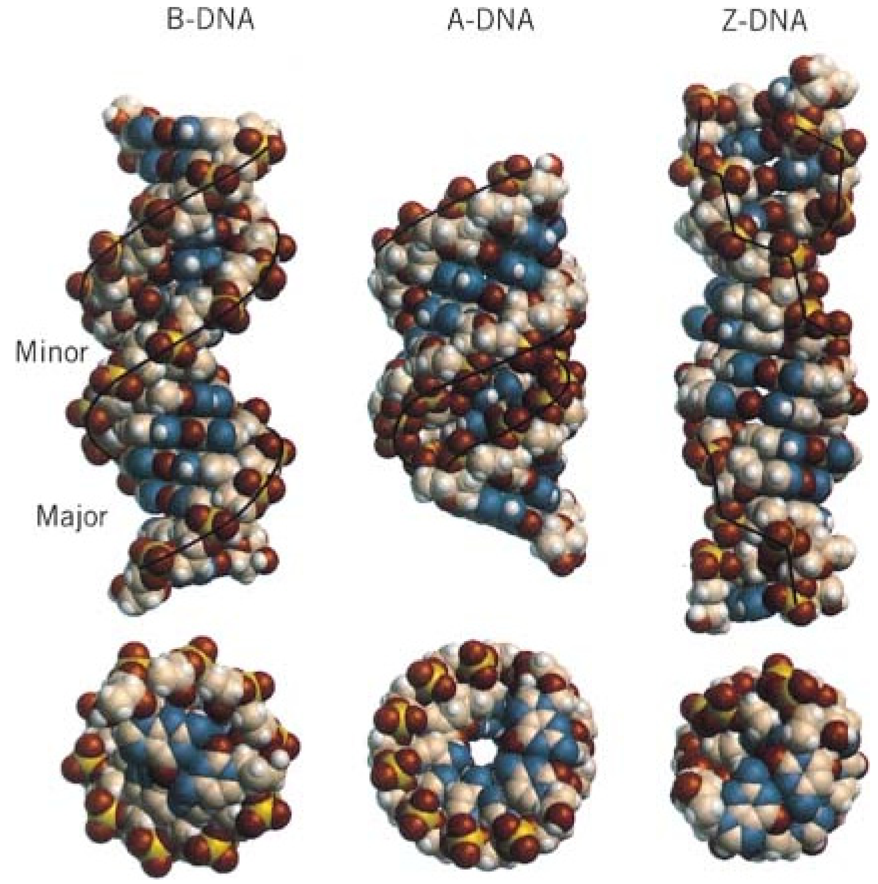


Table 1. Structural parameters of B-DNA, A-DNA, and Z-DNA

Structural Parameter Helical Sense	B-DNA Right-handed	A-DNA Right-handed	Z-DNA Left-handed
Repeat unit (bp)	1	1	2
Base pair/turn (degrees)	10.4	11	12
Tilt (degrees)	~ 0	19	–9
Rise per base pair (Å)	3.3	2.3	3.7
Helical pitch (Å)	34	25.4	45
Glycosyl angle	*anti*	*anti*	*anti* at C/*syn* at G
Sugar pucker	C2′-*endo*	C3′-*endo*	C2′-*endo* at C C3′-*endo* atG
Phosphate conformation (a/z)	–40/–98°	–88° /–44°	–146° /80° at C

			60° /–58° at G
Helical diameter (Å)[a]	~ 20	~ 25	~ 18
Major groove	Wide and deep	Narrow and deep	Flattened
Minor groove	Narrow and deep	Wide and shallow	Narrow and deep

[a] Conversion factor for angstroms to meters is 1.0 × 10⁻.

3. Hydration

The hydration environment around a DNA double helix plays an important role in determining the type of conformation adopted and in determining other properties. Recent structural work suggested that some proteins, such as the Trp repressor (see TRP Operon) and the EcoRI restriction enzyme, recognize DNA sequences through direct hydrogen bonds, nonpolar contacts, indirect structural effects, and, surprisingly, water-mediated interactions. Thus specific water molecules play critical roles in the sequence-specific recognition by proteins. More recently, it was found that water molecules play a different role in that they modulate the binding of sequence-nonspecific DNA-binding proteins (eg, Sac7d) to DNA of random sequence (1). Thus it is now generally accepted that the hydration shell surrounding the DNA molecule plays an important role in DNA recognition by proteins and other ligands, such as DNA-binding anticancer drugs.

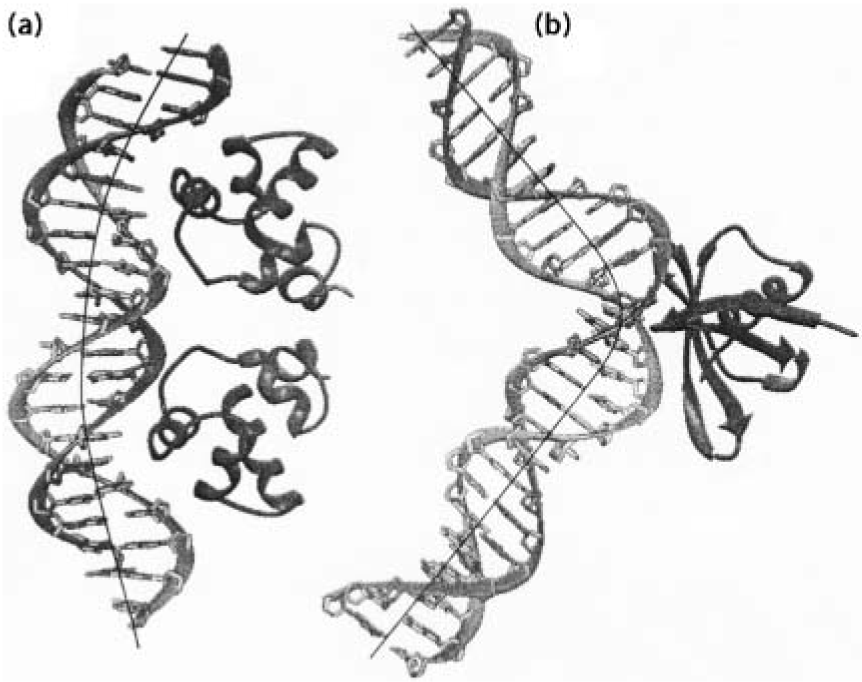
4. Novel DNA Structures

Certain sequences of DNA form three-dimensional structures that are not the common A-, B- or Z-DNA double helices. Those sequences form higher order structures such as a hairpin loop, **triple-stranded** structures, tetrastranded structures, and cruciform. They often involve nonstandard base pairs. For example, the self-pairing of guanine bases are found in the tetrastranded guanine-quartet structure. Specific functions have already been identified for some of these higher order structures. The known multistranded structures include the Guanine Quartet, the I-Motif, the triple helix, and the Cruciform (Holliday Junction), which are described in the individual entries. Some of the novel double-stranded structures are discussed here.

4.1. Bend DNA

Certain DNA sequences have abnormal mobilities in gel electrophoresis. For example, DNA fragments having repeats of $(A)_n$ nucleotides (with $n \geq 4$), separated by another four to five nucleotides and phased with the helical repeat, migrate in the gel significantly more slowly than do those having mixed sequences. It was discovered that the 5′-AAAAA sequence has an intrinsic bending property that can be demonstrated by the increased efficiency of cyclization of those bend DNA fragments. The molecular basis of the intrinsic bendability of the $(A)_n$ sequence has been investigated. The high propeller twist associated with the A-T base pair in the $(A)_n$:$(T)_n$ sequence may play an important role in this property. The bend in those sequences is relatively smooth, resulting in a curved DNA structure. The opening (roll) of the bend is toward the minor groove. Many proteins induce such a smooth bending, by having many small single-step bends, which has been observed in the crystal structures of a number of protein–DNA complexes, exemplified by the structure of the 434 repressor–DNA complex (Protein Database accession number PDR015) shown in Figure 3**a**.

Figure 3. Two types of DNA bending modes. (**a**) Smooth bending found in the 434 repressor–DNA complex (Protein Database PDR015). (**b**) Sharp kink found in the Sac7d–DNA complex (Protein Database 1AZP).



Another type of bend DNA is found to have a sharp kink at a localized site, usually caused and stabilized by DNA-binding proteins bound to DNA. A relevant example is found in a recent structure of the complex between a chromosomal 7-kDa protein Sac7d from the hyperthermophilic archaeabacterium *Sulfolobus acidocaldarius* and DNA oligonucleotides (1). The DNA is kinked sharply at the C_2pG_3 step in the Sac7d-GCGATCGC complex (Figure 3 **b**). The sharp kink is caused by the intercalation of the side chains of amino acid residues Val26 and Met29 of the Sac7d protein into DNA base pairs from the minor groove direction, widening the minor groove at this step.

This type of sharp DNA kink has been observed in the complexes of TATA-box binding protein (TBP), and two **HMG**-box containing proteins, LEF-1 and SRY, with their cognate-specific DNA sequences. Remarkably, both Sac7d and TBP use amino acids on a beta-sheet for the intercalation, whereas in LEF-1 and SRY use the amino acids located at the corner of the **alpha-helical** L-shaped HMG box for the intercalation. A more thorough discussion of the structural basis of the various types of DNA bending has appeared recently (2).

4.2. Triplet-Repeat Sequences

Recently a number of human genetic diseases have been correlated with expansions of triplet repeats of the DNA sequence $(CNG)_n$. The $(CGG)_n$ repeat in the X-chromosome is responsible for fragile-X syndrome, the $(CAG)_n$ repeat is associated with Huntington's disease and spinobulbar muscular atrophy, and finally the $(CTG)_n$ repeat is associated with myotonic dystrophy. How these unusual repetitive sequences correlate with the etiology of these diseases, and the mechanism by which those repeats are expanded during DNA replication, are under intense scrutiny. Some have proposed that a “slippage” process occurs because of the ease of the formation of hairpin structures for these repeating sequences. Certain triplet repeats, such as $(CAG)_n$ and $(CTG)_n$, but not $(CGA)_n$, have a strong propensity to form hairpin structures. Therefore, a DNA duplex encoding the $(CAG)_n$:$(CTG)_n$ repeats may easily exchange between duplex and cruciform, especially under negative **supercoiling** strain. If there are proteins or other ligands (eg, drugs) that can stabilize the stem of the cruciform, this process would be inhibited. The three-dimensional structures of several DNA oligonucleotides associated with those novel triplet repeats have been studied, primarily by NMR. The $(CAG)_n$ repeat can form a stable duplex structure incorporating "sheared" G-A mismatched base pairs. The duplex structure associated with the $(CCG)_n$ repeat appears to have the C nucleotides extruded from the helix. The structural and functional studies of those unusual repeats remain very active (3). (See also Trinucleotide Repeats.)

4.3. Parallel-Stranded DNA Duplex

A new addition to non-canonical DNA structures is the parallel-stranded (PS) DNA structures. The question of whether a stable DNA duplex can be parallel has been addressed previously (4). A series of A,T-containing DNA sequences was designed to form parallel duplexes using reversed Watson–Crick base pairs. The stability of those PS duplexes is modest; for example, the T_m **(melting temperature)** of a 21-mer PS-duplex is 15°C lower than that of the corresponding antiparallel duplex. A different motif was the non-Watson–Crick homo base-paired parallel-stranded DNA, called P-DNA. It was demonstrated that the d(CGA) sequence has a strong propensity to form the P-DNA structure (5).

An important requirement for a hetero base-paired parallel duplex is that the two glycosyl bonds within a base pair have to come from opposite directions, because of the identical chain polarity. For the normal nucleic acid bases, this can be accomplished using the reverse Watson–Crick base-pair conformation. However, A-T and G-C base pairs in a reverse Watson–Crick conformation are not isostructural, due to their hydrogen-bonding restrictions. Therefore, it has not been easy to design a stable PS duplex in which all four bases can be incorporated in random order.

This difficulty has been overcome by using alternative nucleosides, 2′-deoxyisoguanosine (iG) and 2′-deoxy-5-methyl-isocytosine (iC), which can form stable reverse Watson–Crick base pairs with the normal 2′-deoxycytosine (C) and 2′-deoxyguanosine (G), respectively. Indeed, oligodeoxynucleotides containing iG and iC can form remarkably stable parallel-stranded duplexes with the complementary (G,C)-containing DNA or RNA strands (6). The ability of (iG,iC)-containing DNA oligomers to form specific stable parallel-stranded duplexes may offer new opportunities for designing useful probes for applications such as antisense or aptamer molecules.

5. Summary

In conclusion, the importance of DNA structure and dynamics in biology is very clear. The rapid advancement in genomics, molecular biology and structural biology (including synchrotron) offers an exciting future in the investigation of the protein and nucleic acid structures associated with new and significant biological functions. One can now attack problems that were unthinkable just a few years ago. The structure of the nucleosome has been determined at 2.8 Å resolution and the detailed DNA conformation has been presented (7). The structure of the ribosome particle is on its way to be elucidated at a resolution high enough to visualize individual proteins and RNA. It can be certain that many structures of novel DNA sequences and important protein–DNA complexes will be forthcoming at a rapid pace in the next few years.

DNA Synthesis

The introduction of methods for the chemical synthesis of oligo- and poly- deoxyribonucleotides (DNA sequences) has had a very considerable effect on the development of molecular biology. This is clearly apparent from other sections of the Encyclopedia. The three most important factors to be taken into account in the chemical synthesis of DNA sequences are:(1) the choice of suitable protecting groups for the 2’-deoxyribonucleoside building blocks [**1**], (2) the development of phosphorylation procedures that are suitable for the introduction of the internucleotide linkages, and (3) the purification of the synthetic DNA sequences themselves. The choice of protecting groups is of crucial importance. The protecting groups selected should be easy to introduce; they should also remain completely intact throughout the assembly of the DNA sequences and be easily removable under conditions where the synthetic DNA is completely stable.

Structure 1. DNA synthesis.

1. Protecting Groups for 2'-Deoxynucleosides

In order to avoid side reactions during phosphorylation, the adenine, cytosine, and guanine base residues are generally protected with acyl groups [e.g. as in **2a, 3a**, and **4a**, respectively], but thymine residues [**5**] are usually left unprotected (1). It may sometimes be desirable (2) to protect thymine residues [**5**] on *O*-4 and *N*-2-acylguanine residues [**4**] also on *O*-6, but this depends on the phosphorylation procedure used. An important feature of DNA chemistry is that the glycosidic linkages, and especially those of purine deoxyribosides, are very sensitive to acid. Thus, the (di-*p*-anisyl)phenylmethyl (DMTr, [**6**]) and the 9-phenylxanthen-9-yl (Px, [**7**] groups, which are removable under relatively mild acidic conditions, are particularly useful for the protection of the 5'-hydroxy functions of 2'-deoxynucleosides [as in **8a** and **8b**, respectively]. 5'-O-Acyl-protected deoxynucleosides ([**8**] R = acyl) have also been used as starting materials, particularly in the solution phase synthesis (see below) of DNA sequences. Acyl groups are also used to protect the 3'-hydroxy functions of deoxynucleosides [e.g. as in **9a**]. Both *N*-acyl and *O*-acyl protecting groups are usually removed at the end of the synthesis by ammonolysis under conditions where DNA is completely stable.

2. Phosphorylation Methods

There are essentially three phosphorylation methods (Fig. 1) that have been used successfully in the chemical synthesis of relatively high molecular weight DNA sequences.

2.1. Phosphotriester Approach

The first method, which involves coupling a protected nucleoside or oligonucleotide 3'-(2-chlorophenyl) phosphate [**10**] with a protected nucleoside or oligonucleotide component with a free 5'-hydroxy function [**11**] (Fig. 1a), is usually referred to as the *phosphotriester approach* (3) as all of the internucleotide linkages are protected as phosphotriesters throughout the assembly of the target DNA sequences. In a now obsolete method known as the *phosphodiester approach*, the internucleotide linkages were left unprotected throughout the assembly of the DNA sequences. Coupling between the two components [**10**] and [**11**] is usually effected by a condensing agent such as 1-(mesitylene-2-sulfonyl)-3-nitro-1,2,4-(1*H*)-triazole (MSNT) [**12**] in anhydrous pyridine solution (4). The 3'-(2-chlorophenyl) phosphate component [**10**] is usually used in slight (*ca.* 20% to 25%) excess, and the condensing agent (e.g., MSNT), which also acts as a dehydrating agent, is used in greater excess. A very important feature of the phosphotriester approach is that the first unblocking step of the fully-assembled DNA sequence is effected by treatment (4) with an excess each of an appropriate oxime (such as (*E*)-2-nitrobenzaldoxime [**14**]) and N^1,N^1,N^3,N^3-tetramethylguanidine [**15**]. Such oximate treatment leads to complete removal of the 2-chlorophenyl protecting groups without any concomitant cleavage of the internucleotide linkages. *N*- and *O*-Acyl protecting groups [as in **2, 3, 4** and **9**] are subsequently removed by treatment with concentrated aqueous ammonia, and the 5'-terminal acid-labile protecting group [as in **8a** and **8b**] is removed under mild conditions to leave the fully unprotected DNA sequence. The phosphorotriester approach is an extremely versatile method for the synthesis of DNA sequences; it can be used both in solution phase (by the stepwise addition of mononucleotides or by the addition of oligonucleotide blocks) (4) and in **solid phase synthesis** (5).

2.2. H-Phosphoroamidite Approach

The second phosphorylation method is generally based on protected nucleoside 3'-(2-cyanoethyl) *N,N*-di-isopropylphosphoramidites [**17**] and may be referred to as the *phosphoramidite approach* (6). In the presence of relatively weak acids (e.g., 1*H*-tetrazole [**18**]), such phosphoramidites [**17**] become powerful phosphitylating agents and react with protected nucleoside or oligonucleotide components with free 5'-hydroxy functions [**11**] (Fig. 1b) to give protected phosphite triesters [**19**]. These phosphite triesters triesters are sensitive intermediates and are usually immediately oxidized (e.g., by treatment with iodine and 2,6-lutidine in aqueous tetrahydrofuran) to give the corresponding phosphotriesters [**20**]. The 2-cyanoethyl protecting groups are removed from the fully-assembled DNA sequences, together with the *N*- and *O*-acyl protecting groups, by treatment with concentrated aqueous ammonia. A crucial aspect of the phosphoramidite approach is that activated derivatives of *phosphorous* acid are much more reactive than corresponding activated derivatives of *phosphoric* acid. Therefore, in the phosphoramidite approach, coupling yields tend to be somewhat higher, and the coupling recations are faster than they are in the phosphotriester approach. Largely for these reasons, the phosphoramidite approach has become the method of choice for the automated solid phase synthesis of DNA sequences (see text below); it has, therefore, been very widely used in the chemical synthesis of the relatively small quantities of the DNA sequences that are required in most molecular biological studies.

2.3. H-Phosphonate Approach

The third phosphorylation method is based on protected nucleoside 3'-(H-phosphonate) monoesters [**21**] as building blocks and is generally referred to as the *H-phosphonate approach* (78). Both H-phosphonate building blocks [**21**] and 2-chlorophenyl phosphates [e.g., **10**] are very easy to prepare; they are also more stable and easier to handle than phosphoramidite building blocks [**17**]. However, partly perhaps because they are less bulky, H-phosphonates [**21**] undergo coupling reactions more rapidly than the corresponding 2-chlorophenyl phosphates. Thus, coupling between a nucleoside 3'-(H-phosphonate) building block [**21**] and a protected nucleoside or oligonucleotide with a free 5'-hydroxy function [**11**] (Fig. 1c) occurs very rapidly in the presence of a condensing agent such as pivaloyl chloride [**22**] (8) in pyridine solution to give the corresponding H-phosphonate diester [**23**]. Such H-phosphonate diesters [**23**] are particularly sensitive to base-catalyzed hydrolysis, and for this reason almost all synthetic studies involving the H-phosphonate approach have been carried out in the solid phase (see text below). When a particular DNA sequence has been fully assembled, the H-phosphonate diester groups [as in **23**] are oxidized (e.g., with iodine in the presence of a base in aqueous tetrahydrofuran) to give unprotected phosphodiester internucleotide linkages [as in **24**] before the *N*- and *O*-acyl protecting groups are removed by treatment with concentrated aqueous ammonia. Despite its merits and its potential as an important synthetic method, the H-phosphonate has not been as widely used as the phosphoramidite approach in solid-phase synthesis. However, recent studies suggest that a modified H-phosphonate approach (see text below) may well become the method of choice in the solution-phase synthesis of DNA sequences. Indeed, there is no obvious reason why such a modified H-phosphonate approach could not also be applied successfully to solid-phase synthesis.

3. Solid-Phase DNA Synthesis

Relatively high molecular weight DNA sequences have been prepared successfully by the phosphotriester approach in solution by following essentially the procedure indicated in outline in Figure 1a. However, solution-phase synthesis is relatively laborious in that **chromatographic** purification steps are usually necessary after each coupling step. Nevertheless, if a very large quantity of a specific sequence is required (see text below), solution-phase synthesis may very well prove to be the method of choice. If, on the other hand, relatively small (i.e., milligram to gram) quantities of material are required for biological or biophysical studies, there is little doubt that solid-phase synthesis is to be preferred. While all three of the above phosphorylation methods (Fig. 1) have been used in solid-phase synthesis, the phosphoramidite approach (9) has emerged as the method of choice. This is mainly because its use leads to high coupling efficiencies and no significant side reactions. Furthermore, most commercial automatic synthesizers have been designed specifically to accommodate phosphoramidite chemistry. The main advantages of solid-phase synthesis, particularly by the phosphoramidite approach, are: (1) that it is very rapid and a DNA sequence containing, say, 50 nucleotide residues can easily be assembled and unblocked within one day; (2) only one purification step is required at the end of a synthesis as the growing DNA sequence is attached to a solid support (such as controlled pore glass [CPG] or polystyrene), and the excesses of all reagents are washed away; (3) all chemical reactions can be made to proceed in very high yield by using large excesses of reagents; and (4) the whole process may be fully automated in a DNA synthesizer. Solid-phase DNA synthesis has been developed to such an extent that the whole process can be carried out by a competent technician with no specialist knowledge of nucleotide chemistry. Automatic synthesizers, some of which are capable of assembling several different specific DNA sequences simultaneously, are readily available, and all the necessary building blocks [particularly phosphoramidites **17**] and other reagents and solvents may be purchased in containers that are designed to be attached directly to the synthesizer.

The main steps in a synthetic cycle (i.e., the addition of one nucleotide residue) in solid-phase DNA synthesis by the phosphoramidite approach (10) are illustrated in outline in Figure 2a. Bottles containing solutions of each of the four main phosphoramidites [e.g. **17**, B = **2a,3a,4a** and **5**] in acetonitrile and other reagents and solvents are attached to the appropriate ports on the synthesizer. The desired 3'-terminal nucleoside residue is generally attached to the solid support (P; usually CPG or polystyrene) through a succinoyl linker [as in **25**], and this material is contained in a small column that is inserted in the synthesizer. The first step (Fig. 2**a**, step i) in the synthetic cycle involves treatment with acid to remove the 5'-*O*-DMTr protecting group [**6**] from the solid-supported 3'-terminal nucleoside residue [**25**]. The next step (step ii, the coupling step) is the *1H*-tetrazole-catalyzed reaction between a phosphoramidite [**17**] and the released 5'-hydroxy function [as in **26**] to give a phosphite triester [**27**]. A large excess each of the appropriate phosphoramidite [**17**] and 1*H*-tetrazole [**18**] are delivered automatically, leading to an anticipated coupling efficiency of *ca.* 98.5%. It is then important to "cap" any remaining 5'-hydroxy functions. This is effected by reaction with a very large excess of acetic anhydride in the presence of 1-methylimidazole and 2,6-lutidine in tetrahydrofuran solution (step iii). "Capping" in each synthetic cycle ensures that, at the end of the synthesis, most of the truncated sequences will be of significantly lower molecular weight than the target DNA sequence, thereby facilitating its purification. The phosphite triester group [as in **27**] is then oxidized (step iv) to a phosphotriester group. The first synthetic cycle is now complete. A number of washing steps are involved in addition to steps i to iv, and the whole cycle usually requires less than 8 min. The removal of the 5'-*O*-DMTr protecting group [**6**] [to give **28**] is the first step of the second synthetic cycle, and this is followed by another coupling reaction involving the appropriate phosphoramidite building block [**17**]. It is essential that the acetonitrile solutions containing the phophoramidites [**17**] and 1*H*-tetrazole [**18**] should be as dry as possible. The efficiency of the coupling steps may be estimated spectrophotometrically by measuring the quantities of the colored (di-*p*-anisyl)phenylmethyl ($DMTr^+$) cations released at the beginning of each synthetic cycle. It is essential that the "detritylation" and coupling steps (steps i and ii, respectively) should proceed as nearly quantitatively as possible, and that "capping" (step iii) should be as efficient as possible. Clearly, oxidation (step iv) of the phosphite triester to the phosphotriester group should also go to completion in each cycle. If the average coupling efficiency is 98.5%, it should be possible to prepare DNA sequences containing 50 and 100 nucleotide residues in *ca.* 47% and 22% overall yields, respectively. However, if the average coupling efficiency is only 97.5%, then the overall yields of a 50-mer and a 100-mer would fall to *ca.* 29% and 8%, respectively. Therefore, if reasonable care is taken, it should be possible to prepare DNA sequences containing up to *ca.* 100 nucleotide residues by solid-phase phosphoramidite synthesis.

The target DNA sequence [**29**] is fully assembled after *n* complete synthetic cycles. The products must then be released from the solid support, and all the protecting groups need to be removed. Two alternative unblocking procedures are indicated in Fig. 2b. First, the 5'-terminal DMTr protecting group [**6**] is removed in what would be step i of the (*n*+1)th synthetic cycle. The loaded solid support is then treated with concentrated aqueous ammonia, usually at *ca.* 55°C (step v). This leads to the detachment of the synthetic DNA sequence from the solid support, the removal of all of the 2-cyanoethyl protecting groups from the internucleotide linkages and all of the *N*-acyl protecting groups from the base residues. The crude products obtained contain the target DNA sequence [**30**], contaminated with "capped" truncated sequences; this material is usually purified by high-performance liquid chromatography (HPLC) or by polyacrylamide gel electrophoresis (PAGE). In an alternative procedure (Fig. 2b, steps v and vi), the ammonolysis step is carried out before the removal of the 5'-terminal DMTr protecting group. The latter procedure is advantageous if purification of the crude products is to be carried out by **reversed-phase** HPLC as the difference between the retention times of the "capped" truncated sequences and the DNA target sequence, which is still protected with a 5'-*O*-DMTr group, is thereby increased. The DMTr protecting group is then removed by acidic hydrolysis under very mild conditions (step vi).

Automated solid-phase synthesis by the phosphoramidite approach has also been used successfully (11) in the preparation of DNA sequences in which the base residues, sugar residues, and internucleotide linkages are modified. DNA sequences with attached **fluorescent** and other **reporter** groups have also been prepared by solid-phase synthesis. Such modified DNA sequences have found numerous important applications in molecular biology.

4. Solution-Phase DNA Synthesis

Of the three phosphorylation methods described above, only the phosphotriester approach (Fig. 1a) is really suitable for the synthesis of DNA sequences in solution. This method, which was developed largely in the 1970s, is very versatile and is particularly suitable for the coupling of oligonucleotide blocks (i.e., the addition of two or more nucleotide residues at a time) as well as for stepwise synthesis. Phosphotriester block coupling was a key feature of the original synthesis of the human insulin gene (12). Although the methodology has been refined (13) since then, the development of automated solid-phase synthesis (see above) in the 1980s provided a much faster and less labor-intensive method for the preparation of the very small (usually milligram or even smaller) quantities of synthetic DNA sequences that are generally required in molecular biology. Solution-phase synthesis is much more laborious in that it is normally advisable to purify the products by chromatography after each coupling step. Although such purification processes need not necessarily amount to much more than filtration through a bed of silica gel, they are time consuming. Furthermore, solution-phase synthesis has not yet been automated. It is, nevertheless, not at all unlikely that solution-phase synthesis will become the method of choice if really large (i.e., multikilogram to tonne) quantities of moderately sized (containing *ca.* 20 nucleotide residues) DNA sequences or their analogs are required in **anti-sense** or antigene chemotherapy. Automated solid-phase synthesis has recently been scaled-up to the multigram level (14) in order to provide sufficient material for clinical trials. However, if such clinical trials are successful and very much larger quantities of pure DNA sequences and their analogs are required for drug purposes, further substantial scaling-up of solid-phase synthesis may not prove to be a practical proposition. It is quite likely that the solution-phase synthesis or perhaps a combination of solution-phase and solid-phase synthesis might lend itself much more readily to scaling-up. The phosphotriester approach has the further advantage that the fully-protected intermediates obtained are soluble in organic solvents and may, therefore, be purified by conventional chromatographic techniques, and, after all of the protecting groups have been removed, the unprotected DNA sequences obtained may, if necessary, be further purified in the same way as material that has been prepared on a solid support.

It is anticipated that success in the design of oligonucleotide drugs will stimulate further research and consequent improvements in solution-phase synthesis. Indeed, a modified phosphotriester approach involving low temperature H-phosphonate coupling (Fig. 3, step i) has recently been proposed (15).

This method appears to be more efficient than the conventional phosphotriester approach (Fig. 1a) in that virtually quantitative coupling yields are obtained, and no significant side-reactions are observed. The sensitive H-phosphonate diesters [corresponding to **23**] (Fig. 1c) are not isolated but are immediately converted at a low temperature into much more stable *S*-(4-chlorophenyl) phosphorothioates [**34**] by treatment with the phthalimide derivative [**33**] (Fig. 3, step ii). After the desired DNA sequence has been assembled, the *S*-(4-chlorophenyl) phosphorothioate groups [as in **34**] are quantitatively converted into phosphodiesters [as in **16**] by standard oximate treatment (Fig. 1a).

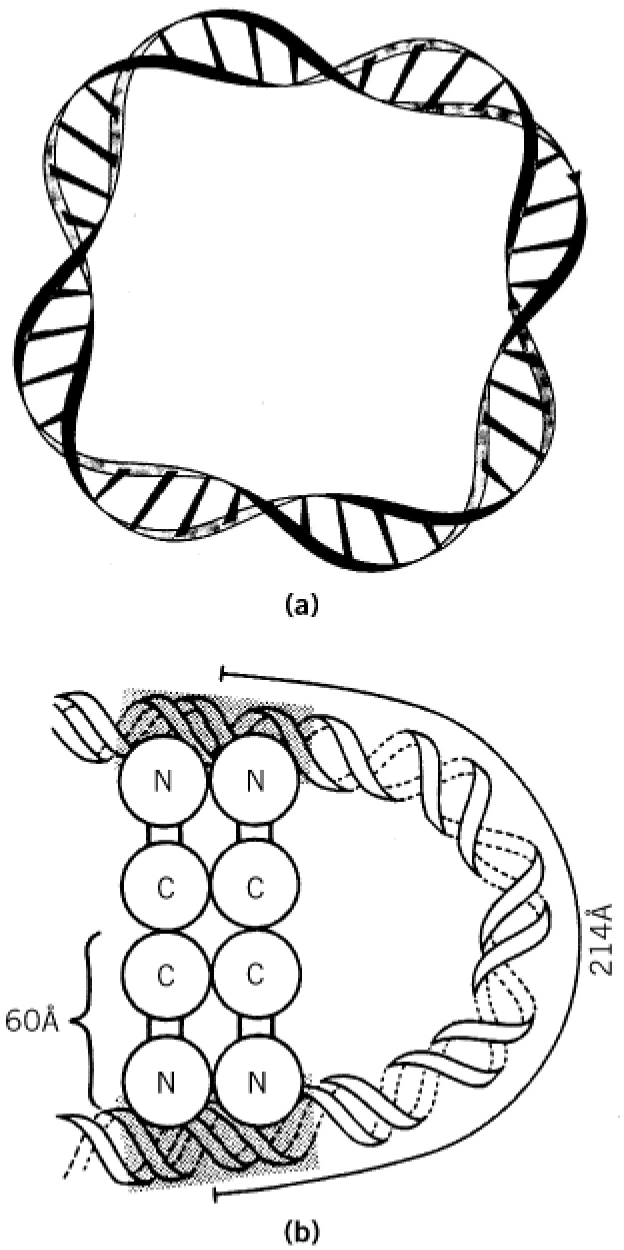
DNA Topology

Double-stranded acquire DNA structures topological properties if organized into a topological domain, which is a closed region in which the two strands are linked. The known types of elementary topological domains are closed circular duplex DNA (cdDNA), in which the two strands are separately covalently continuous; and **protein**-sealed closed DNA loops (Fig. 1) (1). The vast majority of experimental and theoretical work on DNA topological domains has been done with purified closed circular DNA. An elementary topological domain, in which the DNA is topologically monomeric, is one in which the axis of the DNA is not itself linked to that of any other DNA. DNAs of this type are widespread in nature, including bacterial plasmids and episomes, the virion and replicative forms of both eucaryotic and procaryotic viruses, mitochondrial DNA, and many others (2). The nomenclature used to describe these molecules derives in part from protein chemistry and is imprecise when applied to closed circular DNA. Among the terms commonly used are *superhelical DNA* and *supercoiled DNA*. These are not meant to indicate different structural types, but are used as synonyms to indicate that the DNA in question is more compact than either its relaxed closed circular or nicked circular counterpart. They are used interchangeably with the more generic *closed circular DNA* or, alternatively, *closed duplex DNA* (*cdDNA*).

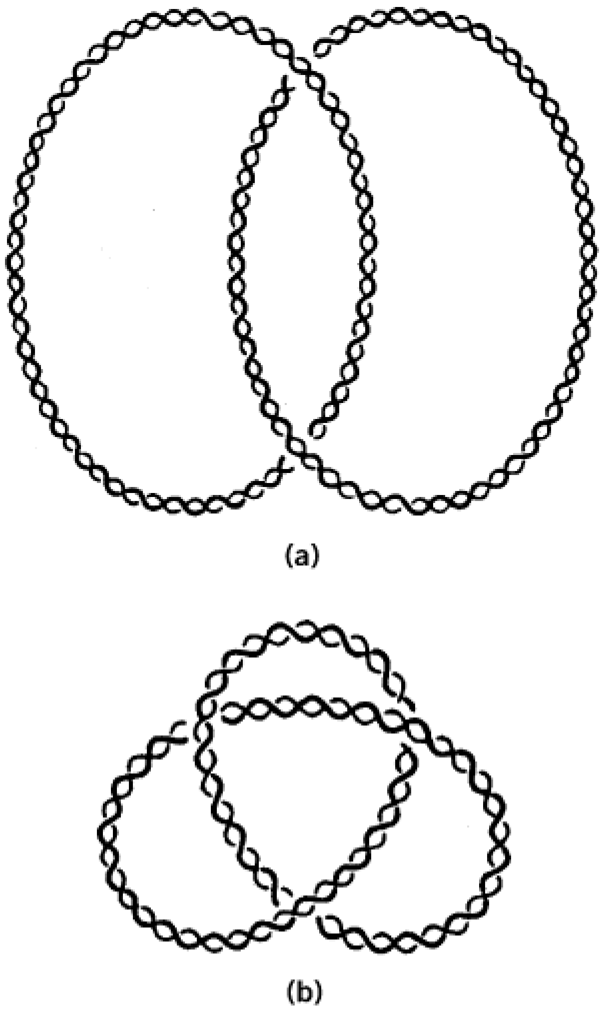
Figure 1. Depiction of the two kinds of elementary topological domains. (**a**) The structure of a closed duplex DNA (cdDNA), shown here as a relaxed duplex (rdDNA). Both strands in this DNA are covalently continuous, and the linking number is an integer. There are eight nodes in the projection shown here, and $Lk = +4$. (**b**) The structure of a DNA loop. The topological domain is maintained by tight binding to a dimeric protein. In the example shown, $Lk \approx 6$. The exact value of Lk depends on the precise location at which the two strands are fixed together by the protein sealant, and Lk can consequently be a fractional number. (Reproduced with permission from Ref. 1; copyright 1986, Macmillan Publishing Co.)



Protein-sealed DNA loops can occur locally in parts of DNA molecules that are not necessarily closed circular. Examples of these are the genome of *Escherichia coli*, which is organized into separate topological domains by bound proteins (3, 4), the **lambda repressor** (5, 6), several prokaryotic transcription regulation systems (7), site-specific recombination and transposition (8), and the binding of the *Sfi*I restriction enzyme (9). It should be noted that protein-sealed DNA loops, in contrast to cdDNAs, are held together by noncovalent bonds. The integrity of this type of topological domain is therefore relatively less certain. Systematic determinations of the stability of DNA loops as a function of linking number have not yet been reported.

DNA can also be organized into higher order (nonelementary) topological domains, in which the duplex DNA axes of one or more circular DNAs are themselves linked. Knotted DNA, one of the possible outcomes of site-specific recombination, represents a class in which the duplex axis of a single DNA forms a knot. Catenated DNA, in which the axes of two or more DNA submolecules are linked, contains one or more higher order topological domains. The submolecules themselves may or may not contain individual elementary topological domains. Schematic depictions of DNA knots and catenanes for some simple cases are shown in Figure 2 (10).

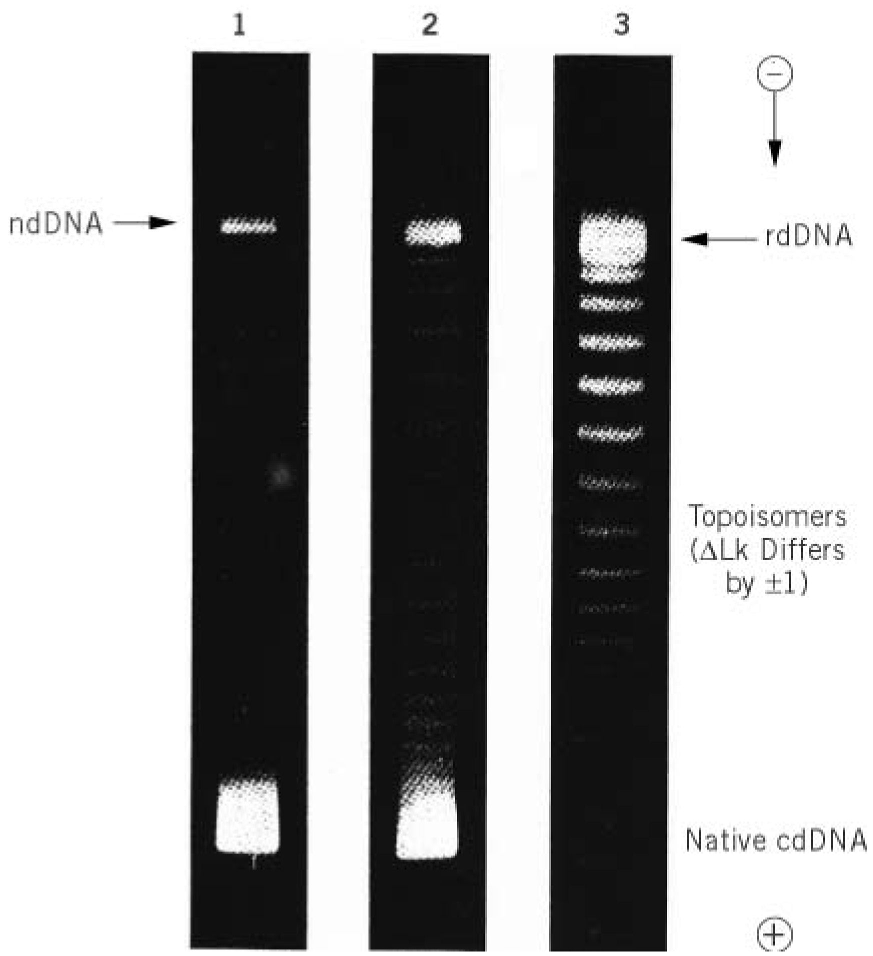
Figure 2. Two kinds of higher order topological domains. (**a**) Two closed circular, but not supercoiled, DNAs are linked once to form a catenane. Here the higher order linking number (called the *catenation* number in this case) is 1, since the axes of the two DNAs are linked once. (**b**) The axis of a single DNA molecule is knotted into a trefoil. (Reproduced with permission from Ref. 10; copyright 1986, Academic Press.)



The formation of an elementary topological domain has a major influence on many DNA properties and, in addition, creates some properties that are entirely new. The properties modified may be roughly divided into two classes: structure (see Supercoiling of DNA) and energetics (see Superhelical DNA Energetics). The principal features of DNA structure affected are the duplex **twist** and the disposition in space of the DNA axis. Neat closed circular DNAs tend to form fairly regular, often branched superhelices in solution. A topological domain has a specific free energy, called either the *topological domain free energy* or the *free energy of superhelix formation*. This quantity generally increases with the extent of supercoiling of either chirality. The equilibria of all binding reactions that involve changes in either the DNA twist or in the writhe are shifted by the inclusion of this free-energy term. Examples are the binding of intercalative drugs, such as ethidium bromide, and of proteins, such as **RNA polymerase**.

The new property created by the formation of a closed circular DNA is the linking number, *Lk*, which is a measure of how many times the two duplex strands are interwound. It is constant for a given topological domain and can be changed only by one or more chain scissions. This makes possible the formation of DNA topoisomers , which are closed circular DNAs that differ only in *Lk*. Topoisomers can be reversibly interconverted with enzymes known as **topoisomerases**. The properties of individual topoisomers depend strongly on the magnitude of the associated linking number. Topoisomers can, under appropriate conditions, be physically separated by means of gel electrophoresis. Figure 3 (11) shows such a fractionation for a representative closed circular DNA.

Figure 3. An example of the separation of DNA topoisomers by electrophoresis in an agarose gel. The three strips show the stepwise relaxation of closed circular SV40 DNA at 0° by incubation with a topoisomerase. Lane 1 shows the original mixture of superhelical (fastest band, labeled “Native cdDNA”) and nicked circular (slowest band, labeled “ndDNA”) species. Lanes 2 and 3 show the formation of topoisomers following 5 min and 30 min of incubation. The lowest energy product DNA is labeled “rdDNA,” and the starting superhelical DNA had D*Lk* = –23. The individual bands contain topoisomers that differ by unity in linking number. (Because of limited gel resolution at higher D*Lk*, not all of the higher topoisomers can be seen in this gel.) (Reproduced with permission from Ref. 11; copyright 1975, National Academy of Sciences.)



Finally, the two DNA backbone strands whose interwinding defines a topological domain contain no chemical bonds in common (except for a possible indirect connection *via* a protein sealant).

Nonetheless, the two strands can be separated only by the breakage of a covalent bond. This type of connection is sometimes termed a *topological bond*.

DNA-Binding Proteins

DNA binding proteins serve two principal functions: to organize and compact the chromosomal DNA and to regulate and effect the processes of transcription, DNA replication, and DNA recombination. The organization of chromosomal DNA is accomplished by abundant proteins which can bind to many sites and lack sequence specificity. In *Enterobacteria* this function is performed by FIS, H-NS, and HU proteins and in eukaryotic nuclei by the histone octamer and the linker histones, H1 and H5. By contrast, regulation of the enzymatic processes that manipulate DNA requires precise targeting to particular DNA sequences. This involves the specific recognition of the base sequence by a protein or proteins. Such proteins act genetically as repressors or activators either by themselves or in combination with corepressors or coactivators.

DNA binding is specified by a large number of disparate protein motifs. Within any particular class of motif the degree of sequence selectivity is highly variable, eg, among proteins with the helix-turn-helix-motif the *lac* repressor shows a high degree of sequence specificity whereas the FIS protein possesses little. The most commonly encountered types of motif are listed in Table 1.

Table 1. Commonly Encountered Types of Motif

Motif	Target	Sequence Specificity	Examples
Histone fold	Backbone	None	Core histones, TAFs
Helix-turn-helix	Major groove	Highly variable	FIS, C_I repressor, CAP
Homeodomain			
POU domain			
Winged helix			HNF3, histone H5
ETS domain			
Zinc-containing motifs			
Zinc finger	Major groove	Generally high	TFIIIA, Tramtrack
Receptor DBD	Major groove		Glucocorticoid receptor
Gal4 DBD	Major groove		GAL4
GATA	Major+minor grooves		GATA-1
bZip	Major groove	High	GCN4, Fos-Jun
Helix-loop-helix	Major groove	High	Myc, Achaete
HMG domain	Minor groove	Variable, but low	HMG1, SRY, TCF-1, UBF
HU class	Minor groove	Variable, but low	HU, IHF, TF1
TBP domain	Minor groove	High	TBP
GRP motif	Minor groove	Low, preference	Hin recombinase, HMG14/17

Frequently more than one type of binding motif is found in a particular protein. In both the l C_I repressor and the Hin recombinase DNA binding by a helix-turn-helix motif is stabilized by additional interactions mediated by an extended strand tracking along the minor groove. Similarly binding in other proteins may be stabilized by contacts between extended peptide loops and the sugar-phosphate backbone. Bivalence, or the ability to bind to two distinct double-helical surfaces, is a characteristic of some proteins, notably the globular domain of histone H5, which can bind two adjacent duplexes, and the l Int protein, which can define a DNA loop.

DNA-Dependent DNA Polymerases

DNA-dependent DNA polymerases synthesize deoxyribonucleic acid (**DNA**), a role that is central to accurately transmitting **genetic** material from generation to generation. This family of polymerases functions in a **template**-dependent manner to insert incoming nucleotides that are encoded by the template onto a growing primer. Polymerases are highly proficient at inserting nucleotides with proper **Watson–Crick base pairing**. DNA-dependent DNA polymerase exhibits unique roles during DNA replication and DNA repair. This article focuses on the characteristics of **prokaryotic** and **eukaryotic** DNA polymerases and the roles of each.

1. Primary Sequence, Structure, and Evolution

Sequence analysis studies (1) have divided the DNA-dependent DNA polymerase family into three subfamilies: (1) pol I type (which includes **Taq polymerase** and those from **bacteriophage** T5 and T7); (2) pol a type (which includes phage T4 polymerase and those from **vaccinia**, adenovirus, and herpes viruses); and (3) pol b type (which includes **terminal deoxynucleotidyl transferase**).

The presence of **homologous** regions in these diverse polymerases suggests that these enzymes evolved from a common ancestor (See Polymerases for a table of common motifs). All three subfamilies share two common motifs (A and C), whereas only pol I and pol a types also share a third (B). The **X-ray crystallographic** structure of the Klenow fragment of pol I suggests that motif A is involved in binding the divalent metal cofactor and deoxynucleoside triphosphates (dNTP), motif B is involved in binding the template and bases of the incoming dNTP, and motif C is involved in binding the metal cofactor. The structure of pol b shows DNA bound in an orientation 180° opposite to that observed in the complexes of DNA with **HIV**-1 **reverse transcriptase** and with the Klenow fragment (2). Thus, it is thought the pol b and terminal deoxynucleotidyl transferase are evolutionarily distinct from the other DNA-dependent DNA polymerases (3).

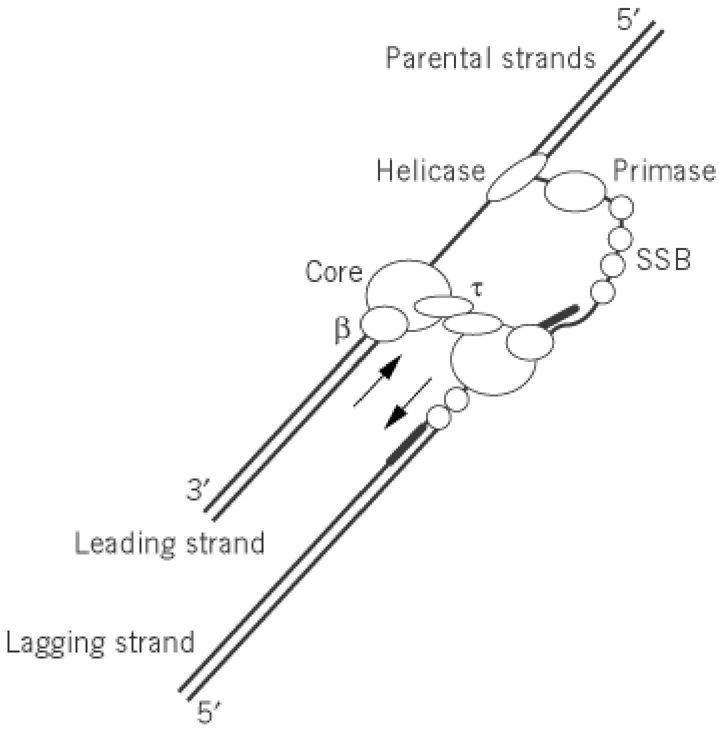
2. Prokaryotic DNA Polymerases

Escherichia coli contains three polymerases, designated DNA pol I, II, and III.

2.1. Pol III

The **holoenzyme** of DNA pol III (Fig. 1) is composed of 10 polypeptide subunits and is present in approximately 15 copies per bacterial cell. It is the principle polymerase responsible for replicating the genome. Pol III is purified either intact or as a core enzyme separate from its accessory factors. The Pol III core consists of the polymerase subunit *a* (140 kDa; expressed from the *DnaE* gene; Ref. 4), a proofreading subunit ε (28 kDa; from *dnaQ* or *mut D* gene; Ref. 5), and subunit q (10 kDa; *holE*). The processivity (i.e., the number of nucleotides synthesized per binding event) of the core enzyme is about 10 (6). This processivity is enhanced to several thousand nucleotides by the addition of subunit b (40 kDa), which functions as a dimer resembling a hexagonal **sliding clamp** (7). The q subunit (71 kDa) dimerizes readily, which, it is thought, facilitates the interaction of two polymerase core molecules. Evidence suggests that two polymerase core molecules act in concert but in opposite directions to synthesize the leading and lagging strands simultaneously (Fig. 1). The final component of the pol III holoenzyme is the g complex, which is composed of two subunits each of d, d′, g, c, and j. The g complex is a DNA-dependent ATPase that functions as a **clamp loader** (8). The hydrolysis of ATP facilitates loading of subunit b onto double-stranded DNA.

Figure 1. Model of the pol III replication complex during leading and lagging strand synthesis. Dimerization of the t domain facilitates the interaction of two core pol III molecules. This dimerization potentially allows concerted synthesis of both leading and lagging strands by one large polymerase complex. Other proteins that assist during repication in *E. coli* include DNA B helicase, primase, and single-stranded binding protein (SSB). Arrows show the 5′-3′ direction of polymerization.



2.2. Pol I

DNA polymerase I (pol I; expressed from the *polA* gene), is a single polypeptide chain that encodes at least three separate catalytic activities. It is present at approximately 400 copies per cell, functions during DNA repair in *E. coli*, and also exhibits a minor role in DNA replication. The three catalytic activities of pol I are: (1) 5′-3′ polymerization, (2) 3′-5′ exonuclease (proofreading); and (3) 5′-3′ exonuclease (involved in **nick translation**). Mild proteolysis of pol I yields an amino-terminal 5′-3′ exonuclease domain and the COOH-terminal Klenow fragment, which contains polymerization and 3′-5′ proofreading activities (9). For details on pol I functions see DNA Polymerase I and Klenow Fragment.

2.3. Pol II

DNA polymerase II (a product of the *polB* gene) contains a 3-5′ exonuclease activity, but lacks a 5′-3′ exonuclease. The amount of Pol II activity is comparable to that of pol III in crude extracts from *PolA- E. coli*, and its nucleotide sequence resembles pol a-type polymerases. However, the precise roles of pol II in DNA metabolism remain to be established. Mutational studies with *E. coli* show that the *pol B* gene is not required for growth or for repair after UV damage.

3. Eukaryotic Polymerases

The six known polymerases in eukaryotes are pol a, b, g, d, ε, and z (see Table 1). Much of our understanding of the proteins and their roles in eukaryotic replication fork has stemmed from studying the SV40 virus replication system *in vitro* (10).

Table 1. Eukaryotic Polymerases

	a	b	g	d	ε	z

Mass of core (kDa)	165	39	140	124	255	173
Mass of other subunits (kDa)	70,58,49			51	55	29

Processivity (nt)	10	5	100	10	1000	?
Core subunit cloned	Yes	Yes	Yes	Yes	Yes	No

3.1. DNA Polymerase a

This polymerase is composed of four subunits: (1) a 165- to 180-kDa phosphorylated **glycoprotein** that exhibits polymerase activity (its gene is located on human chromosome Xp21.3-p22.1.); (2) a 70-kDa phosphoprotein with unknown function; and (3 and 4) 49- and 58-kDa subunits that have primase activity (11). An early study in which monoclonal antibody against human DNA polymerase a was **microinjected** into mammalian cells showed that DNA replication is inhibited (12). Subsequent studies showed that this inhibition results from decreased extension of Okazaki Fragments. It was originally thought the primary function of pol a is to synthesize the lagging strand, but pol a's lack of an exonuclease domain and its poor processivity (about 10 nucleotides) cast some doubts. More recent studies of the SV40 replication system suggest that pol a functions to synthesize the RNA primer for both the leading and the lagging strands *via* its primase subdomain and to extend the RNA primer by several nucleotides on both strands via its polymerase domain (13). The majority of leading and lagging strand synthesis can potentially be carried out by polymerases d and ϵ. Mutational analysis in **yeast** of active polymerase a, d, and ϵ subunits show that each is essential for growth.

3.2. Polymerase b

This is a 39- to 45-kDa monomeric protein in vertebrates that is constitutively expressed (its gene is located on human chromosome 8p11-12) and considered the principle enzyme involved in filling in small DNA gaps resulting from excising damaged bases (14). Although expressed as a single polypeptide chain, pol b contains an N-terminal 8-kDa domain, which has apurinic lyase activity responsible for cleaving the 5′ phosphate-ribose residue during base excision repair, and a 31-kDa C-terminal domain that contains the polymerase active site. Pol b misincorporates noncomplementary nucleotides at a relatively high frequency, one per 5000 nucleotides polymerized (15) and lacks a 3′-5′ exonuclease (proofreading) activity. Thus, DNA repair by pol b may be highly error-prone. Pol b repairs gaps of six nucleotides or less highly processively but exhibits distributive synthesis in longer gaps. Of the three types of DNA repair, base excision repair (which leaves gaps of either one nucleotide or up to 10 nucleotides *via* unique mechanisms), nucleotide excision repair (which leaves gaps of about 30 nucleotides), and mismatch repair (which leaves gaps of hundreds of nucleotides), it is thought that pol b is involved primarily during base excision repair. A **knockout strain** of the pol b gene is embryonically lethal in mice, indicating that pol b is essential for normal development

(16). However, the pol b-like gene of ***Saccharomyces cerevisiae*** (*Pol4*) may be disrupted without affecting yeast viability and only marginally affecting sensitivity to methylmethanesulfonate, a DNA alkylating agent (see Mutagenesis). Apparently, either pol d or ε can substitute for pol b during base excision repair in *S. cerevisiae* (17). It has also been shown that the pol b localizes to synaptic foci during the **prophase** of **meiosis** I, suggesting that pol b activity is required to fill gaps during meiotic recombination in cells (18).

3.3. Polymerase g

This is a monomeric, 140-kDa enzyme that contains both polymerase and 3′-5′, exonuclease activities. Although encoded in the nucleus, pol g is primarily responsible for replicating and repairing the **mitochondrial** genome. The gene that encodes human pol g (located on chromosome 15q24) has just recently been cloned. The amino acid sequence of human pol g is 40 to 50% identical to pol g from yeast and Drosophila, pol g is also highly homologous to *E. coli* DNA pol I (19).

3.4. Polymerase d

This polymerase consists of a large catalytic polypeptide chain of 124 kDa from a gene located on chromosome 19q13.3q13.4, and a small polypeptide chain of 51 kDa from a gene located on chromosome 7. Mammalian pol d was first discovered in and purified from rabbit bone marrow, the catalytic subunit of human DNA pol d has been cloned and expressed in **Baculovirus**-infected cells (20). It is one of two nuclear mammalian DNA polymerases that has 3′-5′ exonuclease (proofreading) activity (21). The processivity of pol d is approximately 10 nucleotides, but this increases to well over 1000 nucleotides after the enzyme associates with a homotrimer of 36-kDa subunits of proliferating cellular nuclear antigen (PCNA), which forms a **sliding clamp** (22). In the SV40 replication system, pol d conducts most of both leading and lagging strand synthesis, complete replication in this system requires PCNA. Other proteins required for efficient pol d function include replication factor C (a phosphatase that loads PCNA onto the Pol d-DNA complex via an ATP-dependent reaction) and replication protein A (a **single-stranded binding protein** involved in reducing secondary structures of the template strand). Because of its high processivity, the Pol d–PCNA complex may also have important roles in filling DNA gaps during mismatch repair, nucleotide excision repair, and long-patch base excision repair (17).

3.5. Polymerase ε

This polymerase has a large catalytic subunit of 170 kDa, whose gene is located on chromosome 12q24.3. It shares many properties with pol d, including the presence of 3′-5′ exonuclease activity and very high processivity. Like pol d, pol ε was also first discovered in rabbit bone marrow. Human pol ε has been purified from HeLa cells and from placenta. The precise size of pol ε remains controversial, as its various subunits continue to be identified. Interestingly, with multisubunit DNA polymerases like pol d and pol ε the large subunit is invariably responsible for DNA polymerization. Unlike pol d, pol ε is thought to be highly processive and synthesizes approximately 1000 nucleotides per binding event even when not associated with PCNA. Pol ε interacts with PCNA at physiological ionic concentrations, thus further augmenting the enzyme's processivity and activity. The *in vivo* roles of pol d and ε have not been adequately distinguished, but it is thought that both have roles in leading and lagging strand synthesis and in mismatch, nucleotide excision, and long-patch base excision repair.

3.6. Polymerase z

This sixth DNA polymerase has been described in *S. cerevisiae*. Pol z is composed of two subunits of 173 kDa (product of the yeast REV3 gene) and 29 kDa (REV7 gene). The Rev3–Rev7 complex incorporates nucleotides across damaged DNA templates (23). DNA lesions including **thymine dimers**, abasic sites, and DNA adducts are potent at arresting DNA synthesis. The translesion bypass function ascribed to pol z could be important when efficient and rapid DNA synthesis across damaged DNA is needed during replication.

DNA:Protein Binding Specificity

DNA-binding proteins that bind to DNA in a sequence-specific manner have evolved to deal with a problem not normally encountered by enzymes, namely that the substrate, a specific segment of DNA, is immersed in a sea of other DNA sequences on the same molecule that are chemically and structurally very similar to the specific substrate. This is a problem that is fundamentally different from the problem of the discrimination of various small molecular substrates by enzymes, which can be based at least in part on the size and shape of the substrates. More than 20 years ago, it was pointed out that the nonspecific DNA-binding sites might be poor substrates when compared to the specific site, but they nevertheless significantly reduce the concentration of the free protein, simply because they are present in huge molar excess (1, 2). All known site-specific DNA-binding proteins also have a finite affinity for the nonspecific sites (3, 4). In this context, nonspecific DNA-binding is defined as binding that is equiprobable at any particular point along the DNA. In practice, specific and nonspecific binding constants are often determined by measuring the apparent dissociation constants of the complex of a protein with DNA containing either a specific DNA site (S) or a sequence that is completely heterologous (NS):

$$\begin{aligned} \mathrm{P} + \mathrm{S} &\rightarrow \mathrm{PS}\, K_{\mathrm{D}}(\mathrm{S}) = [\mathrm{P}][\mathrm{S}]/[\mathrm{PS}] \\ \mathrm{P} + \mathrm{NS} &\rightarrow \mathrm{PNS}\, K_{\mathrm{D}}(\mathrm{NS}) = [\mathrm{P}][\mathrm{NS}]/[\mathrm{PNS}] \end{aligned} \tag{1}$$

Table 1 compares the **dissociation constants** for specific and nonspecific binding for a number of different types of DNA-binding proteins. When referring to Table 1, it must be kept in mind that the apparent dissociation constants depend significantly on the conditions of the measurement, such as the temperature (5-15), pH (15-20), and concentration and type of cations and anions (13, 14, 16, 20, 22). A second complication stems from the fact that the stability of the specific complex is in some cases dependent on the DNA sequences flanking the specific binding site. A 17-fold difference in the dissociation constants is seen for the complexes of the restriction enzyme EcoRV and DNA sequences containing a cognate binding site with different flanking sequences (20). In addition, the apparent dissociation constants of the protein complexes with nonspecific DNA depend on the length of the DNA probe. All values for K_D(NS) in Table 1 were corrected for the length of the DNA probe by dividing the measured K_D(NS) by the twofold difference between the length of the probe and the length of the DNA-binding site of the specific complex.

Table 1. Specificities of Prokaryotic and Eukaryotic DNA-Binding Proteins

Protein	Specific Site	K_D(S) (M)	K_D(NS) (M)	K_D (NS)/K_D (S)	- DD*G* (kcal/mol)	Reference
Repressors						
lac	O^{sym}	8.3×10^{-12}	2.4×10^{-4}	2.9×10^{7}	10.1	27

MyoD/E12	CAGGTG	7.5×10^{-9}	7.9×10^{-8}	1.1×10^{1}	1.4	37

Table 1 shows that the dissociation constants of the specific complexes span a range of approximately six orders of magnitude. The tightest complexes have K_D(S) values that lie in the picomolar concentration range. Interestingly, the specific DNA complexes of bacterial proteins are generally more stable than the complexes of eukaryotic DNA-binding proteins, most probably due to the longer DNA-binding sites in the prokaryotic complexes.

The dissociation constants of the nonspecific complexes listed in Table 1, on the other hand, span only approximately four orders of magnitude. For the nonspecific complexes, the eukaryotic proteins bind to DNA more tightly than the prokaryotic ones. Therefore, the DNA-binding specificity (defined as K_D(NS)/K_D(S)) of prokaryotic DNA-binding proteins is, in most cases, significantly greater than that of eukaryotic transcription factors.

It is interesting to consider these observations in the context of the size of both the bacterial and the mammalian genomes. The *E. coli* genome consists of 4×10^6 bp. Of the proteins listed in Table 1, the restriction enzyme EcoRI displays the highest DNA-binding specificity (K_D(NS)/K_D(S) = 4.7×10^7) (23). The specific DNA-binding site of EcoRI has the sequence GAATTC. Such a hexamer sequence would occur statistically approximately 1000 times in the *E. coli* genome. As a consequence, approximately 1.1×10^4 times more protein is bound to the specific DNA site than to the nonspecific sites:

$$[\mathrm{PS}]/[\mathrm{PNS}] = K_D(\mathrm{NS}) \cdot [\mathrm{S}]/K_D(\mathrm{S}) \cdot [\mathrm{NS}] \qquad (2)$$

On the other hand, to bind 50% of the time to a unique binding site of the mammalian chromosome would require that the specificity of a transcription factor be > 3×10^9 (the size of the mammalian chromosome). Statistically, a minimal length of 16 bp is required to ensure that a given binding site is unique on the mammalian chromosome. Most transcription factors bind, however, to DNA sites that are too short to be unique on the mammalian chromosome. Proteins containing the basic **helix–loop–helix motif** (BHLH), for example, bind to the sequence CAGGTG, which occurs approximately 7×10^5 times on a mammalian chromosome. The expression of MyoD, which recognizes DNA through a BHLH domain, can activate myogenesis in a wide variety of cell types including myoblasts and fibroblasts (24, 25), while the BHLH-protein MASH-1 promotes the differentiation of committed neuronal precursor cells (26). BHLH proteins need to bind to DNA with a specificity of approximately 4×10^3 in order to bind with equal probability to a nonspecific site and to one of the approximately 700,000 specific sites on the mammalian chromosome. But even then, MASH-1 would still activate transcription from MyoD target promoters and vice versa. Such arguments may be part of the explanation why transcriptional regulation in higher organisms relies on multiprotein complexes with the potential for combinatorial interactions.

DNA:Protein Interaction Thermodynamics

1. Specific Interactions

The precise recognition of a defined DNA sequence by a DNA-binding protein requires an optimal shape complementarity between the interacting species. As a result, a large number of noncovalent interactions form at the interface between the DNA and the protein. Individual interactions often contribute only a small amount to the overall stability of the complex. Nevertheless, all of these interactions are important for the preferred binding of the protein to the specific DNA site (or the discrimination of the nonspecific site).

Early concepts about the determination of specificity in DNA protein complexes relied on "direct-readout," which is based on the interaction between the functional groups of the proteins and the DNA bases (1, 2). Structural studies of DNA–protein complexes showed that specific interactions are mediated by hydrogen bonds, electrostatic interactions between charged groups, **and** van der Waals interactions. Constrained hydrogen bonding interactions can be made between the polypeptide backbone or short side chains and the nucleobases. Longer side chains make more flexible contacts with the DNA. They are, however, often orientated in space by other amino acid side chains or by making two contacts to the same base, to adjacent bases, or to a base and a phosphodiester group. In these cases, the **enthalpic** gain of the interaction is often reduced by a negative **entropic** contribution stemming from the reduction of conformational flexibility of the amino acid side chain. The X-ray crystallography structures of the DNA complex of the basic **helix–loop–helix** (BHLH) proteins MyoD (3) and E47 (4) provide examples of bidentate and bridging interactions. Arg(111) of MyoD, which contacts both N(7) of guanine and an oxygen of the adjacent phosphodiester, provides an example of a bridging interaction (Fig. 1). A hydrogen bond between N(e) of Arg(111) and the hydroxyl group of a threonine residue further restricts the mobility of Arg(111). Arg(111) also forms a bidentate interaction with guanine through hydrogen bonds with N7 and O4, the latter being mediated by a water molecule. Another example is provided by the carboxyl group of a Glu(47), which makes hydrogen bonds to N7 of an adenine and to N4 of the adjacent thymine, thereby specifying the first two bases of the Glu(47) binding site (Fig. 2). A neighboring arginine residue orientates the glutamate in space through the formation of a “clamp” between the phosphate backbone and the peptide. An important consequence of the formation of such hydrogen bonding networks that severely restrict the conformational flexibility is that the specificity is achieved, at least in part, through selection of the smallest number of destabilizing interactions (5). The restriction enzymes EcoRI, EcoRV, and BamHI rely for specificity to a large extent on discrimination against noncognate sites (Ref. 6 and references therein).

Figure 1. Diagram showing the structure of the BHLH domain of MyoD from amino acid Asp(109) to Thr(115) and the key contacts of Arg(111) with guanine and the adjacent phosphodiester of the E-box sequence CANNTG (60). Note that the contact of Arg(111) to O6 of guanine is mediated by a water molecule and the stabilization of the arginine side chain through an hydrogen bond with the hydroxyl group of Thr(115). This display was created from the coordinates of the DNA complex of MyoD (3).

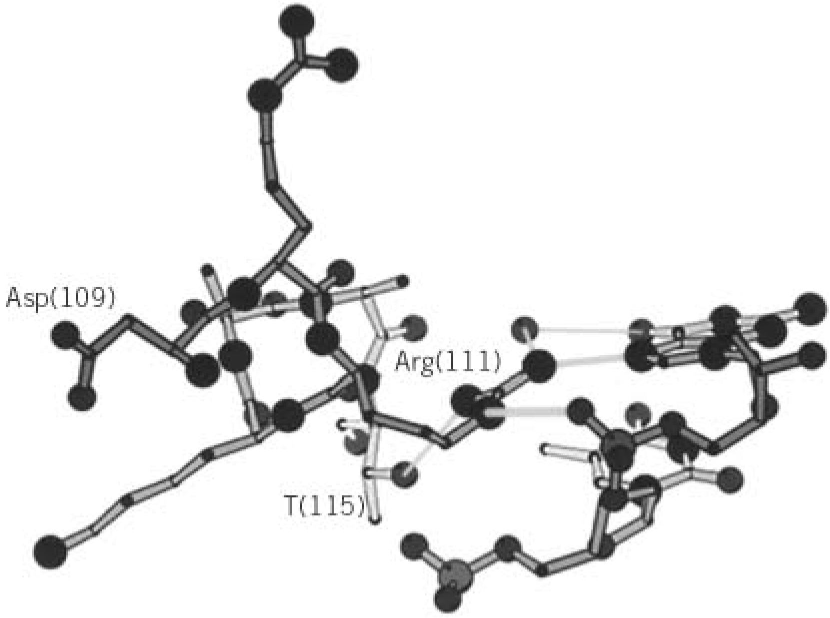

Figure 2. Networked hydrogen-bonding interactions between glutamate(345) and arginine(348) of E47 and the CpA dinucleotide of the E-box DNA sequence (5). E(345) is hydrogen-bonded to N4 of cytosine and to N6 of adenine. Note the “clamp” function of R(348) which connects the phosphate backbone to E(345), thereby locking the conformation of the side chain of E(345). The b and g-CH_2 groups of E(345) make van der Waals contacts to the methyl group of thymine. The program MacMoMo (183) was used to create this display from the coordinates of the DNA complex of E47 (4).

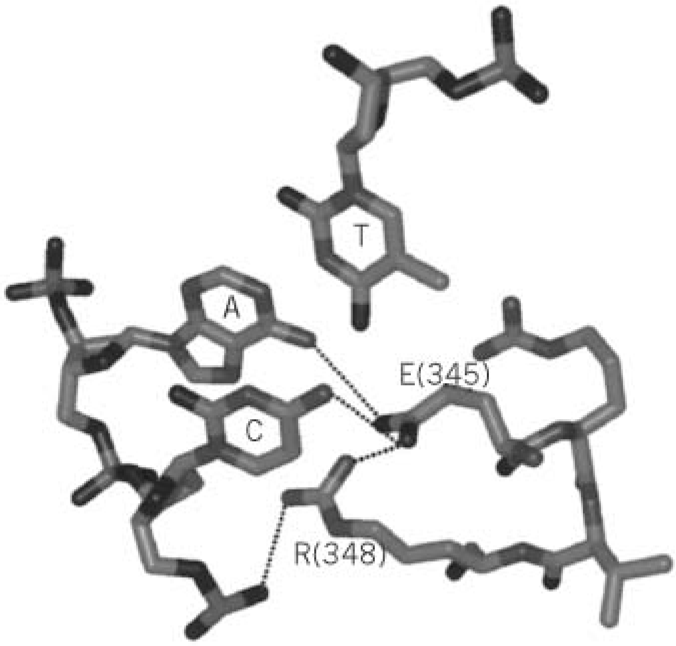


To the best of our knowledge, there is no site-specific DNA-binding protein for which a complete thermodynamic description of the association reaction with DNA is available, and only relatively few data are available for eukaryotic proteins. However, thermodynamic studies with the prokaryotic **Lac**, Mnt, trp, l **Cro**, Arc, and l cI repressors (7-16), the restriction endonucleases EcoRI (17-22), EcoRV (6, 23), BamHI (6), and RsrI (20), the cyclic AMP receptor protein (CRP)/catabolite activating protein (CAP) (24), the DNA-binding domain of glucocorticoid receptor (25), and the consequences of altered interactions between amino acid side chains and bases have been addressed through **site-directed mutation** of either the protein or the DNA. The results from these experiments are difficult to interpret, because of a multitude of subtle energetic changes resulting from the altered bond, perturbation of the local structure of the DNA and/or the protein, and changes in solvation. Nevertheless, a study by the group of Jen-Jacobsen of the interaction of EcoRI with a series of base-analogues in the absence of Mg^{2+} indicated that each hydrogen bond between the protein and the DNA stabilizes the complex by approximately 1.4 kcal/mol (19, 21). For the DNA complex of Trp repressor, the replacement of N7 of individual purines with carbon led to an increase in the **free energy** of binding of approximately 1 kcal/mol when the particular nitrogen atom formed a hydrogen bond to the repressor in the wild-type complex (26). Several other studies confirmed a value of 1 to 1.5 kcal/mol of stabilization for every hydrogen bond formed (23, 27). On the other hand, replacing an adenine, the N6 of which forms a hydrogen bond with a glutamate of the basic helix–loop–helix (BHLH) protein E12 (Fig. 2), with a purine led to a reduction of only approximately 0.8 kcal/mol of the stability of the E12 DNA complex in electrophoretic **mobility shift assay** experiments (5).

Van der Waals interactions between the protein and the methyl group of thymine that projects into the major groove in B-DNA provide another possibility for the formation of specific interactions. A careful thermodynamic study of the interaction between the methyl group of thymine –5 of the O_R3 operator and a methylene group of Lys32 of the Cro repressor from phage l indicated that the van der Waals interaction stabilizes the complex by 1.6 kcal/mol (7). When this methyl group was removed by replacing thymine with uracil, the binding enthalpy was reduced, with no observable change in the binding entropy, as would be expected for such an interaction, especially because the conformation of Lys33 in Cro is stabilized by a bidentate interaction with N7 and O6 of guanine (–4) of O_R3. However, the creation of a cavity by the removal of the methyl group could potentially lead to the trapping of a water molecule. Such a case has been observed for the DNA complex of the DNA-binding domain of the glucocorticoid receptor, where a favorable enthalpic contribution compensated for the unfavorable entropic effect of approximately 1 kcal/mol when a methyl group was removed from a thymine (28) that did not make specific contacts to the protein (29). Other studies confirmed that van der Waals interactions between a protein and a thymine methyl group stabilize the complex by between 0.5 and 2 kcal/mol (7, 19, 23, 24, 27, 30-33).

DNA-binding proteins make extensive contacts to the phosphodiester groups of the DNA backbone through charged and uncharged side chains. It is not easy to estimate the contribution from these interactions to the overall stability of the complex. One approach is to determine the contribution of the polyelectrolyte effect from the dependence of the reaction free energy on the concentration of univalent salts and to add a contribution for the interactions between the DNA phosphates and uncharged amino acid residues. It is important to keep in mind that the polyelectrolyte effect is a consequence of the fact that DNA is a polyanion of high axial charge density (reviewed in Refs. 11, 34, and 35). The association reaction is therefore driven by the release of monovalent cations (at least at low salt concentrations) (36-38). The salt-dependence of binding to various specific and nonspecific DNA sequences is often different, indicating that protein-phosphate contacts are involved in determining the specificity of DNA binding (39-44).

Anions bind to proteins with relatively small binding constants (45), and their effects are most likely not of electrostatic nature (see Hofmeister Series and Salting In, Salting Out). Anions seem to affect the dissociation constants of DNA–protein complexes, especially at high anion concentrations (46, 47). The nature of the anion is important, and replacing chloride with glutamate can increase the sequence-specific DNA-binding affinity by as much as 80-fold (43). At 25°C in a low salt buffer, the leucine zipper protein GCN4 binds to an ATF/CREB site (ATGACGTCAT) and to an AP-1 site (ATGACTCAT) with the same affinity. In a buffer containing 250 mM potassium glutamate, however, the dissociation constant of the AP-1 complex was approximately one order of magnitude smaller than for the ATF/CREB complex (48).

In order to understand fully the DNA-binding specificities displayed by proteins, it is necessary to define the energetic differences between the interactions in specific and nonspecific complexes (see DNA:Protein Binding Specificity). Model studies of the DNA-binding reactions of oligopeptides suggest that the nonspecific complex is a loose association held together by Coulombic interactions between positively charged residues of the protein and the negatively charged phosphate backbone of the DNA (49, 50). In these studies, the number of DNA phosphates contacted, as well as the number of monovalent cations thermodynamically released on binding, was found to be approximately equal to the number of positively charged side chains in the peptides (49-56). Thermodynamic studies indicate that the number of phosphate contacts is often greater in the nonspecific complexes than in the specific ones (6, 11, 57).

Only two structures of nonspecific complexes are currently known, namely those involving the restriction endonuclease EcoRV (58, 59) and the DNA-binding domain of glucocorticoid receptor (29). Glucocorticoid receptor binds to DNA sequences containing inverted repeats separated by three base pairs. In the X-ray crystallography structure analysis of the DNA complex of glucocorticoid receptor, an oligonucleotide was used where the spacing had been increased to four base pairs. Therefore, while one protein subunit bound specifically to the one inverted repeat, the other faced a nonspecific binding site. Both subunits introduced an a-helix into the major groove of the oligonucleotide, which was opened up by approximately 2 Aring; on the specific side. This distortion is most likely achieved through the higher number of interactions in the specific complex. Comparison of the specific and the nonspecific complexes of EcoRV revealed that a loop that penetrates the major groove is partially disordered in the nonspecific case and not well-buried in the groove. The buried surface area (*vide infra*) is more than 1570 Aring;^{2} larger in the specific complex than in the nonspecific one (58).

An interesting case is provided by the BHLH protein MASH-1. The DNA-binding specificity of MASH-1 was found to be very low for all conditions studied (39, 60). While no three-dimensional structure for a "nonspecific" complex of MASH-1 or any other BHLH protein has been determined, the available data suggest that the specific and "nonspecific" complexes are very similar (5, 39, 60, 61), and it appears that BHLH proteins might have only one binding mode. This is most probably a consequence of the exposed recognition a-helix that adopts its helical conformation only on DNA binding (39, 60). In many other proteins that rely on an a-helix for DNA recognition, the conformation of the recognition helix is stabilized through interactions with other parts of the DNA-binding domain.

2. Water-Mediated Contacts

Specific interactions between a protein and DNA are often mediated by bound water molecules. General thermodynamic arguments show that the entropic cost of transferring a water molecule from bulk water to a specific site within a protein or at the interface between the protein and DNA is in the range of 0 to 7 cal $mol^{-1}K^{-1}$, corresponding to a free energy change of between 0 and 2 kcal mol^{-1} at ambient temperature (62). The free energy cost varies thereby with the polarity of the environment of the bound water.

An example of a specific contact that is mediated by a water molecule is shown in Figure 1. The interaction between N(h) of Arg(111) of MyoD and the O6 of guanine is mediated by a well-ordered water molecule (3). Other examples of specific interactions that are mediated by well-resolved water molecules have been found in the DNA complexes of cI repressor (63), Hin recombinase (64), the restriction endonuclease BamHI (65), the DNA-binding domains of estrogen receptor (66), papillomavirus-1 E2 (67), and the **antennapedia**(C39 S) homeodomain (68). The DNA complex of the transcription factor GATA-1 is devoid of water molecules that mediate contacts between the protein and the nucleobases, but several water molecules were found between the protein and the phosphate backbone (69).

The 1.9 Aring; resolution crystal structure of the complex between the Trp repressor and its operator revealed that water-mediated contacts are the principal means for site-specific recognition (70, 71). Of the 90 water molecules that are intrinsic to the chemistry of the complex, 26 are located within the protein–DNA interface (13 in each half-site). Three of these 13 mediate four contacts between the nucleobases and the protein. Interestingly, these three hydration sites are already fully occupied in the free DNA (72). The water molecules should therefore be considered as intrinsic parts of the DNA structure and as noncovalent extensions of the DNA molecule that can be used for the stereospecific recognition of the *trp* operator (see TRP Operon). Similarly, the water molecule that mediates the contact between the backbone NH of Asn(79) and the N7 of guanine is present in all of the refined crystal structures of the uncomplexed repressor, and the water between Asn(80) and the DNA is seen in most of the refined structures of the free protein (73). These water molecules can therefore be considered functional extensions of the protein surface.

While water molecules are clearly important for both affinity and specificity in many DNA complexes of transcription factors, it must be stressed that some DNA–protein interfaces are completely devoid of water. For example, the 3100 Aring;^{2} interface between TBP and TATA-box containing DNA sequences is characterized by a perfect complementarity and complete exclusion of water (74-77).

3. Dehydration Effects

Thermodynamic studies demonstrated that site-specific DNA-binding reactions are characterized by negative and relatively large changes in the **heat capacity**. As a consequence, the enthalpic (D *H*) and the entropic (*T*D *S*) contributions to the free energy change (D *G*) of the binding reactions vary with temperature in an almost parallel manner, making D*G* nearly independent of temperature. Again, there are much more data available for prokaryotic DNA-binding proteins. Only recently have good thermodynamic data for the interaction between eukaryotic transcription factors and DNA become available. The reactions studied include the association reactions between histones and DNA (78), **RNA polymerase** Es^{70} and the P_R **promoter** of lambda phage (79), Lac repressor and the *lac* O^+ operator (80), the mnt repressor and the mnt operator site O_{mnt} (81), the headpiece of Lac repressor and the *lac* operator (82), the restriction endonuclease EcoRI and its cognate binding site (82), Cro repressor and the O_R3 operator site (7), the DNA-binding domain of glucocorticoid repressor and a glucocorticoid response element (25, 28), Trp repressor and operator (8, 9), l cI repressor with various combinations of the three operator sites $O_R(1)$, $O_R(2)$, and $O_R(3)$ (10), the transcriptional activator **cyclic AMP response protein** (CRP) complexed with two molecules of cAMP and its consensus binding site (83, 84), the transcription factor GCN4 and both an ATF/CREB and an AP-1 binding site (48), and the DNA-binding domain of the basic **helix–loop–helix** (BHLH) protein MASH-1 and E-box containing and heterologous DNA sequences (39).

It is now generally accepted that large negative values of the heat capacity change, Dc_p, are the hallmark of biological reactions that form large highly complementary interfaces, irrespective of the overall stability of the complexes formed (9, 82). The areas buried in specific protein DNA complexes range from ~ 1000 to ~ 5500 *Aring*;[2] (29, 39, 48, 75, 84, 85), and the heat capacity changes are caused by the removal of large amounts of nonpolar surface area from water on complex formation, accompanied by release of water. Although the change in water-accessible nonpolar surface area makes the dominant contribution to $D\,c_p$, the changes in water accessibility of the polar surface areas (mainly due to the burial of the peptide backbone) also make a smaller contribution of opposite sign (86) (see Hydration).

Because the observed values of Dc_p for the DNA-binding reactions of some proteins are too large to be accounted for solely by the amount of buried surface area in a "rigid body" association, conformational changes of both the protein and the DNA appear to occur (see below) (84, 87, 88).

Binding of proteins to DNA in a nonspecific fashion involves almost no changes in heat capacity (7, 9, 48), indicating that the formation of nonspecific complexes does not involve major dehydration. An interesting exception is provided by the DNA-binding domain of the transcription factor MASH-1. The association reaction between MASH-1 and an E-box-containing oligonucleotide, the natural target of MASH-1, is characterized by a heat capacity change of –733(±99)cal mol^{-1} K^{-1}, while the formation of a complex with heterologous DNA results in a Dc_p of –575cal mol^{-1} K^{-1} (39). X-ray crystallography studies of the specific complexes of BHLH proteins showed that the DNA is contacted by an a-helix that fits snugly into the major groove (3, 4). Circular dichroism spectroscopy suggested that the protein conformation of MASH-1 was rather similar in the "specific" and the "nonspecific" complexes (39, 60). Unlike other DNA-binding proteins, all DNA complexes of MASH-1 appear to show the thermodynamic characteristics of specific complexes, irrespective of the particular DNA sequence.

The number of water molecules released on formation of a complex between a protein and DNA can be estimated by measuring the dissociation constant as a function of the osmotic strength altered through the addition of neutral salts (89-91). Such osmotic-stress methods have so far been applied to only a few DNA-binding reactions, namely the restriction endonucleases EcoRI (92, 93), EcoRV and PvuII (94), the gal repressor (95), Hin recombinase (96), the cyclic AMP receptor from *E. coli* (97), and the homeodomain containing the transcriptional activators **ultrabithorax** and deformed (98).

Formation of the complex between CRP and the C1 site in the *lac* promoter is accompanied by the release of 79 (±11) water molecules, while 56 (±10) water molecules are taken up when CRP is transferred from the C1 site to a nonspecific site (97). Depending on the neutral salt used, between 100 and 180 water molecules are released when gal repressor binds to the O_I operator site (95). An additional 6 (±3) waters are released when the repressor is transferred from O_I to O_E, to which it binds with enhanced affinity. Interestingly, despite the close sequence similarity in their homeodomains, water activity affects differentially the DNA binding of Ultrabithorax and Deformed (98). Between 22 and 27 water molecules were released for DNA binding by Ultrabithorax, while only 5 water molecules were released when Deformed bound to its optimal sequence. On the other hand, the DNA sequence did not exert a strong effect on the magnitude of the water release associated with DNA binding by Ultrabithorax.

The osmotic-stress methods yield a value for the number of water molecules released, which is the difference between the water molecules released and those taken up, for example as a consequence of the exposure of additional surface area due to unfolding.

4. Conformational Changes of the Protein on DNA Binding

Even though in some specific complexes the tightly packed interfaces between the protein and the DNA result from the docking of well-ordered, preexisting surfaces, in an increasing number of cases the conformations of both the protein and the DNA are found to change markedly in the complex. The DNA-binding reaction of the BHLH protein MASH-1, for instance, is characterized by a transition of the peptide from a largely unfolded to a mainly a-helical conformation (60). Even at concentrations well above the dimerization constant for the MASH-BHLH domain, where the HLH domain is stably folded, the basic region adopts an ordered conformation only upon binding DNA (39). A similar transition was observed with the DNA-binding domains of GCN4, Fos, and Jun, where the basic region undergoes a transition to an a-helical structure upon binding to DNA (99-101). In these cases, the association does not result from a simple alignment of rigid, complementary surfaces, but rather follows what is generally known as an "induced fit" mechanism (102).

Because of a reduction in water-accessible surface area, folding transitions that occur on DNA binding result in a negative heat capacity change Dc_p (see text above). Because experimental values for D c_p are often too large to be accounted for simply by the reduction in water-accessible surface area in a rigid body association, Spolar and Record (84) have suggested how to dissect the various contributions to the entropy change. Consider as an example the DNA-binding reaction of the BHLH domain of MASH-1. This reaction shows a strong temperature dependence for both the measured DH and TD S, which compensate to make DG almost insensitive to temperature. A notable consequence is the existence of a temperature T_S, for which TDS changes sign. Therefore, the following equation holds at T_S:

$$-\Delta S_{\text{other}} = \Delta S_{\text{HE}}(T_{\text{S}}) + \Delta S_{\text{RT}} + \Delta S_{\text{PE}}$$

The total change in entropy consists of a contribution DS_{HE} from the hydrophobic effect, the unfavorable entropic term D S_{RT}, due to the reduction in rotational and translational degrees of freedom on association, the contribution from the polyelectrolyte effect DS_{PE}, and DS_{other}, which results primarily from conformational changes in the protein and/or the DNA (84). DS_{HE} (T_S) can be calculated from measured thermodynamic data according to the equation

$$\Delta S_{\text{HE}}(T_{\text{S}}) = 1.35\Delta c_{\text{p}} \ln(T_{\text{s}}/386)$$

For MASH-1, T_S was determined as 271 K and a value of –357 cal mol^{-1} K^{-1} was calculated for DS_{HE} (T_S) (39). The polyelectrolyte effect could be estimated from the salt dependence as 50 cal mol^{-1} K^{-1} ((39); Meierhans, unpublished results), while DS_{RT} for a bimolecular reaction was taken to be –50 cal mol^{-1} K^{-1} (103, 104). The change in entropy resulting from local folding transitions coupled to DNA could therefore be calculated as 357 cal mol^{-1} K^{-1}. This was interpreted to indicate that approximately 54 amino acid residues of the basic region are involved in the folding reaction, or 27 residues per BHLH subunit; this interpretation is supported by CD studies of the DNA-binding reaction of MASH-BHLH and nuclear magnetic resonance (NMR) studies of the BHLH protein E47 (39, 105).

Comparison of the experimentally determined and the calculated Dc_p for the association reaction of the transcription factor GCN4 and DNA suggested that approximately 7 amino acid residues of the basic region of this basic-zipper protein underwent a transition from a random to an a-helical conformation (48). The high-resolution structures of uncomplexed Trp repressor and its specific DNA complex indicate that 16 residues of helix D are disordered in the free repressor and a-helical in the DNA complex (106-109) [it should be pointed out that this interpretation of the structural data has been challenged (35)]. The same value for the number of residues that change conformation upon DNA binding was obtained from thermodynamic data, where D S_{other} was determined as –94 cal mol^{-1} K^{-1} (8).

Structural data suggest that conformational changes also occur for the DNA-binding reaction of the DNA-binding domain of glucocorticoid receptor (110-113). These results are in good agreement with thermodynamic measurements and indicate a folding transition in approximately 18 residues per protein subunit (25). Another example of a conformational change is provided by the Antennapedia homeodomain. An *N*-terminal extension that is flexible in the free protein becomes ordered on DNA binding and contacts the minor groove of the DNA (114-116). Unfortunately, there are no thermodynamic data available for this system.

Thermodynamic studies suggest conformational changes for the DNA-binding reactions of the following proteins: the lac (117), Gal (118), and Mnt (84) repressors binding to their operator sequences, and **RNA polymerase** binding to the l P_R promoter.

For a number of DNA-binding proteins, complex formation is accompanied by changes in the **tertiary** or quaternary structure. For example, thermodynamic analysis of the DNA-binding reaction of the l Cro protein, under conditions where it exists as a stably folded dimer in solution, indicated a relatively small D S_{other} of 18 cal mol^{-1} K^{-1} (7). Information from the crystal structures of both free and complexed Cro suggests that this entropy change may reflect changes in quaternary structure of the Cro dimer on DNA binding (119, 120).

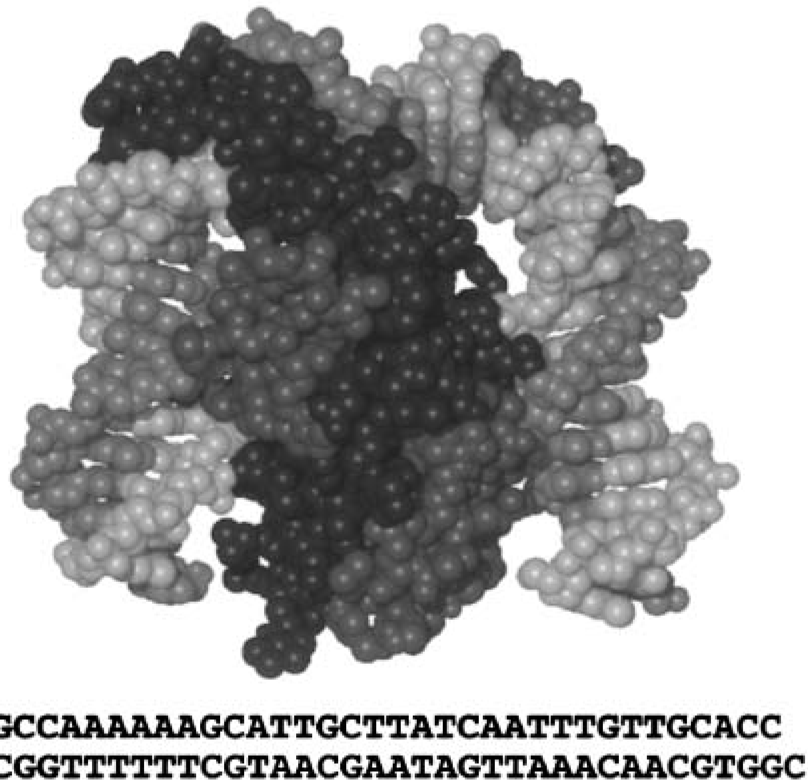
Other proteins for which structural evidence exists for coupled structural changes on binding to DNA include the endonuclease EcoRV and the transcriptional activator CRP. The DNA-binding pocket of EcoRV is not accessible in the free protein, and the cleft between the two protein subunits is too narrow to accommodate the DNA. Consequently, the pocket must be opened up through a combination of tertiary and quaternary structural transitions (58). For CRP, the relative orientations of the amino- and the carboxy-terminal domains change significantly on DNA binding. However, the structures of the DNA complexes of CRP and EcoRV revealed that optimal shape complementarity between these proteins and DNA is achieved not only through conformational adaptations of the protein, but also through changes in the structure of the DNA.

5. Conformational Changes of the DNA upon Protein Binding

While many proteins recognize regular B-DNA through the formation of a number of hydrogen bonds and van der Waals interactions between amino acid side chains and functional groups of the bases, it has long been recognized in many cases that DNA can adopt a bent conformation when bound to a protein (121). A dramatic example of protein-induced DNA bending is provided by the structure of integration host factor (IHF) bound to the H′-site of phage l, in which the 34-bp piece of

DNA is literally wrapped around the protein, creating a buried protein–DNA interface of 4600 $Å^2$ (Fig. 3) (122, 123). The DNA is bent by more than 160°, thereby almost completely reversing the direction of the DNA within a short distance.

Figure 3. Van der Waals representation of the IHF–DNA complex (122). The drawing illustrates both the massive DNA bend induced by the protein and the large contact surface of ~ 4600 $Å^2$ between protein and DNA. The DNA sequence is indicated.



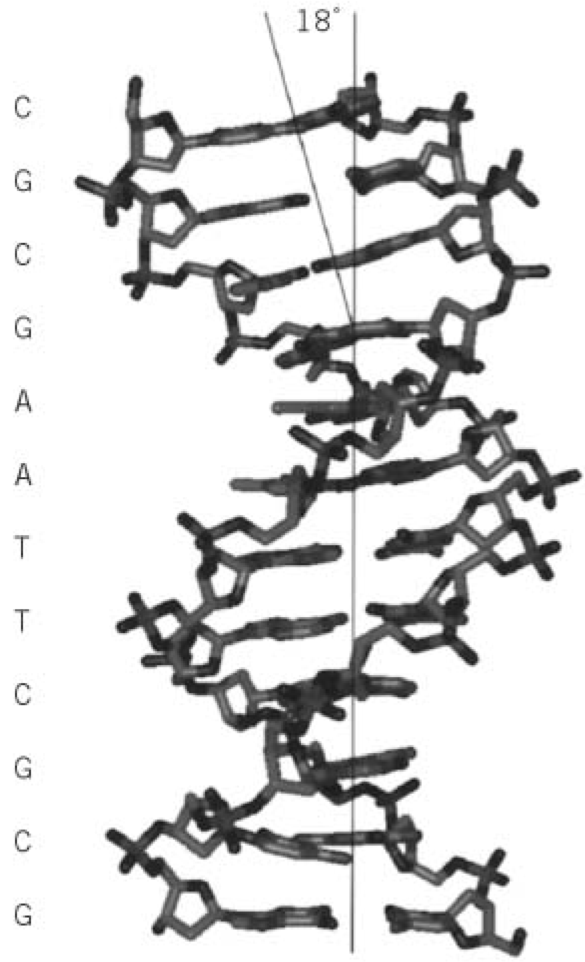
Other examples of strong protein-induced bends are provided by the structures of the DNA complexes of the purine repressor PurR (124), the sex-determining protein SRY (125), the pre-B- and T-lymphocyte-specific factor LEF-1 (126), and the human **oncogene** product ETS1 (127). In none of the above cases would it have been possible to predict the dramatic bends observed in the complexes from simple inspection of the DNA sequence.

Conversely, studies with 434 repressor indicated that its DNA-binding affinity was modulated by the flexibility of the noncontacted nucleobases at the center of the binding site (128, 129). A linear relationship was found between the free energy of the association reaction between 434 repressor and operator mutants and the flexibility of their central sequences (130). Similar results had been obtained for the Cro repressor from bacteriophage l (131). These studies indicated for the first time that intrinsic sequence-dependent properties are important for the formation of DNA–protein complexes.

Sequence-dependent bending of double-stranded DNA often occurs at the junctions between regions of G–C and A–T base pairs. DNA bending of 10° to 20° has been observed in the crystal structures of oligonucleotides containing an AT-core (132). While such sequences can be bent, however, they are not necessarily bent. The transition from G–C to A–T base pairs renders this region of the DNA flexible and capable of potentially undergoing a bend. Such facultative bending is illustrated by the

X-ray structure of the dodecamer d(CGCGAATTCGCG) (Fig. 4), in which a bend of 18° occurs at the GC/AT junction at one end of the helix, while the helix remains unbent at the chemically equivalent junction at the other end of the helix (133, 134). The molecular mechanism of such facultative bending has been reviewed in detail elsewhere (135).

Figure 4. Facultative bending into the major groove at one end of the dodecamer duplex $[d(CGCGAATTCGCG)]_2$ (134). Note the positive roll at the CpG and GpA steps and the negative propeller twisting in the central four base pairs. Overall and local helical axes are shown.



The recognition sequences of **serum response factor** (SRF) (136) (see MADS-Box Proteins), TATA-binding protein (TBP) (74-77), the restriction endonucleases EcoRI and EcoRV (58, 137), and EcoRI DNA methyltransferase (138) all have AT-rich core sequences, characterized by increased bendability. The crystal structure analyses of DNA complexes of these proteins revealed that they take advantage of the inherent bendability of their DNA targets. The DNAs adopt significantly bent conformations in all of these complexes.

Myocyte enhancer factor-2C (MEF-2C) interacts with DNA in a similar fashion to SRF (139, 140), and its consensus DNA-binding site was determined in polymerase chain reaction (**PCR**)-mediated binding site selection assays as $CTA(A/T)_4TAG$ (141). A detailed analysis of the affinities of MEF-2C for DNA of varying sequence revealed that mutations within the central four base pairs are tolerated so long as adenine is replaced with thymine or vice versa (139, 142). However, the replacement of the central bases with guanine and cytosine significantly diminished the affinity for MEF-2C (Table 1).

Table 1. DNA Binding Parameters for MEF-2C (2–117) and GG-MEF-2C(1–117)

[a] Protein concentration for which 50% of the DNA binding sites are filled.

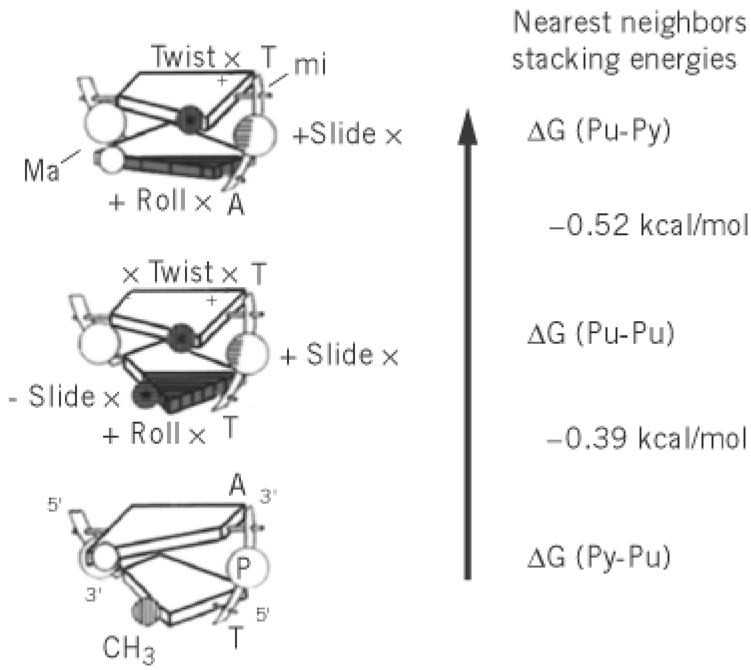
[b] Ref. 139.

[c] Ref. 142.

A correlation was observed between the affinity of MEF-2C for a mutant site and the intrinsic bendability of the site. MEF-2C binds to a DNA site with an alternating run of eight thymines and adenines with maximal affinity, while the affinity for an inherently rigid A-tract sequence is reduced by more than one order of magnitude (Table 1). Because of its poor stacking (Fig. 5), the deformability of a TA step is inherently much greater than that of an AT or an AA step (74, 121, 135, 143-152). A simple mechanical model to explain this observation has been provided by Finch and co-workers (135, 153). The proximity of the methyl groups of two successive thymines and the methyl groups and the phosphate backbone make the helix rather rigid (Fig. 5). In an AT step, the stacking of the methyl group with the adjacent adenine and the intervening sugar phosphate backbone again prevents bending by a roll mechanism. However, in a TA step the methyl group projects into the major groove without any significant stacking interactions with either the adjacent adenine or the phosphate backbone, and this step therefore displays a higher deformability than the AA and AT steps.

Figure 5. Schematic representations of the ApT-, TpT-, and TpA-dinucleotide steps indicating the sequence specific conformational differences between these steps. The DNA is viewed from the major groove indicated by Ma. The thymine methyl groups are indicated by small spheres. The methyl groups belonging to the right strand are shaded. The twist, slide, and roll movements that could create sterically unfavorable interactions are marked with ×. The regions of

the DNA which clash due to these movements are indicated. This part of the figure was adapted from Suzuki et al. (153). The differences in the nearest-neighbor stacking energies are given on the right, indicating that the most favorable stacking interaction is observed for Pu–Py dinucleotide steps (143, 147).



Reducing the length of the AT run from eight to six nucleosides by removing the first and the eighth base of the run (which generates a consensus site for SRF) reduced the stability of the MEF-2C complex almost 20-fold (Table 1). When the six AT bases consisted of alternating thymines and adenines, however, MEF-2C bound to the corresponding oligonucleotide again with almost the same affinity as to a MEF-2C site of length eight. This observation strongly supports the proposal that the inherent bendability of the DNA-binding site is a principal determinant of the DNA-binding specificity of MEF-2C (139, 140, 142). The affinities of the various AT-rich sequences for MEF-2C might be a measure of the relative bendability of the unbound DNA.

Similarly, a comparison of the DNA structure of the free uncomplexed Trp operator with that observed in the trp repressor–operator complex provided evidence that particular DNA sequences might be predisposed to adopt a non-B-form conformation in protein complexes (72).

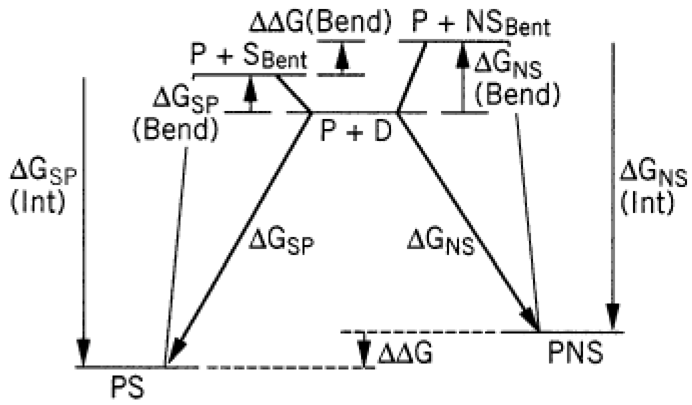
Circular dichroism spectroscopy and bending analysis by circular permutation assays revealed that MEF-2C potentiates the natural tendency of its DNA target to adopt a bent conformation (142). DNA binding by MEF-2C is accompanied by DNA bending of approximately 70°, irrespective of the particular DNA sequence. This observation depends on the presence of the *N*-terminal methionine residue. In its absence, DNA containing a high-affinity binding site is bent by only 49°, while heterologous sequences remain unbent (139, 142). The differences in DNA-binding affinity are much less pronounced in the absence of the *N*-terminal methionine (Table 1). The *N*-terminal methionine appears to anchor MEF-2C to the ends of the AT run, thereby orientating the protein properly on the DNA. In the minor groove, A–T base pairs can be distinguished from G–C base pairs by the lack of a heterocyclic atom at C2 of adenine. Based on the SRF structure (see MADS-Box Proteins), it had been suggested that the *N*-terminal methionine of MEF-2C is located over A4 and could specify the adenine by means of hydrophobic interaction with C2 of adenine (136). However, the observation that MEF-2C can bind with high affinity to a run of three alternating TA steps indicated that the *N*-terminal methionine does not interact with C2 of adenine (154) of the MEF site. With the short TA run, the steric clash between the side chain of methionine and the amino group on C2 of guanine (154) would reduce the stability of the complex significantly (142). It is therefore more likely that the side chain of the *N*-terminal methionine packs against the sugar ring of the nucleotide (154).

When a protein binds to a more rigid DNA sequence, it often does not bend DNA, or a substantial amount of the binding free energy must be used to bend the DNA target. Even in these cases, however, proteins often target the most deformable base step within their target sequence. The purine repressor, PurR, which is involved in the biosynthesis of purines and pyrimidines, binds to runs of four consecutive adenines and thymines, interrupted by the dinucleotide CG (155). PurR bends the DNA into the major groove by 45° through the insertion of a hinge into the minor groove and intercalation of the side chains of two leucine residues into the CG step (124). **Calorimetric** analysis suggested that purine–pyrimidine steps stack more stably than do purine–purine or pyrimidine–pyrimidine steps by approximately 0.52 kcal/mol, while the stacking energy of pyrimidine–purine steps is reduced by another 0.39 kcal/mol (Fig. 5) (143, 147). Therefore, CpG is the step that can be unstacked most easily within the pur operator. Similarly, the bending of 22° of the PRDI site within the **interferon**-b promoter in the complex with interferon regulatory factor (IRF) occurs at the CpA step which is the most easily unstacked dinucleotide in the PRDI sequence, ACTTTCACTTCTC (156). The cocrystal structure of the DNA complex of the chromosomal protein Sac7d from the hyperthermophile *Sulfolobus acidocaldarius* revealed that the DNA is kinked by 61° through the intercalation of two amino acid side chains, namely Val26 and Met29 between the bases of the dinucleotide C(2)G(3) (157). This is the base step that is most easily unstacked in the DNA sequence GCGATCGC. All these examples demonstrate that proteins recognize DNA not only through specific contacts with the nucleobases, but also through inherent, sequence-dependent properties of the DNA. Therefore, considering the properties of both the protein and the DNA makes possible an understanding of the sequence specificity and the observed DNA bend in DNA–protein complexes (135, 158).

The binding specificity of a protein is determined by the difference in binding affinities of the protein for the specific and the nonspecific sites. DNA bending is an energy costly process, even for sequences of enhanced bendability (Fig. 6). Some of the binding free energy must be used to bend a DNA molecule which, in the absence of protein, adopts either an unbent or an only slightly bent conformation. Therefore, protein-induced DNA bending can contribute to the overall specificity of a DNA-binding protein (142, 159-161). MEF-2C, for example, must use some of the binding free energy from specific interactions to induce bending at the specific site. In the case of a MEF-2C mutant lacking the *N*-terminal methionine, however, no binding free energy appears to be used for the bending of the nonspecific complex (139, 142). Consequently, the difference between the free energies of the specific and the nonspecific complexes is reduced because of the unfavorable contribution from bending the specific DNA. On the other hand, MEF-2C(1–117), which contains the *N*-terminal methionine, bends both specific and nonspecific DNA, thereby increasing the difference in the free energy between the specific and the nonspecific complexes. The increased DNA-binding specificity of MEF-2C(1–117) over that of MEF-2C(2–117) relies therefore in part on the fact that MEF-2C(1–117) bends DNA irrespective of the particular sequence. MEF-2C(1–117) appears to select DNA-binding sites that are characterized by increased bendability, because for these DNA sequences less binding free energy must be expedited to force them into the bent conformation necessary for the optimal shape complementarity observed in the complexes. Interestingly, the CD spectra of the DNA complexes of MEF-2C(1–117) indicated that the conformation of the DNA was independent of its sequence, at least within the resolution of CD spectroscopy (142), while the CD spectra of the DNA in the MEF-2C(2–117) complexes varied strongly with the DNA sequence (139, 142). Scanning tunneling microscopy has indicated that the specific and nonspecific DNA complexes of l Cro are characterized by similar bend angles. The bend angle induced by binding of a Cro dimer to DNA was determined as 69° ± 11° and 62° ± 23° for specific and non-specific DNA, respectively (159).

Figure 6. Free energy diagram illustrating the effect of DNA bending on the stabilities of the complexes of protein P

with DNA D. The DNA-binding specificity DD*G* is defined as the difference of the binding free energies for the formation of the specific and nonspecific complexes: DDG = DG_{SP} – DG_{NS}. The total free energy for the formation of the specific and the nonspecific complexes can be partitioned into the contributions from the (favorable) interactions between the DNA and the protein, D *G*(Int), and the (unfavorable) free energy change required to bend the DNA, D*G* (Bend).



$$\Delta\Delta G = \Delta G_{SP} - \Delta G_{NS}$$
$$= \Delta G_{SP}(\mathrm{Int}) + \Delta G_{SP}(\mathrm{Bend} - \Delta G_{NS}(\mathrm{Int}) - \Delta G_{NS}(\mathrm{bend})$$
$$= \Delta\Delta G(\mathrm{Bend}) + \Delta\Delta G(\mathrm{Int})$$

In order to bend DNA, proteins use primarily two mechanisms. In the first, kinks are introduced through the intercalation of amino acid side chains between adjacent base pairs. In the IHF–DNA complex, two intercalating proline residues projecting from the tip of each b-hairpin arm introduce large kinks at symmetrically displaced ApA steps. SRY (125) and LEF-1 (126), which are structurally similar proteins, use nonaromatic, hydrophobic amino acids to intercalate into base steps from the minor grove side of the double helix, creating a widened minor grove and a dramatically bent DNA. TATA box-binding protein induces strong bends of approximately 45° at either end of the TATA box through the intercalation of two phenylalanine rings between two adjacent base pairs (74-77), while the hyperthermophile chromosomal proteins Sac7d bends DNA by 72°, primarily through the intercalation of Val(26) and Met(29) at a single CpA base step (157).

The second mechanism for the introduction of bends into DNA was originally proposed by Rich (162). Asymmetric neutralization of the negative charges of the phosphodiesters by cationic amino acid residues could result in unbalanced Coulombic repulsions between the negative charges on DNA, causing DNA to collapse toward the bound protein (162-164). For example, the X-ray structure of **serum response factor** bound to its target DNA sequence indicated that asymmetric charge neutralization is at least partly responsible for the DNA bend angle of 72° (136). Several positively charged amino acid residues of SRF bind the phosphate groups on only one side of the SRF-site (Fig. 7). The three positively charged amino acids that interact with the distal ends of the DNA provide the hands through which SRF pulls up the far ends of the DNA. In addition, Arg143 lies in an extended conformation along the floor of the minor grove and stabilizes the relatively large propeller twists at the central base steps, which are characteristic of AT-rich regions. These interactions also facilitate the bending of DNA. The members of the MEF-2 family of proteins most probably follow a similar mechanism to induce bends into DNA (142). However, the bending of the AT-rich target sequences of SRF and of the MEF-2 proteins is helped by the intrinsically high bendability of these DNA sequences (135). The X-ray structure of the complex between the bZ protein GCN4 and an ATF-site-containing DNA revealed that the DNA was unbent (165). On the other hand, the heterodimer of the bZ proteins Jun and Fos appears to induce DNA bending when bound to an AP-1 site (166-168), although some controversy exists on this point (169-173). The identity of the amino acids just *N*-terminal to the basic region appears to be important for DNA bending, in that cationic amino acids in these positions contact the negatively charged phosphate diesters on only one face of the DNA, thereby inducing the DNA to bend away from the leucine zipper (174-178). The corresponding amino acids in GCN4 are the uncharged Pro–Ala–

Ala, consistent with the observation that GCN4 does not bend AP1-site-containing DNA. Analysis of the bending properties of GCN4 mutants revealed that cationic amino acids in these positions induce DNA bending toward the neutralized surface, while anionic amino acids induce bending in the opposite direction (179).

Figure 7. Interactions between positively charged amino acid side chains and DNA phosphates in the SRF–DNA complex (136). Note that these contacts occur only on one side of the duplex, causing the DNA to bend towards the protein. The histidines and lysines on either end of the duplex serve as handles to further bend the DNA (the DNA used is too short to allow formation of the His-phosphate contact on the left-hand side).

While DNA bending is the most dramatic change observed upon DNA binding, many other more subtle conformational rearrangements of the DNA have been observed. While a slight bending of the DNA of approximately 25° has been observed in the crystal structure of the 434 repressor–DNA complex (180, 181), the major characteristic is the significantly overwound DNA in the region of the central four base pairs of the binding site. Relative to canonical B-DNA, the net overtwisting is approximately 20°. Although these four base pairs are not in direct contact with the repressor, operators with A–T or T–A base pairs at these positions are bound more strongly than those bearing C-G or G-C (182). A relationship between the intrinsic twist of an operator, as determined by the sequence of its central bases, and its affinity was observed: Operators with lower affinity are undertwisted relative to operators with higher affinity (128).

DnaK/DnaJ Proteins

These proteins were originally discovered because mutations in their encoding genes block the replication of lambda phage in *Escherichia coli* (1). Mutations in these genes were later shown to exert pleiotropic effects on bacterial metabolism, including defects in DNA and RNA synthesis, **proteolysis**, **cell division**, **temperature-sensitive** growth, and the overproduction of **heat shock** proteins. All these effects are believed to result from changes in protein–protein interactions mediated by complexes of DnaK protein with DnaJ protein and a third protein encoded by the *grpE* gene that acts as a nucleotide-exchange factor (2-5). The DnaK and DnaJ proteins act as **molecular chaperones** in the folding (6), export (7), and degradation (8, 9) of both newly synthesized and stress-denatured polypeptide chains, and in the dissociation of oligomeric complexes essential for the initiation of phage and **plasmid DNA** replication (10). This multifaceted property stems from the ability of both DnaK and DnaJ proteins to bind and release **hydrophobic** segments of an unfolded polypeptide chain in an ATP-driven reaction cycle.

Unlike the chaperonins, the DnaK and DnaJ proteins release their polypeptide substrates in unfolded states, and thus their binding serves only to shield such unfolded polypeptides transiently from premature folding during translation and from aggregation under conditions producing a **stress response**. Both the DnaK and the DnaJ proteins also have the unusual property of altering the conformations of proteins that are native, and thus seemingly fully folded; such proteins may expose chaperone recognition elements that are shielded in other proteins. The ability of both DnaK and DnaJ proteins to bind to the **heat shock** transcription factor **sigma** 32 is believed to be part of the autoregulation of stress gene expression in *E. coli* (3, 11).

The DnaK protein is a weak ATPase and is about 50% identical in primary structure to the eukaryotic family of hsp70 proteins (see BiP (Hsp70)), while the DnaJ protein has homologues called hsp40 proteins in the cytosol, mitochondria, chloroplasts, and endoplasmic reticulum of eukaryotic cells (6). Genes for homologues of both DnaK and DnaJ proteins have been identified in *E. coli* (12, 13); the expression of these genes is induced by exposure to low, rather than high, temperatures (14).

Like all the hsp70 proteins, DnaK possesses an N-terminal ATPase **domain** and a *C*-terminal peptide-binding domain; the crystal structure of the latter is known (15), as is that of the ATPase domain of a **homologous** mammalian hsc70 protein (16). Polypeptides bind in extended conformations to a compact b-sandwich containing two four-stranded antiparallel b-strands. Optimal binding is produced by runs of seven hydrophobic residues; the most important determinant of peptide binding is the central binding pocket for a leucine residue. The ATPase domain transmits ATP-dependent conformational changes to the peptide-binding domain. All the DnaJ proteins possess a conserved *J* domain of 70 residues, which interacts with hsp70 proteins. The NMR structure of this *J* domain reveals a scaffolding of four a-helices bearing at its exposed end a conserved tripeptide in a loop region (17); amino acid substitution in this tripeptide prevents binding to DnaK (18). The *J* domain is followed by a glycine-phenylalanine-rich region, and then a cysteine-rich domain resembling a **zinc finger** that is involved in binding to unfolded polypeptides (19). Thus the binding of DnaJ to DnaK combines the functions of two chaperones that have rather different specificities for binding to hydrophobic amino acid residues.

DNase 1 Sensitivity

DNase 1 (deoxyribonuclease 1) is an enzyme that cuts **DNA** with relatively little specificity. The enzyme is reasonably large (>30,000 Da), so that assembing DNA into nucleosomes and chromatin impedes its enzymatic activity by limiting access to the DNA double helix. Sensitivity to DNase I is commonly believed to reflect the degree to which DNA is compacted in the chromosome. However other variables, such as proteins that like to bind DNase I and the actual structure of the DNA, might also influence enzymatic activity. DNase I likes to bind to DNA across the **minor groove** of the **double helix**.

Early experiments demonstrated the selective association of nonspecific DNA-binding proteins (prokaryotic **RNA polymerases**) with **transcriptionally** active chromatin. Following these advances, Weintraub, Felsenfeld, and colleagues showed that a comparable general accessibility to **nucleases** is associated with transcriptional activity (1, 2). This general sensitivity to nucleases includes the coding region of a gene and may extend several kilobases to either side of it, potentially defining a chromosomal **domain** . DNase I normally introduces double-strand breaks into transcriptionally active chromatin more than 10 times more frequently than into inactive chromatin. However, the exact structural basis of this generalized sensitivity is unknown. Careful analysis reveals that the untranscribed regions are just as sensitive to DNase I digestion as the transcribed regions, provided the last-cut approach to the measurement of DNase I sensitivity is used. This is defined as digestion by DNase I to fragments so small (smaller than 50 bp) that the DNA no longer hybridizes efficiently to complementary strands after **denaturation** (3). A certain length of DNA is necessary to allow specific recognition (**hybridization**) of two separated single-stranded regions. An important question not yet completely resolved is whether transcription is required to generate generalized nuclease sensitivity in certain instances or whether sensitivity always precedes transcription.

A useful example of the regulated appearance of DNase I sensitivity of a gene is provided by experiments on the action of **mitogens** on quiescent cells. In response to mitogens, a subset of genes, called the immediate-early genes , is rapidly induced (4). The most studied examples of such genes are *c-myc* and *c-fos*. These two **proto-oncogenes** are transcriptionally activated within minutes. Coincident with transcription, the chromatin structure of the proto-oncogenes becomes more accessible to nucleases. Once proto-oncogene transcription ceases, preferential nuclease accessibility is lost (5). Possible conformational changes in nucleosome structure might account for such effects. It has been proposed that histone H3 cysteine residues might become accessible in nuclease-sensitive chromatin, reflecting conformational changes within the nucleosome. However, the recruitment of **RNA polymerase** or other components of the transcriptional machinery may also provide the thiol groups that bind to the columns retaining active chromatin (6). Nevertheless, the rapidity of the changes in nuclease sensitivity (<90 s) and their propagation in both directions 5′ and 3′ to the **promoter** means that transcription and hence RNA polymerase or **HMG proteins** cannot account for all of the observed changes. This is consistent with some retention due to histone H3 in higher eukaryotes. In fact, the speed of the response suggests that changes in nuclease sensitivity precede transcription, and they may play a role in regulating *c-fos* expression.

It is interesting that one of the earliest mitogen-induced nuclear signaling events coincident with proto-oncogene induction is the rapid **phosphorylation** of histone H3 on serine residues within its highly charged, basic, amino-terminal **domain**. **Acetylation** of the amino-terminal domains of the core histones is also likely to be a component of transcriptional activation. Whether these changes are localized to chromatin regions containing either *c-fos*, *c-myc* or the other immediate-early genes has not yet been determined (7). An additional component contributing to the prior sensitization of the proto-oncogenes to nucleases may come from the existence of trans-acting factors already associated with the promoter (8). Such interactions are responsible for the second landmark in chromatin: DNase I hypersensitive sites. These sites are the first places where DNase I introduces a double-strand break in chromatin. They usually involve small segments of DNA sequences (100 to 200 bp) and are two or more orders of magnitude more accessible to cleavage than in inactive chromatin. As the most accessible regions of chromatin to non-histone DNA-binding proteins, DNase I hypersensitive sites generally denote DNA sequences with important functions in the nucleus. Cleavage at these sites might, however, preferentially solubilize chromatin, leading to an increase in the general accessibility of a chromatin domain to DNase I. The results emphasize the utility of DNase I as a probe for both actively transcribed genes and for detecting of regulatory DNA in the chromosome.

Domain, Chromosomal

A chromosomal domain can be defined at either a structural level or a functional level. At this time, there is frustratingly little information concerning the relationship between these two organizational levels. Our most thorough understanding of chromosomal organization is for the most condensed, and hence most visible, of chromosomes, those at **metaphase** . Although folding of **DNA** into nucleosomes leads to a sevenfold compaction in length, and the subsequent folding of arrays of nucleosomes into the chromatin fiber to a further sevenfold compaction, a massive 250-fold compaction of DNA follows the organization of the chromatin fiber into a metaphase chromosome. One model proposed to account for this compaction suggests an organization of the fiber into loops that are radially arranged along the axis of the chromosome (1). It has also been suggested that such loops represent functional chromosomal domains.

The evidence for the organization of the chromatin fiber into loops attached to a central axis in normal cells comes from several experimental approaches. Long-standing observations on the morphology of lampbrush chromosomes in amphibian oocytes show a succession of loops emerging from a single chromosomal axis. Worcel developed a model for the *E. coli* chromosome that predicted its organization into independent domains or loops. Then these studies were extended to **interphase** chromosomes from *Drosophila* cells. Intact chromosomes were subjected to very mild digestion with **DNase I** to produce single-strand nicks. Then the resulting chromosomal fragments were examined in sedimentation velocity centrifugation experiments to determine their size. It was found that the length of the fragments decreases gradually until a plateau value of approximately 85,000 bp of DNA is reached (2). This suggests that the chromatin fiber is organized into fairly uniform domains containing about 100 kbp of DNA complexed with protein. A second approach to determinating the size of structural domains in the chromosome involves **electron microscopic** examination of nuclei extracted from histones by exposure to high-salt solution. It is possible to measure the length of DNA directly on the microscope grid from where it exits a residual nuclear structure (the nuclear matrix or scaffold) to where it reenters this structure. Estimated loop sizes between 40 and 90 kbp were obtained using this technique, which were consistent with biochemical measurements (3).

The development of pulsed-field gel electrophoresis allowed more systematic analysis of the separation of cleavage sites following mild nuclease digestion of nuclei (4). This technique allows resolving very large DNA molecules by agarose electrophoresis. Nuclei of **eukaryotic** cells contain an **endonuclease** (which was first responsible for the discovery of the nucleosomal repeat) that can be activated under controlled conditions (by the addition of exogenous Ca^{2+}/Mg^{2+} to nuclei) and which is believed to have little sequence specificity. It might be expected that cleavage of DNA by this enzyme would be inhibited by folding of DNA into the chromatin fiber, but that structural discontinuities, perhaps where the loop is attached to the chromosomal axis, might allow cleavage if the enzyme were activated. Activation of this enzyme followed by resolving the resultant DNA fragments on pulsed-field gels would potentially allow determining loop sizes. A related approach to this problem uses the observation that topoisomerase II is a major component of chromosomes and, potentially, of the nuclear matrix or scaffold. The enzymatic action of topoisomerase II introduces a double-strand break into DNA, which is then resealed. These double-strand breaks can be stabilized by the use of specific drugs (e.g., epipodophyllotoxins) that inhibit the enzyme (5). Preferential cleavage sites in nuclei spaced 50 to 300 kbp apart were detected using both the endogenous nuclease or topoisomerase II in the presence of the specific inhibitors of the rejoining of the double helix. Closer analysis revealed a hierarchy of digestion, where the 300-kbp cleavage products appeared before those of 50 kbp. It has been suggested that the 50-kbp intermediate in digestion represents the first level of organization of the chromatin fiber into loops, whereas the 300-kbp kinetic intermediate represents the next level of organization. Taken together, these observations establish a strong case that large independent loops (50 to 100 kb) of the chromatin fiber represent a unit of chromosomal structure.

Many studies have focused on the non-histone proteins in the nucleus that might represent sites of attachment of chromatin at the base of loops and the DNA sequences associated with them. The biochemical nature of the nuclear skeleton, the nuclear scaffold, and the nuclear matrix that might organize DNA in the nucleus has been the subject of much debate. Initially, the metaphase scaffold of a chromosome had a morphological definition as the complex structure at the axis of a mitotic chromosome, visualized after swelling and extraction of the histones. Biochemical extraction with high-salt (2 M NaCl) or with the detergentlike lithium diiodosalicylate (LIS) was used to define the residual nucleoprotein complex at which DNA was attached to the chromosome during interphase. Now this nuclear “matrix” (after high-salt extraction) or “scaffold” (after LIS extraction) is known to contain a substantially more complex group of proteins than the metaphase scaffold itself (6). The use of these nonphysiological extraction procedures was criticized because they cause rearrangements of protein–DNA interactions and nonspecific aggregation. An alternate strategy to study nuclear infrastructure is to encapsulate cells in agarose, to extract most of the chromatin, and to leave the nucleoprotein complexes essential for nuclear integrity under physiological conditions. This last methodology generates a nuclear “skeleton” that can transcribe and replicate DNA,which indicates that functionally relevant enzymatic complexes are retained. Recent comparative experiments confirm that the nuclear matrix or scaffold interacts with gene-poor regions of the genome, whereas the nuclear skeleton interacts with gene-rich regions (7). It is now clear that the function and composition of the nuclear skeleton is very different from that of the nuclear matrix or scaffold. All define chromosomal domains, yet the reasons for generating attachments to the chromatin fiber differ.

The nuclear “scaffold” is the best-defined entity with respect to both biochemistry and genetics. A major set of proteins found in the scaffold fraction includes Sc (scaffold proteins) I, II, and III (8). The function of Sc III is unknown. Sc I (170 kDa), however, is now known to be topoisomerase II, and Sc II is known to be a heterodimeric coiled-coil protein. The enzymatic activity of topoisomerase II passes DNA strands through one another. It can cause a double strand break in DNA and rejoin it. Antibodies to topoisomerase II allowed demonstrating that the protein is an integral component of mitotic chromosomes (9). Moreover, the efficiency of recovery of total cellular topoisomerase II in the scaffold fraction (>70%) makes it unlikely that the association with the scaffold fraction is accidental. Consistent with the current view that the chromatin fiber folds further into the chromosome, immunolocalization data show that topoisomerase II is found in a large number of discrete foci scattered throughout the axial region of chromosomes. These foci are very uniform in size, suggesting that they represent discrete structural complexes. Each is believed to be an anchoring complex to which chromatin loops are attached. The presence of topoisomerase II in these complexes can be rationalized by the necessity of unraveling DNA knots and tangles that are inevitably generated during processive enzymatic processes, such as DNA replication and transcription . In fact, if topoisomerase II is inactivated *in vivo* by mutation, the mutant cells die because they cannot separate their chromosomes at the end of mitosis (10).

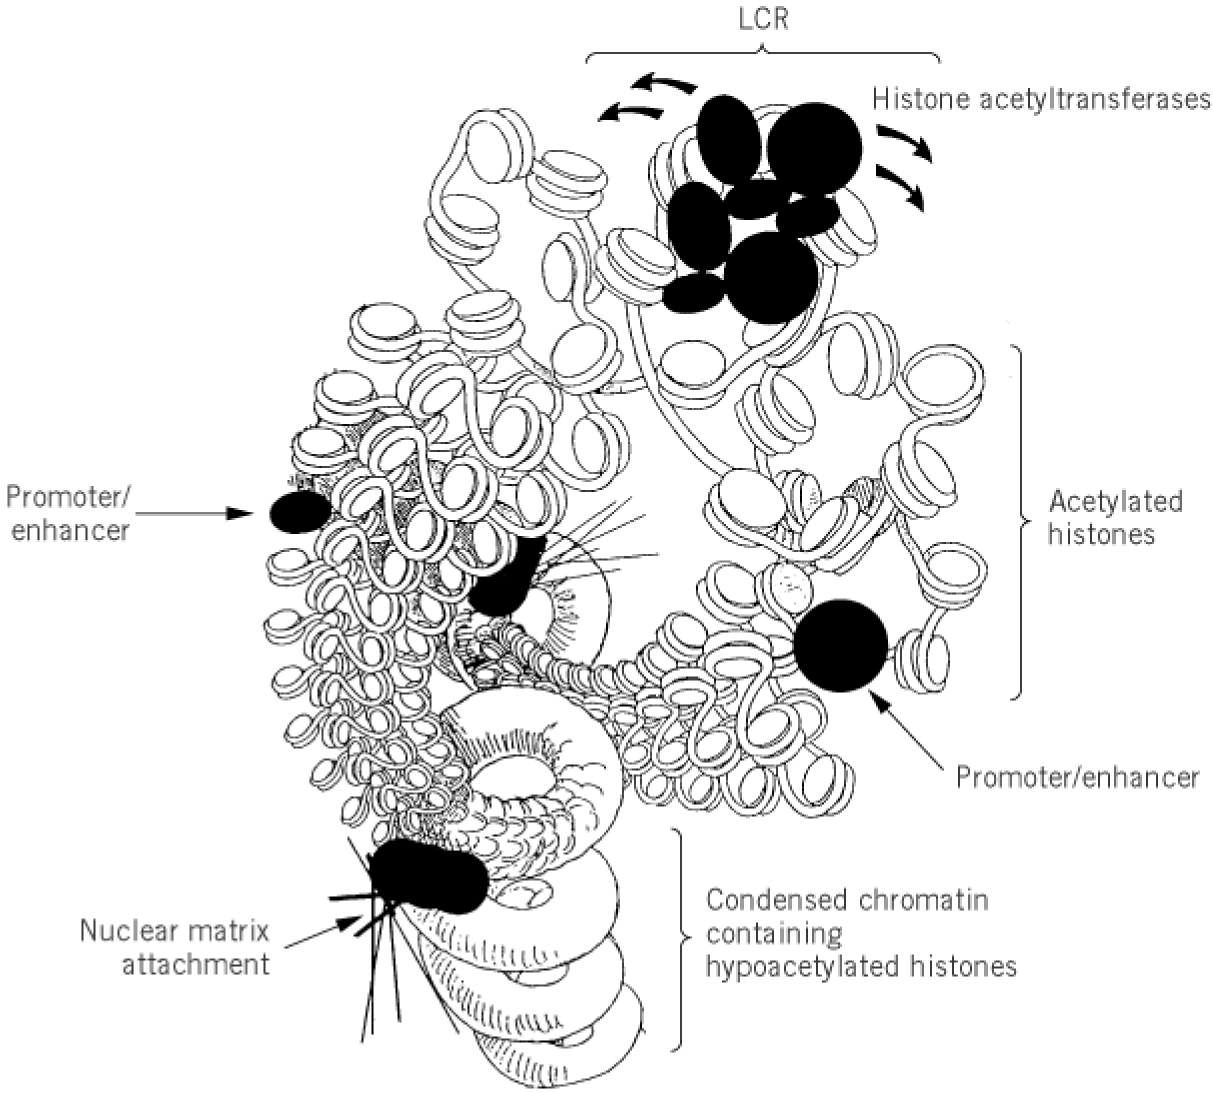
The Sc II protein has a much more active role in directing mitotic chromosomal condensation than topo II. Now ScII is recognized as a member of the stability and maintenance of chromosomes (SMC) family of proteins. The function of this family of proteins was first characterized in the **yeast**, *Saccharomyces cerevisiae* (11). SMC proteins are conserved in structure from **fungi** to vertebrates. Each consists of five major regions: a **nucleotide-binding region**, a region of the alpha-helix with the potential to form a coiled-coil protein–protein interaction domain, a hinge region, a second coiled-coil domain, and a carboxy-terminal region. Mutational analysis indicates that all of these domains are required for SMC protein function. SMC proteins assemble into **oligomeric** structures. There are at least four different SMC proteins in *S. cerevisiae*, and all are essential for viability, which suggests that they have essential nonoverlapping functions. The phenotypes of SMC mutant cells in yeast fail to undergo **mitosis**, and the undivided nucleus splits partially. This **phenotype** is very similar to that of topoisomerase II mutants in yeast. Closer investigation reveals that SMC mutant cells fail to condense and segregate their chromosomes (11). In spite of this clear genetic evidence that topoisomerase II and the Sc II proteins have essential roles in chromosomal organization, evidence that they have a specific association with DNA is lacking thus far. Thus the nucleic acid contribution to the assembly and function of chromatin loops or structural domain remains unclear.

It has been suggested that the nuclear matrix or scaffold contains specific DNA sequences known as scaffold or matrix attachment regions (SARs and MARs). Evidence that the sequences function in chromosomal dynamics comes from the synthesis of an artificial protein that preferentially binds to these AT-rich sequences (12). This protein interfered with the chromosomal dynamics normally observed during nuclear decondensation or chromosomal condensation in *Xenopus* egg extracts. In the absence of the identification of *bona fide* scaffold attachment sequence-binding proteins *in vivo* and examination of their function, however, whether scaffold or matrix attachments have an active role in chromosomal function remains speculative. Such attachments might promote transcriptional activity *in vivo* (13). In **plants** there is compelling evidence that AT-rich segments of the genome that have been biochemically defined as scaffold attachment regions promote the activity of genes in *cis* . Histone H1 binds preferentially to these AT-rich DNA sequences. It has been suggested that proteins, such as high mobility group (**HMG** I/Y) might displace histone H1 selectively from scaffold attachment regions that contribute to the local control of transcriptional activity (14). It must be proven that this type of selective association of proteins with scaffold attachment regions occurs *in vivo* . It has long been known that lysine-rich proteins like histone H1 interact with AT-rich DNA. Hence the significance of *in vitro* binding experiments that enrich lysine-rich proteins bound to AT-rich scaffold attachment regions remains questionable. A subfamily of sites determined by such procedures as matrix attachment sites (A elements) can be found at the boundaries of a 24-kbp region of **DNase I-sensitive** chromatin containing the chicken lysozyme gene. Sippel and colleagues demonstrated that the A elements insulate a gene from chromosomal effects in stable transformants, but they are not required in transient assays for high levels of gene activity. These A elements also give high-level position-independent, copy-number dependent expression of a *trans* gene in **transgenic** mice (15).

Evidence for the functional specialization of chromosomal domains came initially from cytological analysis of polytene chromosomes. Immunologic staining has revealed the specific distribution of several non-histone proteins, including RNA polymerase II and proteins apparently responsible for generating inactive heterochromatin (HP1, see Chromocenter). Grossbach and colleagues used antibodies against variants of histone H1 to demonstrate that the localization of particular linker histones is highly specific for individual chromosomal domains within polytene chromosomes (16). In contrast, a similar approach with antibodies raised against HMG14-related proteins led to the general **immunofluorescent** staining of transcriptionally active domains. Turner found that individual chromosomal domains within polytene chromosomes can be significantly enriched with forms of histone H4 that have particular states of posttranslational modification (17). This is where a covalent modification such as acetylation of lysine residues is added by an enzyme after the protein has been synthesized. These experiments indicate that specific proteins and modifications can be targeted to particular chromosomal regions.

Additional support for the division of the chromosome into individual functional domains came from the discovery of **locus control regions** (**LCR**). DNase I hypersensitive sites are useful in defining important DNA sequences. DNase I cleavage of the human b-globin locus revealed the existence of four strongly nuclease-sensitive sites located 10 to 20 kbp upstream of the cluster of human b-globin genes (18) (see Contiguous Genes). These sites, known as locus control regions (LCRs), represent cis-acting elements that allow genes integrated into a chromosome to be expressed independently of chromosomal position, i.e., position effects are abolished. Consequently, LCRs allow each copy of a gene integrated in multiple copies to be expressed equivalently within a particular chromosomal domain, so that gene expression is copy-number dependent. When all four DNase I hypersensitive sites comprising the LCR are placed adjacent to reporter genes, they function like enhancers. However, three of the four sites do not function as enhancers in transient expression sites but only do so after incorporation into the chromosome. This suggests that the LCRs may play a special role in stabilizing an accessible chromatin structure distinct from the function of a normal enhancer element (19) (Fig. 1). Several models have been proposed for LCR function, including unraveling of the chromatin fiber, functions similar to normal enhancers, and stabilization of specific nucleoprotein complexes that are functional for transcription only in the presence of the LCR. Evidence consistent with the propagation of an altered chromatin structure comes from transgenic experiments in which LCRs confer hypersensitive sites and general DNase I sensitivity, whereas promoter elements do not. This suggests that LCRs may be able to overcome the inhibitory influences of localized regions of heterochromatin. It has been suggested that LCRs or regions adjacent to them might define the boundaries of an active chromatin domain through attachment to a nuclear matrix or scaffold. At this time there is no positive evidence to suggest that this is the case *in vivo*.

Figure 1. A model for locus control region (LCR) function where the LCR defines a functional chromosomal domain. We propose that the LCR recruits histone acetyltransferases that acetylate histones in the functional domain and lead to an expanded and destabilized chromatin fiber. Within this domain are promoter and enhancer sequences that themselves function more effectively when chromatin higher order structure is destabilized. In this model nuclear matrix attachment sites are boundaries to separate the LCR-controlled chromosome domain from condensed chromatin containing hypoacetylated histones.



Schedl and colleagues have used transposable elements (P-elements) that can introduce stable transformants into the germ line of *Drosophila melanogaster* to define a distinct "insulator" element that might help delimit functional chromosomal domains. Using the *hsp70* gene, these investigators defined DNA sequence elements that contain DNase I hypersensitive sites to either side of the *hsp70* genes. These specialized chromatin structural (scs) elements conferred position-independent, **copy-number**-dependent transcription from the white **promoter**, with the exception of one insertion into heterochromatin within the *Drosophila* X-chromosome. Importantly, the scs elements do not behave as scaffold attachment regions that establish a functional separation between the two sequences (20). It has been recognized that the *Drosophila* **suppressor** of hairy-wing protein and the complex that it assembles with the gypsy transposable element have comparable "insulating" properties.

It is important to observe that scs, gypsy, or A elements block enhancer function if the element is between the enhancer and the promoter. This capacity to block activation or silencing effects has led to the current definition of these elements as insulators. Enhancers normally act over very long distances (many kilobases). It is hard to imagine how a short DNA sequence (100 to 200 bp) could inhibit DNA looping, which suggests that enhancers in this case function by an alternate mechanism, perhaps related to chromatin folding or nuclear compartmentalization (see Figure 1). Additional insight comes from experiments suggesting that gene regulation occurs by progressively altering the structure of chromatin domains that are continuous in the chromosome. In the bithorax complex, three genes (*Ubx*, *abd-A* and *Abd-B*), are aligned 5′ to 3′ in the order in which they are expressed during development and, remarkably, in the structures whose origin they control in an anterior to posterior direction in the fly. It has been suggested that each of these three large (> 20 kbp) segments of DNA are activated in succession. Several mutations in the bithorax complex are consistent with this hypothesis because by removing a boundary between two domains of chromatin, the anterior-posterior boundary between different structures is also removed. In this model, boundary elements prevent the propagation of a particular chromatin modification by functioning as a barrier. Once again, this type of genetic analysis provides strong evidence for the existence of chromosomal domain boundaries.

Domain, Protein

Protein domains, sometimes referred to as protein folds or modules, are thought to be the building blocks of protein structure, function, and evolution. A domain is generally defined as that part of a protein's structure that can fold independently of the remainder of the protein. The tertiary structure of a protein's polypeptide chain is assembled into one or more protein domains, each domain usually incorporating between 50 and 150 amino acid residues. Proteins having fewer than 100 residues in their polypeptide chains are usually single-domain proteins. Multidomain proteins incorporate more than one domain in their structure and have long polypeptide chains. Generally, the individual domains of a multidomain protein are formed from consecutive stretches of sequence that are connected by a single short length of linking polypeptide chain. These linking regions may be the source of conformational flexibility in the tertiary structure of the protein, and the links can be susceptible to cleavage by proteinases (thereby producing stable protein domain fragments).

Individual domains within a protein structure often have distinct roles, including catalytic, regulatory, binding, recognition, or oligomerization functions. Protein domains are categorized into different structural classes (1, 2) based on their **secondary structure**, including (a) those containing mostly a-helix (all-a), (b) those containing mostly b-strands arranged in antiparallel beta-sheet (all-b), (c) those containing mostly alternating a-helix and b-strand elements (a/b), and (d) those containing a-helix and b-strand elements that are separated rather than alternating in the polypeptide chain (a + b). Some also classify small proteins (<10 kDa) that are stabilized by disulfide bonds or metal ion interactions as a separate class. Recently a new class of protein domain, called the parallel b-helix, that contains only parallel b-strands has been identified (3). Classification of domain structure beyond this level is complex, but databases that define different structural types of protein domains have been developed (4-7) (see Structure Databases).

Domain Shuffling

Proteins are often composed of one or more functional **domains**. In particular, when a certain protein possesses more than one domain, it is called a mosaic protein. Domain shuffling is a phenomenon where the **gene** segments coding for functional domains are shuffled between different genes during evolution. The boundaries between different domains may or may not correspond to the intron–exon boundaries of the encoding gene. In fact, in certain cases a single domain is encoded by more than one exon, whereas an exon contains a number of functional domains. Therefore, the "exon shuffling" theory is not necessarily the same as the "domain shuffling" theory. Although there are many cases where domain shuffling must have taken place, it is not known what molecular event causes this, and this is important to determine. For more details, see Exon Shuffling.

Dorsal/Cactus Complex

In the *Drosophila melanogaster* embryo, dorsoventral polarity is determined by a concentration gradient of the transcription factor Dorsal in the nucleus (1-3). Prior to axis formation, Dorsal is held in the cytoplasm by an inhibitor, Cactus (4-6). During early embryonic development, **proteolysis** of Cactus in response to a signal transduced on the ventral side of the syncytial embryo releases Dorsal (7-9). Free Dorsal translocates into ventral nuclei, where it directs expression of ventral-specific **genes** and represses expression of dorsal-specific genes (10). In this manner, the spatially graded disruption of the Dorsal/Cactus complex establishes the dorsoventral body axis (11).

Dorsal and Cactus are **translated** from messenger RNAs synthesized in the ovary and form a complex distributed uniformly in the unfertilized egg. Following fertilization, 14 rounds of replication and nuclear division occur prior to cellularization, so that axis formation occurs in the context of a syncytium containing hundreds, and eventually thousands, of nuclei. Within this syncytium, spatially regulated **protein degradation** of Cactus leads to a gradient of Dorsal nuclear localization, with the highest levels of nuclear Dorsal along the ventral midline and lowest levels in the dorsal half of the embryo.

Dorsal and Cactus were identified on the basis of **maternal-effect** mutations that disrupt embryonic pattern formation (12). Embryos generated by females lacking Dorsal have a dorsalized phenotype; there is no nuclear Dorsal and hence only dorsal-specific tissues are formed. Females homozygous for a mutation that inactivates Cactus generate embryos with an opposite, ventralized phenotype, in which Dorsal enters nuclei on both the ventral and dorsal sides of the embryo (4). Ten additional genes mutate to a dorsalized phenotype; these loci encode components of the signaling pathway that regulates release of Dorsal from the Dorsal/Cactus complex.

The signal transduction pathway that directs the asymmetric nuclear translocation of Dorsal is initiated by Pipe, Nudel, and Windbeutel, the products of three genes expressed in the somatic cells of the ovary (13). A ventrally localized signal is then amplified by an extraembryonic serine proteinase cascade involving the Gastrulation Defective, Snake, and Easter proteins (14-16). The result is a proteolytically activated form of Spätzle, the activating ligand for the transmembrane receptor **Toll** (17). Transduction of a signal from activated Toll to the Dorsal/Cactus complex requires a scaffolding protein, Tube, and a protein kinase, Pelle (18, 19). Dorsal binds specifically to both Tube and Pelle, which also bind to one another (20, 21). Both Dorsal and Cactus appear to undergo **phosphorylation** in response to Toll activation (8, 22, 23). Phosphorylation of Cactus is critical for signal transduction; the role of Dorsal phosphorylation in signaling is not yet clear.

Once within ventral nuclei, Dorsal serves to activate expression of ventral-specific genes (eg, *twist*) and repress expression of dorsal-specific genes, e.g., *zen* (24). By themselves, Dorsal dimers activate transcription; repression requires binding to a corepressor, the Groucho protein (25). Dorsal function is not uniform across the ventral half of the embryo. Instead, the gradient of nuclear localization is translated as a series of threshold responses into stripes of gene activation and cell fate determination

(26).

Whereas maternally expressed Dorsal, Cactus, Toll, Tube, and Pelle function in embryonic patterning, zygotically expressed forms of these proteins mediate an immune response in the fat body, the *Drosophila* organ most similar to the mammalian liver (27). The immune response, which directs expression of **peptide antibiotics** upon infection, also involves at least two other proteins closely related in sequence to Dorsal. These proteins, DIF (Drosophila immunity factor) and Relish, appear to be regulated in a manner similar to that observed for Dorsal (28, 29).

The immune function of the Dorsal/Cactus complex has been broadly conserved during evolution; NF-kB and IkB, homologues of Dorsal and Cactus, play a critical role in the mammalian acute phase response, as do counterparts of Toll and Pelle (30-32). Activation of NF-kB in response to stimulation of cells with **cytokines**, such as **tumor necrosis factor**-a and **interleukin**-1, leads to activation of genes that regulate both the inflammatory and immune responses. Recent data suggest that the NF-kB/IkB complex, like the Dorsal/Cactus complex, may also function in pattern formation (33, 34).

The central feature of the Dorsal protein is a multifunctional region termed the Rel homology **domain**. This region mediates the binding of Dorsal to itself, to Cactus, to other specific protein pairing partners, and to DNA (6, 20, 35, 36). The Rel homology domain also contains a nuclear localization signal (NLS) that drives translocation of free Dorsal into the nuclei of the syncytial blastoderm (see Nuclear Import, Export). It is thought that Cactus retains Dorsal outside nuclei, not by actively tethering Dorsal in the cytoplasm, but rather by occluding this NLS and thereby blocking nuclear translocation (36).

The Dorsal/Cactus complex consists of a dimer of the *Drosophila* transcription factor Dorsal bound to a monomer of its cytoplasmic inhibitor, Cactus (37). Complex formation requires an interaction between the Dorsal Rel domain and a set of six tandemly arrayed motifs in Cactus. These motifs, termed ankyrin repeats, are found among proteins of widely varying function and have been shown to serve as sites of protein–protein interaction. Interaction with Dorsal requires all of the ankyrin repeats in Cactus (5, 6). Carboxy-terminal to the ankyrin repeats is a **PEST domain** . PEST domains, rich in the amino acid residues proline, glutamine, serine, and threonine, are found in many proteins whose activity is regulated by proteolysis.

Two regions of Cactus govern its susceptibility to degradation (7-9). The PEST domain influences the overall stability of Cactus, whereas a motif amino-terminal to the ankyrin repeats is specifically required for degradation in response to Toll-mediated signaling. The activities of both sites appear to be regulated by phosphorylation (8, 9, 38). Similar sites govern the proteolysis of the IkB proteins, for which it has been directly demonstrated that phosphorylation of serine residues in the amino-terminal motif triggers a rapid and efficient degradation mediated by the proteasome (39-42).

Dorsoventral Polarity

The establishment of dorsoventral polarity in the *Drosophila* embryo has been the subject of extensive genetic, developmental, and biochemical analyses. At least three different signaling pathways are required for proper dorsoventral polarity, two that are under **maternal control** and a third pathway that requires expression of the genes in the embryo itself. All of these signaling pathways must operate correctly for normal dorsoventral patterning of the embryo.

During oogenesis, the oocyte is surrounded by specialized somatic cells called follicle cells. The follicle cells secrete the various layers of the chorion, or egg shell, during oogenesis. The chorion differs in structure along the dorsoventral axis, showing that the follicle cells have dorsoventral positional information. In addition, the oocyte itself, as well as the resulting embryo, has a dorsoventral polarity. The coordination of dorsoventral polarity between the follicle cells and the growing oocyte involves a signaling pathway of at least 13 different genes and appears to involve signaling from the oocyte to the follicle cells, and then signaling back from the follicle cells to the oocyte (1). That the oocyte sends a dorsalizing signal to the follicle cells is shown by mutations in several genes, including the gurken gene. The *gurken* gene encodes a transforming growth factor a (TGFa)-like protein that must be expressed in the oocyte in order for the follicle cells to make dorsal chorion structures (2). Loss of *gurken* function in the oocyte leads to ventralization of the follicle cells. That the follicle cells in turn send a dorsalizing signal is shown by mutations in the *torpedo* gene. Loss of *torpedo* function in the follicle cells causes the oocyte (and embryo) to be ventralized (3). The *torpedo* gene encodes an **EGF receptor**. Human TGFa has been shown to bind and activate an ectodermal growth factor (EGF) receptor (4), which suggests that *torpedo* proteins in the follicle cell membranes are receptors for *gurken* proteins secreted by the oocyte.

Signaling back from the follicle cells to the oocyte involves another pathway that is conserved in the human immune system. This pathway is the ***dorsal*** pathway in *Drosophila*, and it includes at least 12 maternally acting genes (5). Mutations in 11 of these genes cause the oocyte and resulting embryo to be dorsalized. These are the dorsal group of mutations, because they all seem to function to activate the *dorsal* protein in the embryo (6). The *dorsal* protein is homologous to the NF-kB/rel proteins required for signaling in the human immune system (7). Mutations in the *cactus* gene cause the oocyte and embryo to be ventralized. *Cactus* encodes a homologue of the IkB protein (8), which binds and inhibits NF-kB/rel. *Cactus* appears to bind and inhibit *dorsal* in *Drosophila* (9). The nuclear localization of *dorsal* protein in the embryo initiates the third signaling pathway in dorsoventral patterning in the *Drosophila* embryo.

The third signaling pathway required for dorsoventral patterning in the *Drosophila* embryo is encoded by zygotically active genes, in contrast to the maternal requirements for the first two signaling pathways. This zygotic signaling pathway appears to use the TGFb homologue decapentaplegic (*dpp*) as the dorsal signal. Loss of *dpp* activity in the embryo causes ventralization (10). Another TGFb homologue, *screw*, also appears to be required zygotically for dorsalization of the embryo (11). *Dpp* and *screw* may act synergistically in dorsalizing the embryo, because injection of *dpp* messenger RNA can partially suppress the phenotype of *screw* mutants, and antimorphic *screw* mutations enhance loss of *dpp* activity (11). Three other genes required for dorsalizing the embryo encode homologues of subunits of vertebrate TGFb receptors. These are the genes *punt, thick veins*, and *saxophone* (1). Activation of these receptors by the *dpp* and *screw* proteins appears to activate transcription of the *zerknüllt* (*zen*) gene. *Zen* is a **homeobox**-containing transcription factor that is required for dorsalization of the embryo (12). Thus, dorsoventral polarity in the *Drosophila* embryo begins with a signal from the developing oocyte to the follicle cells, a return signal from the follicle cells to the oocyte confirming dorsoventral polarity, and the final activation of at least one transcription factor in dorsal cells of the embryo.

Dosage Compensation Effect

Dosage compensation is a mechanism by which the activity of X-linked **genes** is made equal in the two sexes of the type XX and XY, in which one sex has two X-chromosomes and the other only one. In placental mammals, marsupials, and some monotremes, compensation is achieved by the inactivation of one X-chromosome in **somatic cells** of females (1). During embryonic development of the mouse, both X-chromosomes are active, and differentiation between the active form Xa and the inactive form Xi occurs in the primitive **ectoderm**. Once inactivation has been initiated at this stage, the same X-chromosome remains inactive in the descendants of each cell after **mitosis** throughout the life of the mouse. Reactivation of chromosome Xi in females occurs at the time of **meiosis**, so that both X-chromosomes are active in oocytes. In male **germ cells**, the single X-chromosome becomes inactive at the late spermatogonial stage.

The chromatin of chromosome Xi is in the condensed state, and its DNA replication begins later than in Xa or in autosomes. The cytosine bases of CpG Islands near the 5′ **promoter** regions of genes are heavily methylated on chromosome Xi, but not on Xa (2) (see Methylation, DNA). Differential hypersensitivity to digestion by **deoxyribonuclease** indicates altered binding of proteins to the DNA and different packaging of nucleosomes in the two X-chromosomes (3).

During studies of translocations between the X- and autosome chromosomes in mice, it was observed that only one of the two X-chromosomes undergoes inactivation which spreads from the inactive segment into the attached autosomal material. It appears as if an inactivation center existed on the X-chromosome, which becomes blocked on one X-chromosome (which becomes Xa) only at the time inactivation is initiated. The location of the inactivation center has been accurately mapped in human and mouse from studies of chromosomal translocations and deletions. A gene, called *XIST* in humans and *Xist* in the mouse, maps in the region of the inactivation center and is expressed by Xi but not by Xa (4). In the male, *Xist* is expressed only in the testis, suggesting a role in inactivation of the single X-chromosome in male germ cells. No protein product of *Xist* or *XIST* has yet been identified.

In **Drosophila** *melanogaster*, where X-chromosome is not inactivated, both X-chromosomes are transcribed in females. Compensation occurs by up-regulation and a doubled rate of transcription of the single X-chromosome in males. As a result, the level of transcription of the genes carried by the X-chromosome is the same in both sexes. The increase in the rate of transcription in males is caused by binding of transcription factors, called *msl-1*, *msl-2*, and *msl-3*, to *enhancer* elements on the X-chromosome. These transcription factors appear to act at the level of the chromatin structure and have been extensively studied in the polytene salivary gland chromosomes, where they bind codependently to the same set of sites along the male X-chromosome. Molecular characterization of the protein coded by *msl-2* has to a great extent solved the question of how *msl*-mediated dosage compensation is restricted to males. Cloning and molecular analyses of the *msl* genes have substantiated the proposal that the MSL proteins function as a multimeric complex to mediate dosage compensation (5), (6).

In the nematode **Caenorhabditis elegans**, equalization of transcription seems to occur by down-regulation in XX animals.

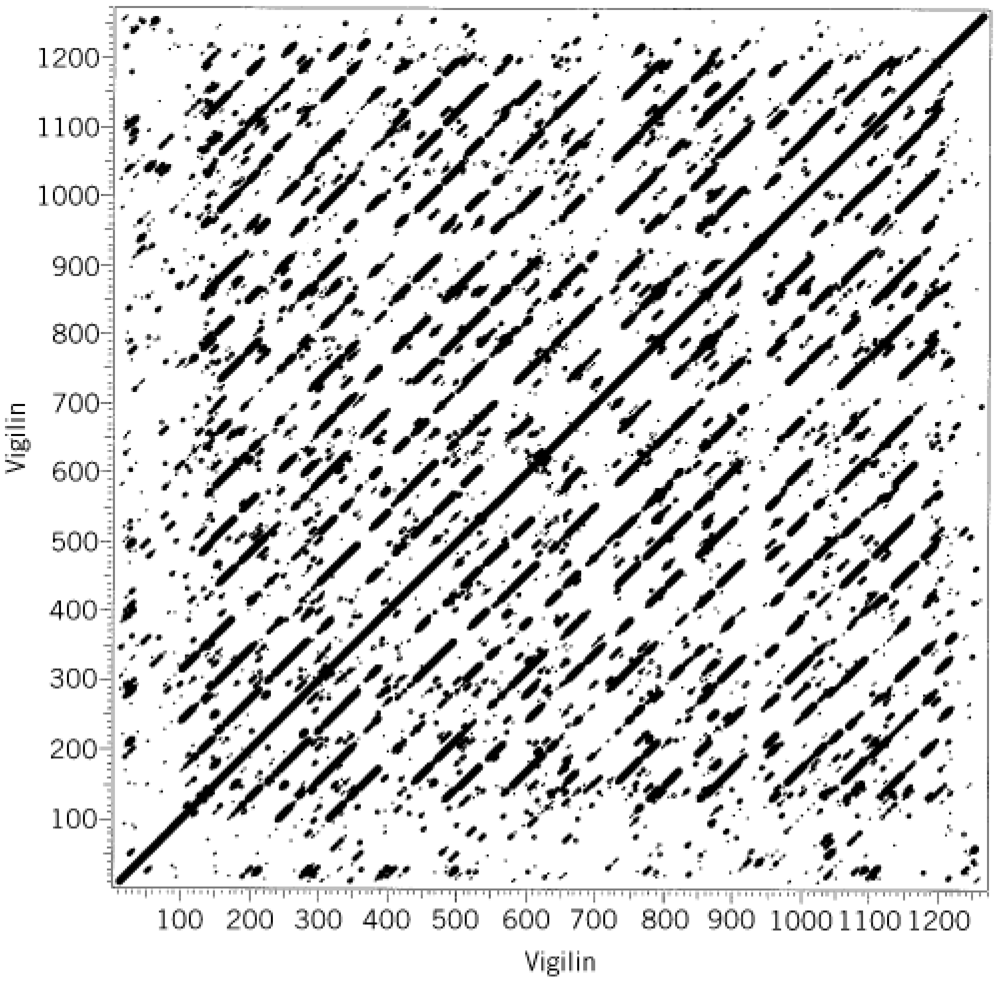
Dot Plot

The dot plot, introduced by Gibbs and McIntyre (1), is a two-dimensional visual comparison method, useful for revealing regions of similarity between pairs of sequences or structures (2). Typically, the *X* axis represents one sequence and the *Y* axis represents the other. Every point in the plot is then scored for the similarity of the residue in sequence X with the similarity of the residue in sequence Y, and the point is plotted if the residues are scored as similar in a residue substitution matrix. Diagonal lines in the plots then indicate regions where consecutive residues are scored as similar. Insertions and deletions (Indels) are revealed by termination of a diagonal segment, followed by initiation of a new but offset diagonal. To improve the signal-to-noise ratio, it is usual to sum the scores in short windows spanning each residue: overall, fewer points are plotted, but divergent matches with rather few identities can be revealed. Cutoffs determining which points are plotted may be set using a variety of heuristic or probabilistic measures. The "double matching probability," introduced by McLachlan (3), is an estimate of the likelihood that the given score would arise by chance in two infinitely long sequences and is widely used to provide the scale for plotting points. The user can then choose the significance level cutoff to determine which points to plot.

Dot plots can reveal recurring similarities within a sequence by self-comparison. In this case, repeated sequences appear as a series of off-center partial diagonals. Tandem Repeatsresult in a regular set of diagonals, consecutively decreasing in size by one repeat, moving away from the central diagonal (Fig. 1). Dispersed repeats also provide dispersed diagonals, one between each repeat element.

Figure 1. Dot plot showing 15 tandemly repeated KH domains in the chicken vigilin sequence. The larger the dots, the higher the matching segment score. A break in the diagonals spanning position 940 indicates a ~ 40-residue insertion in one of the domains.



Dot-plot self-comparisons can be used to reveal elements of double-stranded secondary structure in folded RNAs. In the simplest case, points are plotted whenever a pair of residues are able to **base pair**. More sensitive dot-plot algorithms use energy rules based on base pairing, base stacking, bulging, and looping, allied to dynamic programming algorithms (4). Therefore diagonals indicate runs of complementary residues able to form double helices . Looped out *bases*, which often occur in *RNA secondary structure*, are indicated by short offsets in consecutive diagonals.

Another variety of dot plot (5) may be used to compare two protein tertiary structures for regions of similarity, although interpretation is more complex. In this case, the plotted points typically represent distances between Ca carbons, so the plots are also known as distance plots or contact maps. Characteristic recurring patterns indicate **secondary structure** elements such as a-helices and b-strands. Long-range contacts are distributed irregularly in the plot. A useful automatic method to detect structural similarities by analyzing and superposing sets of self-contact plots has been implemented in the program Dali available on the WWW (6).

Dot plots are sometimes used in other ways for presenting sequence or structure information. For example, contact plots are a convenient way to summarize the residue contacts revealed in a structural investigation by nuclear magnetic resonance (NMR).

Double Minute Chromosome

Double minute chromosomes (DMs) are generated as a consequence of DNA **amplification**, which is a large increase in the numbers of a specific gene and its adjacent DNA on either side, because of their selective replication. Some types of amplification result from specific developmental requirements, such as the synthesis of multiple copies of the large ribosomal RNA genes in *Xenopus laevis* **oocytes** (1). This amplification of ribosomal RNA genes meets the enormous needs for ribosomal synthesis during *Xenopus* oogenesis. More typically, DNA amplification of the type that leads to the appearance of DMs occurs as part of an environmental **stress response** in cells in culture.

Tissue culture cells exposed to a toxic substance, such as those used in cancer chemotherapy, often eventually become resistant to the substance. One way of achieving a resistant state is to amplify a gene whose product metabolizes the toxic substance into a safer nontoxic form. A typical example is the amplification of the gene encoding dihydrofolate reductase (DHFR), an enzyme involved in thymidine synthesis, in response to methotrexate, which is an inhibitor of DHFR synthesis (see Aminopterin, Methotrexate, Trimethoprim, and Folic Acid). Amplification of the DHFR gene can also be stimulated in response to other environmental conditions, such as UV light and hydroxyurea (2).

Two visible manifestations of the amplification process occur at the chromosomal level. One is the appearance of extended regions in the chromosome known as homogeneously staining regions (HSRs), whose staining characteristics differ from those of normal chromosomal. These HSRs are the sites of DNA amplification (3). The second visible change in chromosomal material is the appearance of DMs that contain the same amplified DNA, but have become extrachromosomal. The relationship between DMs and HSRs is not completely clear, but it is likely that DMs are unstable precursors of HSRs. Human primary tumors contain DMs 90% of the time, 7% contain HSRs, and 3% contain both DMs and HSRs. When cell lines are grown for extended periods of time under drug-resistant conditions, greater numbers of HSRs appear and fewer DMs are found.

DMs are basically **acentric** extrachromosomal elements that are small fragments of chromosomes. Each DM contains between 1 to 2 megabase pairs of DNA and can replicate itself. Therefore DMs function as minichromosomes . The physical organization of the DNA is that of a **supercoiled** circle (4). Because DMs are acentric they are progressively lost during **cell division**, unless they replicate multiple times in any cell cycle. In general they segregate randomly between daughter cells at **mitosis**, leading to unequal numbers in daughter cells. As many as 20 DMs containing DHFR DNA are found in some methotrexate-resistant **cell lines**. **Oncogenes** might also be present in the amplified DNA of DMs and HSRs. For example, the *c-Ki-ras* oncogene is amplified more than 30-fold in DMs and HSRs in certain adrenocortical tumor cell lines (5). Double minute chromosomes are important indicators of abnormal cellular behavior, and they may well reflect an advanced stage of malignancy.

Downstream

Nucleotide sequence elements located downstream from protein-coding sequences are defined by the direction of transcription. They are primarily involved in termination of transcription and in messenger RNA (mRNA) processing, in particular, polyadenylation. Prokaryotic terminators typically have runs of T at the termination point, preceded by complementary symmetrical sequences, which provide the potential for formation of hairpin structures at the ends of the mRNA (1). The hairpins presumably cause transcription to pause, a phenomenon known as **attenuation**, before the complete arrest.

The mechanism of transcription termination in eukaryotes is not fully understood (2, 3). There are usually many alternative locations for the termination points for the same gene, within a downstream region as large as several thousand bases. It appears that, in a manner similar to that in prokaryotic terminators, transcription elongation in eukaryotes first slows down, due to formation of secondary structure in the mRNA, and then terminates within a nearby U-rich sequence (3). At the noncoding 3′-end of newly formed eukaryotic RNA transcripts several polyadenylation signals usually exist with the **consensus sequence** AAUAAA. One of these sites (but not always the same in different rounds of transcription of the same gene) is somehow selected for the RNA cleavage, which occurs about 20 bases downstream from the site, and for subsequent polyadenylation of 3′-end of the mRNA. Polyadenylation of mRNA is also known in prokaryotes, although it is not as site specific or extensive as in eukaryotes (4).

The eukaryotic downstream sequences—in particular those located within 3′-ends of the RNA transcripts—are also involved in many external functions. For example, they can act in *trans* and control the efficiency of the, stability, and compartmentalization of an mRNA (5).

Drosophila EGF Receptor

Processes of cell–cell interaction are the key to development of distinct cell and tissue fates in embryonic and postembryonic stages. Focusing on signaling pathways triggered by transmembrane receptors provides molecular clues to these events. In addition, genetic approaches allow the identification of signaling elements in the pathway and provide the hierarchy. For every pathway triggering morphogenesis, it is necessary to understand how signals triggering the pathway are initiated in a defined point in space and time, and how these signals spread to activate the receptor in neighboring cells. It is also crucial to know how different levels of signaling by the receptor are translated to distinct patterns of gene expression and, finally, which mechanisms are employed to restrict or terminate signaling.

The *Drosophila* epidermal growth factor (EGF) receptor is a case in point. Only a single receptor of this family has been identified in the *Drosophila* genome. This receptor carries out an extremely diverse array of functions throughout development. In all cases, a conserved signaling "cassette" is utilized. The signaling elements identified thus far constitute a robust signaling system that leads to reproducible patterning, in spite of possible variations in the levels of individual components.

1. Components

1.1. Receptor
The EGF receptor of *Drosophila* shows a high degree of sequence homology to its vertebrate counterparts, in both its intracellular **tyrosine-kinase** domain and its extracellular ligand-binding domain (1, 2). The receptor is expressed ubiquitously throughout most stages of development. Thus, local activation of the pathway must be regulated by other means.

1.2. Ligands
The singularity of the receptor in *Drosophila* is compensated by several ligands that confer different aspects of regulation. The primary activating ligand is called Spitz. It is a protein containing a **signal sequence**, a single EGF motif, a putative dibasic cleavage signal, and a **transmembrane**, and a cytoplasmic **domain** (3). This structure is reminiscent of transforming growth factor a (TGFa), an activating ligand of the vertebrate EGF receptor. Like the receptor, the precursor form of Spitz is ubiquitously expressed. However, because the precursor form is inactive, this does not lead to receptor activation. The key to receptor activation is the **proteolytic** processing of Spitz, to release the secreted form containing the EGF motif (4). Although the precise regulation of this cleavage is still unknown, components regulating it will be described below. Secreted Spitz is a very active ligand, and its misexpression leads to dramatic changes in cell fates through high levels of activated MAP kinase.

A second activating ligand is Vein, which contains a signal peptide, a single EGF motif, and an immunoglobulin domain (5). Vein is secreted constitutively and is a weaker ligand; its absence or misexpression do not induce dramatic changes in cell fates. While in some contexts Vein functions as a single ligand (6), in other cases it appears to cooperate and complement Spitz in the same tissues.

A third activating ligand is Gurken, encoding a protein with an overall structure similar to Spitz (7). There is no evidence that Gurken must be cleaved in order to be active. Gurken expression and activity are restricted to the female ovary, where it is responsible for inducing initially the posterior cell fates of the follicle cells covering the oocyte, and subsequently the dorsal cell fates. The expression of Gurken, and especially the localization of its messenger RNA in the proximity of the oocyte nucleus, is highly regulated.

Finally, a fourth ligand is Argos, encoding a secreted protein with a signal peptide and a single EGF motif (8). In contrast to the other ligands, Argos is an inhibitory ligand. Its expression abolishes the capacity of the receptor to respond to activation by Spitz (9). Transcription of Argos is induced by the activated EGF receptor pathway, thus constituting an inhibitory feedback loop (10).

1.3. Accessory Signaling Molecules

Among the mutants that displayed a phenotype similar to *spitz* were the genes *rhomboid* and *Star*, encoding novel transmembrane proteins with multiple and single transmembrane domains, respectively (11-13). A variety of observations suggest that these two proteins regulate the processing of Spitz. Ectopic expression of secreted Spitz can overcome the *rhomboid* and *Star* mutant phenotypes (4). In addition, Rhomboid and Star can function nonautonomously; namely, their expression in one set of cells will give rise to activation of the EGF receptor pathway in neighboring cells, consistent with their capacity to induce a diffusible signal (14). How Rhomboid and Star contribute to Spitz processing is an open question, as they have no **proteinase**-homology domains. Rhomboid homologues have been identified in Caenorhabditis *elegans* and humans, raising the possibility that the same molecules may be regulating ligand processing in other species.

The clue to the dynamic activation pattern of the EGF receptor pathway seems to lie in the expression pattern of Rhomboid. It is possible to follow the activation of the EGF receptor pathway, as well as that of other tyrosine kinase receptors, by an antibody directed against the activated (double **phosphorylated**) form of MAP kinase. The pattern induced by EGF receptor activation can be identified, and it disappears specifically in mutants for the EGF receptor, *spitz*, *rhomboid*, or *Star*. This pattern follows precisely the expression of *rhomboid* (15).

2. Biological Example of Single Signaling Burst: The Embryonic Ventral Ectoderm

The earliest function of the EGF receptor pathway in the embryo entails the induction of ventral ectodermal cell fates. Following gastrulation, a group of ~ 8 cells on each side of the ventral midline are designated as neuroectodermal cells. Within this region, different rows of cells assume different fates, through activation of the EGF receptor pathway. The capacity of the pathway to induce graded fates stems from the fact that the activating signal, secreted Spitz, emanates from a single row of cells, the midline glial cells, positioned at the ventral midline (14). Diffusion of the ligand to neighboring cells generates graded activation of the pathway, which can be visualized by the distribution of activated MAP kinase (15).

The ectodermal cells respond differently to the varying levels of EGF receptor activation. The cells closest to the source of the ligand, induce a dual response. On the one hand, MAP kinase phosphorylates and inactivates the **transcriptional** repressor Yan, an ETS domain protein. On the other hand, MAP kinase induces the transcription of Pointed P1, an ETS domain transcriptional activator. This leads to the transcription of Pointed P1-target genes in the cell row closest to the midline (16). The transcriptional responses of the cells lying further from the midline are not known.

A central target gene for Pointed P1 is *argos*. Thus, activation of the EGF receptor leads to the production of Argos protein, which diffuses to neighboring cells and reduces the level of signaling in these cells, maintaining the EGF receptor activation gradient. This system is very robust.

Reproducible patterning of the ventral ectoderm is obtained, regardless of the absolute levels of secreted Spitz. As long as Spitz is emanating from the midline and induces the inhibitor Argos in the cells receiving maximal signaling, the pattern will be generated correctly. EGF receptor signaling in the ventral ectoderm is illustrated schematically in Figure 1.

Figure 1. Signalling by the EGF receptor pathway in the embryonic ventral ectoderm. (**a**) Scheme of embryonic cross se
midline cells, positioned in the center of the ventral ectoderm. (**b**) (1) The fate of the midline cells is determined by the tı

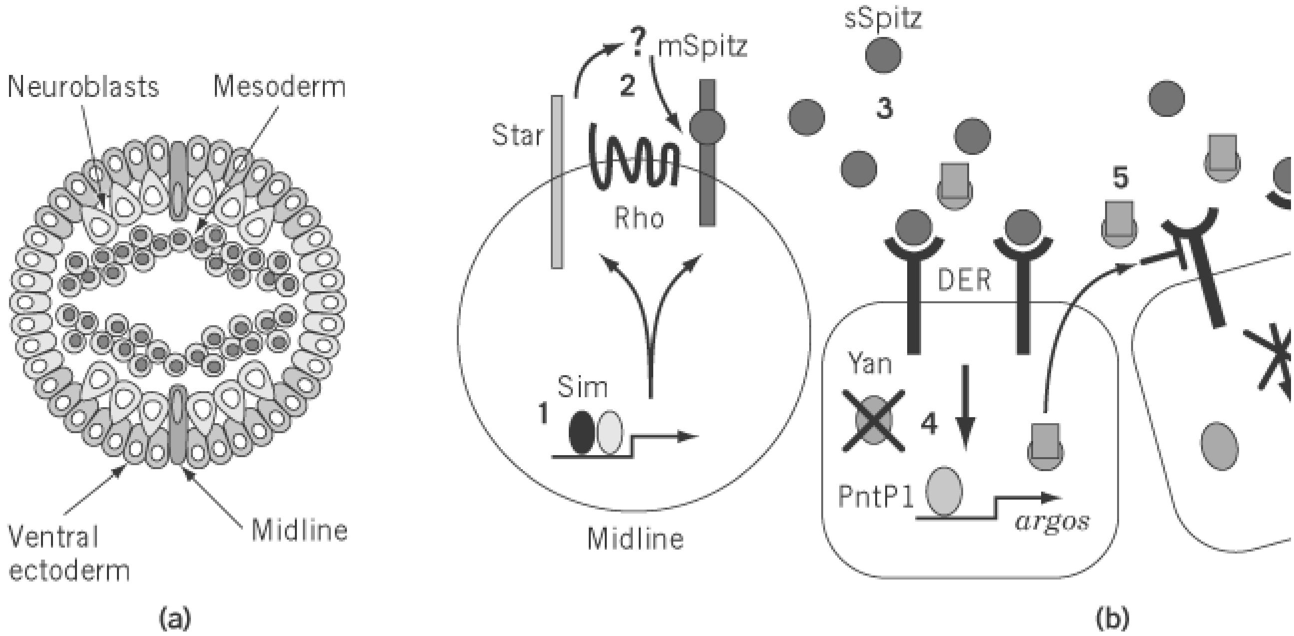
reduction or termination of receptor activation in the lateral cells.



3. Multiple Bursts of Signaling: The Ovary and Eye

The above example represents a simple case, in which the pathway is only activated once. More complicated scenarios involve multiple activation cycles of the pathway in the same tissue, each time leading to different consequences. In the ovary, signaling from the oocyte to the surrounding follicle cells determines the polarity of these cells. Initially, when the egg is small and the oocyte nucleus is positioned at the posterior end, localized Gurken, a ligand for the EGF receptor, will trigger posterior cell follicle cells fates (17, 18). Subsequently, the oocyte nucleus migrates to the future dorsal anterior corner of the oocyte. Activation of the receptor by Gurken at this stage leads to the induction of dorsal follicle cell fates (19). Finally, Induction of Rhomboid expression by the EGF receptor pathway leads to a third cycle of activation by allowing processing of a ligand expressed in the follicle cells (possibly Spitz), this time patterning specific follicular structures called dorsal appendages (20). It should be noted that the final cycle of activation of the receptor was obtained by inducing Rhomboid.

This aspect becomes even more dramatic in the induction of photoreceptor cell fates in the developing eye. The first photoreceptor in each ommatidium R8 is induced independent of the EGF receptor pathway. This cell serves as a source for secreted Spitz, which will activate the receptor in neighboring cells and induce the first cohort of photoreceptors (21, 22). These newly induced cells will now also produce Argos, which prevents the signal from progressing further. It seems that the differentiating cells also express the processing machinery for Spitz, and thus induce a new round of activation. This continues for several cycles, inducing first distinct sets of photoreceptor cells and subsequently cone or pigment cells.

In conclusion, an amazingly diverse set of roles is fulfilled by the EGF receptor pathway, only a sample of which were mentioned above. They include the induction of cell fates in different contexts, as well as cell proliferation (eg, in the wing imaginal disc). In most cases, a common signaling pathway is used, both upstream and downstream of the receptor. This raises the question of specificity. It is clear that the induction of MAP kinase signaling cannot determine the final outcome. Rather, in different cell types, the same pathway induces different responses, depending on the repertoire of transcription factors that are responsive in that tissue. Differential regulation of the receptor itself appears to be directed by the multiplicity of ligands, being regulated in different ways in terms of their expression or localization, or conferring varying levels of activation.

Drug Resistance

The resistance of cancer cells to cytostatic agents has been a significant impediment to the effective chemotherapy of cancer. Studies with model systems, where cancer cells grown *in vitro* were selected for resistance to specific anticancer drugs, identified two major classes of drug-resistant cells: (i) cells resistant to a single class of drugs with the same mechanism of action, and (ii) cells resistant to chemically diverse drugs with multiple mechanisms of action. The latter phenomenon was called multiple drug resistance (MDR). Some metastatic cancers are intrinsically resistant to chemotherapy, whereas others respond to treatment initially but subsequently acquire resistance, not only to the chemotherapeutic agents used against them, but to other chemically unrelated drugs as well (1). Numerous factors have been associated with MDR. These include elevated levels of protein kinase C, enhanced sodium pump activity, mutations of topoisomerase II and tubulin, and altered levels of calcium and calmodulin. It has not been possible, however, to correlate any of these clearly with the MDR **phenotype**. A large body of evidence, on the other hand, derived from studies of cells in culture, transfection experiments, histochemical studies of a wide variety of tumors graded for resistance to chemotherapy, and studies in reconstituted systems, strongly implicates energy-dependent pump systems that either exclude or extrude chemotherapeutic agents from MDR cells.

Besides human cancer cells and their rodent models, MDR pumps have been found in a wide array of organisms: bacteria, protozoa, and fungi, and mammalian cells; even plant cells have MDR pumps. These share the unique feature of excluding a fairly broad range of chemically unrelated compounds from the cell. Only some of these belong to the ATP Binding Cassette (ABC) superfamily of transporters, and they do not ubiquitously use ATP as their energy source. The majority of the bacterial pumps, for example, use the energy of the proton motive force. The ATP-dependent system that has been most extensively characterized is the *MDR*1 gene product, the multidrug transporter or P-glycoprotein (P-gp).

Many cells selected for drug resistance do not show increased levels of P-gp but nonetheless are resistant to a broad range of natural product drugs. Another member of the ABC superfamily, the MDR-associated protein (MRP1), is expressed in some of these cell lines at elevated levels. MRP1 is similar to P-gp in that it is capable of decreasing intracellular levels of drugs and is ATP-dependent. While P-gp has two membrane-spanning domains, MRP has three. The presence of a third such domain is observed in several other ABC proteins, all of which are more closely related to MRP than to any other member of this superfamily of transporters. There are now at least a dozen ABC proteins that together constitute the MRP branch of the superfamily. The most important members are (i) the human MRP, which is an anionic conjugate transporter, (ii) the multispecific organic anion transporter, MOAT or MRP-2, and (iii) SUR1, the sulfonylurea receptor. There are other significant differences between MRP and P-gp: (i) MRP1 catalyzes the efflux of anionic or neutral drugs conjugated to glutathione, glucoronate, or sulfate; (ii) some substrates of P-gp, eg, taxol, are not substrates for MRP; (iii) MDR effected by P-gp is reversed by verapamil and cyclosporin A, but not that caused by MRP. It is thus quite likely that both P-gp and MRP are drug transporters but that their detailed mechanisms of action may differ (2).

Additionally, a 110-kDa protein, the lung resistance protein, has been identified in non P-gp-resistant lung carcinoma cells. This protein is a major constituent of an intracellular ribonucleoprotein (vault) complex that consists of three other proteins of 210 kDa, 190 kDa, and 54 kDa, plus an RNA molecule. There is increasing evidence that the vault complex is involved in MDR (3).

Duplication, Chromosomal

There are numerous types of chromosomal duplications. Each chromosome itself is duplicated during the **S-phase** of the normal cell cycle. There are also various duplications that arise from chromosome breakage and reunion cycles (see Dicentric Chromosome), which might be an important contributory factor in the evolution of genomes. There are also duplication events that encompass whole genomes. In the frog *Xenopus laevis*, different species have evolved that contain multiple sets of related chromosomes. This is called **polyploidy**. *Xenopus tropicalis* is the progenitor **diploid** species, whereas *Xenopus laevis* is pseudotetraploid (1). Although many duplicated genes are silenced, genes that remain active often show tissue or developmental differences in activity. Thus specialized gene family members may arise by both genomic duplication and by genetic duplication (see Contiguous Genes). Other examples of chromosomal duplication result from gene **amplification** (see Double Minute Chromosome).

Chromosomal duplication occurs through a variety of mechanisms, some that operate in evolutionary time, and others that occur in specialized cells during development or in response to environmental stress. The most common form of chromosomal duplication results from unequal sister chromatid exchange. This is caused by misalignment of two sister chromatids during **prophase** followed by **reciprocal recombination**, which duplicates one chromosome, whereas the other has a deficiency. Amplification of the large 18 S and 28 S ribosomal RNA genes in *Drosophila melanogaster* might occur through many reiterations of events of this type (2). It is also possible that the presence of thousands of short interspersed nuclear elements, such as **Alu** repeats or the long interspersed nuclear element (**LINE**)-1 in mammalian chromosomes, might lead to many misalignments and chromosomal duplications.

Gene amplification is another form of local chromosomal duplication. In cultured cells, treatment with methotrexate and hydroxyurea results in multiple replicative cycles of the **dihydrofolate reductase** (DHFR) gene. The molecular mechanisms controlling this overreplication of the DHFR gene are not understood, but it is assumed that the replicative process leads to the generation of free

DNA ends that then undergo homologous recombination (3). If the over-replicated DNA circularizes, double minute chromosomes are formed.

Chromosome duplication also occurs following modification of chromosomeal behavior during the cell cycle. Normally the DNA in chromosomes replicates once during **S phase**. If multiple replicative cycles occur, however, then duplicated chromosomes can coexist in the same somatic cell nucleus. If the chromosomes separate, the cell is called endopolyploid. If the chromosomes do not separate, polytene chromosomes are formed. This repeated replicative process is called endoreduplication (4). Endopolyploid cells and those containing polytene chromosomes never divide, so they represent, a somatic dead end or a state of terminal differentiation, respectively.

Dynactin

Dynactin is a large protein complex that is important for the function of cytoplasmic dynein in intracellular motility (see Motor Proteins). Dynactin was first identified as a protein complex that stimulates dynein movement of membranous organelles along microtubules (1). It has been proposed that dynactin functions to bind cytoplasmic dynein to its membranous organelle cargo. Work in diverse species from fungi to mammalian neurons suggests that an alternative function of dynactin is to link cytoplasmic dynein to the actin cortex for the movement of microtubules (2).

The backbone of the dynactin molecule is a short (~40nm) filament composed of 8 to 12 molecules of actin-related protein 1 (Arp1) (3). Arp1 shares many of the binding domains of actin, including the spectrin, myosin, and villin binding sites. Actin-capping protein is bound to one end of the dynactin filament, and a unique capping protein is located at the other end. The p150^{Glued} subunit projects from the filament. This protein is the product of the *Glued* gene of *Drosophila*, and it binds both microtubules and the intermediate-chain subunit of cytoplasmic dynein. Overexpression of another major subunit of dynactin, p50, obstructs assembly of the dynactin complex, and thus it is named *dynamitin* (4). Overexpression of p50 disrupts localization of both dynein and dynactin to membranous organelles or kinetochores. Genetic studies indicate that dynein and dynactin act in the same pathways (5).

Dynamic Light Scattering

Dynamic light scattering (also known as photon correlation spectroscopy) from particles in solution can be used to deduce information about the size, shape, and dynamics of biological macromolecules and supramolecular assemblies. Structural analysis of individual biomolecules, conformational transitions, and intermolecular interactions can also be probed. The major use of dynamic light scattering in biology is the rapid determination of the translational diffusion constant for macromolecules in solution. The interpretation of **diffusion** constant data is frequently strengthened by combination with other information from methods, such as electron microscopy, static light scattering, and neutron or X-ray small-angle scattering. Biological systems are well-suited to study by dynamic light scattering, because they are generally large enough to be strong scatterers at low concentrations and their diffusion constants are such that they give rise to autocorrelation functions that can be readily measured. Dynamic light scattering measurements have been used for studying objects ranging in size from proteins as small as 6000 Da to intact cells as large as micrometers.

1. Theory of Dynamic Light Scattering

Dynamic light scattering measures light scattering intensity fluctuations in a small volume of a sample. For small proteins (~25kDa) these fluctuations are on the microsecond timescale, while for cells they are in milliseconds. The fluctuations are related to the Brownian motion of the particles giving rise to density fluctuations caused by variations in the number of molecules in the scattering volume and random agglomerations. This measurement in the time domain is related to the spectral density of the fluctuations in the frequency domain by a Fourier transformation. In practice, diffusion coefficients are determined using an autocorrelation function that is measured by accumulating the product of the number of photons arriving at the detector from successive time intervals. This operation is repeated thousands of times and averaged. The intensity autocorrelation function, $G_2(t)$, is obtained by storing the average products $I_{t'}I_{t+t'}$, where t is an incremented time delay, in successive channels to yield

$$G_2(t) = \langle I_{t'} \cdot I_{t+t'} \rangle \tag{1}$$

For a solution of macromolecules, assuming a Gaussian distribution of fluctuations, $G_2(t)$ is related to the scattered electric field autocorrelation function $G_1(t)$ by

$$G_2(t) = \langle I^2 \rangle + G_1(t)^2 \tag{2}$$

For translation diffusion of monodisperse particles that are small with respect to the incident wavelength, l:

$$G_2(t) = A + Be^{-2\Gamma t} \tag{3}$$

where A and B are constants that depend upon experiment geometry, and

$$D = \frac{\Gamma}{Q^2} \tag{4}$$

D is the translational diffusion coefficient, and G is the reciprocal of the characteristic decay time,

$$Q = \frac{4\pi \sin\left(\frac{\Theta}{2}\right)}{\lambda} \tag{5}$$

where O is the scattering angle. For a continuous polydisperse system, equation (4) is integrated over all sizes, and hence G values, to give

$$G_1(t) = \int G(\Gamma) e^{-\Gamma t} d\Gamma \tag{6}$$

where G(G) is a distribution function that can be evaluated.

Rotational diffusion and internal dynamics can also influence the autocorrelation functions measured in a dynamic light scattering experiments. The internal dynamics of a macromolecule in solution become important only if the amplitude of the motions is not very much smaller than the wavelength of the light. For large motions, different parts of the sample molecule will scatter out of phase, and the internal dynamics will contribute one or more relaxation times that will contribute to the decay of the autocorrelation function in a single or multiple-exponential fashion.

1.1. Examples of Dynamic Light Scattering Applications

The transcription, translation, and replication of genetic information contained in the sequences of DNA is controlled by interactions of proteins with DNA and with RNA. These interactions can be probed using dynamic light scattering. For example, the enzyme DNA gyrase (see **Topoisomerases**) catalyzes the ATP-dependent **supercoiling** of DNA. The diffusion constant for DNA gyrase measured by dynamic light scattering (1) is significantly smaller than expected based on its molecular weight, and binding of DNA to the gyrase produces no change in the diffusion constant, indicating that there is no overall conformational change. These observations, combined with parallel small-angle neutron scattering experiments to determine radius of gyration values for the gyrase and its complex with DNA, have led to the conclusion that the gyrase has grooves on its surface to accommodate the DNA in a very compact complex.

Dynamic light scattering has played a role in drug development. The pharmacological effects of drugs can depend upon their behavior in solution and the characteristics of aggregates they may form (2). Lipids can be used to “solubilize” drugs that may be insoluble in aqueous media, and hence enhance their transport and efficacy. Dynamic light scattering has been used to evaluate aggregation behavior of antidepressants (3), critical micelle concentrations, and sizes of micelles designed to encapsulate the drug Indomethecin (4), as well as to evaluate how the opiate drug loperamide alters the temperature-induced phase transition of phosphatidylcholine vesicles (5).

Dynamic light scattering has also been used to monitor the assembly of enveloped **viruses**. Lyles et al. (6) used a combination of dynamic and static light scattering with stopped flow to study matrix protein binding to nucleocapsids of vesicular stomatitis virus. Dynamic light scattering has recently become a common tool for assessing the crystallizability of macromolecules and macromolecular assemblies (7, 8). Because modern molecular biology techniques have provided sufficient amounts of pure materials, dynamic light scattering can be used automatically to “screen” large numbers of crystallization conditions to determine diffusion constants and hence evaluate possible aggregation states that inhibit crystallization.

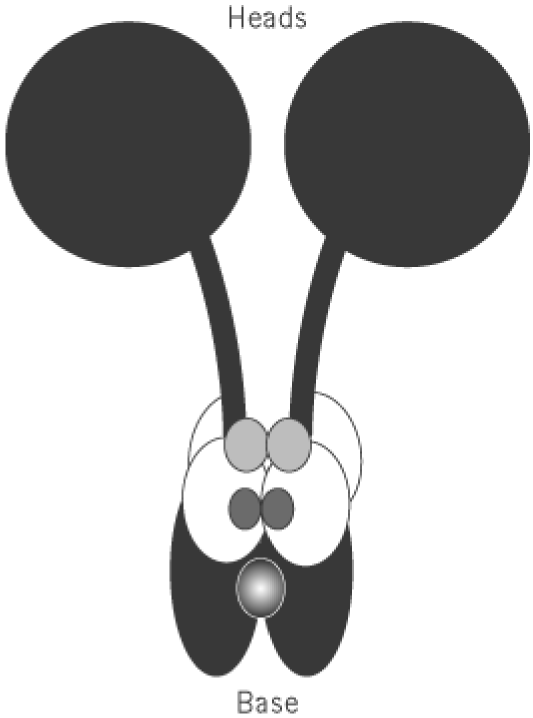
Dynein

Dyneins are **microtubule**-based motor proteins that use the energy released by the hydrolysis of ATP to move toward the minus end of a microtubule. The dyneins are classified as either cytoplasmic or flagellar (also known as axonemal), and the flagellar dyneins are further divided into outer and inner arm dyneins. The first dyneins to be identified were the flagellar dyneins, which are the arms that project from the A microtubules of **ciliary** and flagellar axonemes. Flagellar dyneins generate the sliding force between microtubules that is the basis for the propulsive bending of flagella (and cilia) that moves cells through fluids. Cytoplasmic dyneins move membranous organelles and kinetochores along microtubules and assist in assembling the mitotic spindle. Each dynein is a large molecular complex, composed of one or more large polypeptide chains of ~500kDa, known as heavy chains, and various accessory intermediate chains (50 to 140 kDa) and light chains (8 to 45 kDa). Often the heavy chain alone is referred to as a dynein. An ~350kDa portion of each heavy chain forms a large globular head **domain**, and the rest of the heavy chain extends from the head as a thin flexible stalk. The globular head contains the motor part of the molecule, the microtubule-binding site, and the ATP hydrolysis region. Two or three dynein heavy chains are often connected by their thin stalks to a common base. The base is made up of the intermediate and light chains, which are important for binding dynein to the organelles that it transports (its cargo).

There are at least 12 different flagellar dynein heavy-chain **genes**. To date, only two uniquely cytoplasmic dynein heavy-chain genes have been identified. The major cytoplasmic dynein (Fig. 1) has a native molecular weight of 1.5×10^{6}Da and contains two identical heavy chains associated with two 74-kDa intermediate chains, four 55-kDa light intermediate chains, and light chains of 22, 14, and 8 kDa. The heavy chain of this dynein is encoded by one gene, but multiple genes have been identified for the intermediate and light intermediate chains and for the 14-kDa light chain. The heavy chain of the minor cytoplasmic dynein is encoded by a unique gene, but the intermediate or light chains, with which it is presumed to be associated, have not yet been identified. Unlike cytoplasmic dynein, flagellar outer arm dyneins have two or three different heavy chains. Inner arm dyneins are either heterodimers or monomers of heavy chains and have various accessory polypeptides.

Figure 1. Schematic representation of the overall structure of a cytoplasmic dynein.



Structural analysis of the heavy-chain motor domain indicates that the head is made up of seven lobes arranged in a ring surrounding a central cavity (1). Each heavy chain has four consensus **nucleotide-binding sites** known as P loops. The first P loop, P1, is believed to be the site of ATP binding and hydrolysis for force generation (2). The role of the other P loops is unknown. In the presence of vanadate, the heavy chains are cleaved by UV photolysis into two fragments at the first P loop. The different types of dynein hydrolyze MgATP at different rates. Dyneins can be attached to glass coverslips via their bases and their heads will bind microtubules. Using computer-enhanced video microscopy, it can be observed that this bound dynein translocates microtubules across the coverslip in the presence of ATP. The velocity of cytoplasmic dynein microtubule movement *in vitro* is ~1micron/second.

Flagellar dyneins attach via their base to one of the outer doublet microtubules (the A microtubule) of the axoneme and bind directly to tubulin or to other axonemal microtubule-binding proteins. Their head domains bind to the B microtubule of the neighboring outer doublet in an ATP-sensitive manner and use the hydrolysis of ATP to push them toward the tip of the axoneme. Cytoplasmic dyneins bind to other cellular organelles. The mechanism by which dynein binds to these organelles is unknown. However, cytoplasmic dynein binds directly to artificial lipid membranes, liposomes, so dynein may bind directly to the organelle (3). There is also evidence, however, that an accessory protein complex, dynactin, is also important for cytoplasmic dynein binding to cargo (4). One dynactin subunit binds the dynein intermediate chain *in vitro*. Although they bind to different cargoes, cytoplasmic and flagellar outer arm dyneins have closely related cargo-binding subunits, the intermediate chains. The C-termini of the intermediate chains are conserved, and it is believed that they interact with the heavy chains. It is thought that the distinct intermediate-chain N-termini allow binding to different cargoes (5). Deletion of the cytoplasmic dynein heavy chain is lethal in multicellular organisms. Nonlethal mutations of cytoplasmic dynein heavy and light chains lead to axonal pathfinding defects and other pleiotropic **developmental** defects in *Drosophila* . Dyneins are regulated *in vivo*. During flagellar bending, only a subset of the flagellar dyneins function at a time. The **phosphorylation** state of an inner dynein-arm intermediate chain modulates this regulation (6). Genetic methods have also identified several proteins that make up a dynein regulatory complex, although the mechanism of the complex remains unknown. Cytoplasmic dynein heavy-chain, intermediate-chain, and light-intermediate chains are phosphorylated *in vivo*, and phosphorylation of each has been implicated in regulating dynein.

Dystrophin

Dystrophin is a very large protein (molecular weight 427 kDa) located at the cytoplasmic face of the sarcolemma membrane of striated, smooth, and cardiac muscle cells and, most specifically, in the transverse tubules of the triadic structure. It represents only about 0.01% of the total skeletal muscle protein present in the tissue (1). Its absence, however, appears to be correlated with the fatal muscle-wasting disease known as *Duchenne muscular dystrophy* (incidence about 1 in 3500 of live male births). Becker muscular dystrophy, a milder form of muscular dystrophy (incidence about 1 in 35,000 of live male births), is related to defects/deletions in the dystrophin sequence. Muscular dystrophy is not related solely to the absence or mutation of dystrophin, however, because evidence has been presented to show that some membrane **glycoproteins** that normally interact with native dystrophin are **degraded** at abnormally high rates in either its absence or when it is mutated. This indicates that dystrophin may bind to and hence stabilize the structures of these dystrophin-associated proteins *in vivo*. It seems likely that dystrophin's structural role in muscle and nerve is comparable to that played by ankyrin and spectrin with membrane proteins in kidney, brain, and erythrocytes (1).

Dystrophin is a member of the spectrin superfamily of proteins and has many structural similarities with both spectrin and a-**actinin** . Each has a central rod domain, as well as globular regions located at the *N*- and *C*-termini. Like b-spectrin and a-actinin, the *N*-terminal domain of dystrophin contains a sequence that has high homology with the **actin**-binding site in a-actinin (2). *C*-terminal to the rod domain of dystrophin there is a **cysteine**-rich region about 150 residues that is somewhat akin to that in a-actinin, followed by a further 420 residues that is unique to dystrophin (1). Two putative **calcium-binding** sites occur within the *C*-terminal domain, although the sequences do differ from the consensus EF-Hand Motif, possibly significantly. Most of the defects/deletions in dystrophin that cause clinical symptoms are located within the rod domain; and very few are found in the cysteine-rich or *C*-terminal domains. These portions of the molecule *in vivo* provide the site of association with a well-characterized transmembrane protein complex. The *C*-terminal domain has been modeled as a pair of **heptad repeat**-containing regions (five and six heptads in length) separated by a proline-rich region (2). The *d* position in the heptads is largely occupied by leucine residues and is thus reminiscent of the leucine zipper structure. These regions are compatible with the formation of a two-stranded coiled-coil structure composed of parallel chains. These data suggest that dystrophin molecules may form a homodimer, or that dystrophin may form a heterodimer with *utrophin* (a dystrophin-related molecule). It is also known from electron microscopy that dystrophin molecules can assemble in a staggered manner and that these in turn may assemble further to produce end-to-end aggregates.

The rod domain in dystrophin (length estimates derived from electron microscope studies vary between 100 and 175 nm) consists of about 25 repeats, each about 109 residues long. Significant variations do occur, nonetheless; and although the repeats are homologous to those in spectrin and a-actinin, they are very much less regular, especially with regard to length. Ten of the 25 repeating motifs are largely complete (3), in contrast to the remaining 15 repeats, which lack some part(s) of the three constituent a-helices that comprise the three-a-**helix** motif (see Spectrin, where details of the conformation adopted are given). It has been proposed that dystrophin contains four **proline**-rich hinge regions within the rod domain that confer flexibility to the molecule and provide sites sensitive to **proteolysis**.

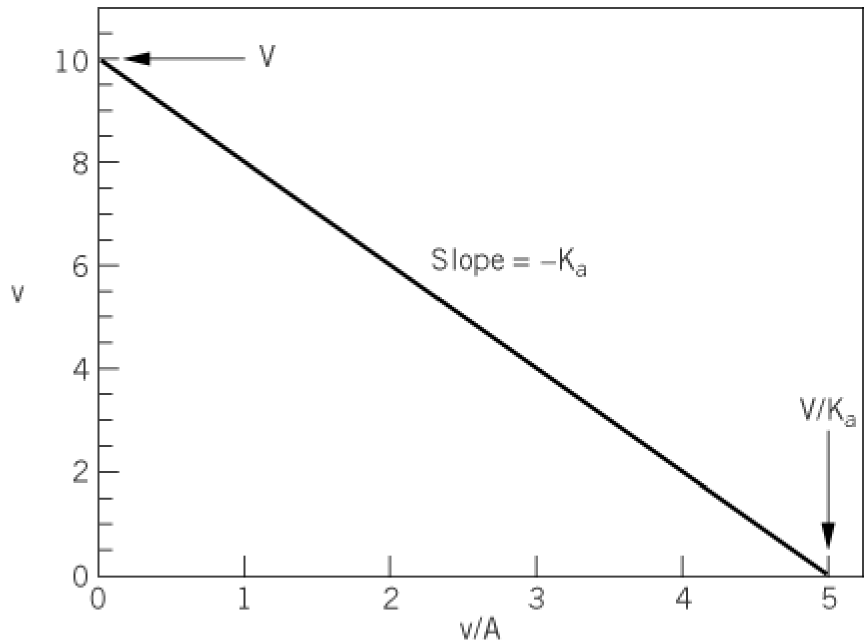
Eadie–Hofstee Plot

The Eadie–Hofstee plot was developed by Eadie (1) and Hofstee (2) and is one of three graphical procedures for determining values of the kinetic parameters for an enzyme-catalyzed reaction that conforms to Michaelis–Menten kinetics. It involves rearrangement of the initial velocity equation to a linear form that differs from that of the Lineweaver–Burk plot . The plot is derived from the Michaelis–Menten equation describing the dependence of the enzyme-catalyzed velocity v on the concentration of the substrate A and its Michaelis constant K_a; it is described by Equation (1):

$$v = -K_a \frac{v}{A} + V \tag{1}$$

where V is the maximum velocity of the reaction. Consequently, a plot of v against v/A yields a straight line with negative slope, equal to $-K_a$, a positive intercept on the abscissa that is equal to V/K_a, and a positive intercept on the vertical ordinate that is equal to V (Fig. 1).

Figure 1. Example of an Eadie–Hofstee plot for the determination of kinetic parameters for an enzyme-catalyzed reaction. The plot was produced by using the values of 10 and 2 (in arbitrary units) for V and K_a, respectively.



When values of V and K_a were being obtained by graphical methods, there were arguments for using this type of plot over that proposed by Lineweaver and Burk (3). But graphical procedures have now been supplanted by the use of regression analysis with computers (4).

A graphical procedure is required for the presentation of kinetic data. However, results that are presented as the variation of a dependent variable as the function of the ratio of a dependent and an independent variable, as in the Eadie–Hofstee plot, are not as readily interpreted as those presented as the variation of a dependent variable with the concentration of an independent variable. Further, the form of the kinetic equations for multisubstrate enzyme reactions becomes unnecessarily complex with the Eadie–Hofstee plot.

Ecdysone

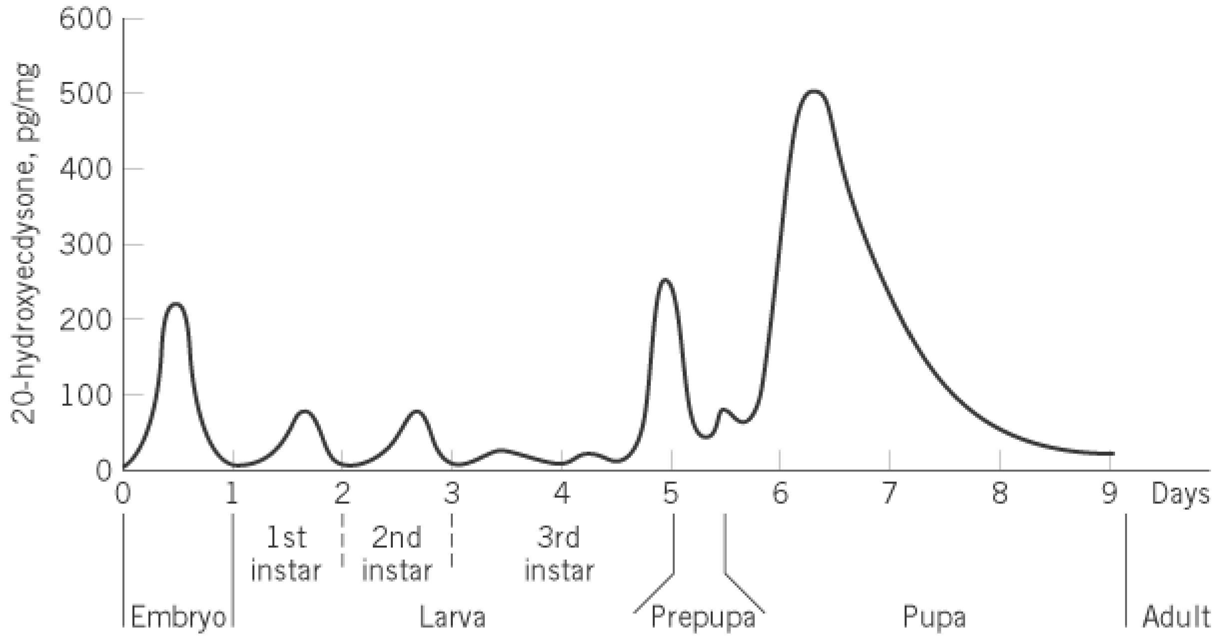
Pulses of the steroid hormone ecdysone coordinate postembryonic development in insects. In recent years, significant progress has been made in understanding the molecular mechanisms of ecdysone action in the fruit fly, *Drosophila melanogaster* (see ***Drosophila***). Ecdysone, bound to its **receptor** protein, directly activates primary-response genes. A subset of these genes encodes transcription factors that induce large batteries of secondary-response target genes. Dynamic changes in ecdysone titer, combined with cross-regulatory interactions among these transcription factors, determine the timing and order of regulatory **gene expression** during the onset of metamorphosis. Furthermore, connections are now being made between these genetic regulatory hierarchies and the biological responses they direct. Studies of ecdysone action in *Drosophila* have provided a foundation for understanding the molecular mechanisms of steroid hormone action during development.

1. Ecdysone Pulses During *Drosophila* Development

At specific times during development, and in response to environmental cues, neurons in the insect central nervous system release prothoracicotropic hormone (PTTH). This neuropeptide signals the adjacent ring gland to secrete the steroid hormone ecdysone into the hemolymph of the circulatory system (1). Some peripheral tissues, most notably the larval fat body, modify ecdysone into its biologically active form, 20-hydroxyecdysone. This hormone can then directly regulate gene expression through its interaction with the ecdysone receptor. Although insect endocrinologists use the term "ecdysone" to refer to the inactive form of the hormone, this word is synonymous with 20-hydroxyecdysone in the molecular biology literature.

Ecdysone pulses direct *Drosophila* through its life cycle, with peak hormone titers signaling the major postembryonic developmental transitions (Fig. 1). Larval development progresses through three **instars**, each punctuated by ecdysone-triggered molting of the cuticle. A high-titer ecdysone pulse at the end of the third instar triggers puparium formation and the onset of prepupal development. This is followed, 10–12 hours after puparium formation, by another ecdysone pulse that initiates the 3.5 days of pupal development, followed by eclosion of the adult fly (Fig. 1). Most larval tissues are destroyed during the early stages of metamorphosis and are replaced by adult tissues that develop from clusters of imaginal progenitor cells. The crawling larva thus undergoes a complete transformation, resulting in the formation of a highly motile, reproductively active adult fly. Remarkably, this transformation occurs in apparent response to a single steroid hormone, ecdysone. One focus of current research is understanding how the systemic hormonal signal is refined into the appropriate stage- and tissue-specific developmental pathways that direct this transformation.

Figure 1. The ecdysteroid titer profile during *Drosophila* development. The composite ecdysteroid titer is depicted, in 20-hydroxyecdysone equivalents from whole-body homogenates (44). Each of the developmental stages of the *Drosophila* life cycle are also shown, below a time scale in days. Reprinted with permission from Thummel (45). Copyright held by Cell Press.



2. Ecdysone Regulation of Primary-Response Genes

Ecdysone manifests its effects on development by activating its receptor, a heterodimer of two members of the nuclear receptor superfamily: EcR and USP (see Hormone Receptors) (2, 3). Interestingly, at least two of the three protein **isoforms** encoded by the *EcR* gene are expressed in a tissue-restricted manner that can contribute to the specificity of developmental responses to ecdysone (4). EcR-B1 is expressed primarily in larval tissues that are fated to die, whereas EcR-A is expressed in developing adult structures and tissues. Both high-affinity DNA binding and ecdysone binding require EcR heterodimerization with USP, a homologue of vertebrate retinoid X receptor (see Retinoic Acids) (5, 6). The ecdysone/EcR/USP complex can then bind DNA and activate the transcription of target genes (see Hormone Response Elements). It is interesting to note that a *Drosophila* **orphan receptor**, DHR38, a homologue of the vertebrate NGFI-B receptor, can also heterodimerize with USP (7). This raises the possibility that ecdysone signaling may be modified through distinct heterodimer combinations of receptors, similar to the interactions that have been demonstrated in vertebrate organisms.

Many genes are induced directly by the ecdysone-receptor complex, presumably reflecting their immediate requirement following ecdysone pulses (8). Some of these genes, like *IMP-E1* (9) and *Fbp-1* (10), are induced by ecdysone in a restricted tissue-specific manner, whereas others, like *hsp23* (11) and *Eip28 / 29* (12), are expressed in multiple ecdysone target tissues.

A subset of primary-response genes encode transcription factors that function at the top of ecdysone-triggered genetic regulatory hierarchies. Most of these genes were defined as **puffs** that are induced directly by ecdysone in the larval salivary gland polytene chromosomes . Detailed studies by Michael Ashburner and co-workers demonstrated that these so-called early puffs appeared to encode regulatory proteins that both repress their own activity and induce large sets of secondary-response late puffs (13). The protein products of the late puffs were, in turn, thought to play a more direct role in specifying appropriate biological responses to the hormone.

Four early puff genes have been described at the molecular level. One of these, *E63-1*, encodes a calcium binding protein related to calmodulin (see Calcium Signaling), providing the possibility of cross-regulation between hormone and calcium signaling pathways (14). The remaining three genes each encode multiple transcription factor isoforms. The *Broad-Complex* (*BR-C*) encodes more than a dozen proteins, each of which carries one of four possible pairs of **zinc fingers** (15, 16). The *E74* early gene contains nested **promoters** that direct the synthesis of two related proteins, E74A and E74B, that share an identical C-terminal **ETS domain** that binds DNA (17). Similarly, the *E75* early gene contains nested promoters that direct the synthesis of three orphan members of the nuclear receptor superfamily, designated E75A, E75B, and E75C (18). Curiously, three other orphan receptor genes, *DHR3*, *E78*, and *bFTZ-F1*, correspond to ecdysone-regulated puffs in the polytene chromosomes, suggesting that this family of transcription factors may play an important role in ecdysone signaling during development (19-21).

Ecdysone dose-response studies have revealed that each early promoter is activated at a specific critical threshold hormone concentration. Combined with ecdysone titer measurements, these dose-response studies have led to a model for the timing of early gene expression during the onset of metamorphosis (22). The *EcR*, *BR-C*, and *E74B* promoters are most sensitive to ecdysone, and are induced in mid-third instar larvae in apparent response to a low-titer hormone pulse (Figs. 2 and 3). The high-titer late larval ecdysone pulse then represses some of these messenger RNAs, such as *EcR* and *E74B*, as it induces the less-sensitive promoters, including *E74A*, *E75A*, *E75B*, and *DHR3* (Figs. 2 and 3) (22, 23). The ecdysone titer drops during mid-prepupal development, allowing *bFTZ-F1* to be expressed. This gene is repressed by ecdysone and thus depends on the decrease in hormone titer for its induction (24) (Fig. 3). The rapid rise in ecdysone titer in late prepupae then recapitulates the larval pattern of early gene expression, with a burst of *EcR* and *E74B* expression preceding that of *E74A* and *E75A* (Fig. 2). In addition to these dose-dependent responses to ecdysone pulses, many early genes also cross-regulate their activity, ensuring that they will be expressed at the correct time and for the appropriate duration (see text below).

Figure 2. Temporal patterns of ecdysone-regulated gene expression during the onset of metamorphosis. A schematic representation of the ecdysone pulses is shown at the top, with the magnitude of each pulse represented by the width of the stippled bar. Developmental time proceeds from left to right, with the major ecdysone-triggered transitions marked by dotted lines. The dotted line on the left represents the second-to-third instar larval molt, and the dotted line on the right represents head eversion and the prepupal-pupal transition. Dark grey bars show the timing and duration of primary-response regulatory gene transcription, the light grey bar represents *bFTZ-F1* transcription, and the black bars represent secondary-response gene transcription. Reprinted with permission from Thummel (46).

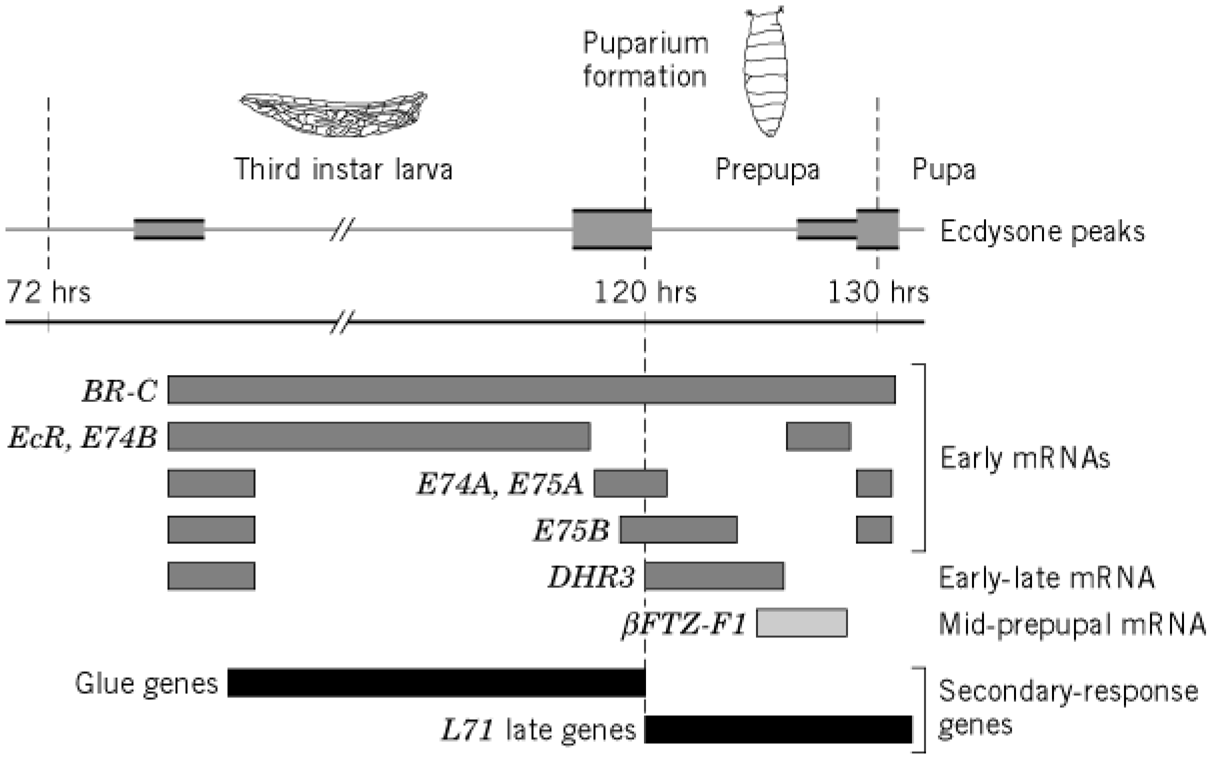


Figure 3. Multiple ecdysone-triggered regulatory hierarchies direct the onset of *Drosophila* metamorphosis. This figure summarizes regulatory interactions discussed in the text. Bars represent repressive effects, and arrows represent inductive effects. Reprinted with permission from Thummel (46).

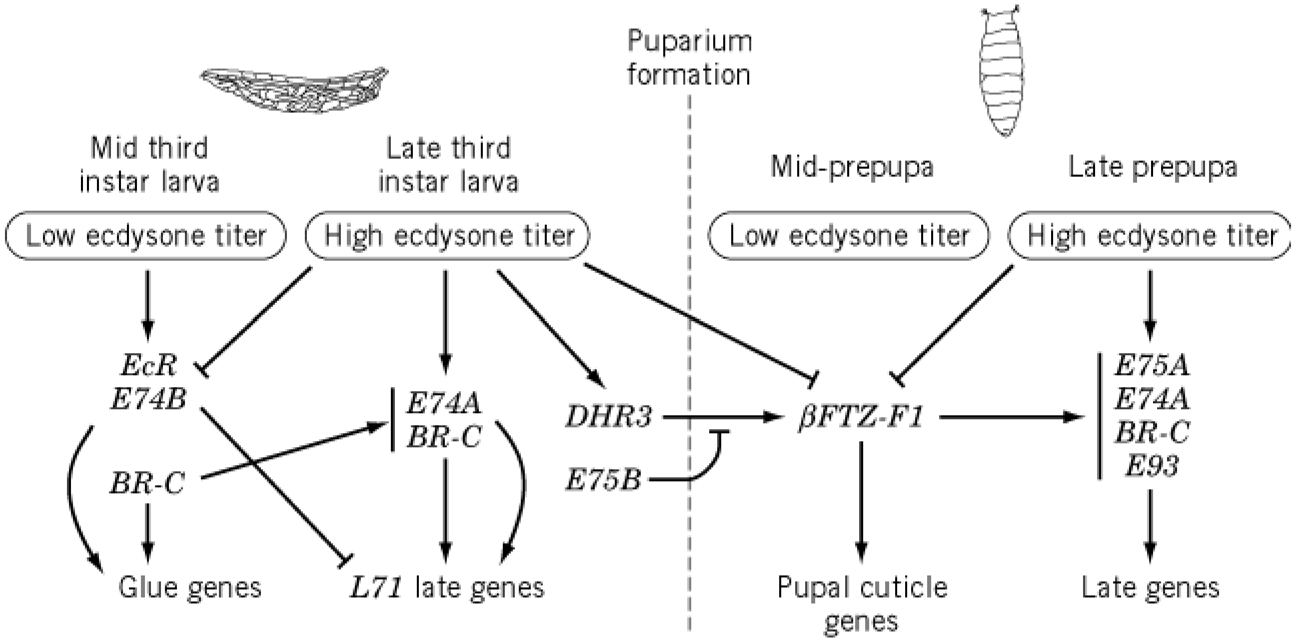

3. Regulation of Ecdysone Secondary-Response Genes

Molecular and genetic studies have demonstrated that these stage-specific patterns of primary-response regulatory gene expression are transduced into corresponding patterns of secondary-response gene activity. Two classes of secondary-response genes have been studied in the larval salivary glands: the glue genes (25, 26) and the *L71* genes from the 71E late puff (27). The glue genes are induced in mid-third instar salivary glands and encode a **polypeptide** glue that is used by the animal to affix itself to a solid surface for pupariation. In contrast, the *L71* genes are of unknown function and are induced at puparium formation, as the glue genes are repressed (Fig. 2).

Both *BR-C* and *E74B* are required for proper glue gene induction, defining a mid-third instar regulatory hierarchy in the salivary glands (Fig. 3) (28). BR-C binding sites in the glue gene enhancers are required for proper induction, indicating that this is a direct regulatory link (29). The tissue specificity of this response is directed by the Fork head **homeodomain** transcription factor that binds adjacent to the BR-C in glue gene enhancers (30, 31).

The *L71* late genes also depend on *BR-C* and *E74* for their proper induction in late third instar larval salivary glands (Fig. 3). *E74B* maintains the *L71* late genes in a repressed configuration during third instar larval development. The high-titer late larval ecdysone pulse then shuts off the E74B repressor and induces the E74A activator, which, together with the *BR-C*, directly induces *L71* transcription (Fig. 3) (32-34). These studies provide molecular support for Ashburner's proposal that early puff proteins direct the induction of late puff genes. In addition, they establish an important paradigm for understanding the mechanisms of hormone signaling in vertebrates, in which regulatory hierarchies are more difficult to define.

4. Cross-Regulation Among Ecdysone-Induced Transcription Factors

In addition to their roles in regulating ecdysone secondary-response genes, the ecdysone-induced transcription factors also regulate one another. *BR-C* is required for maximal ecdysone-induced early gene transcription in late third instar larvae (Fig. 3) (35). In this sense, *BR-C* is functioning as a competence factor that facilitates the subsequent regulatory response to ecdysone. Similarly, the early induction of *EcR* by a mid-third instar hormone pulse allows for increased levels of ecdysone receptor in preparation for the high hormone titer at the end of larval development (4).

Evidence has also been obtained for cross-regulatory interactions among the ecdysone-regulated orphan receptor genes. *DHR3*, which is induced by ecdysone in newly formed prepupae, is an inducer of *bFTZ-F1* expression in mid-prepupae (Fig. 3) (36, 37). Furthermore, this induction can be inhibited by heterodimerization of DHR3 with E75B (37). E75B protein levels normally decay during early prepupal development, thus determining the time at which DHR3 can activate *bFTZ-F1* (Fig. 2). *bFTZ-F1*, in turn, appears to be a critical competence factor for maximal reinduction of the early genes (Fig. 3) (24). Furthermore, *bFTZ-F1* is sufficient to induce the stage-specific *E93* early gene in the salivary glands of late prepupae (38). The DHR3, E75B, and bFTZ-F1 orphan receptors thus provide a regulatory link between the late larval and prepupal responses to ecdysone. Their stage-specific expression confirms that a critical developmental stage has been achieved and that the next response to the hormone should be distinct from the last response. These receptors thus provide a mechanism by which a hormonal signal can be refined into stage-specific developmental pathways.

5. From Gene Regulation to Biological Responses

Studies are currently under way that attempt to link ecdysone regulatory hierarchies with their appropriate biological responses during metamorphosis. As mentioned in the text above, most larval tissues are destroyed during prepupal and early pupal development. Recent studies have revealed that the destruction of the larval midgut and salivary gland occurs as stage-specific programmed cell death responses that display many of the hallmark features of apoptosis (39). Furthermore, the *Drosophila* death inducer genes *reaper* and *head involution defective* are coordinately induced in these tissues immediately preceding their destruction. A current focus of research is aimed at understanding how these death inducers are regulated by ecdysone at the appropriate time and place during metamorphosis. Specific neurons in the central nervous system also undergo programmed cell death in newly eclosed adults, in response to a decrease in ecdysone titer (40). Interestingly, these neurons can be distinguished by their high expression of the EcR-A isoform, suggesting that this receptor may play a key role in directing the death of these neurons.

As the larval tissues are being destroyed, the adult fly is being constructed. During prepupal development, the imaginal discs evert and elongate to form rudiments of the adult appendages. *BR-C* and *E74* both play a critical role in this process (41, 42). Studies have also shown that *bFTZ-F1* is sufficient to induce the pupal cuticle genes in mid-prepupal imaginal discs, providing a mechanism for the stage specificity of pupal cuticle deposition (Fig. 3) (43). It seems likely that future studies will provide more links between the ecdysone regulatory hierarchies and the biological responses to ecdysone during the onset of metamorphosis.

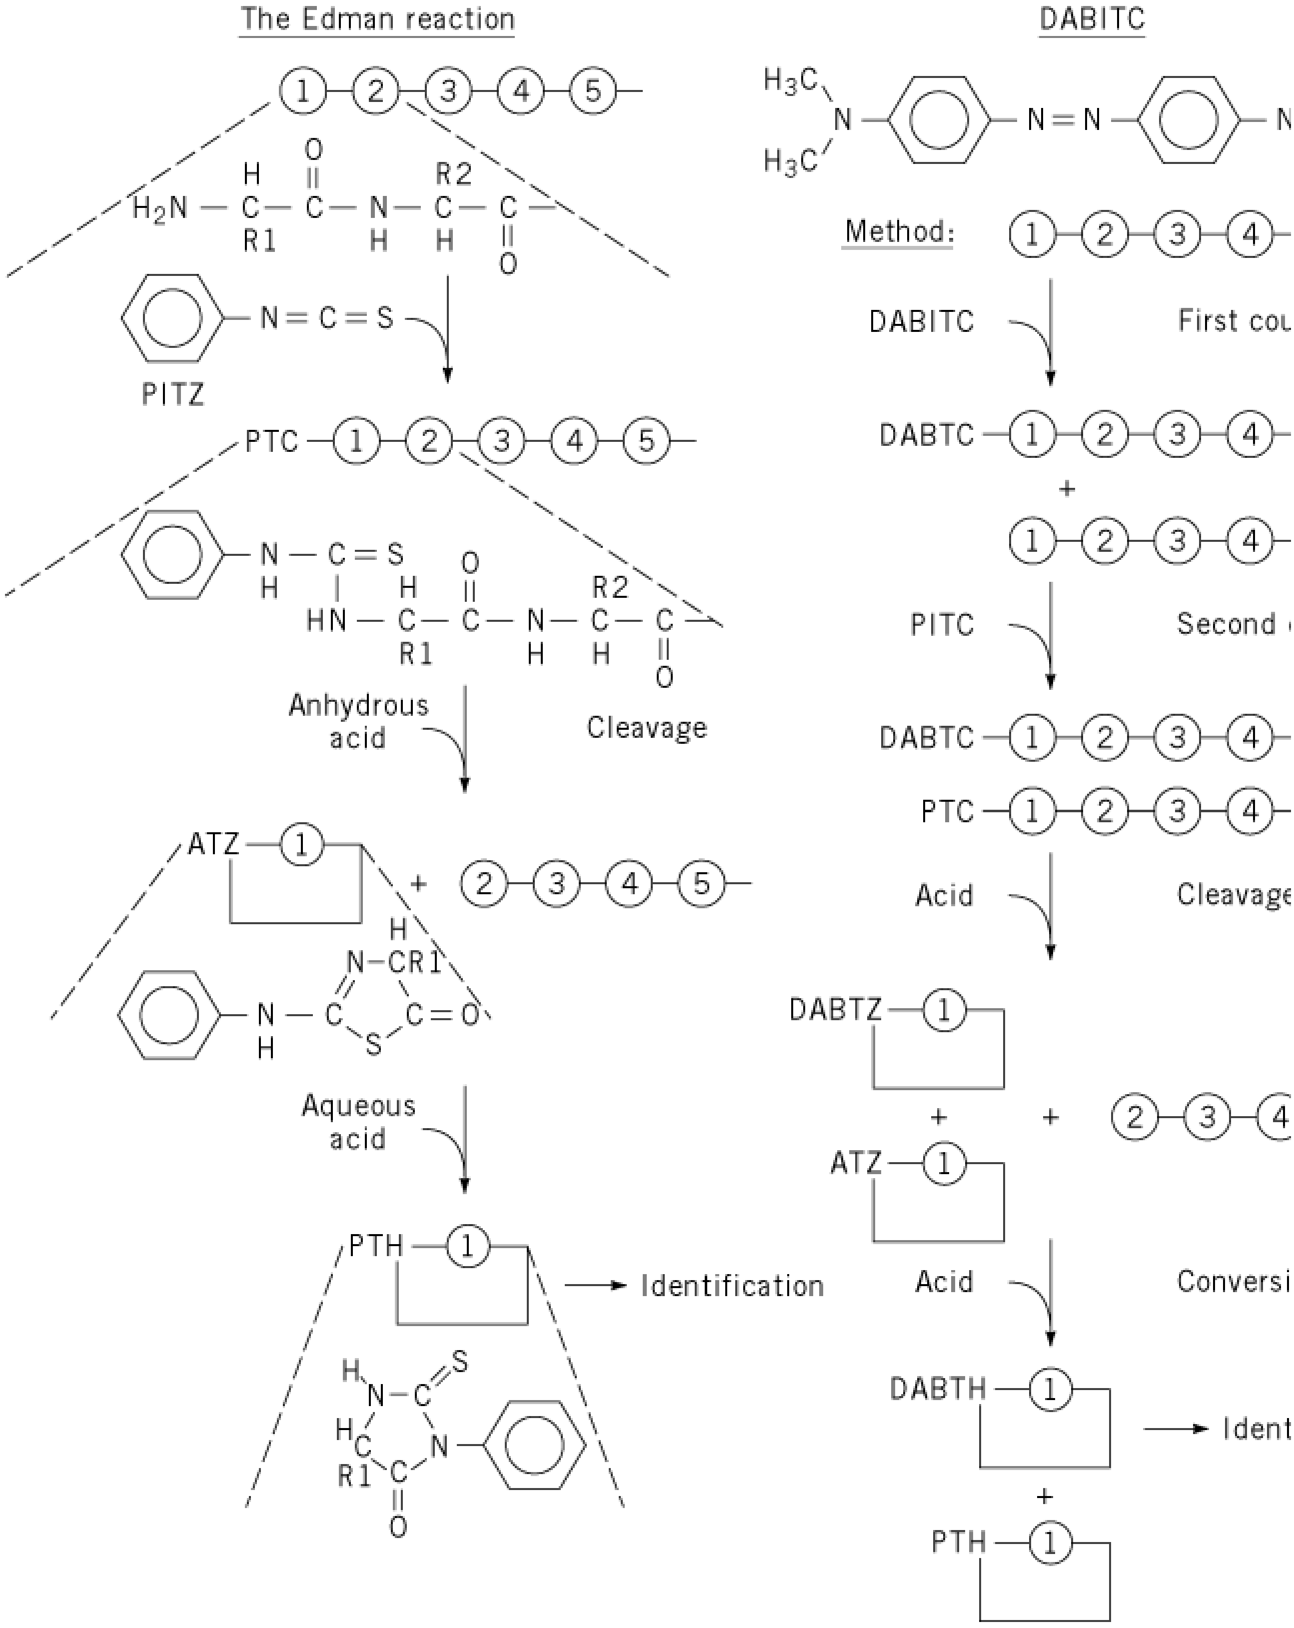
Edman Degradation

This reaction for determining the sequences of peptides and proteins from their N-terminus was reported by Pehr Edman in the early 1950s (1-3). It now constitutes one of the oldest, if not the oldest, molecular method that is still much in use (see Protein Sequencing). It uses a three-stage reaction cycle for step-wise removal of amino acid residues from the N-terminus of a polypeptide chain. The three stages of the Edman cycle (Fig. 1) are (i) coupling, (ii) cyclization, and (iii) conversion.

Figure 1. Principles of the Edman reaction (left). Also shown is the DABITC (right) double-coupling method. Key: PIT phenylisothiocyanate; ATZ, anilinothiazolinone; PTH, phenylthiohydantoin; Dansyl (or DNS), 1-dimethylaminonaphtha sulphonyl; DABITC, 4-N,N-dimethylaminoazobenzene-4′-isothiocyanate.



(i) *Coupling* involves a nucleophilic attack of the N-terminal a-**amino group** on the thiocyanate carbon of phenylisothiocyanate (PITC), to form the phenylthiocarbamyl-peptide derivative (PTC-peptide).

(ii) *Cyclization* constitutes the formation of the anilinothiazolinone derivative (ATZ-amino acid) in anhydrous acid, thereby liberating the N-terminal amino acid residue in a cyclic form, and leaving the remaining peptide truncated by one residue (Fig. 1).

(iii) *Conversion* involves the rearrangement of the liberated ATZ derivative to the corresponding phenylthiohydantoin derivative (PTH-amino acid) by opening of the CS bond and re-closure with the CO bond.

The reaction of protein amino groups with cyanate was known before Edman's report, but the degradative yield using cyanate was low. Edman increased the yields to useful levels by introducing thiocyanates in place of cyanates, and by determining the exact reaction conditions and pointing out the need for pure chemicals.

This reaction constitutes the start of protein chemical sequencing on a routine scale; hence it really marks the start of molecular biology as a whole. The reaction is still used in most protein laboratories worldwide, it is the basis of chemical protein sequencers, and a classical method still "modern" in molecular biology at the end of the 1990s. Essentially, the only changes that have occurred during the 50 years to this reaction are:

- use of other solvents, giving alternative and more rapid protocols,
- continued automation, miniaturization, and increase in reaction speed, now making the reaction useful for routine applications at the picomole level in 30-min cycles per residue.

It was a remarkable accomplishment of Edman to design this reaction and to directly set out all the conditions, so that it has stayed unsurpassed for 50 years of worldwide protein chemistry.

1. Protein Sequencers

After development of the Edman reaction, Edman automated the process, developing a machine to make all additions, extractions, and lyophilisations. This constituted the birth of the protein sequenator (or sequencer); the basic concept for a complete machine was published by Edman and Begg in 1967 in a now classic paper (4) in the then newly-started *European Journal of Biochemistry*.

In the first-generation sequencers, a "spinning cup" constituted the reaction center, and the sample was kept in place by centrifugal force, making extractions and reactions possible. Extraction losses were a problem in each cycle, however, soon leading Laursen and others to the idea of solid-phase attachment of the peptide to be degraded (see **Solid-phase synthesis**). Consequently, only a few years later, the solid-phase sequencer was reported (5). Although both types of sequencers were based on the same Edman chemistry (3), their different properties, including the different attachments of the samples, made them suitable for different analyses. The liquid-phase sequencer was excellent for proteins, and the solid-phase instrument was better for short peptides, because of their different sensitivities to extractive losses and to build-up of background signals.

2. Manual Edman Degradations

Once the Edman reaction and the protein sequencer existed, the really limiting factor was peptide purification on the one hand, and phenylthiohydantoin (PTH)-amino acid identification on the other. For a long time, suitable chromatographic methods did not exist, hampering both purification and identification. Peptide purification, especially the separation of large peptides, was a problem. Similarly, identification of the PTHs liberated in each Edman cycle was also a problem. The PTH derivatives were initially identified by paper chromatography, which was not fully reliable (all derivatives did not separate in one analytical step) and also required the use of several solvent systems, which wasted time and material. Subsequent developments introduced gas chromatography and **thin-layer chromatography**, both increasing the speed of identification, but still not giving a reliable one-step identification of all amino acids. These limitations contributed to the development of alternative methods, such as the dansyl and DABITC types of analysis, which did not require a major investment in equipment. One major manual method was that using dansyl (1-dimethylaminonaphthalene-5-sulphonyl) chloride to detect the new N-terminus after each Edman cycle (6) (see Dansyl Chloride). The main advantage was that it was easier to identify the residues released sequentially. Its primary importance is that it made protein sequence determination accessible to many laboratories.

A similar and later development in manual sequence analysis was the DABITC (4-N,N-dimethylaminoazobenzene-4′-isothiocyanate) method (7). In this case, protein degradation is carried out by coupling with the strongly colored DABITC, in place of PITC (Fig. 1). The DABTHs produced, which correspond to PTHs, are easily detectable by **thin-layer chromatography** (7). However, DABITC has a low coupling yield in the Edman reaction, necessitating a second coupling stage with ordinary PITC (Fig. 1, right) before the subsequent cyclization step.

At the time, both the dansyl and the DABITC methods were important, but since the 1980s these methods have gradually decreased in importance because of reliable sequencer on-line **HPLC** identification of PTH-derivatives (see below).

3. HPLC

The PTH-amino acid identification problem was finally solved with the introduction of **HPLC** in 1976 (8); subsequently, PTH amino acid identification became rapid, routine, and reliable. Although some identifications may still be difficult, PTH identification no longer constitutes the limiting factor in time or reliability.

At the same time, HPLC separations and the subsequent development of a whole battery of different chromatographic media soon also solved the problem of purification of peptide fragments from proteolytic digests.

4. Second-Generation Chemical Sequencers: Automation of All Steps

With the development of protein sequence analyzers, it became possible to determine amino acid sequences routinely, and there was an exponential increase in known protein sequences. However, analysis at this stage was still time-consuming and nonautomatic, requiring knowledge and real research. Gradually, however, a set of further inventions increased the automation and brought the actual sequence analysis more or less to the present-day automatic stage. This development essentially relied on three further inventions/improvements.

One concerned the attachment of the protein/peptide to the sequencer for analysis. This important step had several sub-steps. One was the realization that an organic cationic polymer, Polybrene (9, 10), was a suitable material capable of binding proteins and peptides to glass surfaces or other membranes. The resulting minimization of extraction losses in the washing steps of each cycle made degradations possible through to the very C-terminus of most peptides. More importantly, apart from the improvement in the lengths of degradation possible, use of Polybrene also meant that the peptide for degradation could be attached to surfaces; this therefore opened the way to the abandonment of the use of centrifugal force for attachment of the peptide for degradation. Instead, peptides could now be attached to membranes, essentially moving the degradation from the traditional "liquid phase" system to the advantageous "solid phase" (which had been started earlier by covalent attachments, cf. above) and "gas-phase" systems (11). The latter are solid phase for the attachment of the peptide to a support, and gas phase for the introduction of some reagents. These approaches are still in use and now allow rapid and sensitive analysis. Many other sub-steps in this transformation were involved. In particular, perhaps the introduction of chemical attachments of peptides to membranes (12), and the successive development of alternative, miniature column attachments for sample introductions and preparations (13), should be mentioned.

The second improvement at this stage, was the introduction of dead volume-free valve blocks, allowing use of valves with an absolute absence of cross-contamination between the reagents used in the reaction (14). In this manner, further increases in speed (because of less washing) and sensitivity (because of higher yield from lack of cross-contamination) made sequencers still more useful and rapid. Recently, this has been carried still further, and soon “chip-based blocks” may be encountered in sequencers, with all solvent delivery and removal stages in extremely small volumes of “chip-blocks” (15).

The third major advance at this stage was the introduction of automatic methods for the conversion of a thiazolinone from each cycle into the corresponding thiohydantoin. This became possible because of the introduction of a second reaction vessel (16), with separate reagents and reactions.

Once the conversion had become automated, it became possible also to link the subsequent PTH identification step to the cycle of automatic events in the sequencer, thus opening the road to on-line identification of the liberated amino acid derivative in each cycle. These on-line modes were started very early, with the introduction of HPLC, and were soon commercialized and perfected in a new set of complete sequencers, starting with the “gas-phase sequencer” that was available in the 1980s (11). Soon, the on-line approach was coupled with post-PTH-identification data treatments, allowing extensive computer interpretation at each step. All chromatograms can now be stored and compared with on-line computers and further interpreted and related to sequences in **databanks**, analyzed in modeling programs, and submitted to further computerized adjustments.

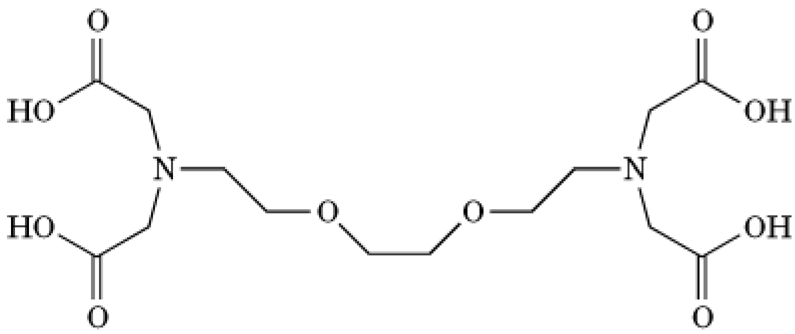
EDTA (Ethylenediamine-*N*,*N*,*N*′,*N*′-Tetraacetic Acid)

EDTA is a chelating agent widely used, along with EGTA, to control the concentration of divalent and trivalent cations in aqueous solutions. Its structure is given in Figure 1. It is an essential ingredient in such diverse products as laundry detergents and film developers. In the field of molecular biology, EDTA is present in many buffer solutions used for experiments where the presence of divalent and trivalent cations would interfere with the desired outcome. For example, it is used in most buffers for the initial steps of protein purification (1) from biological material, to suppress the activity of metal-dependent proteases that would otherwise degrade the desired protein.

Figure 1. Chemical structure of EDTA (ethylenediamine- *N,N,N′,N′*-tetraacetic acid).



The flexibility of the molecule, and the variety of potential liganding sites within it, permit EDTA to accommodate a wide variety of cation types, preferred ligand geometries and bond lengths, thus contributing to its high affinity for most cations (Table 1) (2). In contrast to many other complexing agents, EDTA will form only a 1:1 complex with either divalent and trivalent cations, in which a single ion is chelated by all four carboxyl groups, which greatly contributes to the stability of the resulting complex. Hence, EDTA can maintain the concentration of free cations at very low levels. The high affinity of EDTA for cations is also used to removed metals from metalloproteins and to maintain them in their metal-free state. It is important to note that the binding of cations by EDTA is pH-dependent; protonation of the carboxylate moieties at low pH dramatically lowers their affinity for cations.

Table 1. Affinity of EDTA for Various Cations[a]

Metal Ion	$\log_{10} K_a$
Mg^{2+}	8.64
Ca^{2+}	11.0
Zn^{2+}	16.4
Cd^{2+}	16.4
Mn^{2+}	13.8
Cu^{2+}	18.7
Fe^{2+}	14.33

Fe^{3+}	24.23
Co^{2+}	16.3
Co^{3+}	36
Pb^{2+}	18.3

[a] The logarithm of the association constant [K_a in units of M^{-1} (reciprocal molars)] are compared at pH 7.0, 25°C, and 0.1 *M* ionic strength (2).

EDTA as the free acid is a white powder, has a molecular weight of 292.25 Da, decomposes at 240° C, and is relatively insoluble in water (0.34 g/100 mL at 25°C). The sodium and potassium salts of EDTA are also white powders and are much more readily soluble in water.

Effective Molarity

A reaction or interaction between two different molecules in dilute solution is relatively straightforward and is governed by their concentrations in that solution, plus the appropriate rate or equilibrium constant (see Kinetics). In more complex situations, however, the situation may differ from that expected from the bulk concentrations of two reactants. If they attract each other, for example by **electrostatic** or **hydrophobic interactions**, their *effective* molarities will be greater than their bulk concentrations. Similarly, a nonpolar reagent that partitions into the interiors of membranes, or any reagent that concentrates in one organelle or compartment, will react there at a much greater rate than if it were dispersed evenly throughout the system.

A special situation occurs when two reactive or interactive groups are part of the same macromolecule, such as a **protein** or **nucleic acid**. The rate constant for reaction between two such groups, or their association constant, might be known when they are individual molecules, when the observed rate or equilibrium is given by this constant times their respective concentrations, but for an intramolecular reaction or interaction, their concentration within the solution is irrelevant. Instead, it is the *effective concentration* of the two groups within the macromolecule that is important for the intramolecular interaction. The effective molarity will depend upon the structure of the macromolecule, in particular the extent to which it brings the two reactants together or keeps them apart, plus the environment in which the two groups are kept. The effective molarity for the intramolecular reaction will be essentially zero if the macromolecular structure keeps the two groups apart (of course, groups on different molecules can still react, and their bulk concentrations still govern this *intermolecular* reaction). At the other extreme, when the macromolecular structure keeps the two groups in the correct proximity and orientation for reaction, their effective molarity can be extremely large, up to 10^{10} M, concentrations that are not feasible with two independent molecules. Such values are predicted by theoretical considerations (1) and are also observed experimentally, from the ratio of the rate or equilibrium constants for the same reaction when the groups are on the same molecule and on separate molecules (2).

The large effective concentrations that are observed are believed to be due primarily to the much smaller loss of entropy that occurs when two groups on the same molecule interact. Two independent molecules that interact in solution must lose substantial translational and rotational entropy when they interact, depending upon the rigidity of the interaction. Two groups attached to the same macromolecule have already lost varying degrees of this entropy. In the ideal case, when the two reactive groups are held by the macromolecular structure in precisely the correct position for them to interact, so that there is no change in their entropy, the maximum effect and the maximum effective molarity are observed. Of course, other considerations also apply, such as if the environment of the groups is different in the macromolecule, or if they are strained and this strain is relieved upon their reaction.

Whatever the exact reason for the large effective molarities that can be measured in macromolecules, this has important consequences for understanding the stabilities of the folded structures of macromolecules. For example, the question of the role of hydrogen bonds in stabilizing protein structures has been very controversial (see Protein Stability). One might expect *a priori* that hydrogen bonds would contribute nothing to the net stability because any hydrogen bonds in the folded state would be replaced by equivalent hydrogen bonds, with the water, in the unfolded protein. But the two cases differ because the hydrogen bonds in the folded state are intramolecular, whereas those with the solvent are intermolecular. If the hydrogen bonding groups have effective molarities in the folded state greater than the solvent concentration, 55 M for water, the hydrogen bonds in the folded state will be more stable than those in the unfolded state, and they will stabilize the folded conformation. Another way of thinking about this is to consider the increased entropy of the water molecules that are liberated when the protein folds and forms intramolecular hydrogen bonds. Effective molarities of up to 10^{5} M have been measured between cysteine residues in forming disulfide bonds during **protein folding** (3). Consequently, it is not surprising that folded macromolecular structures can be stabilized by many intramolecular interactions that individually are very weak in an unfolded conformation, but occur simultaneously and cooperate to generate a folded conformation (4). The large effective molarities of reactive groups in the active sites of enzymes are also important for explaining enzymatic catalysis.

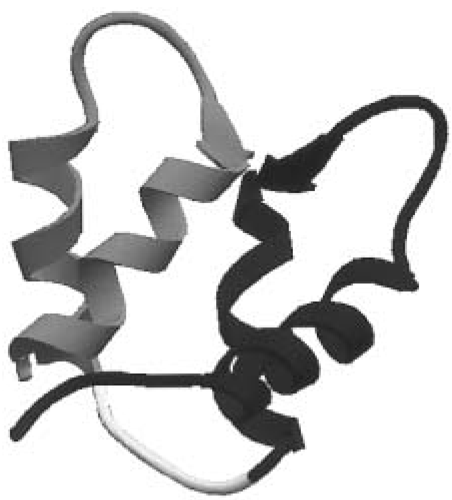
EF-Hand Motif

The majority of calcium-binding proteins involved in intracellular Ca^{2+} signal transduction are characterized by a common helix–loop–helix structural protein motif in their Ca^{2+}-binding sites that is termed the EF-hand. Well over a thousand EF-hand motif sequences have been identified. An exquisite fine-tuning of the packaging of EF-hands provides these proteins with both high selectivity for Ca^{2+} and the ability to respond rapidly and efficiently to the modest (100-fold) changes in concentration associated with Ca^{2+} signals. In fact, the unique relationship between the EF-hand motif and Ca^{2+} binding extends beyond the ability to transduce Ca^{2+} signals, as other members of this protein family have critical roles in the uptake, transport and homeostasis of Ca^{2+}.

The term "EF-hand motif" was introduced by Kretsinger on examination of the three-dimensional structure of parvalbumin, the first member of the EF-hand Ca^{2+}-binding protein family whose three-dimensional structure was determined (1). A great deal of structural insight into the variability of the EF-hand motif has been obtained from subsequent X-ray crystallography and NMR solution structure analysis of EF-hand calcium-binding proteins. EF-hand motifs almost always occur in pairs packed together in a face-to-face manner, forming a stable globular domain (Fig. 1). The pairing of sites is presumed to stabilize the protein conformation, increase the Ca^{2+} affinity of each site over that of isolated sites, and provide a ready means for the **cooperativity** in the binding of Ca^{2+} that is critical to their function. The conformations of EF-hands are variable and are dependent on whether ions are bound (see Calcium-Binding Proteins).

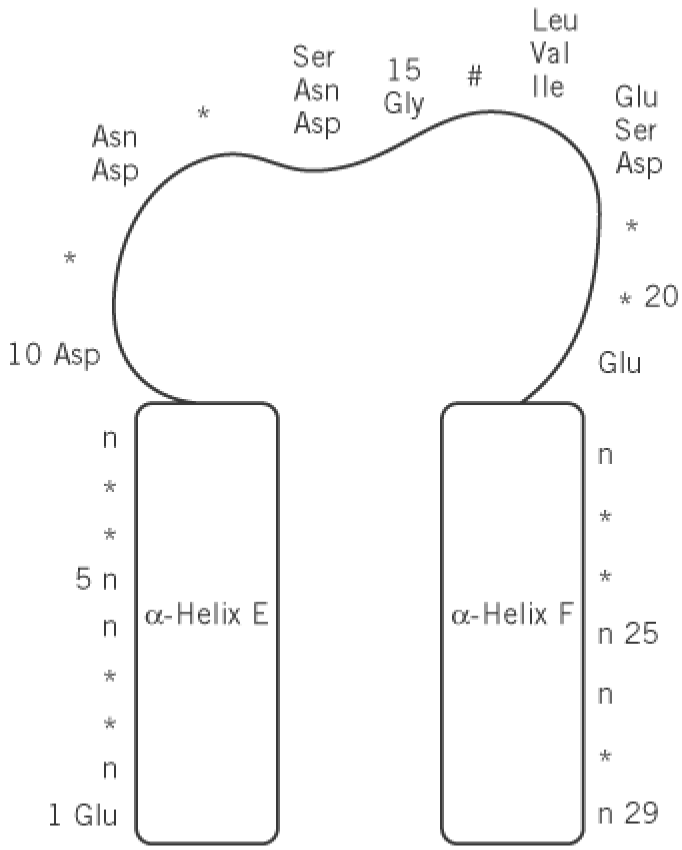
Figure 1. Ribbon diagram of the canonical EF-hand of the *N*-terminal domain of calmodulin using the coordinates of 1CFC (3).



The canonical EF-hand consists of a 29-residue contiguous segment of polypeptide chain containing an a-helix designated as E in the original parvalbumin structure (residues 1–10), a loop around the calcium ion (residues 10–21), and a second a-helix designated F (residues 19–29). The consensus sequence is shown in Figure 2. Residues 10, 12, 14, 16, 18, and 21 chelate the Ca^{2+} ion. Residues 10, 12, and 14 provide monodentate oxygen ligands, and residue 21 provides a bidentate oxygen ligand, all via side-chain carboxyl groups. Residue 16 directly coordinates Ca^{2+} via its main-chain oxygen. Residue 18 ligates Ca^{2+} indirectly, through a stably bound water molecule. Other residues have been assigned specific roles in stabilizing the EF-hand motif. For example, a central

hydrophobic core is formed from the side chains of residues 2, 5, 6, and 9 of helix E; 22, 25, 26, and 29 of helix F; and 17 from the binding loop.

Figure 2. Schematic diagram of the consensus sequence for the EF-hand Ca^{2+}-binding motif. Residues marked with * have no constraints on which amino acids occur there. Residue 16, #, chelates the calcium by its backbone carbonyl oxygen atom. The residues of the E and F helices marked "n" must be nonpolar for packing of the two helices.



Most EF-hand proteins use this canonical motif. The S100 proteins (an important subfamily of Ca^{2+}-binding proteins), however, have a two-residue insertion and a modified coordination scheme in the first binding loop. In these pseudo-EF-hands, residues 10, 13, 15, and 18 chelate the Ca^{2+} ion via their main-chain carbonyl oxygen atoms, whereas residue 20 chelates indirectly via a water molecule, and acidic residue 23 provides bidentate ligation via its side-chain carboxylate. The role of these pseudo-EF-hands in modulating the structure or function of S100 proteins is still under investigation, although there is evidence that the packaging of a pseudo-EF-hand and a canonical EF-hand attenuates the changes in the structure and dynamics of the protein induced by the binding of calcium (2).

EGF Motif

The EGF motif is a common structural **domain** found in many protein structures, especially those of proteins associated with blood clotting, fibrinolysis, neural development, and **cell adhesion**. The motif is characterized as a protein module of ~ 45 residues having six conserved cysteine residues (designated CI through CVI) that form three internal disulfide bonds with the connectivity CI-III, CII-IV and CV-VI. The motif was first found in epidermal growth factor (EGF), hence the name EGF motif or EGF-like domain. Although found as a single unit in EGF and transforming growth factor a, the EGF domain is often present as a repeating unit in much larger proteins. For example, the protein fibrillin has over 30 EGF domains. Furthermore, EGF motifs in proteins are frequently present in combination with repeating units of other modules such as the Kringle domain.

The sequence of the EGF motif is often recognizable from just the primary structure of a protein. The consensus sequence is X–X–X–X–Cys–X(2–7)–Cys–X(1–4)–(Gly/Ala)–X–Cys–X(1–13)–t–t–a–X–Cys–X–Cys–X–X–Gly–a–X(1–6)–Gly–X–X–Cys–X, where X is any amino acid (the number in brackets defining a variable number of X residues), *a* is an aromatic residue, and *t* is a **nonhydrophobic** residue (1). The tertiary structure of the EGF motif is also highly conserved and can be described as having a two-stranded antiparallel b-sheet scaffold upon which the three disulfide bonds are positioned (Fig. 1). The disulfide bonds link the *N*-terminal and *C*-terminal loop regions to the core. Binding of **calcium** ions to some classes of EGF domain further stabilizes the *N*-terminal region and is thought to cause the formation of long helical arrangements of multiple EGF motifs (2); this property may account for their proposed function of mediating protein–protein interactions.

Figure 1. Schematic representation of the backbone structure of an EGF domain (2). b-Strands are shown as arrows, and the three disulfide bonds are shown in light gray, with the sulfur atoms depicted as spheres. The *N*- and *C*-termini are labeled. This figure was generated using Molscript (3) and Raster3D (4, 5).

Egg

An *egg* is the female **gamete**, which is originally haploid and in most cases nonmotile. After fertilization by a sperm, the egg provides the basis for producing a completely new individual. Regarding this subsequent development, eggs belong to the least restricted cell types of the body, as they have the power to produce every other differentiated cell type. Eggs cannot be regarded as nonspecialized cells; instead, they prove to be very specialized cells to accomplish this task.

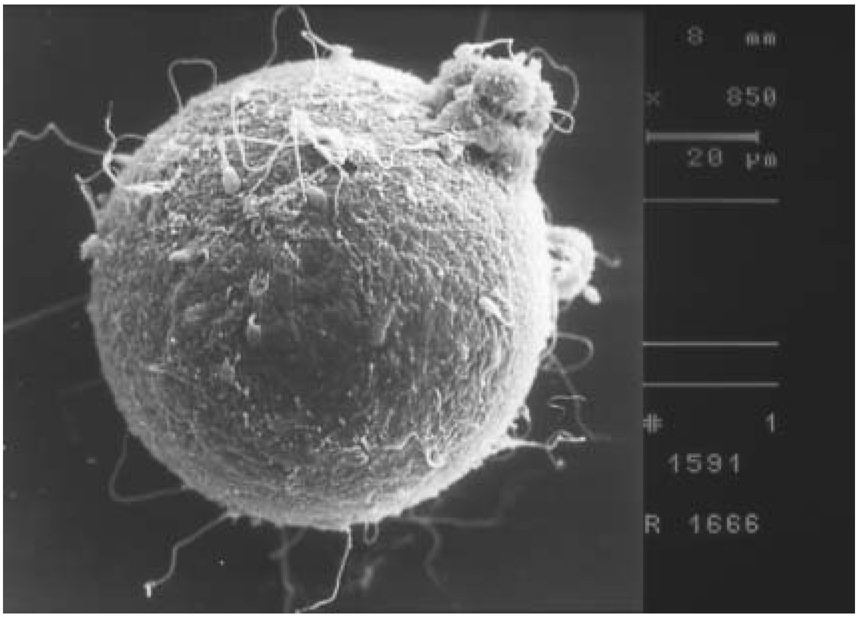
First, they must mediate sperm–egg interactions. This means that they must be able to induce metabolic pathways in the spermatozoon and biochemical signals from the spermatozoon must be understood, thus leading to intracellular reactions in the egg to promote fertilization. Second, after fertilization with a spermatozoon, the egg needs a machinery to promote biochemical actions that are necessary to fuse the male and female **pronuclei**. Third, the egg must be able to guide and support the very early cell divisions without, or with only minimum, nuclear control of the developing embryo. Thus, the egg must provide appropriate amounts and species of many different basic elements, such as transfer RNA, ribosomes, and many different proteins, including basic elements like transcription factors. These gene products have been **transcribed**, and in some cases **translated**, previously and are stored in the oocyte cytoplasm.

1. Morphology

Unlike other cells, eggs consists of an outer porous extracellular matrix, the *zona pellucida* (1). The zona pellucida is not primarily for mechanical protection of the egg, but its foremost task is to mediate sperm–egg interactions. It is made of long filaments consisting of three types of **glycoproteins** . In all species thus far investigated, zona pellucida glycoproteins are expressed by the ZPA, ZPB, and ZPC gene family (1). Post-translational modification of the zona pellucida glycoproteins, however, varies with the species. Most of the investigations concern the situation in the mouse. Regardless of their genetic origin, but for functional reasons, the processed glycoproteins are divided into three classes. Murine zona pellucida glycoprotein 1 (ZP1) has a molecular weight of 200 kDa and is assumed to be responsible for the structural integrity of the matrix. Zona pellucida glycoproteins 2 and 3 (ZP2, ZP3) exhibit apparent molecular weights of 99 kDa and 83 kDa, respectively; both act as sperm receptors (2). In the ZP3 receptor, an O-linked oligosaccharide of 3.9 kDa molecular weight plays a central role in recognition and binding of sperm. After induction of the cortical reaction by fertilization, both receptors are converted to their inactive forms, ZP2f and ZP3f, thereby providing a secondary block against polyspermy. In species with extracorporal fertilization, such as sea urchins, the zona pellucida is surrounded by a jelly layer. In mammals, a number of corona cells adhere to the zona pellucida at the time of fertilization.

Between the oocyte plasma membrane and zona pellucida is a region that is termed the perivitelline space. On entrance of a sperm and its fusion with the oocyte plasma membrane, calcium is released from intracellular calcium stores (see Calcium Signaling). As a consequence, the cortical granules are activated and release their proteolytic contents into the perivitelline space, which subsequently diffuse into the zona pellucida. This results in the conversion of ZP2 and ZP3 into their respective inactive forms ZP2f and ZP3f. Calcium release is necessary not only to prevent fertilization from further spermatozoa, but it is also involved in (*1*) nuclear envelope breakdown, (*2*) triggering intracellular **phosphorylation** events, and (*3*) activation of cell cycle -control proteins leading to **mitosis** after syngamy.

Figure 1. Electron microscope picture of an oocyte. The oocyte is surrounded by spermatozoa that aim to penetrate the zona pellucida. (With the friendly permission of Dr. H.-W. Michelmann.)



Within the oocyte plasma membrane, the egg is filled with cytoplasm that contains basic metabolites necessary for the initial divisions of the cell. Unlike the cortical granules, not all compounds of the cell cytoplasm are located uniformly. This can be seen by light microscopy and has led to a distinction of the egg's compartments. In the frog, for example, macroscopic partitioning is visible: The nucleus is located at the **animal pole**, whereas yolk is located at the vegetal pole.

Depending on the species, eggs vary considerably in their sizes and shapes. In mammals, nutrition can be provided during the very early stages of life by diffusion and then by active transport after implantation of the embryo. Therefore, there is no need for substantial nutrition in the egg and, hence, the entire egg is no larger than 0.1 mm. In species in which extracorporal development of the offspring is the rule, the situation is different. The sizes of eggs can range up to a couple of inches, due to large amounts of yolk, as is the case, for example, with birds.

Eglin C

Eglin c is a widely studied, strong inhibitor of serine proteinases [see Serine Proteinase Inhibitors, Protein]. Its reactive site P_1 Leu^{45} residue endows it with specificity toward many, but not all, subtilisins, chymotrypsins, and elastases. It is an exceptionally strong inhibitor ($K_I < 10^{-13}$ M) of *Streptomyces griseus* proteinases A and B. As an efficient inhibitor of human leukocyte elastase, cathepsin G, and proteinase 3, the three human leukocyte enzymes responsible for the lung damage in emphysema and in related diseases, eglin c is of great interest to pharmaceutical companies. Eglin c consists of a single polypeptide chain of 70 amino acid residues. In spite of its lack of disulfide bridges, it is a standard-mechanism canonical inhibitor. It is a member of the potato I family, a family of inhibitors whose members either lack disulfides or contain only one. Most members of the potato I family are isolated from plants. In contrast, eglin c was isolated from the leech *Hirudo medicinalis*, where its physiological function is not known.

EGTA (ethyleneglycol bis(b-aminoethyl ether)-*N,N,N′,N′*-tetraacetic acid)

EGTA is a chelating agent widely used to control the concentration of Ca^{2+} cations in biological solutions (see also -Tetraacetic Acid)). Its structure is given in Figure 1. EGTA binds Ca^{2+} 3×10^5-fold more strongly than Mg^{2+}, which makes it useful to control Ca^{2+} levels in the presence of physiological concentrations of Mg^{2+} (1-3). The binding of cations by EGTA is pH-dependent; at low pH the carboxylate moieties will be protonated, dramatically lowering the cation affinity. The high selectivity of EGTA for Ca^{2+} over Mg^{2+} is readily explained by the structure of their respective complexes (Fig. 2, see top of next page) (4, 5). While EGTA fully wraps around Ca^{2+} in a very stable octadentate complex, it cannot similarly satisfy the more stringent binding requirements of the smaller Mg^{2+}. The preference of Mg^{2+} for oxygen ligands over nitrogen ligands is so great that it binds to EGTA via the carboxylate groups only. The remaining positions in the ligand shell are filled by water. Although these complexes can be crystallized and their structure determined, they are very dynamic in solution. NMR analysis of the Ca^{2+}-EGTA complex indicates that the carboxylate moieties interchange positions rapidly on the NMR time scale, and inversion at the nitrogen atoms is observed at elevated temperatures (5), which further indicates that the complex is very dynamic. The great stability of the Ca^{2+}-EGTA complex comes from the fact that all ligands are provided by a single molecule, specifically, the stability constants have a very high entropic contribution.

Figure 1. Molecular structure of EGTA.

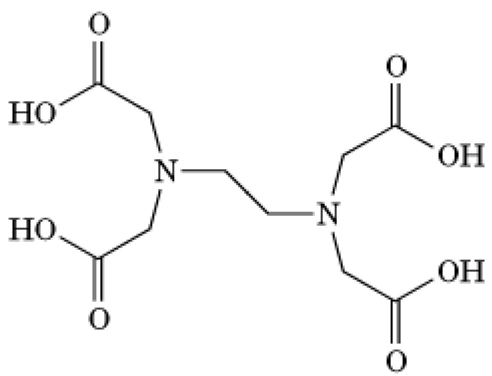

Figure 2. Three-dimensional structures of complexes of EGTA with (**a**) Ca^{2+} and (**b**) Mg^{2+}.

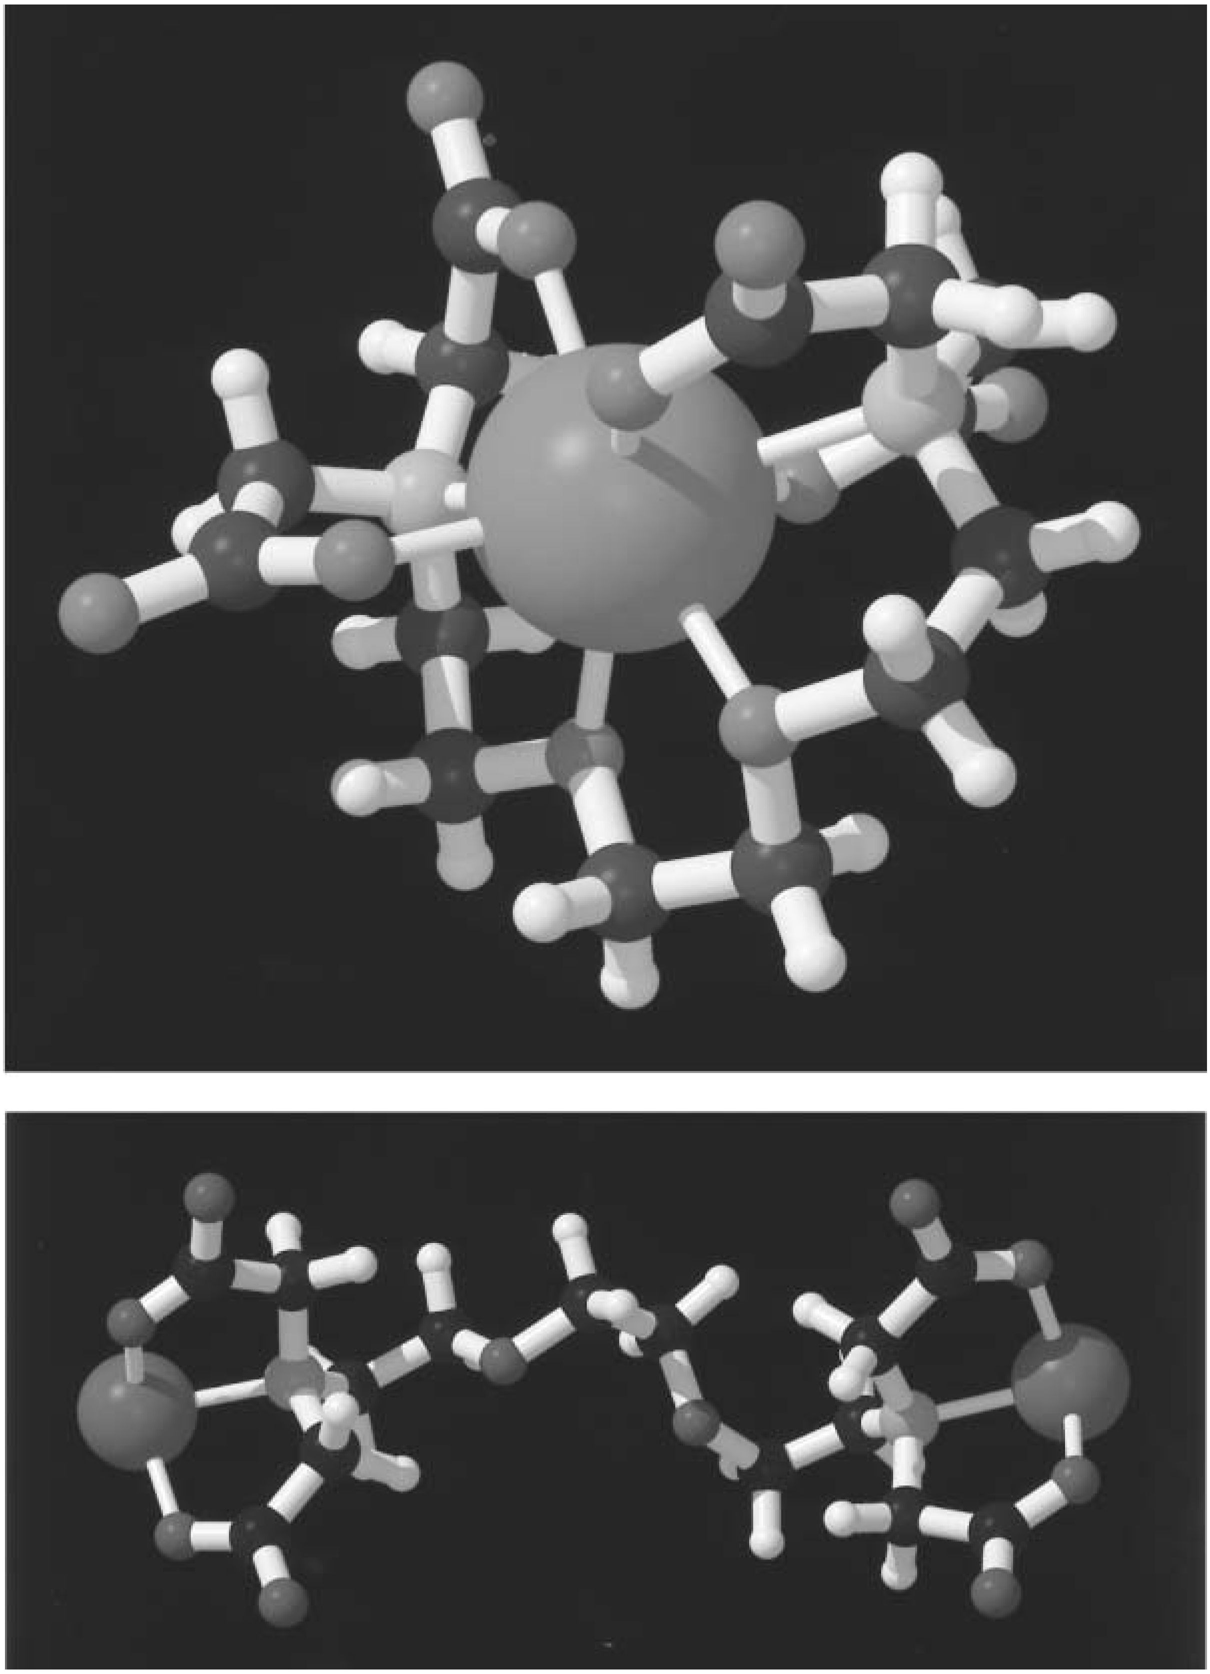

EGTA as the free acid is a white crystalline powder and has a molecular weight of 340.35 Da. The affinities of EDTA and EGTA for several cations are compared in Table 1(6).

Table 1. Comparison of Affinities of EDTA and EGTA for Various Cations[a]

Metal Ion	$\log_{10} K_{m\text{-EDTA}}$	$\log_{10} K_{m\text{-EGTA}}$
Mg^{2+}	8.64	5.3
Ca^{2+}	11.0	10.9
Zn^{2+}	16.4	12.6
Cd^{2+}	16.4	16.5

[a] The logarithms of their association constants (K_M in units of M^{-1}) are compared at pH 7.0, 25°C, and 0.1 M ionic strength (6)

Ehrlich Cells

1. Origin

Ehrlich cells, more properly known as Ehrlich–Lettre ascites carcinoma, were originally established as an ascites tumor of mice (1) from Ehrlich's "Strain 7" transplantable mouse carcinoma (2), which was probably of mammary origin. Several successful attempts at tissue culture have been performed, the earliest being hanging drop preparations that were passaged for 12 years (3). Subsequently, several other laboratories have cultured Ehrlich's cells (4-9), but the cell line that has been used most frequently, and which is lodged in the American Type Culture Collection (ATCC) repository as ATCC CCL-77, is the Strain E of Ehrlich–Lettre ascites (10). These cells were established as a monolayer from a 7-day-old tumor in NCTC 109 culture medium with 10% calf serum, and subcultured by scraping. The culture lodged with ATCC has been maintained in a later modification of NCTC 109, NCTC 135 supplemented with fetal calf serum.

2. Properties

Strain E has a short population doubling time *in vitro*: 20–24 h in Strain E and 14–16 h in Strain E (4). Strain E(4) was derived from alternate *in vitro* and *in vivo* passage, adapts rapidly to culture following *in vivo* passage, and is, presumably, the strain that was submitted to ATCC. The cells tend to have a fusiform morphology *in vitro*, suggesting an undifferentiated **phenotype**, and have a hyperdiploid karyotype (modal number 44, $2C = 40$) with distinctive A chromosome, metacentric, and minute markers.

3. Usage

The Ehrlich ascites became popular because it could be expanded manyfold by *in vivo* passage, making it useful for biochemical studies involving large amounts of tissue, while it could still be maintained *in vitro* for more physiologically controlled studies. With the advent of large-scale cell culture techniques that can yield 10^9–10^{12} cells, ascites passage is less attractive, due to the contamination of the tumor with a variety of host inflammatory cells and the development of legislation limiting the use of ascites tumors.

Elastase

This is the designation for enzymes that degrade elastin, the elastic protein found in tissues, such as that of the lung and the aorta, that undergo repeated stretching. Elastase (E.C. 3.4.21.36) is a 25-kDa protein produced in the pancreas, in the form of an inactive precursor that is activated on secretion into the small intestine, and it helps digest dietary proteins. A different elastase found in neutrophil granulocytes (E.C. 3.4.21.37), and one of its functions may be to degrade bacterial cell walls during phagocytosis (1). The elastases are serine proteinases of the **trypsin**/chymotrypsin family, with specificity for peptide bonds involving amino acids with small side chains eg, alanine and valine).

Leukocyte elastase, a 30-kDa **glycoprotein**, degrades extracellular matrix proteins in addition to elastin, and in this regard it probably plays a role in neutrophil migration and perhaps tissue remodeling (2). It facilitates the activation of plasminogen, a protein involved in the dissolution of

blood clots (3), and it may play an important role in tumor metastasis (4). It also has an important pathological action in pulmonary emphysema (5). Under normal conditions, its activity is controlled by a1-Antitrypsin, a member of the serpin family of proteinase inhibitors. Some individuals have an inherited deficiency of this inhibitor, which leads to a proteinase/antiproteinase imbalance in lung tissue, tissue degradation, and eventually emphysema. Leukocyte elastase may also contribute to rheumatoid arthritis and inflammation.

An elastase from human alveolar macrophages has been identified as a 92-kDa enzyme that is also a *gelatinase*, that is, it degrades denatured collagen (6). This enzyme is not a serine proteinase but a zinc **metalloenzyme** and a member of the matrix metalloproteinase family. It is not yet clear whether this enzyme has a significant role in the pathogenesis of emphysema.

Elastin

Elastin is the major macromolecule found in the ECM of elastic tissues such as the lung, skin, and blood vessels. The molecular properties of elastin are responsible for the elasticity. Elastin is a hydrophobic protein of about 800 amino acids that assumes a random coil configuration. Networks of elastin near the cell surface are covalently cross-linked via lysine residues, and elasticity is thought to be achieved by stretching the random coils. The protein has an abundance of proline and glycine, similar to collagen, but unlike collagen, elastin has only a small amount of hydroxyproline and lacks both hydroxylysine and carbohydrate side chains. The elastic layer is strengthened by an additional layer of microfibrils made of the protein fibrillin.

Cells may interact with elastin via an unusual 67-kDa elastin receptor. The receptor protein, unlike matrix receptors in the integrin class, is a secreted rather than transmembrane protein. It appears to mediate cell adhesion to elastin via interactions with cell surface proteins. The same receptor also binds laminin, and harbors a lectin like activity for binding sugar moieties. This protein is also found inside the cell where it may act as a chaperone to facilitate tropoelastin secretion and assembly of elastic fibers.

The functional importance of elastin is demonstrated poignantly by the recent discovery that deletions in the human elastin gene give rise to a disease known as Williams syndrome. People affected with this disease are mentally retarded (although occasionally mathematically or musically gifted), have an elfin like facial appearance and are prone to blood vessel narrowing and aneurysms.

Another disease, supravalvular aotric stenosis (SVAS), results from haploinsufficiency of elastin, and is also characterized by lumenal narrowing in blood vessels.

Electroelution

Molecules and particles purified by gel electrophoresis can be recovered from the gel by their electrophoresis into solution, a process termed electroelution . The procedure consists of excising the gel slices of interest, loading them onto a concentrating (stacking) gel, and electrophoresing the material contained in the slice into a recovery cup or dialysis bag attached to the bottom of the stacking gel. If the electroelution employs a single electrophoresis buffer, the sample moves directly into the recovery vessel. Electroelution of the band of interest into the stacking gel of a discontinuous buffer system of disc electrophoresis has the advantage that the material to be eluted is concentrated into a single band visualized by a tracking dye, so its collection can be visually monitored. This type of electroelution is practical with microgram amounts of sample, which can be recovered with a typical yield of 70%. Polymeric impurities in the electroeluate may be removed by gel filtration (1).

More directly, electroelution can be conducted at a right angle to the direction of migration, with instant monitoring of recovery until it is complete (2). Sequential elution of bands into a buffer chamber flushed continuously or discontinuously (designated “elution-PAGE”) is available for samples of up to milligrams, but it involves dilution of the eluate and the risk of losses in the elution chamber (3).

Electroendosmosis

Electroendosmosis (EEO) is the flow of solvent in the electric field during electrophoresis. EEO is caused by stationary charged groups in the gel (see Agarose) or along the inner wall of the vessel (see Capillary Zone Electrophoresis); negatively charged acidic groups in the gel or silicate groups embedded in glass surfaces bind mobile positively charged counterions electrostatically. The positively charged counterions migrate in the electric field, transporting their water of hydration and thereby giving rise to the water flow of EEO in that direction. Since the flow rate decreases with increasing distance from the glass wall, EEO is responsible for the parabolic profile of the electrophoretic band when a gel is replaced by a polymer solution (see Particle Electrophoresis). EEO can be used to enhance resolution, but more frequently it is suppressed by covering the stationary charged groupings with a neutral polymer (see Capillary Zone Electrophoresis).

EEO can be measured as the displacement in the electric field of uncharged compounds, such as cyanocobalamin in the neutral pH range or mesityl oxide. EEO decreases semilogarithmically with gel concentration, in complete analogy to electrophoretic mobility (see Ferguson Plot). Quantitative measurements of electrophoretic mobilities need to be corrected for the EEO.

Electron Crystallography

Knowledge on the molecular basis of many biological processes has rapidly evolved as a result of the development of complementary techniques of molecular biology and high-resolution structural biology. Quite often the mode of action of biological macromolecules can only be understood at the atomic level. Thousands of protein structures have been solved to atomic scale resolution using X-ray crystallography, but only a handful by electron crystallography. However, electron microscopy is a technique intrinsically capable of atomic resolution. The transmission electron microscope itself can achieve resolution on the order of 0.2–0.3 nm, and the structures of small organic and inorganic molecules are routinely determined at atomic dimensions. It is now well established that the principal limitation to obtaining atomic resolution of biological specimens using electron microscopy is the specimen itself (1). Because biological molecules are sensitive to electron radiation, one must record electron micrographs of unstained specimens with very low levels of electron irradiation (this is called low-dose imaging) in order to preserve high-resolution information. Unfortunately, such low electron doses yield images with a very low signal-to-noise ratio, too low to observe any structural detail. High signal-to-noise ratio images can be obtained by averaging hundreds or thousands of low-dose images of identical structures (2). Two-dimensional crystals, thin crystals which are only one unit cell thick along one axis, currently offer the best way to average images of many molecules to build up the signal-to-noise at atomic or near-atomic resolution (3, 4). It was estimated that the average of ~5 million molecules was required to produce a 3-D density map of bacteriorhodopsin that had recognizable amino acid side chains (1, 5). Similarly, ~2.6 million molecules of light-harvesting complex II were averaged to obtain an equivalent resolution (6).

Electron crystallography encompasses the use of electron diffraction (7) and imaging of thin crystals suitable for the electron microscope. All electron images are 2-D projections of a 3-D object along the path of the electron beam. Hence, to reconstruct an object in 3-D it is necessary to collect images from different angles. The minimal number of tilted views needed to reconstruct an object at a given resolution can be calculated from geometrical considerations (8).

Once a 2-D or thin 3-D crystal is grown, the best way to evaluate its quality is to study its diffraction pattern. The quickest and easiest method is to exam electron micrographs by optical diffraction. In this technique, an electron micrograph is illuminated with laser light focused with a series of lenses to form an optical diffraction pattern showing the distribution of Fourier transform intensities in the same manner as an X-ray diffraction pattern of a 3-D crystal. The spacing and distribution of intensities in an optical diffraction pattern offers clues to the molecular packing and secondary structure (9). Optical diffraction is also an important step in judging image quality in terms of astigmatism, defocus, and drift. More information can be obtained from the computed diffraction produced by calculating the Fourier transform of the digitized image. Unlike X-ray diffraction patterns, the computed diffraction pattern will have both structure factor amplitudes and phases in the "weak phase object approximation" (thin object and sufficiently high electron energy). Hence, a reconstruction of the object can be calculated from the Fourier transform of the image using the structure factor amplitudes and phases of the crystal; this results in a reconstructed image of the average unit cell of the crystal with noise removed. Furthermore, the phase relationship of the symmetry-related spots in the computed diffraction pattern can be used to determine the crystallographic symmetry.

Diffraction patterns, similar in principle to those obtained in X-ray diffraction, are formed in the back focal plane of the objective lens in the electron microscope. By adjusting the current in the diffraction lens, the diffraction pattern can be observed on the viewing screen. The type of pattern observed depends on the arrangement of molecules in the crystal and on how well ordered they are. How the molecules are arranged within the repeating unit of a crystal (unit cell) can be determined by the symmetry of the diffraction pattern and the intensities of the diffraction spots. In addition to the molecular arrangement, diffraction patterns can reveal the degree of specimen preservation and show the distribution of ordered regions of the specimen. The further the spots extend, the higher is the resolution of the preserved detail. Diffraction patterns can be used to assess radiation damage to the specimen with increasing electron dose, as judged by fading of the higher-order diffraction spots. The size of crystals most amenable for electron diffraction of biological macromolecules is a few microns on edge and one unit cell thick, usually described as a 2-D crystal (10). However, the electron diffraction patterns of 3-D crystals can also be examined if they are less than a few hundred Angstroms thick (11); Perkins, unpublished results). Electron diffraction can also ascertain the effects of different methods of specimen preparation. If a protein has secondary structural elements aligned in parallel, as in fibers, the spacings of the diffraction spots or streaks can indicate if there is predominantly a-helix or b-sheet (12). One disadvantage of electron diffraction is that relatively large crystals (~ 100 × 100 unit cells) are needed before high-resolution spots are observed. Another disadvantage is that like X-ray diffraction, electron diffraction does not produce structure factor phases; hence the structure cannot be determined from electron diffraction alone (13).

For high-resolution structural studies, advances in imaging, computer image processing, and preservation of specimens without negative stain and fixative have been critically important. The native conformation of specimens must be preserved under high vacuum conditions, and this can be achieved using one of two types of embedment media: sugars (14-16) and vitreous ice (17), which have both been shown to preserve the protein crystal structure well enough to produce images at a resolution of 0.3 nm. In addition, the development of computer-controlled spot-scan imaging has improved the efficiency of transfer of high resolution image information (18). Improvement in the rate of data acquisition has been made using cameras employing a cooled charge-coupled device (19). Because the high-resolution signal-to-noise is low, averaging over several large (20) or many more small (4) images is necessary to restore the signal above the background. Despite several noteworthy breakthroughs, the rate of progress in determining high-resolution structures of biological macromolecules by electron microscopy has been slowed by the paucity of suitable, well-ordered crystals. Recent reviews have described crystallization methods for both water-soluble and membrane proteins (21-23). Perhaps further improvements in collecting high-resolution information from single particles will obviate the need for crystals (1).

Electron crystallography offers a viable alternative to X-ray crystallography when crystals are not large enough for X-ray diffraction or for membrane proteins (24). Integral membrane proteins have the advantage that they can be routinely reconstituted in their native environment, the lipid bilayer, and often can be forced into ordered arrays through the judicious choice of lipid/protein and detergent/protein concentrations. The first membrane protein structure revealed by electron crystallography was bacteriorhodopsin in which seven a-helices were resolved (25). Since this early work, the field of electron crystallography has advanced to the point that atomic models have been built for two membrane proteins (5, 6, 26) and good progress made toward this goal for several others (27-29). Tubulin crystals also diffract to high resolution, and electron crystallography has shown the location of the taxol-binding site (30, 31). The highest resolution structures have been generated by taking the phases from the images and the amplitudes from the electron diffraction patterns. The electron diffraction amplitudes are generally more accurate than the image amplitudes because the image amplitudes require correction for instrumental factors that affect image quality, and methods for this correction have not been fully developed (20). However, it is not always necessary for electron microscopy to be performed at high resolution to contribute to atomic resolution structures. Electron microscopy provided a critical link allowing the actin crystal structure determined by X-ray diffraction to be fit into the actin filament determined by electron microscopy (32, 33).

The structure of biological macromolecules with helical or icosahedral symmetries can be determined using the same underlying principles of electron crystallography, although the operational approaches will be different (34). Helical structures produce diffraction patterns in which the helical information is confined to regularly spaced layerlines perpendicular to the helix axis instead of discrete spots. The pattern of intensities along the layerlines usually produce X-shaped patterns. Helical symmetry provides different views of a molecule in a single image as identical molecules are arranged along a helical path, so in principle only one image is needed for a low-resolution 3-D reconstruction. As with electron crystallography, however, higher resolution requires many images in order to obtain views at many different angles and to average many images in order to improve the signal-to-noise ratio (35). The structures of helical assemblies have been solved to 0.9 nm resolution (35, 36), and higher resolution is shortly anticipated. Close to 0.7 nm resolution has been reported for a viral structure with icosahedral symmetry (37). Even with the benefits of high symmetry elements afforded by an icosahedron, more than 6000 images needed to be averaged to achieve this resolution.

Electron Imaging

Particle/wave dualism is evident in experiments with electrons. They form a beam of particles, for instance, in a synchrotron, but behave as waves in an **electron microscope**. Electrons are scattered by matter just as X-rays are (see X-Ray Crystallography). Electrons are scattered by the atomic coulombic potential distribution in the atoms. This scattering is much stronger than for X-rays and can be recorded from very tiny specimens. This is particularly valuable for obtaining information on individual regions extending over only a few unit cells of a two-dimensional crystal (see Crystallography). The imaging experiments are performed in an electron microscope at a wavelength between 0.02 and 0.04 Å, much shorter than for X-rays. Then, the Ewald sphere (see Reciprocal Space) can be regarded as a flat surface, and diffraction from a stationary crystal shows essentially the reflections in a planar section of reciprocal space. By tilting the specimen, several intersections can be obtained and combined in a more complete image of reciprocal space. The short wavelength would result in a very high image resolution if the quality of the microscope lenses were not a limiting factor. At best they allow reaching a resolution of 1.5 Å. Simple switching of lens currents changes the observation from a diffraction pattern to a real image.

Transfer of energy to the specimen and the resulting radiation damage is a limitation in applying electron scattering. This is especially serious in studying biological material. However, with very thin specimens of two-dimensional crystals and with the molecules embedded in vitreous ice or glucose, extremely interesting results have been obtained from biological specimens by short exposure times, low beam intensity, cryocooling, and a combination of diffraction data and image analysis. The phases of the structure factors of the diffracted beams are calculated from the image (see Phase Problem). They are combined with the measured amplitudes of the diffracted beams and, exactly as in X-ray diffraction, a Fourier summation gives the atomic distribution in the specimen. At the present time, the maximum resolution is 3 Å.

Electron Paramagnetic Resonance

1. Introduction to Electron Paramagnetic Resonance (EPR) Spectroscopy

Electron paramagnetic resonance (EPR) refers to spectroscopy of unpaired electrons, and some aspects of the technique are termed "electron spin resonance" (ESR) or "electron magnetic resonance" (EMR). Unpaired electrons in biological systems are in much lower abundance than nuclei; thus, EPR is a technique that focuses on local sites, whereas nuclear magnetic resonance **(NMR)** tends to be more global. A connection exists between EPR and NMR in the variations of EPR that are termed "electron spin echo envelope modulation" (ESEEM) and "electron nuclear double resonance" (ENDOR). In these techniques, the energies of the transitions involving electrons are modulated by nearby nuclei, and this effect provides information about the type and geometry of nuclei around the site of an unpaired electron. The term "spin" in the designations of various forms of magnetic resonance spectroscopy refers to a property of electrons (or nuclei), and it is the interaction of the spin with the magnetic field that leads to separation of energy levels between which the spectroscopic transition occurs. A magnetic field is usually required for EPR, as is a source of energy to effect transitions. In addition, a few cases exist where spin transitions can be detected in the absence of a magnetic field.

Electron transfer systems (for instance, those in **photosynthetic** membranes) provide excellent opportunities to follow the intimate details of the transfer process with EPR spectroscopy. Other naturally occurring sources of unpaired electrons that are subjects for this form of spectroscopy include complexes of a variety of molecules with nitric oxide, quinone and flavin **cofactors** in enzymes, free radical enzyme intermediates, and metal ion sites in proteins (see Metalloproteins). By definition, a free radical has a homolytically broken bond with an unpaired electron. The range of applications of EPR spectroscopy is not limited to these natural sources of unpaired electrons. The EPR probe technique of spin labeling is being applied to examine dynamics of **DNA** and proteins, to study **protein folding**, and to unravel the complex motions of membrane components.

Molecular biological approaches extend the applications of spin labeling, and these applications are generically referred to as site directed spin labeling. In addition, unpaired electrons in free radical intermediates that have a short lifetime can be studied by trapping them to give a longer-lived, secondary radical in an EPR-related technique called "spin trapping." The text below will give examples of the type of information that can be obtained by applying EPR spectroscopy to these instances of unpaired electrons in biology.

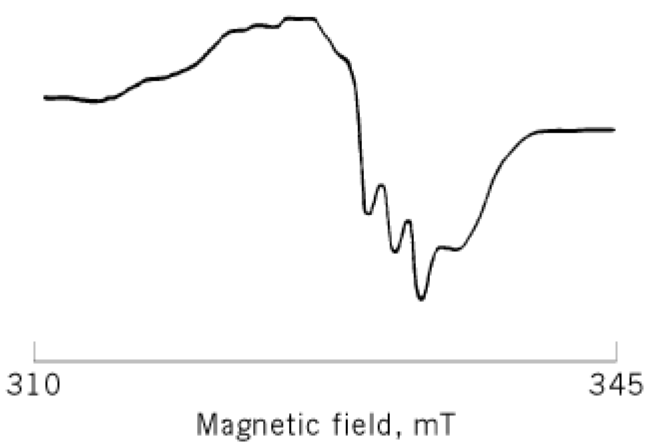
2. EPR in Photosynthesis

One of the long-standing puzzles of electron transfer in photosynthetic membranes is that the photoreaction center has pairs of molecular components arranged apparently symmetrically about a plane perpendicular to the membrane surface, yet electron transfer among the components follows a path involving primarily one-half of the dimer (see Photosynthesis and Photosynthetic Reaction Center) (1). EPR studies, especially of oriented crystals of reaction centers (2), provide precise information about small differences in symmetry of the two halves of the system. From EPR studies, it is possible to determine the orientation of orbitals involved in electron transfer between cofactors, and the positions of light atoms, such as hydrogen, on the cofactors can be determined by ENDOR with great precision (1). The various components of the electron transfer pathway—chlorophylls and quinones—can be selected for EPR by optical experiments, selective depletion of some components, and molecular biology. High-frequency EPR (1) helps to separate the spectra of different sites of unpaired electrons, much as higher frequency NMR gives better resolution of different nuclei. The manner in which electrons flow ultimately into the photosynthetic oxygen-evolving complex, which contains varied numbers of unpaired electrons associated with a cluster of four manganese atoms, is another challenge. ESEEM and ENDOR studies, together with isotope labeling (3) provide details of the structure of this site.

3. EPR of Nitric Oxide Complexes

Molecular adducts of nitric oxide give a diverse set of EPR signals that can be employed to determine the pathway of nitric oxide in tissues. Ferrous iron may or may not have unpaired spins, depending on whether it is low or high spin, but, in either case, it is, respectively, an impossible or difficult subject for EPR spectroscopy. Fortunately, the adduct of nitric oxide with ferrous iron in heme is quite suitable for EPR spectroscopy and provides a characteristic signature, shown in Figure 1. This spectrum is distinct from those of the nitric oxide adduct of either **amino**- or **thiol**- groups of protein side chains, as well as from copper adducts and adducts with other forms of iron. For further delineation of the location of nitric oxide in tissues, “spin traps” for nitric oxide are available (see section below on spin trapping). Typical spin traps for nitric oxide are ferrous ion chelated with *N*-methyl-D-glucamine dithiocarbamate or with diethylthiocarbamate.

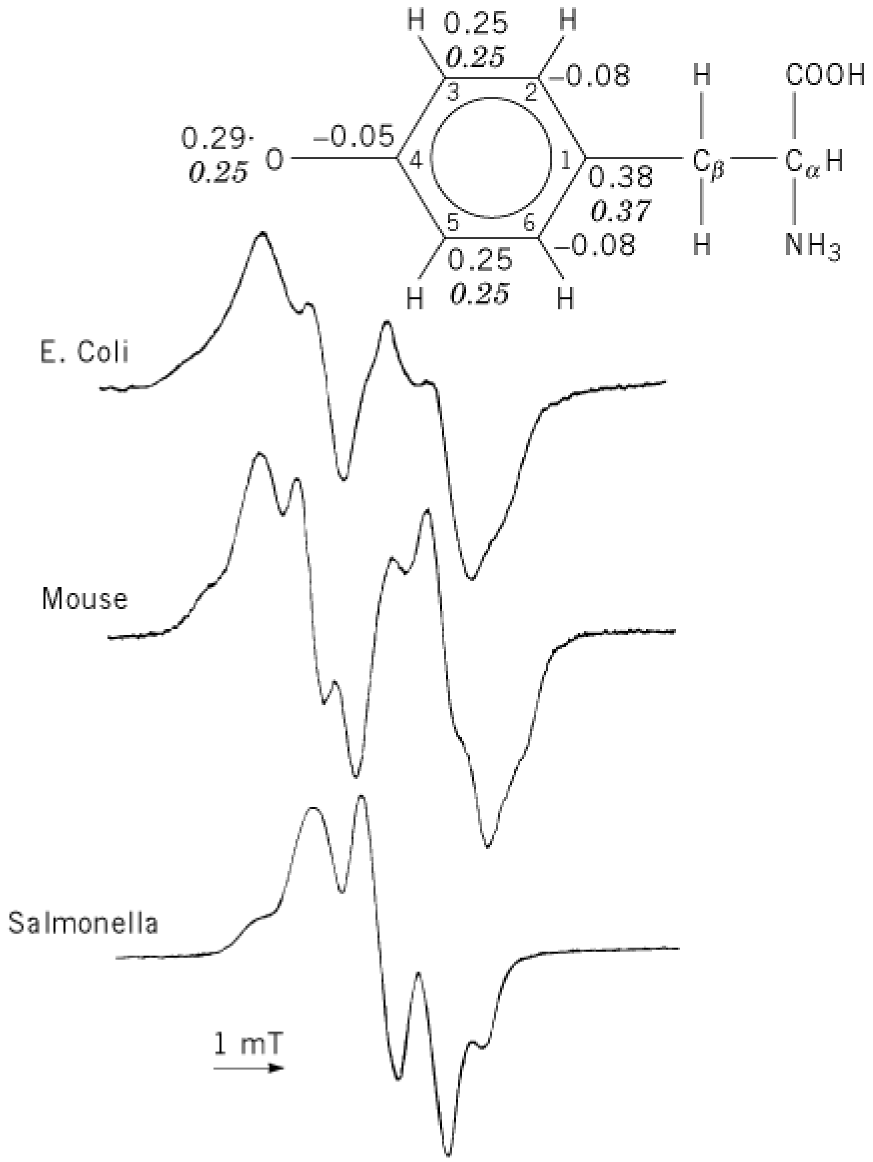
Figure 1. The EPR spectrum of deoxymyoglobin to which nitric oxide (NO) gas was added. The spectrum was recorded at 77K and a frequency of 9.1 GHz. (Reproduced with permission from Ref. 4, Fig. 8.)



4. EPR of Free-Radical Protein Intermediates

Ribonucleotide reductases use metals and free radical chemistry to carry out reduction of ribonucleotides to deoxyribonucleotides. (56) In different sources of the enzyme, the presence of free-radical intermediates has been demonstrated to involve side chains of the amino acids tyrosine, tryptophan, cysteine and glycine. EPR spectroscopy of tyrosine radicals has been used in this system, as well as in photosynthetic membranes, to demonstrate that the unpaired electron density at the various carbon atoms of the tyrosine aromatic ring is fine tuned by hydrogen bonds to the phenolic oxygen and by the protein environment. Figure 2 gives examples of EPR of tyrosine radicals from ribonuclotide reductases of several sources. The process by which involvement of metal ions and radical side chains lead to a free radical intermediate of the ribonucleotide is thought to involve long-range electron transfer. Organic cofactors, such as flavins, also form intermediates that can be detected in EPR studies of enzyme reactions.

Figure 2. EPR spectra of tyrosine freeradicals of ribonucleotide reductase R2 subunits from different organisms. The EPR spectra were recorded at temperatures of 20 to 30K at ~9 GHz. The numbers given on the structure are the spin density distributions for the *E. coli* and *S. typhimurium* enzymes. (Reproduced with permission from Ref. 6, Fig. 3).

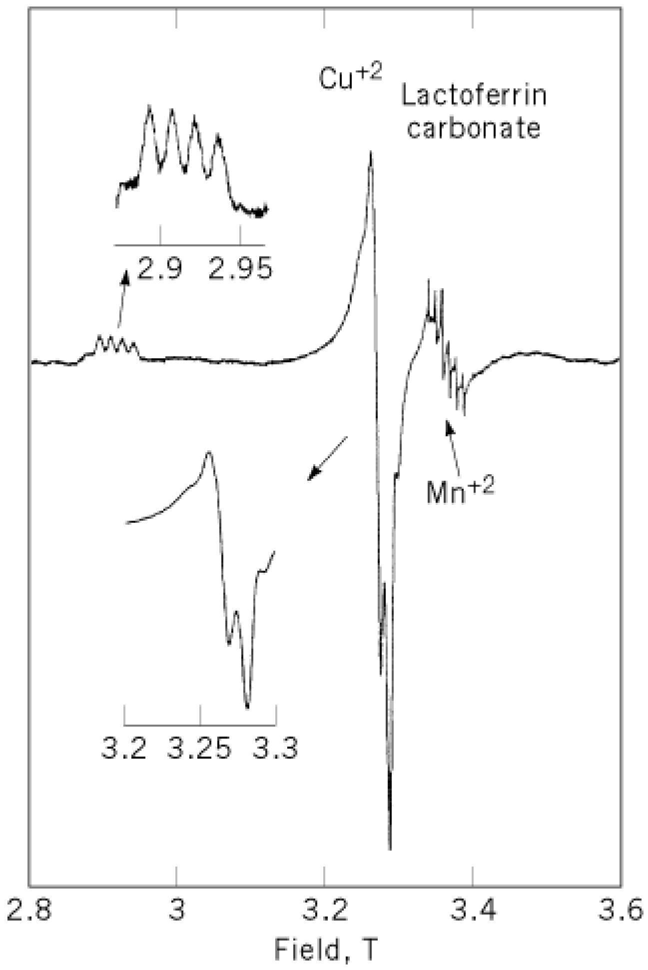


5. EPR of Metal Ions in Biology

All metals ions containing one or more unpaired electrons (paramagnetic ions) are in principle subjects for study by EPR, but the conditions for the experiments are quite varied (7). The paramagnetic ions in proteins that are commonly studied include manganese $^{2+}$, copper $^{2+}$, iron $^{3+}$, occasionally iron $^{2+}$, nickel^{3+}, and cobalt^{2+}. The conditions for the spectroscopy differ drastically, depending on which metal is the subject of study. Sometimes, mangenese ions can be detected with high sensitivity in solution at room temperature, but detection of ^{17}O ligands to the Mn^{2+} (for example from a threonine side chain in p21 ***ras***) required both low temperature and high frequency EPR (8). ENDOR and ESEEM (1) are alternative methods for detecting nuclei, such as nitrogen or hydrogen bound to, or near, metal-ion sites. Copper sites also can be detected at room temperature, but sensitivity is improved by conducting the EPR experiments at or lower than liquid nitrogen temperature. Studies of iron are almost always done at a temperature near that of liquid helium. The two primary reasons that low temperature is used in metal ion EPR are that relaxation times are too fast for temperature studies, and the signal intensity increases inversely with temperature.

Quantitative evaluation of the number of unpaired spins in different sites within a complex biochemical electron transfer system can be made by EPR and associated studies. For experiments of this type, calculations of the theoretical spectra are often needed for interpretation. Recent advances in EPR spectroscopy, particularly high-frequency EPR, provide improved resolution in samples with multiple EPR-detectable sites. Figure 3 shows a high frequency EPR spectrum of copper ion in lactoferrin, in which the copper spectrum is well separated from the signal of a manganese impurity (8, 9). At lower EPR frequencies, the manganese signal is superimposed on the central portion of the copper signal.

Figure 3. High-frequency EPR spectrum of di-cupric lactoferrin. The spectrum was recorded at 40 K and 94.1 GHz. The two regions from which significant information can be obtained are amplified in insets on the left. A feature indicated on the right is the EPR signal from an impurity of manganese ion in the sample. (Reproduced with permission from Ref. 9).



6. Spin Trapping and EPR Imaging

The EPR spectrum shown in Figure 1 was actually from a spin trapping experiment (4). In that case, the effluent from stimulated endothelial cells was passed into a solution of deoxy myoglobin, and the nitric oxide was trapped as the myoglobin heme adduct. Spin traps can also exhibit therapeutic effects in inhibition of lipoprotein oxidation (10). In a sense, EPR imaging of oxygen concentration in tissues of animals is also a spin trap experiment, but, in this case, only the magnetism of oxygen is "trapped" through its magnetic, but not chemical, interactions with a **spin label**. The degree of broadening of the EPR signal is transformed into an image (11).

Electron Microscopy

High-resolution electron microscopy presents to the molecular biologist advantages and disadvantages compared to both X-ray crystallography and NMR. The advantages are that (i) the macromolecule of interest need not necessarily be highly purified, provided that it can be unambiguously recognized, (ii) only small quantities (mg rather than mg amounts) are required, (iii) even very large macromolecules or complexes with no symmetry can be imaged easily, (iv) specimens can be imaged in their natural environment, and (v) unlike X-ray diffraction patterns, images contain both structure factor amplitudes and phases. The major disadvantages are that (i) the contrast of biological preparations in the electron microscope is inherently low, (ii) the specimen must be imaged in a high vacuum, and (iii) biological material is easily damaged by electron radiation. Electron microscopy has developed to the state where it can complement X-ray crystallography and NMR; this is especially true in the case of cryoelectron microscopy of frozen specimens with the application of computer image processing techniques. An example of how all three techniques may complement each other was the structural characterization of dihydrolipoyl transacetylase (1-3). X-ray crystallography provided the rigid core structure. NMR provided information about the flexible domains of this molecule, and electron microscopy integrated both packets of information into a detailed model.

The transmission electron microscope (TEM) is the electron counterpart to the transmission light microscope. A high-velocity, homogeneous electron beam passes through a specimen and is imaged on a phosphorescent screen or a charge-coupled device (CCD). The mechanism of image formation, however, for the TEM is by scattering, which is quite different from that of the light microscope, which is by absorption. TEMs are divided into different classes, depending on the accelerating voltages. A conventional TEM (CTEM) accelerates electrons with typical voltages between 60 and 120 kV; an intermediate-high voltage TEM (IVEM) operates between 200 and 400 kV; and a high-voltage TEM (HVEM) operates above 500 kV. The principal advantages of higher voltage TEMs are (i) the capability of imaging thicker specimens, and (ii) increased resolution of biological crystals and ice-embedded particles.

1. Thin-Section CTEM

The vast majority of biological specimens are much too thick as they occur in nature to be penetrated by the electron beam. A CTEM allows for quality imaging of specimens generally no thicker than 200 nm. Hence, the requirement for thin sections of biological material that are able to withstand both the high vacuum in the electron microscope and electron irradiation is apparent. Electron microscopy of thin sections of cells and tissues provides in situ visualization of cellular morphology and the spatial relationships of subcellular components. In order to preserve detailed structural information, the tissue must be well-fixed, dehydrated and embedded in plastic. The resolution achieved with tissue prepared this way is usually limited to 2–3 nm. Sections from the embedded tissue should be of a known and uniform thickness and free from breaks, folds, wrinkles, and chatter to produce standardized and reproducible observations (4). Because it is difficult to differentiate among the electron opacity of various cellular components, selective staining is necessary. Commonly used stains are heavy metals such as uranyl acetate and lead salts.

2. Freeze Fracturing and Etching

Thin-section techniques can be complemented by examining specimen surfaces by freeze fracturing/etching. The freeze fracture method involves the following steps: (i) cryofixation of the specimen by rapid freezing, (ii) fracturing of the specimen by cleaving it with a knife edge or breaking it, (iii) replication of the freeze-fracture plane by coating with heavy metals under high vacuum, (iv) removal of the specimen from the replica, and (v) observation of the replicas with a CTEM. The most important contribution of this technique has been the elucidation of the molecular architecture of biological membranes. During freeze fracturing, membranes are split through the hydrophobic moiety, thus exposing intramembraneous surfaces. The fracture plane often follows the contours of membranes and leaves either protrusions or depressions where it passes around organelles or vesicles (4). Smooth areas represent the lipid monolayer face, whereas particles represent integral membrane proteins.

Freeze etching is a slight modification of freeze fracturing through the process of controlled sublimation of water vapor (transition from the solid state to the gas state, bypassing the fluid state) to expose membrane surfaces or macromolecules just below the fracture plane. By etching, extracellular and intracellular structures, such as the cytoskeleton, can be visualized which would otherwise be masked. The etching can either be "normal" (< ~ 100 nm) or "deep" (up to ~ 3 µm).

Related techniques involve shadowing of macromolecules adsorbed or deposited onto a flat surface and dried by methods which minimized deformation during drying. Drying is best accomplished by sublimation as in freeze-etching and requires access to a freeze-fracture instrument; this is referred to as freeze drying and shadowing (5). A simpler method developed by Branton requires only a conventional vacuum evaporator (6). This technique involves (i) preparing the macromolecule in a high-concentration glycerol solution, (ii) spraying this solution onto mica, (iii) evaporating the solvent under vacuum, (iv) rotary shadowing with a metal such as platinum, (v) carbon coating the shadowed specimen, (vi) floating the carbon replica onto water, and (vii) picking up the replica on an electron microscope grid. Rotary shadowing is particularly useful for visualizing fibers or rod-shaped complexes such as actin/myosin. The double strands of spectrin (which forms rods ~200 nm long) were resolved using this technique with tantalum/tungsten shadowing, which produced small metal grains that increase the resolution (7).

Electron Tomography

Electron tomography is defined as the generation of a 3-D reconstruction from an electron microscope tilt series (1). This powerful technique is closely related to computerized axial tomography used by CAT scanners in radiological imaging in the computational methods used to calculate a 3-D structure from many two-dimensional images or projections recorded over a wide range of tilt angles. The use of tomography has proved valuable not only for the determination of macromolecular complexes (2-4), but also for the visualization and analysis of relatively large, complex biological structures. Because of variable size, large-scale biological structures such as organelles elude crystallographic or single-particle approaches that require multiple images of identical structures. Electron tomography is especially powerful for these complex structures, but until recently, it has not enjoyed widespread application because of obstacles that are now being removed (5). Electron tomography presently is the imaging technique that provides the highest 3-D resolution (capable of 5–10 nm) of the internal features of organelle-size structures. This is accomplished by recording a series of images of a single specimen over a wide range of tilt angles with a small interval of tilt angle. Typically such a tilt series would consist of 61 images recorded at tilt angles from –60° to +60° in 2° increments. The individual images must be digitized (unless recorded directly in digital form using a CCD camera attached to the microscope), aligned to a common origin, and processed using computer algorithms, similar to those used in computerized tomography in medical imaging, to reconstruct a 3-D volume from a series of 2-D projections. Since whole cells and organelles, such as mitochondria, are relatively large, the images must be recorded from specimens embedded in semithick sections, 0.25–1 µm thick. Such thick specimens require the use of higher voltage electron microscopes, intermediate voltage electron microscopes (IVEM's) with accelerating voltages up to 400,000 volts, or high-voltage electron microscopes with accelerating voltages up to 1,200,000 volts. By comparison, typical transmission electron microscopes have accelerating voltages of approximately 100,000 volts. The higher voltage electron microscopes are relatively expensive, and most users wishing to do electron tomography of thick specimens must use instruments made available in national facilities.

Until recently, the bulk of our knowledge of the architecture of organelles and bacteria has come from untilted images of sections. The 3-D architecture is usually inferred from these images, sometimes with the aid of stereo imaging or serial-section reconstruction. Although thin-section electron microscopy provides relatively high-resolution images, an incorrect impression of the 3-D structure may be obtained because one is looking at only a very thin slice through a complex 3-D object. On the other hand, electron tomography offers an opportunity to map topology more accurately by providing improved resolution along the *z*-axis, while circumventing major deficiencies in stereo imaging and serial-section reconstructions. This technique provided the resolution necessary to observe characteristics of mitochondrial structure that differ from long-held conceptions (6,7). These newly appreciated characteristics include: (i) All observed cristae connect to the inner boundary membrane via narrow, tubular openings, termed crista junctions. (ii) Tubular cristae merge, sometimes from opposite ends of the mitochondrial periphery, to form lamellar compartments. (iii) Contact sites are not clustered about crista junctions. The full power of electron tomography is now being explored to generate 3-D distributions of specifically labeled or immunolocalized components.

Electron Transfer Proteins

Biological electron transfer (ET) encompasses reactions that are essential for life, such as those involved in **light harvesting, nitrogen fixation**, and **production of the high-energy metabolites**. In proteins, ET occurs between redox centers that are separated by distances much longer than a chemical bond and that in many cases are carried by different molecules. Moreover, the temperature-dependence of ET rates is often atypical (ie, non-Arrhenius type).

A general theory (1) can describe ET and thus provide a framework to guide experimentalists in their investigations on the structural control of biological ET. From these studies, it emerged, as is frequent in biology, that different solutions have evolved in different systems to solve the same general problem.

Several families of proteins involved in biological ET, with variable structures and catalytic complexity, are known in detail (see **Redox proteins**). Although a compilation is beyond the scope of this article, a brief synopsis is provided. Many of these are one-electron carrier proteins that are usually small (about 100 amino acid residues), and display no associated enzymatic function. In these proteins, the electron resides on a special cofactor, such as a heme or a metal atom, which often can donate the electron to different partners. Examples of this group are the cytochromes, cupredoxins, and ferredoxins. Other more complex proteins consist of one or more **domains** and may perform chemical reactions, such as oxidation or reduction of organic molecules. Some of them can convert the flow of charge from single electron to pairs (or more) using (i) cofactors like flavins and quinones, forming stable radical intermediates, or (ii) radicals of amino acid side chains, such as those of tyrosine or tryptophan, together with metal centers. Among others, it is worth mentioning the various respiratory complexes located in organelle and plasma membranes, the large class of detoxifying enzymes (eg, cytochrome P-450s), and photosynthetic reaction centers .

1. General Theory and Intramolecular ET

The probability of electron transfer depends on the overlap between the electron-containing orbital (wavefunction) of the donor with that of the acceptor. This overlap can be very small, because redox centers in proteins are buried and often located 10–15 Å apart; nevertheless, biological ET is usually extremely fast and specific.

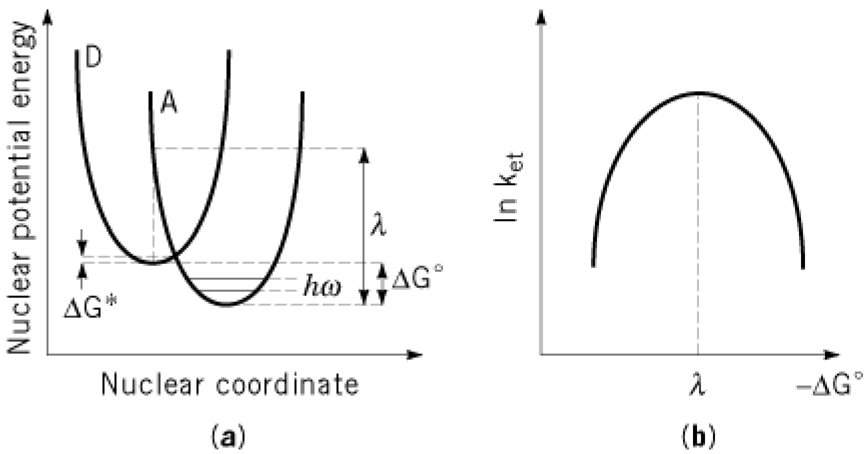
In intramolecular ET, the electron must move through the protein matrix, which has been assigned a low dielectric constant (D = 2 to 4). In a classical picture, this energy barrier would be too high to be crossed by the electron; in a quantum-mechanical view, however, the electron can tunnel through the barrier with a finite probability. To relate tunneling theory and experiments, a simple description of the ET rate is given by Fermi's Golden Rule, which applies to nonadiabatic ET occurring between weakly coupled redox centers:

$$k_{et} = (\text{electronic factor})^*(\text{nuclear factor}) = (2\pi/\hbar)H^2_{AB}(\text{FC}) \qquad (1)$$

The electronic factor (H^2_{AB}), which describes the electronic coupling between donor and acceptor, can only be understood in quantum-mechanical terms and will be discussed below; $\hbar$ is the Planck constant/2p. The nuclear factor, or Franck–Condon term (FC), states that during ET the nuclei do not have time to respond, because of their large mass relative to that of the electron.

Marcus and Sutin (1) have provided a simple description of the energy terms that comprise the FC factor using potential energy curves (Fig. 1). The energy terms that determine the rate of ET are the **free energy** change (D*G*°), or driving force, and the reorganizational energy (l) (which is required to distort the equilibrium geometry of the reactant to that of the product, but without actually transferring the electron). ET will occur when the potential energies of reactants and products are equal.

Figure 1. (**a**) Potential energies of the ET donor (D) and acceptor (A), as a function of the reaction coordinate. The energies with their surrounding medium are approximated as harmonic oscillator potentials. The Franck–Condon factor can be described classically, provided that the nuclear vibration energy (w/2p) is not too high relative to the thermal energy (k_BT). (**b**) Dependence of the logarithm of the ET rate constant on –D*G*°. The ET rate is maximal at the point where –DG° = l (activationless regime).



In general, the activation barrier (D*G**) is given by the expression:

$$\Delta G^* = (\Delta G^\circ + \lambda)^2/4\lambda \qquad (2)$$

Depending on the sign of (DG° + l), one can distinguish normal, activationless, and inverted regions, respectively with (DG° + l) > 0, = 0, and < 0. The ET rate goes through a maximum for DG° = –l (activationless regime), and decreases on both sides (Fig. 1), as shown in simple systems and in several redox proteins. For example, in the photosynthetic reaction center, charge recombination is prevented because the very large driving force for the initial charge separation drives the recombination reaction into the inverted region, slowing down the corresponding rate.

Using the classical approximation for the FC factor, the Fermi equation becomes

$$k_{et} = (2\pi/\hbar)H_{AB}^2(4\pi\lambda k_B T)^{-1/2}\exp[-(\Delta G^\circ + \lambda)^2/4\lambda k_B T] \quad (3)$$

where k_B is the Boltzmann constant and T is the temperature. According to Eq. (3), the main temperature-dependence comes from the exponential factor, but when the activation energy is zero ($e^0 = 1$), a weak temperature-dependence remains because of the preexponential factor, causing the rate to decrease as the temperature increases. Again this behavior has been observed for some reactions of the photosynthetic reaction centers.

The temperature-independence of some ET reactions can be explained, however, only by using a semiclassical description of the FC term, proposed by Hopfield (2), in which the term 2l$k_B T$ has been replaced by l $\hbar$w coth($\hbar$ w/2l$k_B T$). If the temperature falls below $\hbar$w/2k_B, the rate becomes nearly temperature-independent at any value of DG°.

The other term influencing the ET rate, the electronic factor (H_{AB}), represents the weak coupling of the reactant and product wavefunctions, where H stands for "Hamiltonian," the quantum-mechanical description of the system. H_{AB} yields the overlap between the orbitals A and B and is often referred to as the "electronic coupling matrix element." The degree of orbital overlap depends on the distance between the redox centers and the nature of the intervening medium, which in biological ET is the protein matrix and the solvent.

Because wavefunctions decay exponentially with distance, the electronic coupling will decrease with the distance (r–r_0) according to:

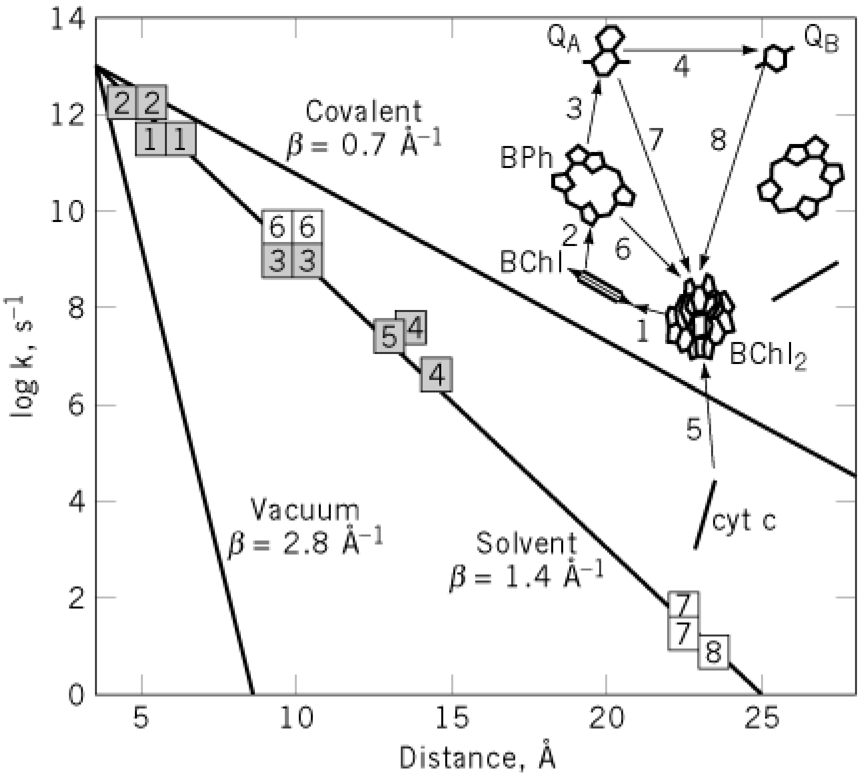
$$H_{AB}^2 = (H_{AB}^0)^2 e^{-\beta(r-r_0)} \quad (4)$$

where $H_{AB}{}^0$ represents the electronic coupling between A and B when the redox centers are in **van der Waals** contact ($r = r_0$), and its decay with distance ($r - r_0$) occurs with the coefficient b. The latter therefore describes the contribution of the intervening medium in propagating the wavefunction, and its dependence on protein structure is a matter of intense research and debate.

To obtain a correct description of the role of the intervening medium and distance on k_{et}, it is necessary to work in the activationless regime (DG° = –l) (Fig. 1). The photosynthetic reaction center proved to be an excellent test system for several reasons: (i) The three-dimensional structures of a number of reaction centers are known at atomic resolution; (ii) it contains several redox cofactors at various fixed distances; (iii) the driving force can be varied experimentally; and (iv) ET can be studied over a wide temperature range. Using experimental data obtained with proteins where the primary quinone was substituted with other compounds of different oxidation/reduction potential, Dutton and coworkers (3, 4) have shown a linear dependence of ln k_{et} on distance (over 12 orders of magnitude), with b = 1.4 Å^{-1}, r_0 = 3.6 Å, and a preexponential factor [(4p ^{2}/$\hbar$($H^2{}_{AB}$)] of 10^{13} s^{-1} (Fig. 2). These authors concluded that the ET rate in any protein follows an exponential decay of the electronic wavefunctions with distance, implying a homogeneous intervening medium.

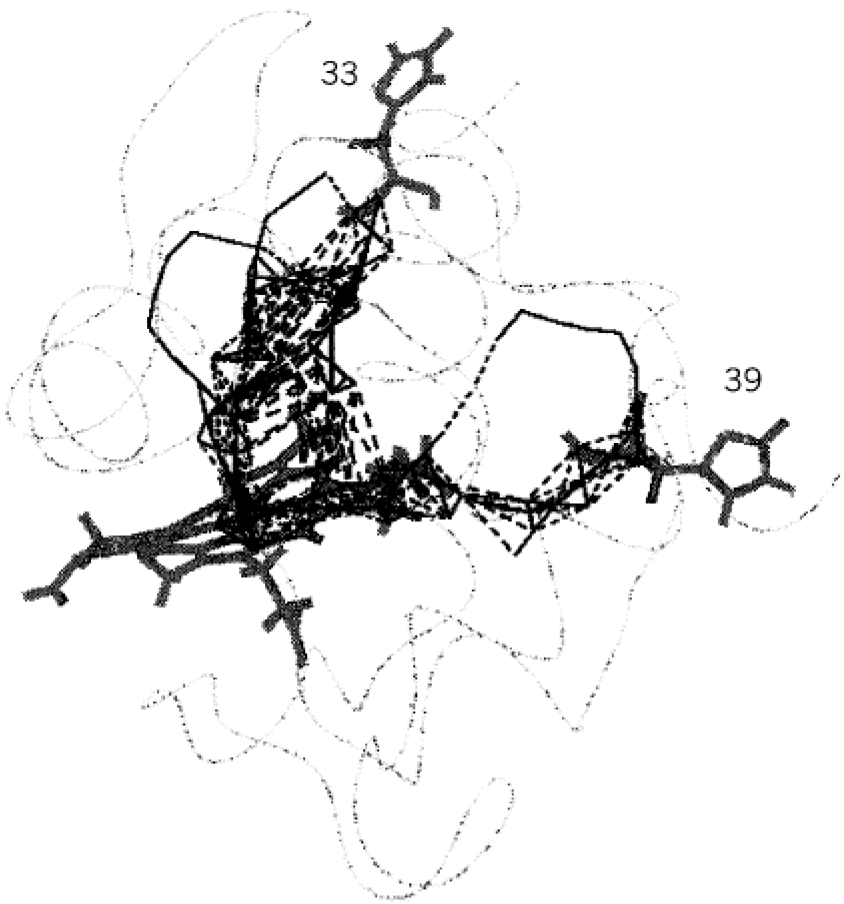
Figure 2. Effect of distance on the intraprotein ET rate in the photosynthetic reaction center, according to Moser and Dutton (3). Following light excitation of the bacteriochlorophyll dimer ($BChl_2$), ET progresses sequentially through bacteriochlorophyll monomer (BChl), bacteriopheophytin (BPh), primary quinone, and secondary quinone (Q_A and Q_B). The resulting positively charged oxidized dimer can be re-reduced by the nearest of the four cytochromes c (cyt c). The experimentally determined rates within the reaction center fit a straight line with b = 1.4 Å^{-1}, compared to 2.8 Å^{-1}

in vacuum and to 0.7 Å^{-1} in a rigid covalent system. The line through the experimental data extrapolates to 10^{13} s^{-1} at 3 ANGSTROM, the van der Waals distance. (From Ref. 8, reproduced with permission. Copyright BIOS Scientific Publishers, 1996.)



This exceptional result (Fig. 2) does not prove, however, that the tunneling barrier between the redox centers is microscopically uniform, but rather that the observed value represents an average. Gray and coworkers (5) have used proteins modified by incorporation of ruthenium (mainly myoglobins and cytochromes) as model systems to investigate the dependence of b on the structure of the intervening medium, that is, the detailed protein structure. In this and other similar studies, a plot of ln k_{et} against distance does not always yield a linear relationship, suggesting that the protein does not always provide a homogeneous energy barrier. Given the intrinsically heterogeneous packing inside a protein, and thus the variable dielectric constant, a model that takes into account the detailed structure of the intervening medium is needed. Onuchic and Beratan (6) have developed such a model, which views coupling between redox centers via pathways. In this model, the exponential decay of the electronic coupling depends not only on the distance between redox sites, but also on the detailed contacts along the ET pathway. Along a pathway, electronic decay factors (ε) through different connectivities, involving covalent (ε_C), hydrogen-bond (ε_H), and through-space (ε_S) jumps, come into play. The coupling strength decreases in the order covalent > hydrogen bond > through-space, and the total decay across the pathway is given by the sum of the individual contributions. An algorithm searching for potential ET pathways in proteins of known three-dimensional structure has been developed by these authors (Fig. 3). This model has been applied to different redox proteins in order to define the role of the intervening medium and of **secondary structure** elements on the ET rates. The model predicts that (i) hydrogen bonds provide shortcuts for the electron between otherwise unconnected protein segments, (ii) beta-sheet proteins will exhibit a greater degree of coupling than **alpha-helical** proteins, and (iii) pathways always arise in families, giving rise to the concept of “fattened” pathways and pathway tubes. The existence of multiple pathways is a challenge to protein engineering of ET proteins to enhance or inhibit ET rates by modification of residues along the most probable pathways.

Figure 3. Connectivity between redox centers according to Beratan, Onuchic, and coworkers. The figure depicts the structure of cytochrome *c*, with the heme group highlighted and the polypeptide chain sketched as a continuous line. The two histidine residues at position 33 and 39 are the sites of chemical modification with ruthenium. Dotted lines represent the calculated pathway for ET. The strongest coupling is provided by bonds at the center of a tube of pathways that connect the donor–acceptor couples within the protein. The decay factors were calculated to be: covalent bonds, $\varepsilon_c = 0.6$; hydrogen bonds, $\varepsilon_H = \varepsilon_c^2 e^{-\beta(r-r_0)}$; through-space jumps, $\varepsilon_s = 1/2\varepsilon_c e^{-\beta(r-r_0)}$), where r_0 is the reference distance for covalent bonds (1.4 Å) or hydrogen bonds (2.8 Å) and b is the decay length for through-space jumps (1.7 Å). (From Ref. 9, with permission. Copyright American Chemical Society.)



The large body of experimental data available today indicates that the two models (homogeneous and heterogeneous) are not necessarily exclusive. In some cases, the protein behaves as a homogeneous medium with “distance-dependent” exponential decay, as for photosynthetic reaction center, ruthenated azurin, and ruthenated cytochrome b_5, although different b values were reported. In other cases, the coupling decay factor was shown to be anisotropic (eg, in cytochrome *c*), giving rise to a view in which “hot” and “cold” spots for ET can be identified. Of particular importance are studies on the role of dynamic fluctuations on through-space contacts.

2. Intermolecular ET

The principles underlying ET between two proteins offer another theme for variation and control, namely, molecular recognition and protein–protein interactions as a prerequisite for ET. Some general features that have emerged from many studies will be presented in this section.

The Marcus theory ([1](#)) described above states that electron coupling between redox centers depends primarily on distance. For efficient ET, diffusible proteins must interact in such a way to maximize proximity between the redox centers within a collisional complex (AB), given that most redox active proteins are asymmetric, with their cofactor/metal generally located on one side of the macromolecule. The kinetic model that describes interprotein ET is

$$A^+ + B \underset{k_{-a}}{\overset{k_a}{\rightleftarrows}} (A^+B) \overset{k_{et}}{\rightarrow} (AB^+) \rightarrow A + B^+ \tag{5}$$

Under pseudo-first order conditions (eg, [A]≫[B]), the overall rate constant k_{12} is given by

$$k_{12} = k_a k_{et}[A]/(k_{-a} + k_{et} + k_a[A]) \tag{6}$$

Within this model, two limiting conditions can be envisaged, where either complex formation or intracomplex ET are rate-limiting.

Marcus theory allows describing the overall rate constant k_{12} as a function of the equilibrium constant K_{12}, the self-exchange rate constants of the two partners, k_{11} and k_{22}, and the work term W_{12} involved in the configurational change of reactants and products along the reaction coordinate:

$$k_{12} = (k_{11}k_{22}K_{12}f_{12})^{1/2}W_{12} \tag{7}$$

where

$$W_{12} = \exp(w_{11} + w_{22} - w_{12} - w_{21})/2RT \tag{8}$$

Equation (7) can be simplified when (a) the work terms cancel one another (ie, homonuclear and heteronuclear ET involve the same energy terms) and (b) f_{12} is close to unity, which is often the case provided that K_{12} is not too large. Under these conditions, equation (7) becomes

$$k_{12} = (k_{11}k_{22}K_{12})^{1/2} \tag{9}$$

which is frequently used and is generally referred to as the "cross-relation." For redox reactions between inorganic metal ions or complexes, Marcus theory has been experimentally verified many times, either in the general or in the "cross-relation" formulation. It has also been used to calculate reaction rates or equilibrium constants that are difficult to determine experimentally. The "cross-relation" approach has also been used to interpret protein–protein ET: Table 1reports a set of experimentally determined rate constants for some copper and heme proteins, together with the values calculated on the basis of equation (8). When comparison with known equilibrium and self-exchange rate constants was possible, the discrepancy between calculated and measured values was found to be no greater than one order of magnitude (which is considered good). In cases in which larger deviations were observed (>100 fold), efforts have been made to rationalize this discrepancy, possibly reconsidering the applicability to the system of some of the theoretical assumptions described above. The obvious assumption that may not apply is related to the anisotropy of the redox protein and thereby to the contention that ET with any partner always occurs through one and the same contact surface.

Table 1. Comparison of Experimentally Determined and Calculated (According to Marcus "Cross-Relation") Second-Order Rate Constants for Different Redox Couples

Oxidant[a] (1)	Reductant[a] (2)	K_{12}[b]	R_{11}[c] (M^{-1} s^{-1})	k_{22}[c] (M^{-1} s^{-1})	k_{12} calc. (M^{-1} s^{-1})	k_{12} exp. (M^{-1} s^{-1})
Azurin	Cyt *c*	19	8×10^5	2.5×10^2	5.5×10^4	6.4×10^4
Azurin	Cyt c_{551}	3	8×10^5	1.2×10^7	4.8×10^6	6×10^6
Cyt *c*	Cyt c_{551}	1	2.5×10^2	1.2×10^7	5.5×10^4	5×10^4
Plastocyanin	Cyt *c*	40.4	10^3	2.5×10^2	3.2×10^3	1.5×10^6
Plastocyanin	Cyt c_{551}	40.4	10^3	1.2×10^7	7×10^5	7.5×10^5
Stellacyanin	Cyt *c*	0.06	1.2×10^5	2.5×10^2	1.3×10^3	3.5×10^2
Stellacyanin	Cyt c_{551}	0.08	1.2×10^5	1.2×10^7	3.3×10^5	1.6×10^5

[b] Equilibrium constants were calculated on the basis of midpoint redox potentials ($E_{m,7}$).

[c] Electron self-exchange rates at 20°C used in the calculation of k_{12} according to Marcus "cross-relation."

In the **diffusion**-limited case, maximal second-order rate constants for ET proteins are in the range of 10^8 to 10^9 M^{-1} s^{-1}. A negative steric factor, due to the fact that only a small fraction of the total surface of a protein is near the redox active cofactor, is partially compensated for by the solvent cage effect and long-range electrostatic interactions. The solvent cage effect increases the lifetime of the so-called encounter complex because, after collision, the two proteins are momentarily trapped by the solvent and thus experience a large number of mutual contacts by two-dimensional diffusion. Long-range electrostatic forces come into play, because many ET proteins display an anisotropy in surface charge distribution that results in a permanent dipole moment, favoring their association. This effect has been investigated through (i) the ionic-strength dependence of the second-order rate constant k_{12}, (ii) the effect of surface-charge modification by chemical modification or protein engineering, and (iii) the influence of the computed electrostatics of the redox partners in simulated docking experiments. An interesting generality related to the electrostatic makeup of ET proteins is that the docking surfaces often show a "loose" specificity, which also explains the high degree of cross-reactivity observed both *in vitro* and *in vivo* between donors and acceptors. This is shown in Figure 4 for the widely studied redox couple cytochrome *c* and cytochrome-*c*-oxidase of the respiratory chain, where the complex between the two redox partners is stabilized by multiple electrostatic interactions, and the ET pathway crucially depends on two aromatic side chains inside a patch of negative charges on the cytochrome-*c*-oxidase binding site (7).

Figure 4. Models of the three-dimensional structures of *Paracoccus denitrificans* cytochrome-*c* oxidase and horse heart cytochrome *c*, in a CPK representation. Electrophoresis

Electrophoresis is the movement of charged molecules or particles in an electric field. Electrophoresis may be conducted for the purposes of analytical identification or physical characterization of the various components of a sample, or for their preparative separation.

Electrophoretic migration of a molecule in any medium proceeds in the direction toward the electrode of opposite polarity to the net charge of the molecule (eg, negatively charged molecules migrate toward the positively charged electrode; cations move toward the cathode, anions toward the anode). The medium needs to be buffered at a pH that produces the appropriate direction and rate of migration. The mobilities of proteins generally increase the further the pH is from their isoelectric points (pI), increasing their net charge. However, resolution based on net charge differences improves as the net charge is reduced and is optimal when the net charge approaches zero at the pI (see Isoelectric Focusing). **Nucleic acids** and proteins complexed with the anionic detergent SDS (sodium dodecyl sulfate) exhibit high mobilities over a range of pH values above neutrality, due to their high surface negative charge densities. In addition to pH, the ionic strength, composition of the solvent, presence of detergents (see Hydrophobic Electrophoresis), and temperature govern the electrophoretic mobilities of all species in a sample, their separation, and the maintenance of their native conformations. For example, nucleic acid stability depends on the Na^+ level. Proteins aggregate at low ionic strength; high ionic strength may exceed the Joule heat dissipation capacity of the electrophoretic apparatus and "cook" the sample during electrophoresis.

Different species can often be separated on the basis of differences in their electrophoretic mobilities, which is defined as the ratio of the migration rate (cm/s) to the electric field strength (V/cm). The mobility (cm^2/s V) of a macromolecule is a function of the ratio of its surface net charge to its accessible surface area, plus the resistance to migration exerted by the medium in which the separation takes place. The resistance due to the viscosity of the medium affects species of all sizes equally and therefore does not contribute to their separation; it may, however, be augmented by the presence of polymer networks and permit separations based on differences in size and shape (see also Gel Electrophoresis; Agarose; Polyacrylamide; SDS-PAGE).

For practical reasons, samples subjected to electrophoresis need to be protected from convective mixing. This can be accomplished within a liquid sample using a density gradient when the migration of the boundary of a region of sample is observed, or in tubes of less than 0.2 mm in diameter, as in capillary zone electrophoresis. Much more commonly, electrophoresis is carried out with a gel when the sample usually migrates as a zone. In this case, the electrophoretic migration rate depends on the pore size of the gel. Alternatively, the sample may migrate within a stack of moving boundaries of buffer components, with a mobility regulated by that of the boundary (see Disc Electrophoresis; Isotachophoresis).

Separations by electrophoresis and chromatography share many of their principles of operation, but electrophoresis excels in its ability to provide simultaneous separations of many components, to exploit charge and size differences simultaneously, to be compatible with a continuum of polymer or gel concentrations that produce a "molecular sieve," and to be applicable to particle sizes ranging from simple organic acids to very large complexes and small cells (see Particle Electrophoresis).

1. Sample detection and quantification

The zone or moving boundary comprising the sample of interest can be identified and quantified by its absorbance, fluorescence, or radioactivity, by specific **antibodies** (see Protein Blots (Western Blots); Immunoelectrophoresis), by its biological activity (see Overlay Assay: Enzyme Zymography of Plasminogen Activators and Inhibitors), or by stains specific for the class of molecule. Staining with reagents specific for proteins or nucleic acids is the most common method. Before staining samples in electrophoresis gels, the sample normally must be fixed, ie, made insoluble, so that it does not diffuse during the staining process. Solvents such as acetic acid or trichloroacetic acid are often used to fix proteins; frequently, the fixing solution also contains the stain. The most general and sensitive staining method is silver stain (1). Coomassie Brilliant Blue R-250 is the most widely used protein stain, although it requires destaining by removing the excess dye, unlike the corresponding G-250 stain (2). Moreover, the commonly used acetic acid solutions are poor fixatives compared to trichloroacetic acid solutions (2, 3). Other widely used protein stains are Ponceau S and Amido black.

Rather than stain after an electrophoretic separation, the analytes can be prestained prior to electrophoresis. Prestaining is required for capillary zone electrophoresis and automated gel electrophoresis. It must be remembered, however, that the prestaining can alter the charge and shape properties of the molecules of the sample. Prestaining of proteins commonly employs derivatization by fluorescein isothiocyanate (see Gel Electrophoresis); that of nucleic acids uses the intercalating dye ethidium bromide (which is also used for poststaining without fixation), or the more recently introduced dyes DAPI (4), TOTO, or YOYO (5).

It is often possible to estimate the quantity of a particular species present in a sample by electrophoresis. Densitometry of stained gel bands has been the classical method (6). When a sample is radioactive, it may be detected and quantified by autoradiography or by counting extracted or solubilized gel slices. There are now commercial instruments for counting radioactivity in entire gel patterns (7). Fluorescence detection is especially useful with capillary zone electrophoresis or in automated gel electrophoresis apparatus (8).

Electrospray Ionization

Electrospray ionization (ESI) is a method of generating ionic forms of molecules for mass spectrometry . It generates ions directly from solution (usually an aqueous or aqueous/organic solvent system) by creating a fine spray of highly charged droplets in the presence of a strong electric field (1), as shown in Fig. 1. Subsequent vaporization of these charged droplets results in the production of multiply charged gaseous ions. The number of charges retained by an analyte can depend on such factors as the composition and pH of the electrosprayed solvent, as well as the chemical nature of the sample (2-4). For large molecules, the ESI process typically gives rise to a series of multiply charged species for a given analyte. Because mass spectrometers measure the mass-to-charge (*m*/*z*) ratio, the resultant ESI mass spectrum contains multiple peaks corresponding to the different charged states (Fig. 2).

Figure 1. The electrospray ionization process.

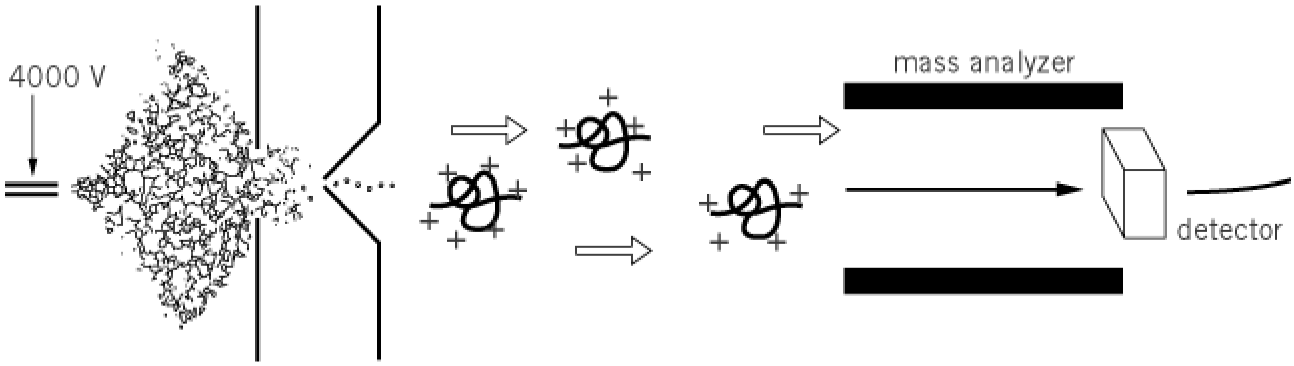

Figure 2. Examples of data generated on an ESI mass spectrometer. Proteins (left) typically produce positive multiply cl
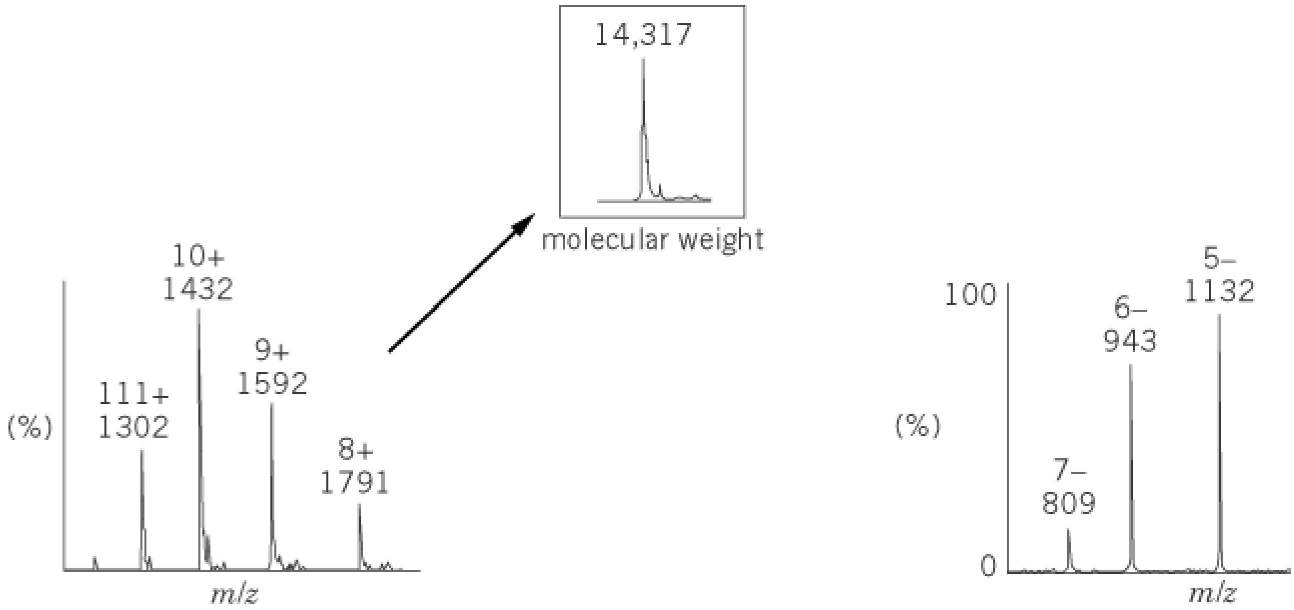
generate negative multiply charged ions. The insets for each part show the molecular-weight spectra computer-generated



The extent of multiple charging that occurs in ESI is a unique characteristic of the technique that enables an analyte's mass to be determined with great precision, as masses can be independently calculated from several different charged states (5). The multiple charging in ESI also permits the analysis of high-molecular-weight analytes, using conventional mass analyzers that are normally limited to the detection of ions with relatively low *m/ z* ratios. For example, a 50-kDa protein will typically retain on the order of 30 to 50 charges in ESI, yielding multiply charged species with *m/z* ratios between 1000 and 2000 that are easily detected with *quadrupole mass analyzers* . Another advantage of ESI-MS is its compatibility as an interface with liquid chromatography (see Liquid Chromatography Mass Spectrometry). Electrospray ionization is compared to the other common method of ionization in Matrix-Assisted Laser Desorption/Ionization.

Electrostatic Interactions

Electrostatic forces originate from the electric charges and dipoles of atoms and groups of atoms. They function inside macromolecules to maintain and to stabilize the molecular structure and to regulate the biological functions of catalysis and electron transfer. Electrostatic forces between molecules, facilitate specific molecular recognition and molecular assembly. The specific electrostatic field is determined by contributions from several factors, which originate from the intrinsic heterogeneity of biological macromolecules and from aqueous solvents.

1. Ionic Charges

In proteins, aspartic acid and glutamic acid residues have negatively ionizable side chains, and lysine, arginine, and histidine are positively ionizable. The amide and carboxyl termini of the polypeptide chain can also ionize, with, respectively, positive and negative charges. The intrinsic pK_a values of these groups in a normal aqueous environment are listed in Table 1. The actual pK_a value of a group in a folded protein can deviate from its intrinsic value, depending on the electrostatic field it experiences. The net charge of a protein is the sum of the positively and negatively ionized amino acid groups, plus any cofactor ions, and depends on the pH of the solvent. The pH at which a protein has no net charge is known as its isoelectric point. At neutral pH, most proteins are amphoteric, having both cationic and anionic groups at specific locations in the folded conformation.

Table 1. pK_a Values for Amino Acids in Peptides[a] and Bases in Nucleosides [b]

Amino Acids in Peptides	pK_a	Bases in Nucleosides	pK_a
a-NH_2	7.8	Adenine (N_1)	3.52
a-COOH	3.6	Cytosine (N_3)	4.17
Asp (C_gOOH)	4.0	Guanine (N_1)	9.42
Glu (C_dOOH)	4.5	Guanine (N_7)	3.3
His (imidazole)	6.4	Uracil (N_3)	9.38
Lys (ε-NH_2)	10.4	Thymine (N_3)	9.93
Arg (guanidine)	≈12		
Tyr (OnH)	9.7		
Cys (SgH)	9.1		

[a] Ref. 23.
[b] Ref. 24.

In **nucleic acids**, only the negative phosphate groups are charged at neutral pH, so nucleic acids do not show amphoteric properties. At very acidic or alkaline pH values, however, protonation or deprotonation of bases occurs, depending upon their pK_a values (Table 1).

2. Permanent Electric Dipoles

A molecule or a group of atoms has a permanent electric dipole if it has an unequal electron distribution. This dipole spontaneously produces its own electric field, and the molecule or group is then described as *polar*. One of the more important polar groups in macromolecules is the peptide bond, which has a large dipole moment. The polar groups interact electrostatically with other polar groups in the same or other molecules or with polar solvent molecules or ions. Permanent dipoles within most macromolecules are small and are distributed in different orientations, except for the alpha-helix. It possesses a large permanent dipole moment due to the cooperatively aligned electric dipoles of the peptide bonds of the backbone (1)

3. Polarizability and Dielectric Constant

In an external electric field **E**, an electric dipole is induced even in a neutral, nonpolar molecule or group because the outer field modifies the electrostatic balance between the electrons and the nucleus in each atom. The magnitude of this dipole is given by $m^{induced} = a_0\mathbf{E}$, where the coefficient a_0, the electronic polarizability, is proportional to the volume of the molecule or group. When the molecule or group also has additional permanent dipoles, they also reorient because of the external field. Consequently, the polarizability of a molecule is the sum of its electronic and orientational polarizabilities. The contribution from the orientational polarization of a polar group is generally much larger than that of the electronic polarization (2).

When a material is physicochemically homogeneous in a macroscopic volume, the dielectric constant of the material is related to the polarizability through the *Clausius–Mossotti* equation. Thus, the dielectric constant reflects the degree of polarizability of the material. A pure, polar liquid has a much larger dielectric constant than a nonpolar liquid. For example, the dielectric constants at 20 °C of water and cyclohexane are 80 and 2, respectively. The magnitude of the electrostatic interactions between charged groups or dipoles is relatively straightforward in such a homogeneous medium. It is inversely proportional to the distance between each pair of charges and to the dielectric constant of the medium. In contrast, proteins and nucleic acids are so heterogeneous, with polar and nonpolar groups distributed nonuniformly, that it is impossible to define an dielectric constant. Roughly speaking, however, the dielectric constant should be small in a **hydrophobic** core, perhaps 2 to 4, whereas the surface regions have larger values of 10 or larger (3).

4. Electrostatic Shielding by Polar Solvents

When a charged, polar biological macromolecule is dissolved in a polar aqueous solvent, the solvent molecules rotate in response to their interaction with the solute macromolecule in an attempt to decrease the **free energy** of the entire system. Thus, the electrostatic force produced by the solute macromolecule is significantly shielded. This free energy is called the *self-energy*, the interaction of a solute charge or electric dipole with the dielectric environment (2). In addition, the density distribution of small ions in the solvent also changes to shield the electric field originating from the solute molecule. Small metal cations are located near the negative charges, and anions are near the positive point charges, as described by the *Debye–Hückel* approximation. Double-stranded DNA or RNA has a very high negative charge density of phosphate groups of the backbone, which is almost neutralized (about 88%) by condensed counterions, which are strongly restricted along the duplex, in addition to the Debye-Hückel type interaction. The density of the condensed counterions is relatively independent of the solvent conditions, but they are released from the polymer when the double helical conformation is deformed (4).

When the response to a given electric field is monitored directly, changes in the orientation and density distribution of the solvent molecules are the major responses to an external field. Therefore, passive measurement of the individual pK_a values of the ionizable groups (5) and of the NMR chemical shift values of the nuclei (6) are good reporters of the local electrostatic field inside macromolecules. Both measurements are possible with the aid of multidimensional NMR techniques using stable isotope labeling (7). The charges and polarities of interest in proteins can be changed by site-directed mutagenesis, and the free energy difference associated with the electrostatic interaction can be evaluated (8).

5. Theoretical Approaches

Theoretical approaches to electrostatic interactions are divided between two types of theories: the macroscopic or continuum and the microscopic or molecular. In the continuum theory, the *Poisson* or *Poisson–Boltzmann* equation is solved for the solute–solvent system, assuming that the system is large enough to define its dielectric properties. Kirkwood first obtained an analytical solution for a simple spherical solute molecule embedded in a solvent with a high dielectric constant (9). With the aid of high-speed computational techniques, the exact shapes of biological macromolecules can be considered and the equations solved numerically (10). The computer program GRASP (11) is widely used to compute the electrostatic potential based on this method and to illustrate the electrostatic molecular surfaces of biological macromolecules and their assemblies, using red and blue colors for negative and positive charges, respectively. The drawbacks of the continuum theory (3) are (1) that the solute–solvent system is too heterogeneous to introduce the dielectric constant parameters and (2) that the calculations are based on static molecular conformations. Therefore, strict agreement between experiments and calculations is not expected. In the molecular theory, all of the atoms of the solute and solvent molecules are incorporated into the calculation, using the vacuum dielectric constant. Because the electric force is essentially long-range and the solvent molecules are significantly polar, reliable results are obtained only if the dynamics of the system are simulated for a sufficiently long period without simply cutting off the electrostatic forces.

6. Roles in Folded Conformations

Statistical analyses of the charge distributions on protein surfaces indicate that the charged groups are, on average, surrounded by charges of opposite sign and they tend to form ion pairs, which contribute to conformational stability (12, 13). The electrostatic contribution of ion pairs to protein stability is context-dependent, and the interaction energy of a single ion pair exposed to the solvent or even buried in the protein interior, varies experimentally from 0.5 to 5 kcal/mol. The entropic cost of forming rigid salt bridges is an opposing factor that reduces the free energy of the folded protein (14). A cooperative salt-bridge network can contribute significantly to protein stability (15), as observed frequently on the surfaces of proteins of thermophilic origins. Acidic residues occur near the positive pole of the helical dipole at the N-terminus of an a-helix (12) and basic residues near the negative pole. They represent the helix caps (16). These interactions are not context-dependent, but only the first one or two turns of an a-helix give the essential contribution to protein stability by at most about 2 kcal/mol, independent of the length of the a-helix (17).

Unfavorable electrostatic interactions destabilize the folded conformation and are important in proteins. Unpaired buried charges and isolated hydrogen bonds are energetically expensive within the hydrophobic core because of the large self-energy. Thus, **secondary structures**, such as a-helices and beta-sheets, can usually be depicted in protein cores as simply the backbone structures because they do not leave any backbone hydrogen bond donors or acceptors unpaired (18).

The condensation of counterions contributes to the conformation and the stability of double helices of DNA and RNA, which are highly charged due to the ionized phosphate groups of the backbone. The ordered double-stranded conformation depends markedly on the ionic strength, and the melting temperature of the conformation is increased as ionic strength increases. Divalent cations interact with these duplexes more strongly than monovalent cations.

7. Enzyme Catalysis

Efficient enzyme catalysis is based on the decrease in the free energy of the transition state, and it is mediated by a well-designed active site structure and the electrostatic field. Protein engineering studies employing site-directed mutagenesis have highlighted the importance of ionizable or polar residues at the active site. In the catalytic reactions of proteins, the thiol group of **cysteine residues**, the hydroxyl group of serine or the imidazole group of histidine acts as a nucleophilic catalyst at the initial stage. Ionizable side chains can act as acid and base catalysts by giving and receiving a proton, respectively. Generally, when two ionizable groups are adjacent their pK_a values deviate greatly from the intrinsic values. One value becomes higher and the other becomes lower because of the strong coupling interaction between the two ionization states. Thus, even at a neutral pH, two such ionizable side chains can form acid and/or base catalysts, which are often observed to have unusual pK_a values at the active sites of enzymes. In addition, ligated metal ions play important roles in many examples of catalysis by correctly positioning the substrate molecules, by stabilizing the transition-state conformation, or by activating water molecules to form hydroxide ions.

The **electron transfer** reaction is an essential event in energy acquisition during respiration and photosynthesis. Several prosthetic groups in proteins, such as hemes, iron–sulfur clusters, and some transition metals, such as Cu, directly govern the reaction. The electron transfer reaction is finely controlled by the surrounding peptide chains of proteins through electrostatic interactions (19). In addition, because the prosthetic groups are often buried deeply in the protein, electrons are considered to transfer from the protein surface through certain, but not unique, paths in the protein molecule (20). Electrostatic interactions often trigger large-scale structural changes, especially when coupled to ATP and GTP hydrolysis. The ionic and polar interactions of proteins with the phosphate groups of ATP and GTP become reordered after their hydrolysis. This local phenomenon causes domain movement in multidomain proteins and results in large structural changes (see ATPase and Gtpases). Likewise, several **allosteric** transitions are considered to be mediated by **salt bridges**.

8. Molecular Recognition

Molecular recognition is a major focus of modern biology and biochemistry. Specific molecular recognition of individual biological macromolecules is involved in many biological phenomena. Protein–protein interactions are critical in biological signal transduction, and they guide the assembly of multimeric proteins, generally found in cell **organelles**, **cytosol**, and cell membranes. Protein molecular surfaces are involved in the recognition of other molecules. Hydrogen bonds and salt bridges often provide specificity, which is derived from the distinctive electrostatic complementarity between the molecular surfaces. At protein–protein interfaces, on average, 0.88 hydrogen bonds are found per 100 $Å^2$ of buried accessible surface area, and from 0 to 5 intersubunit salt bridges are observed between protein dimers (21).

Protein–nucleic acid interactions are the origin of complex genetic regulation. The backbone phosphate groups interact with the basic side chains of the protein, and specific base sequences are generally recognized through hydrogen bonds and hydrophobic interactions with the protein side chains (22). In the process of association, a basic protein approaches the DNA double helix by a long-range, electrostatic attractive force. Then the protein condenses, like a group of counterions, along the DNA duplex. Some of the condensed counterions are released. Then the protein slides along the double helix by one-dimensional diffusion, scanning the sequence, until it finally becomes positioned at the specific binding site. Specific basic residues in the protein molecule form ion pairs with the exposed phosphate groups of the DNA backbone. Thus, the local DNA backbone structure, which is completely neutralized, is deformed. In fact, the DNA structures bound by proteins are often deformed from the typical B-type conformation.

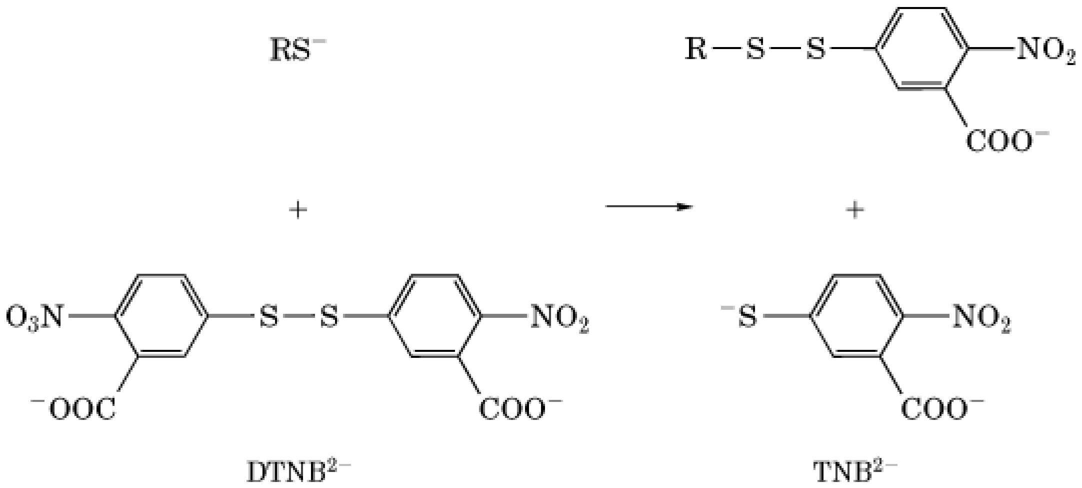
Ellman's Reagent, 5,5′-Dithiobis-(2-Nitrobenzoic Acid), DTNB

Barrett and Seligman (1) in 1952 used 2,2′-dihydroxy-6,6′-dinaphthyl disulfide to demonstrate thiol groups in proteins histochemically. Six years later, Ellman reported the use of bis-(*p*-nitrophenyl) disulfide for spectrophotometric measurement of thiol groups, and subsequently enhanced its water solubility by introducing carboxyl groups into the benzene rings (2). This reagent, 5,5′-dithiobis-(2-nitrobenzoic acid), DTNB, is now known as Ellman's reagent and is one of the most useful reagents for measuring thiol groups quantitatively.

The cysteine thiol groups undergo thiol–disulfide exchange with the disulfide bond of DTNB at about pH 8, to produce a mixed disulfide between them, plus 5-thio-2-nitro-benzoic acid, TNB.



(1)

The TNB is intensely colored. Its absorption maximum is normally at 409.5 nm, but shifted to 421 nm in 6 M **guanidinium chloride** (GdmCl), which is often used to unfold proteins and make their thiol groups accessible (3). For historical reasons, however, the reaction is generally monitored at 412 nm, where the molar absorbance coefficient is 14,150 M^{-1} cm^{-1} in standard buffers and 13,700 in 6 M GdmCl. The reaction goes essentially to completion because an excess of Ellman's reagent is used, plus the pK_a of the thiol group of TNB is approximately 4.5, considerably more acidic than normal thiol groups, which have pK_a values near 9. This helps to drive the reaction to completion, as thiol–disulfide exchange favors the more acidic thiol group. Irrespective of whether the original thiol groups react only with the Ellman's reagent or also with the mixed disulfide, one mole of TNB is produced per mole of original thiol group.

The ease of use of the Ellman assay makes it widely used, and many variants of Ellman's reagent have also been devised for special purposes, such as kinetic studies at acidic pH (4).

Elongation Factors (EFs)

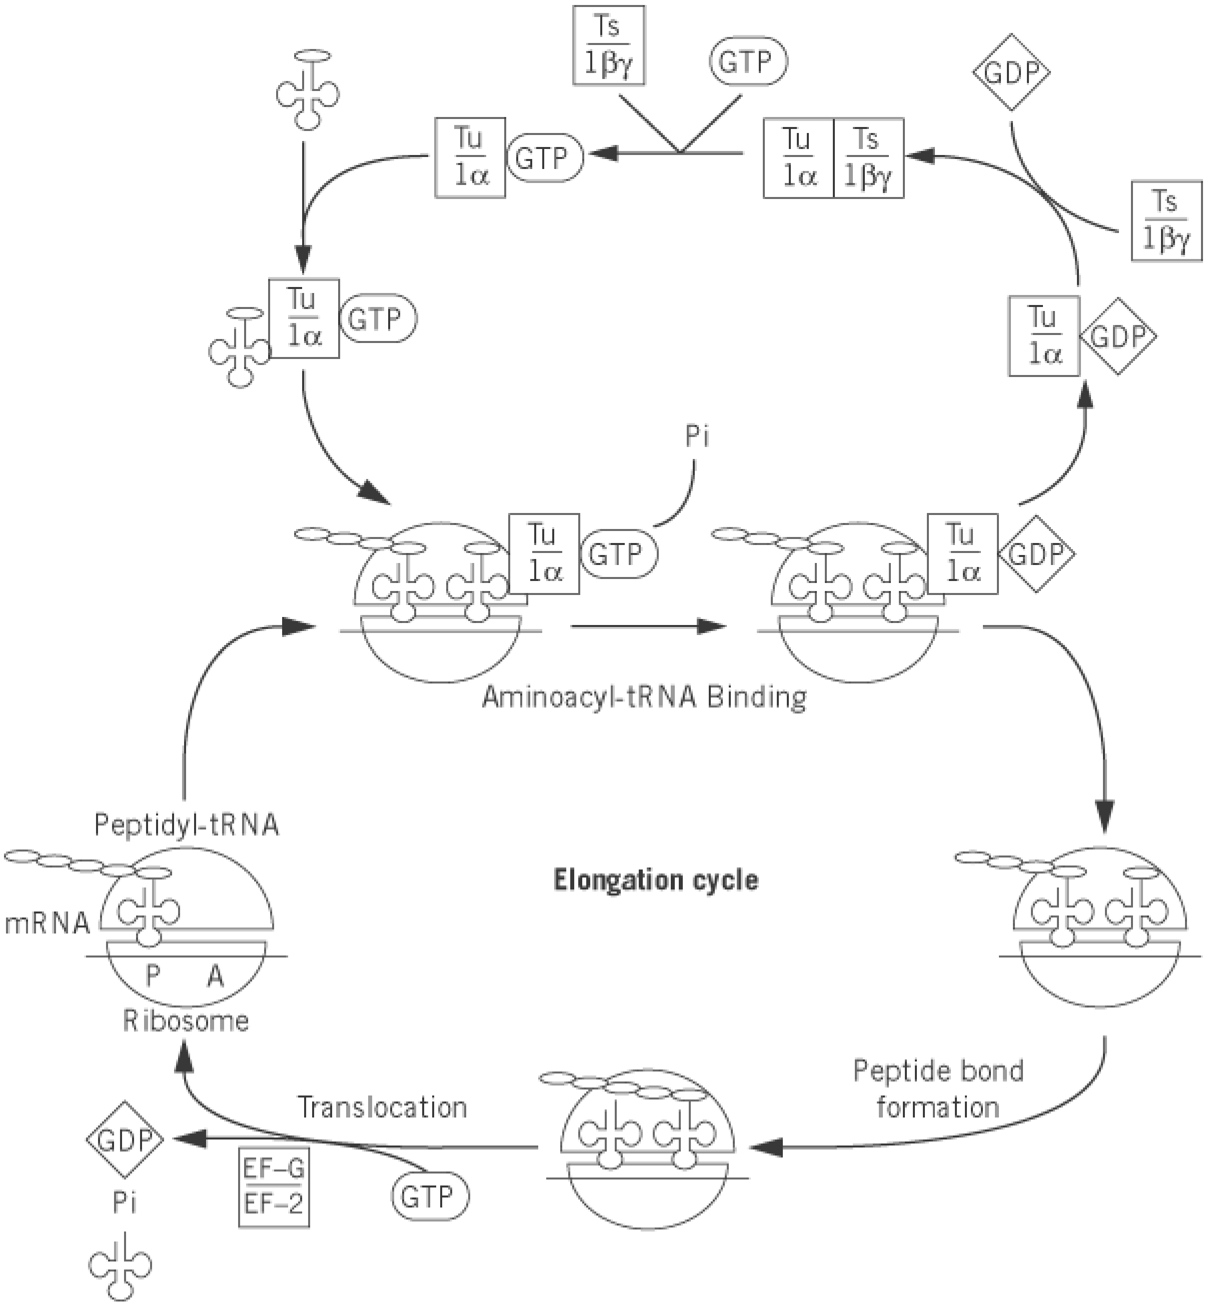
Elongation of the nascent polypeptide chain during translation of protein biosynthesis requires three elongation factors (EF-Tu, EF-Ts, and EF-G) in prokaryotes and requires four factors, (EF-1 a, EF-1 b, EF-1 g and EF-2) in eukaryotes (Table 1). The basic function of these elongation factors is to recycle the delivery of aminoacyl-transfer RNA molecules to the A site of the ribosome and to **translocate** the ribosome one **codon** forward after the **peptidyl transfer** reaction. Because of this common scenario, elongation factors share high functional and structural similarities in prokaryotes and eukaryotes: EF-Tu is equivalent to EF-1 a, EF-Ts to EF-1 bg, and EF-G to EF-2 (1).

Table 1. ***Escherichia coli*** **Elongation Factors**

Factor	Molecular Mass	Number of Amino Acids	Gene	Function
EF-Tu	43,195	393	*tufA*	Bind aminoacyl-tRNA to A site; GTPase
	43,225	393	*tuf B*	Same as above
EF-Ts	30,257	282	*tsf*	GDP/GTP exchange on EF-Tu
EF-G	77,444	703	*fus*	Translocation; GTPase

The polypeptide elongation cycle can be divided into three steps: (i) delivery of aminoacyl-tRNA to the ribosome, (ii) peptidyl transfer, and (iii) translocation of the ribosome (Fig. 1). Aminoacyl-tRNA first forms a ternary complex with EF-Tu (EF-1 a) and GTP. EF-Tu is one of the most abundant proteins. In *Escherichia coli*, it comprises about 5% of the soluble protein, and the EF-Tu/ribosome ratio is up to 7:1 in rapidly growing cells. The aminoacyl-tRNA:EF-Tu:GTP ternary complex binds to the A site of the ribosome. The proper binding of EF-Tu to the ribosome and the correct base-pairing between codon and the anticodon of the tRNA trigger hydrolysis of EF-Tu-bound GTP to GDP through activation by the GTPase active center on the ribosome. Note that both EF-Tu and EF-G carry conserved G-domains for binding guanine nucleotides, but they need the common GTPase center for stimulating the hydrolysis of GTP (ribosome-dependent GTPase). Once GTP is hydrolyzed, the GDP form of EF-Tu no longer remains bound to the ribosome because of protein conformation is altered. Common to the functioning of G-proteins is that activation occurs by binding GTP, while deactivation is achieved by GTP hydrolysis. GTP and GDP act as **allosteric** effectors on their target proteins, thus altering the conformation (see GTP-Binding Proteins).

Figure 1. Elongation pathway of protein synthesis. Prokaryotic (upper) and eukaryotic (lower) elongation factors are represented in boxes.



EF-Tu alone is very unstable, but is readily stabilized by GTP, GDP, or EF-Ts. EF-Ts (EF-1bg) is involved in the guanine nucleotide exchange of aEF-Tu (EF-1a). EF-Ts catalyzes conversion of the EF-Tu:GDP complex to EF-Tu:GTP, promoting the recycling EF-Tu for new ternary-complex formation.

After peptidyl transfer, the elongated peptidyl-tRNA is bound to the A site of the ribosome while the deacylated tRNA is bound to the P site. EF-G (EF-2) is a translocase protein that forwards peptidyl-tRNA from the A site to the P site on the ribosome and forwards the deacylated tRNA from the P site to the E site. The GTP form of EF-G is the active state and binds to the ribosome. Translocation of the ribosome is coordinated with the hydrolysis of GTP bound to EF-G. Presumably, GTP hydrolysis induces conformational constraints on the ribosome that lead to the movement of the ribosome. Then, the GDP form of EF-G dissociates from the ribosome.

EF-3 appears to be a unique translation factor that is found only in yeast and **fungi** (2). Together with yeast or mammalian EF-1a and EF-2, it is required for protein synthesis with ribosomes, except for mammalian ribosomes. This has prompted the suggestion that a corresponding activity in higher eukaryotes may be part of the ribosome; alternatively, EF-3 may be unique to yeast and fungi. EF-3 is known to promote the ejection of deacylated tRNA from the E site of the ribosome following translocation *in vitro*, thereby enhancing the binding of an aminoacyl-tRNA to the A site.

The three-dimensional (3D) structure of *Thermus thermophilus* EF-G comprises six subdomains, G, G′, and II–V (Fig. 2, left). The *C*-terminal part, domains III–IV, appears to mimic the shape of tRNA (3-6). The 3D structure of the ternary complex of Phe-tRNA, *Thermus aquaticus* elongation factor EF-Tu, and the nonhydrolyzable GTP analog, GDPNP, is almost completely superimposable with EF-G:GDP [Fig. 2, right (5)], showing that domains III, IV, and V appear to mimic the shapes of the acceptor stem, anticodon helix, and T stem of tRNA in the ternary complex, respectively. Domain IV of EF-G forms a protruding “rod” conformation, which is similar to the shape of the anticodon arm of tRNA. These findings strongly suggest a common requirement for the structure and function on the ribosome. This resemblance of part of EF-G and tRNA represents a novel concept of “molecular mimicry between nucleic acid and protein.”

Figure 2. The structures of elongation factor EF-G:GDP (right) and EF-Tu:GDPNP:Phe-tRNA^{Phe} (left). Domain II in EF-G and domain II in EF-Tu were placed in identical orientations, and the structures are shown side by side in a schematic representation to the same scale.(Reproduced from the diagram kindly generated by A. Ævarsson and A. Liljas.)

Embryology

Embryology, the study of **embryos**, is the field that deals with how a single cell multiplies and changes during development to form a multicellular organism. This process by which an organism is formed is known as *embryogenesis* . Embryology can be divided into a number of smaller fields. Descriptive embryologists describe the actual events that occur during embryogenesis. Comparative embryologists study embryology in different organisms to understand how developmental mechanisms have arisen and changed during evolution. Experimental embryologists manipulate embryos in the laboratory to uncover the cellular and biochemical processes, while the more recent field of molecular embryology studies the molecules that underlie early development.

A number of species have been used extensively to study the patterns and underlying mechanisms of embryogenesis. These include the nematode *Caenorhabditis elegans*, the fruit fly *Drosophila melanogaster*, several species of marine invertebrates, such as sea urchins, starfish, and marine annelids, the African clawed toad ***Xenopus*** *laevis*, the domestic chicken, and the house mouse *Mus domesticus*.

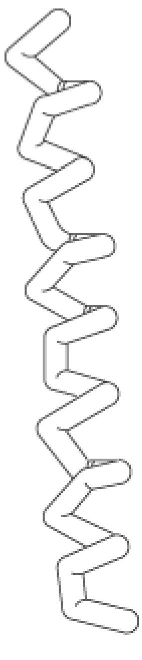
Enantiomer

An enantiomer is an object that has a nonsuperimposable mirror image. A right-handed helix and its mirror image are enantiomers, as shown in Figure 1. Thus, a molecule and its nonsuperimposable mirror image are both enantiomers and are both necessarily **chiral** (1). Enantiomeric molecules differ in how their solutions rotate the plane of polarized light (+ and –, for dextro and levo rotations, respectively). Enantiomers interact identically with achiral compounds, but can have different interactions with other chiral objects. The enantiomers have different **configurations**. This configuration is designated by the formally accepted rules proposed by Cahn et al., (*R*) and (*S*) (2), as described under Configuration. Because enantiomers differ in how their atoms are oriented in space, they are a special type of stereoisomer. Most enantiomers are most readily recognized by determining if each corresponding chiral center has an opposite configuration.

Figure 1. Enantiomers of a helix. The left-handed helix cannot be superimposed on its mirror image, the right-handed helix. This property makes both helices chiral and enantiomers of each other.



Two identical functional groups are called enantiotopic if their substitution by an isotopic label generates enantiomers (3) (see Prochiral). Thus, the protons on the amino acid glycine are enantiotopic because they are the same functional group, and alternate substitution of ^{2}H for each ^{1}H will generate the enantiomeric (*R*)- and (*S*)-[2-^{2}H]glycines.

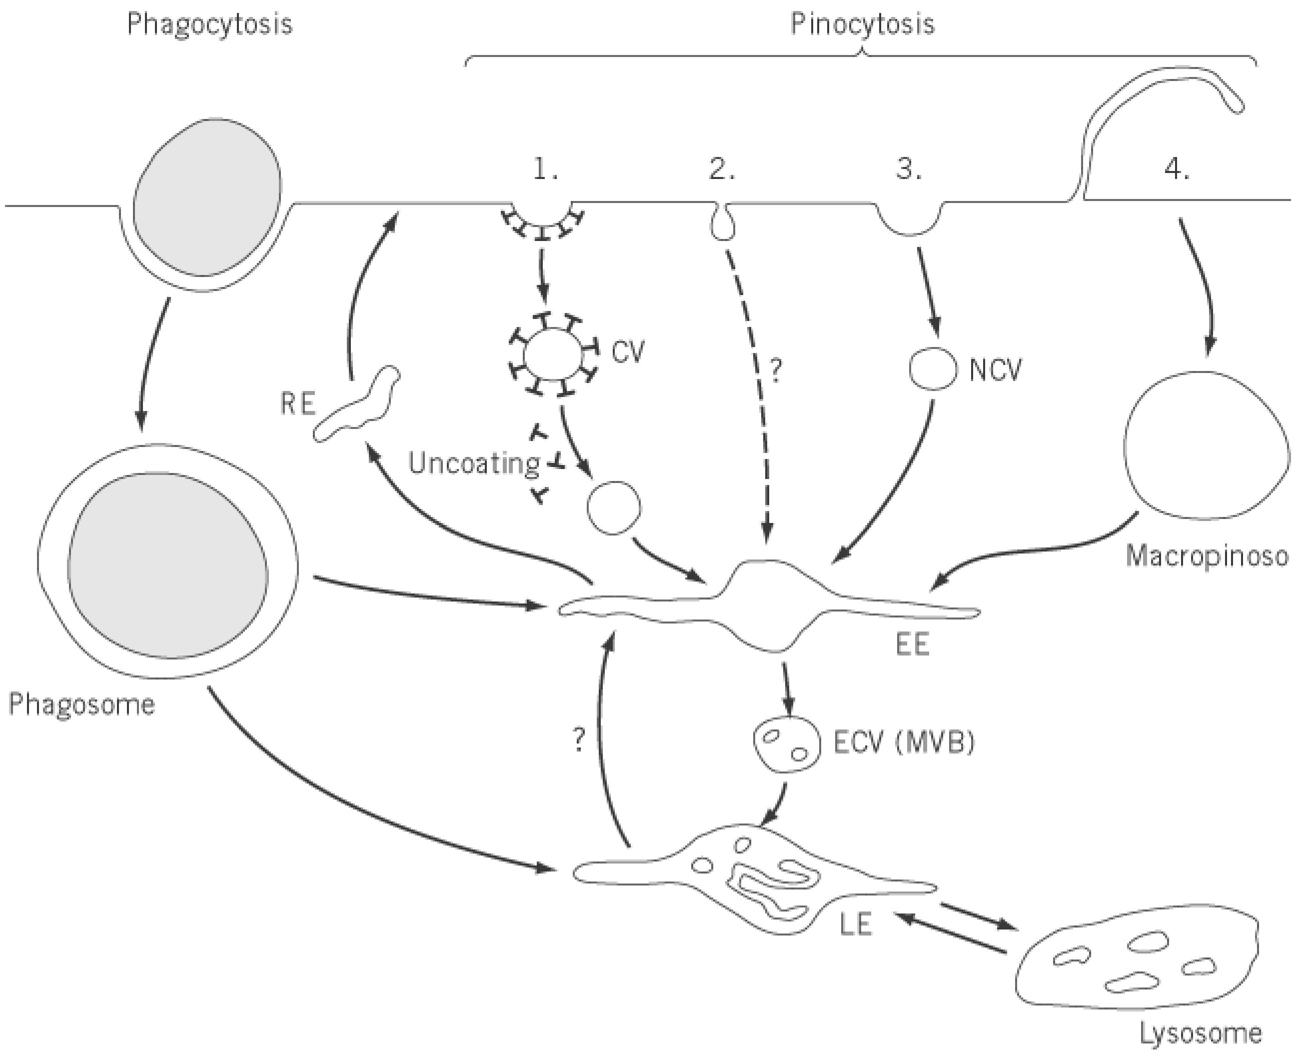
Endocytosis

Endocytosis is the process whereby eukaryotic cells internalize material from their surrounding environment. Internalization is achieved by the formation of membrane-bound **vesicles** at the cell surface that arise by progressive invagination of the plasma membrane, followed by pinching off (scission), and the release of free vesicles into the cytoplasm (Fig. 1). Several different types of vesicle are generated. Each carries extracellular fluid, **macromolecules**, and particles into the cell. Extracellular materials are either free within the lumen of the vesicle or bound to its lumenal surface. Endocytosis is believed to be essential for cell viability and is required for numerous cellular functions, including (1) the provision of certain essential nutrients; (2) the removal of unwanted, nonfunctional or potentially harmful material from the extracellular medium; (3) the internalization, processing, and presentation of **antigens** by major histocompatibility complex (MHC) molecules (see Antigen Processing, Presentation); (4) the transfer of macromolecules across polarized epithelial cells; and (5) the transmission of neuronal, metabolic, and proliferative signals (see Growth Factors; Insulin). In addition, endocytosis maintains cellular homeostasis by continually monitoring the plasma membrane composition and selectively removing redundant or defective **glycoproteins**, lipids, or glycolipids for repair or degradation. Endocytosis mediates the rapid recovery of membrane components inserted into the plasma membrane during secretion and is crucial for regenerating of synaptic vesicles (see Exocytosis, Secretory Vesicles/Granules, Protein Secretion). Endocytosis is also used by a range of viral [eg, influenza virus (1)], bacterial (eg, *Legionella pneumophila*), and protozoan (eg, *Toxoplasma gondii*) pathogens, and certain protein toxins produced by plants (eg, see **Ricin**) or bacteria (eg, see Diphtheria toxin; Cholera toxin), to enter target cells (2).

Figure 1. Schematic illustration of endocytic pathways. Four different mechanisms for pinocytosis are illustrated: (1) *via* clathrin-coated pits and vesicles (CV); (2) *via* caveolae; (3) *via* noncoated pits and vesicles (NCV); and (4) *via* macropinosomes. The abbreviations used are EE, early endosome; LE, late endosome; RE, recycling endosome; ECV, endosomal carrier vesicle; and MVB, multivesicular body.



1. The Endocytic Pathway

The endocytic pathway encompasses all of the organelles in the cell that are involved in endocytosis. The pathway starts at the cell surface, which provides the membrane that forms endocytic vesicles and contains the receptors responsible for binding specific ligands internalized by these vesicles. Endocytic vesicles [phagosomes, **clathrin**-coated vesicles, caveolae, macropinosomes, and nonclathrin vesicles (see later)] derive from the plasma membrane and are directed to fuse with and deliver their membrane and content to the intracellular organelles of the endocytic pathway, the endosomes and **lysosomes**.

Lysosomes are usually regarded as the graveyard of the cell, the site where ligands internalized from the cell surface and destined for degradation are delivered and hydrolyzed. Although many receptors recycle to the cell surface, others, such as growth factor receptors, remain associated with their ligands and are delivered to lysosomes for degradation. Lysosomes are usually vesicular (~0.5 to 1 µm in diameter) and are located primarily, although not exclusively, in the perinuclear region of the cell. The pH within lysosomes can be as low as 4.8, the optimum for the many hydrolytic enzymes they contain. They derive their content from late endosomes, probably through repeated cycles of fusion with and fission from these organelles (3). In antigen-presenting cells, late endosomes and lysosomes contain large amounts of MHC II antigens and have been termed MIICs (4). In addition, lysosomes in **haematopoietic** cells are secretory organelles that undergo regulated fusion with the plasma membrane (5).

The membrane proteins, lipids, and hydrolases that make up the membrane and content of endocytic organelles are synthesized in the endoplasmic reticulum (ER) and Golgi apparatus and are subsequently transported to endosomes and lysosomes by vesicular transport. Many hydrolases carry the mannose 6-phosphate recognition marker that enables delivery *via* the mannose 6-phosphate receptors. By contrast, the membrane proteins of endosomes and lysosomes carry sorting signals (see later) that facilitate their delivery.

The endocytic pathway is extremely dynamic. In some tissue culture cells, approximately 1500 coated vesicles internalize from the cell surface every minute. This is equivalent to internalizing the membrane of the entire cell surface every 30 to 60 min (6). The surface area of early endosomes is approximately one-fifth that of the cell surface, and the entire surface area of these organelles turns over approximately every 12 min (7). Receptors, such as the **low-density lipoprotein** (LDL) receptor, are internalized very rapidly at rates of 10 to 30% of the cell surface pool per min and are recycled in 10 to 15 min back to the cell surface. Each individual receptor may mediate many rounds of internalization and recycling in its life time (8). The organization of endocytic organelles within the cell is regulated by interaction with **cytoskeletal** elements. **Actin**-based systems have been implicated in the formation of endocytic vesicles from the plasma membrane (see later), and actin/myosin and the microtubule system have been implicated in moving and positioning endocytic organelles within the cell.

2. Endocytic Mechanisms

Classically, endocytosis has been divided into phagocytosis ("cellular eating") and pinocytosis ("cellular drinking") (Fig. 1). Phagocytosis describes the internalization of large particles (>0.2 µM in diameter) following particle binding to specific plasma membrane receptors. Therefore, phagocytosis is receptor-mediated and depends on the presence of appropriate ligands. Pinocytosis is the formation of generally smaller vesicles (50 to 150 nm diameter) that transport extracellular fluid (fluid-phase endocytosis) and macromolecules specifically (receptor-mediated endocytosis) or nonspecifically (adsorptive endocytosis) bound to the plasma membrane. These vesicles are often formed constitutively from **clathrin**-coated pits independently of the presence of specific ligands, but there are alternatives to clathrin-mediated uptake (see later). The different endocytic mechanisms, more than one of which coexist and function in a single cell, are classified as phagocytosis, pinocytosis, **macropinocytosis**, and noncoated vesicles.

2.1. Noncoated vesicles

Endocytosis still occurs when clathrin-mediated uptake is blocked, as evidenced by the internalization of **ricin**, **interleukin**-2, and fluid-phase markers. Morphologically, the vesicles thought to mediate this uptake noncoated, ~80 nm in diameter, and distinct from caveolae and macropinosomes. At present, nothing is known about the molecular mechanisms responsible for this uptake process, although the continued uptake of ricin in the presence of a dominant-negative mutant form of **dynamin** suggests that it may be dynamin-independent (9).

3. Endocytosis Signals

Receptors and other proteins that undergo efficient endocytosis from the cell surface contain endocytosis signals. The signals associated with proteins that internalize through clathrin-coated pits are those that are best characterized. Four classes of endocytosis signal have been identified and studied in some detail. First are tyrosine residues within motifs similar to Phe-X-Asn-Pro-X-Tyr or Tyr-X-X-O (where X = any amino acid and O = a large **hydrophobic** amino acid), which are the endocytosis motifs identified in the LDL receptor and transferrin receptor, respectively (10). It has been proposed that these motifs form turn structures and interact either directly with clathrin (11) or with the m2 subunit of the AP-2 complex [(10) see Pinocytosis], respectively. Generally these signals are constitutively active, and proteins that contain them undergo continuous endocytosis and recycling.

A second group of signals requires pairs of hydrophobic amino acids, frequently leucine residues, although isoleucine, methionine, or valine substitutes for one of the leucines in some circumstances [e.g., MHC class II invariant chain (12)]. These so-called dileucine signals are less well characterized. There is evidence, however, that they also bind AP-2 complexes through a site or sites distinct from those bound by the Tyr-based signals. There is also evidence that in some cases (e.g., CD4) the activity of these signals is regulated by phosphorylation of adjacent serine residues (13). The signal is active when the motif is phosphorylated and inactive when dephosphorylated.

The third class of internalization signal has been identified in members of the family of seven transmembrane-domain **heterotrimeric G protein**-coupled receptors that are internalized following ligand binding. For several of these receptors, in particular the b2-adrenergic receptor, ligand-induced phosphorylation of serine residues in the serine-rich C-terminal domain of the molecule leads to recruitment of b-arrestins that uncouple associated heterotrimeric G proteins and function as adaptor complexes to recruit the receptor into clathrin-coated pits (14). Finally, in *S. cerevisiae*, a factor-induced phosphorylation of serine residues in the Ste2p receptor protein C-terminal domain leads to **ubiquitination** of Ste2p and its subsequent internalization (15). A number of mammalian cell surface receptors, including the growth hormone receptor, are also ubiquitinated following ligand binding (16). Whether this modification is required for endocytosis of the receptor and how the modification facilitates interaction with the endocytosis machinery are unclear.

Sorting signals also operate within endosomes and other sites in the endocytic pathway to specify the routing of specific proteins. The signals themselves are not well characterized. Recycling to the plasma membrane is the default pathway and may not require specific signals. However, the Tyr-X-X-O and dileucine motifs discussed previously function to target internalized proteins from early endosomes to lysosomes (12), and receptor cross-linking by multivalent ligands or antibody complexes directs sorting from early endosomes to lysosomes (17). The low pH of endocytic compartments may also influence sorting by inducing dissociation of pH-sensitive ligand-receptor interactions. Other signals, for example, a diaromatic amino acid-containing motif in the cytoplasmic domain of the cation-dependent mannose 6-phosphate receptor, function as a lysosome-avoidance motif to prevent proteins from being transported to lysosomes. How these sorting signals are interpreted is unclear for the most part, although coat proteins and adaptors have been implicated in certain steps (19). A subset of the COP1 coatomer complex has been found associated with early endosomes (20), as have clathrin and AP adaptor complexes.

4. Medical Significance

The endocytic pathway is crucial for many cellular functions. Defects in functions associated with the endocytic pathway have been linked to a number of clinical conditions. For example, failure to internalize serum LDL is associated with atherosclerosis, and defects in producing or effectively targeting lysosomal hydrolases results in a range of inherited lysosomal storage diseases. It is believed that the problems associated with Chediak-Higashi syndrome result from defects in sorting associated with late endosomes and lysosomes. Chromosomal translocations of genes that encode proteins involved in coated vesicle formation have been found in a number of lymphomas and leukemias. In addition, many bacterial, protozoan, and viral pathogens enter cells and establish infection through the endocytic pathway. It is likely that many other conditions will be linked to endocytic functions. However, the endocytic pathway is likely to provide one of the most effective routes to target and deliver drugs, DNA, or other therapeutic agents to cells.

Endopeptidase

Peptidases are enzymes that catalyze the hydrolysis of the **peptide bonds** that link amino acids into linear **polypeptide chains**. The Enzyme Commission of the International Union of Biochemistry and Molecular Biology classifies them as E.C. 3.4, *peptide hydrolases*. The chemical reaction that occurs can be depicted in its most simplified form as $R - CO - NH - R' + H_2O \leftrightarrow R - CO - OH + H_2N\text{-}R'$. In a linear polymer of x amino acids (x can range from 2 to >1000), there are $x - 1$ peptide bonds. Enzymes that catalyze the hydrolysis of the first or second (or sometimes even the third) peptide bond in such a linear polymer are called *exopeptidases* and, more specifically, aminopeptidases (E.C. 3.4.11–15). This is because the amino group of the first amino acid in a linear polymer of amino acids is not part of a peptide bond, and hence this end of the chain of x amino acids is called the *amino terminus* (or N-terminus). Enzymes that catalyze the hydrolysis of the last or the penultimate peptide bond in this chain are also exopeptidases, but in this case they are carboxypeptidases (E.C. 3.4.16–19). The carboxyl group of the last amino acid in the chain is similarly not part of a peptide bond, and this end of the chain is therefore the *carboxy terminus* (or C-terminus).

Peptidases that catalyze the hydrolysis of internal peptide bonds in the polypeptide chain are called *endopeptidases* (E.C. 3.4.21–24, 99). The subclass to which they are assigned depends on the particular type of mechanism they employ to achieve catalysis (see Proteinases).

Endoplasmic Reticulum

The endoplasmic reticulum (ER) is an extensive network of membranous cisternae that extends throughout much of the cytoplasm (Fig. 1). The three main functions of this organelle are: (i) biosynthesis of proteins that are destined to be secreted, deposited on the cell surface, or reside in other organelles of the exocytosis and endocytosis pathways (see Protein Secretion). (ii) synthesis of lipids; and (iii) regulation of calcium (Ca^{2+}) storage (see Calcium Signaling). Because the ability to perform these functions is essential for growth and differentiation of all cells, the ER is ubiquitous. Yet it undergoes dynamic changes that allow it to adapt to the changing physiological demands of various cells and tissues. The unique shape and architecture of the ER reflect its functional connections to other organelles. At the cell center, the ER is contiguous with the **nuclear** envelope. At the cell periphery it becomes a long, tubular network, often enveloping mitochondria and sometimes extending to the proximity of the plasma membrane (Figs. 1–2). This reticular architecture mediates the physical connections, as well as the chemical communication, between the ER and most other cellular compartments. A recurrent theme in the sections that follow, describing individual functional aspects of the ER, is the multitude of ways through which the ER exchanges biochemical components, be they ions, lipids, or proteins, with other organelles.

Figure 1. Light microscopic image of the ER. Immunofluorescence staining of a COS-1 cell expressing an ER-retained form of immunoglobulin light chain. The ER staining fills most of the cytoplasm, with the reticular appearance most evident at the periphery (arrow). The typical staining of the nuclear envelope is visible as a prominent ring (arrowhead) around the nucleus (N). Bar, 10 µm.

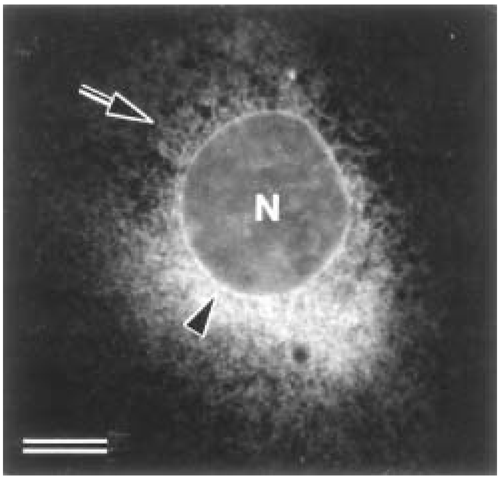

Figure 2. Electron micrograph of a plasma cell. A murine antibody-secreting cell exhibiting a typically expanded ER. Arrow, a region of the endoplasmic reticulum with stacked flattened cisternae of rough ER, each with the typical beaded appearance due to densely bound ribosomes. N, nucleus. M, mitochondrion; bar, 1 µm.

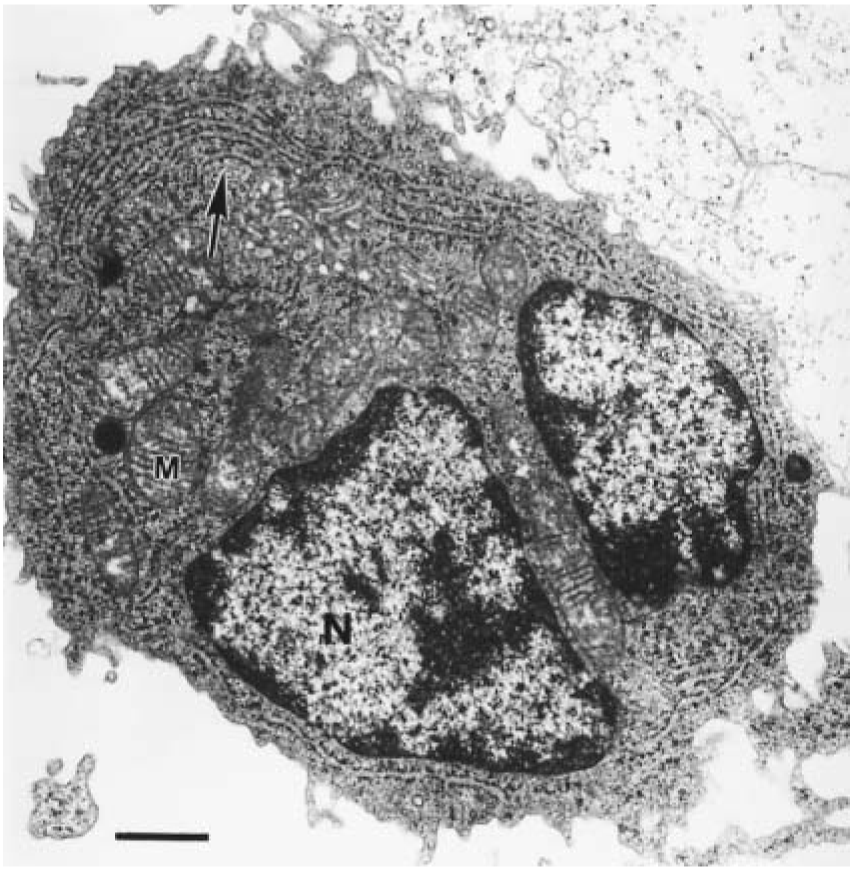

1. The Structure of the ER

The reticular architecture of the ER is maintained by numerous dynamic contacts between the ER membrane and microtubules. These connections are mediated by the molecular motor complex kinesin, which attaches to microtubules via its globular, *N*-terminal head **domain** and to the ER membrane via its *C*-terminal domain. The latter interaction is presumably mediated by kinectin, a 160-kDa integral membrane protein of the ER, which has been shown to be a kinesin receptor (1, 2). These attachments enable the ER cisternae to extend or contract along microtubules, which themselves assemble and disassemble dynamically. The dynamic nature of the ER structure is evident when cells are stressed: Drastic changes in cell shape, caused by depolymerization of microtubules, are accompanied by collapse of the reticular ER toward the cell center (3). The precise molecular regulation of the attachment to microtubules, and possibly other **cytoskeletal** elements, are yet to be elucidated. Other important unresolved issues include how the ER cisternae maintain a flattened structure, with a very high surface-to-volume ratio, and what the physiological implications are of this cisternal structure.

2. Subcompartments of the ER

In higher eukaryotes, that part of the ER to which ribosomes are attached is known as the rough ER, due to its distinctive beaded appearance in electron micrographs (4) (see Fig. 2). In "professional" secretory cells, the rough ER is the vastly predominant form, because of the demand for high throughput of **protein biosynthesis**, folding, and trafficking (see text below). The morphology of the rough ER reflects these biosynthetic roles, and underlying it is a distinct protein composition. The rough ER membrane is the site of expression of ribophorins and many other components involved in docking ribosomes and in translocating nascent proteins across the membrane (eg, see Refs. 5 and 6) (see Protein Secretion).

The remainder of the ER, devoid of attached ribosomes, is called the smooth ER. The smooth ER membrane is the site of residence of cytochrome P450 and other components of the mixed-function oxidase system. The smooth ER is also involved in synthesis of various lipids and in the assembly of lipoprotein particles. Thus, the smooth ER predominates in cells where the expression of such proteins is high (eg, hepatocytes), while it is only a small fraction of the ER in secretory cells like pancreatic acinar cells.

The ER membrane proteins are clearly segregated between the smooth and rough subcompartments, although the molecular mechanism for this segregation is unresolved. Microscopic studies following the distribution of proteins like the binding protein BiP or protein disulfide isomerase (PDI) in a variety of cells suggest that the entire lumen of the ER is contiguous, with no obvious separation between smooth ER and rough ER lumen or between the reticular ER in the cell periphery and the nuclear envelope.

In excitable cells, the ER is specialized both morphologically and biochemically and is known as the *sarcoplasmic reticulum* (SR). Smooth cisternae of the SR make frequent contacts with the membrane of muscle cells. These terminal cisternae contain complexes of proteins involved in Ca^{2+} modulation, including membrane proteins like the ryanodine receptors and specialized SR calcium-binding proteins, like calsequestrin. The segregation of proteins is clearly related to Ca^{2+} storage and release, as general lumenal proteins in the SR (like BiP) do not exhibit similar subcompartmentalization (7).

3. Protein Translocation

The rough ER is the organelle that couples protein biosynthesis to membrane translocation, allowing segregation of secretory and membrane proteins from cytosolic or nuclear proteins. Secreted and membrane proteins are marked for translocation by a **signal sequence**, which is usually cleaved early in the biosynthesis of the proteins (8). Signal sequences are generally *N*-terminal, consist of around 20 amino acid residues, and are characterized by a central string of **hydrophobic** amino acids flanked by clusters of charged residues, and a residue with a small side chain precedes the cleavage site (9). Once a signal sequence has emerged from a ribosome, that ribosome is targeted to the ER membrane, where the nascent chain is translocated across the membrane. This targeting is accomplished primarily by a cytoplasmic ribonucleoprotein complex, the signal recognition particle (SRP) (10). SRP performs three distinct activities: (i) binding to the signal sequence that is exposed on the surface of a **translating** ribosome; (ii) retarding further elongation of the nascent polypeptide; and (iii) docking onto the SRP receptor in the ER membrane. Upon completion of this sequence of events, the SRP detaches, and the signal sequence is inserted into the membrane. Due to the intrinsic hydrophobicity of signal peptides, they themselves may interact with the lipid bilayer and thus aid the translocation process at this stage. After the initial association of the nascent chain with the membrane, the ribosomes bind more avidly to the ER by protein–protein interactions with the Sec61p complex, a seven-component transmembrane complex of proteins.

Nascent polypeptides cross the lipid bilayer through a protein channel (11), known as the *translocon*. The minimal translocon has been reconstituted *in vitro* (12, 13), and the necessary components were shown to be the SRP receptor, the Sec61p complex, and a translocating chain-associated membrane protein (TRAM). Purified mammalian and yeast Sec61p complexes in detergent solution or in proteoliposomes form cylindrical oligomers of three to four heterotrimers each, with a diameter of approximately 85 Å and a central pore of approximately 20 Å. Formation of the reconstituted translocon is stimulated by association with ribosomes or with the Sec62/63p complex (14).

At early stages of translocation, prior to signal sequence cleavage, nascent chains can be shown by chemical **cross-linking** to contact the Sec61a subunit and the signal sequence receptor (p34), via both the signal peptide and the remainder of the polypeptide chain (15, 16). At later stages of translocation, which can be trapped experimentally with the use of truncated translocation intermediates, the proximity to Sec61p is markedly reduced. These data are in line with the interpretation that, at early stages of translocation, nascent chain-Sec61p interactions are in part mediated through interactions of the ribosome with components of the ER membrane, but that subsequent translocation can occur after dissociation of the ribosome (15).

Once the signal sequence enters the lumen, it is cleaved off most proteins. The enzyme responsible for this cleavage, signal peptidase, is a hetero-oligomeric membrane protein containing subunits of 12, 18, 21, 22 / 23, and 25 kDa. The 18- and 21-kDa subunits are mammalian homologues of Sec11p, a yeast protein that is necessary for signal peptide processing and cell viability. The topology of signal peptidase places the bulk of the protein in the ER lumen, including its putative **serine**-containing active site, located in the 18- and 21-kDa subunits (17).

A second route for protein entry into the ER is post-translational and independent of SRP. In this route, which is more extensively used in yeast than in higher eukaryotes, a complete polypeptide chain is made in the cytoplasm and held in an incompletely folded state by **molecular chaperones** such as cytosolic hsp70. Fully synthesized secretory precursors then engage the ER membrane by interaction with the Sec complex, which in post-translocational translocation contains further protein subunits that are required for function, in addition to those of the co-translational Sec61 complex. It is not yet known what distinguishes a polypeptide chain that uses the co-translational route from a polypeptide that is translocated post-translationally. Productive post-translational interaction with Sec61p requires displacement of hsp70 from the precursor polypeptide. This reaction is facilitated by the chaperone Ydj1p, a homologue of the *E. coli* DnaJ protein, which stimulates the inherent ATPase activity of the hsp70 chaperone. In the ER lumen, another hsp70-like chaperone, BiP, is an important part of the translocation machinery. In yeast ER, BiP is known to associate with the translocation complex via its contact with the DnaJ-homologous domain of the transmembrane protein Sec63p (18). The membrane-bound BiP can hydrolyze ATP, and the polypeptide moves through the channel formed by the Sec complex and is released at the lumenal side (19). The process of post-translational translocation is made vectorial because of the cleavage of signal sequences and because the interactions with the hsp70s on either side of the membrane are unequal; cytosolic hsp70 and BiP cannot replace each other.

In the mammalian ER, as in yeast, BiP is required for the completion of polypeptide translocation. Moreover, BiP in its ATP-bound, non-substrate-binding state also functions to seal the translocon (20). In this fashion, it sustains the permeability barrier of the ER membrane, which otherwise would be compromised by the existence of thousands of translocation channels (21).

4. Protein Post-translational Modifications

Membrane and secreted proteins can be modified by a number of post-translational modifications, the most common being glycosylation and phosphorylation. The most prevalent glycosylation is via the addition of a 14-sugar oligosaccharide onto certain Asparagine (Asn, N) residues, termed N-glycosylation. The oligosaccharide usually consists of three glucose (Glc), nine mannose (Man) and two *N*-acetylglucosamine (GlcNAc) residues and is called *high mannose*. This oligosaccharide is assembled onto a dolichol lipid carrier by a series of enzymes that reside in the ER membrane. The first seven sugars are assembled by enzymes facing the cytosol. The $Man_5GlcNAc_2$-dolichol intermediate is then translocated across the membrane, and the final assembly steps are performed on the lumenal face (22, 23).

A multisubunit enzyme, oligosaccharyltransferase (OST), is responsible for the transfer of the preassembled high-mannose oligosaccharide from the dolichol-linked donor onto Asn acceptor sites in nascent proteins on the luminal side of the ER membrane (24). These acceptor sites are within the tripeptide Asn-X-Ser/Thr (where X is any amino acid except Pro), provided that this tripeptide is accessible to OST.

Immediately upon addition to the protein, the high-mannose oligosaccharide is subjected to progressive trimming. First, the terminal Glc is removed by glucosidase I, followed by sequential removal of the next 2 Glc by glucosidase II. These steps are followed by a third trimming enzyme, a mannosidase that trims the oligosaccharide down to the Man_5–Man_8 forms (25). Additional trimming occurs after the glycoproteins traffic to the Golgi apparatus, before final remodeling to complex types of oligosaccharides.

A second type of glycosylation, O-glycosylation of serine or Threonine (Thr, T) residues by shorter and different carbohydrates, is a less frequent modification and is currently thought to take place mostly in the Golgi complex and not in the ER.

Another common protein modification is phosphorylation of Ser/Thr residues, and this modification is thought to play a regulatory role in the function of these proteins. A number of itinerant and resident ER proteins are known to be phosphorylated, on cytoplasmic domains as well as on luminal domains. The former phosphorylation can be performed by a number of known kinases in the cytosol. The phosphorylation of luminal domains has, in most cases, the hallmarks of a casein kinase II-like enzyme. However, no ER-specific kinase has yet been purified. The phosphorylation of Tyr residues, of major importance in signaling at the plasma membrane, has not yet been observed within the ER.

5. Lipids

In addition to its role in protein synthesis, the ER is a major site of lipid synthesis, and both phospholipid and sterol biosynthesis enzymes reside in this organelle. While some phospholipids are synthesized by cytosolic enzymes, much of phospholipid biosynthesis is performed by base-exchange enzymes and phospholipase D in the ER. Base-exchange enzymes alter the polar head group, allowing for interconversion of different phospholipid species. Phospholipase D hydrolyzes phospholipids to phosphatidic acid, which is used for further lipid biosynthesis.

The ER houses enzymes involved in cholesterol biosynthesis, as well as those that participate in oxidation of cholesterol to bile acids. Of them, HMG-CoA reductase is a key rate-limiting enzyme in steroidogenesis, and the intricate control of its expression is another manifestation of the communication between the ER and other organelles.

Because cholesterol and the apolipoproteins are both synthesized in the ER, much of the assembly of lipoproteins takes place in this organelle. The bulk of the very-low-density lipoprotein (VLDL) triacylglycerol and some VLDL phosphoglyceride is introduced early in the secretory pathway, soon after apolipoprotein synthesis. On the other hand, a significant fraction of VLDL phosphoglyceride associates with the resulting triacylglycerol-rich lipid–protein complexes in more distal secretory compartments, just prior to their secretion as mature VLDL.

6. Calcium

Changes in intracellular Ca^{++} concentration are a common signal transduction device linking plasma membrane receptors with the initiation of specific cellular responses, including cell growth, muscle cell contractility, and exocytosis in secretory cells. The ER and its specialized form, the SR, is a major dynamic calcium storage organelle in eukaryotic cells. Its Ca^{2+} concentration is estimated to reach 10 mM, whereas free Ca^{2+} in the cytosol is only in the nanomolar range. The ER Ca^{2+} storage capacity is provided by a multitude of luminal proteins. Among them are the ubiquitous and abundant chaperones, like GRP94, calreticulin (see Calnexin/Calreticulin), and the PDI-like proteins, or proteins whose expression is tissue-specific, like calsequestrin in the SR. Most of the Ca^{2+} binding is via multiple (as many as 50) low-affinity ($K_d = 1$ mM) binding sites per protein, but some proteins have a few high-affinity sites, including **EF-hand** domains (26). The ER membrane regulates the flow of Ca^{2+} via three types of proteins: (i) the ER/SR- Ca^{2+}-ATPase (SERCA), which is a pump that can be inhibited by the drug thapsigargin; (ii) **calcium channels**, which are either the ubiquitous inositol trisphosphate receptors or the ryanodine receptors; (iii) and Na^{+}/Ca^{2+} exchangers. Together, the membrane Ca^{2+} gates and the luminal binding proteins provide a rapid response system to mobilize Ca^{2+} as physiological conditions demand. Release of ER-stored Ca^{2+} into the cytosol affects diverse sets of proteins, such as EF-hand proteins, annexins, and the C2 region proteins (26).

The Ca^{2+} homeostasis function of the ER is most specialized in muscle cells, where Ca^{2+} mobilization is an important component of the contractile apparatus. Ca^{2+} binding proteins and Ca^{2+} channels are highly expressed in the SR, often employing muscle-specific versions of these proteins. For example, calsequestrin is an SR-specific Ca^{2+} buffer that has structural homology to calreticulin, which is expressed ubiquitously in higher eukaryotic cells. In nonexcitable cells, the need to store Ca^{2+} can be satisfied by many of the luminal proteins. For example, even though calreticulin can store Ca^{2+}, its ablation reveals that it is an essential modulator of integrin adhesive functions and integrin-initiated signaling, but is dispensable for the storage of luminal Ca^{2+} (27).

As discussed above, the structure and biochemical composition of the SR reflect its important role in mediating signals emanating from cell-surface receptors. The proximity to the plasma membrane of distal SR cisternae enriched in inositol trisphosphate and ryanodine receptors position the relevant receptors to interact with second messengers generated during signal transduction and to respond by modulating the storage or release of Ca^{2+}. Another example is the expression of phospholamban, a 52-residue protein that assembles into a pentamer in SR membranes. Phospholamban plays a role in regulating the resident Ca^{2+} ATPase through an inhibitory association that can be reversed by phosphorylation. The phosphorylation of phospholamban is initiated by b-adrenergic stimulation, identifying phospholamban as an important component in the stimulation of cardiac activity by b-agonists (28). These examples illustrate the functional connections that exist between the ER and the plasma membrane, connections that are important for efficient signal transduction.

7. Protein Folding in the ER

The lumen of the ER is the environment where all secretory polypeptide chains and those destined to reside in various cellular organelles fold. Like other **protein folding** compartments, the ER has a very high concentration of soluble proteins (estimated to be as high as 100 mg/mL), a factor that is conducive to aggregation. The ER is very different from other folding compartments in its higher oxidation/reduction potential, high Ca^{2+} concentration, and lack of energy source (ATP is imported via a special permease). These conditions necessitate the presence of a number of ER enzymes and chaperones to facilitate protein folding. Moreover, a number of mechanisms have evolved to ensure that only properly configured proteins proceed along the secretory pathway and that defective molecules are disposed of (29, 30). Indeed, most of the abundant luminal proteins are involved in protein folding.

One of the main ER chaperones is BiP/GRP78, which is the ER member of the hsp70 family of **stress-response** proteins. *In vitro*, BiP (and other hsp70 proteins) bind hydrophobic peptides, preferring peptides of 7–10 amino acids with either alternating (31) or clustered aromatic or large aliphatic residues (32). *In vivo*, BiP probably binds similar hydrophobic sequences that are exposed in the folding polypeptide chain, but inaccessible in the native structure. One important result of this activity is to minimize aggregation of the unfolded polypeptide chain. Peptide binding stimulates the slow ATPase activity of BiP, and the substrate is released after either nucleotide exchange or hydrolysis (33), allowing it another chance to bury its hydrophobic sequences as its folding progresses. In its capacity as a peptide-binding protein, BiP is often found to associate preferentially with nonsecretable or misfolded mutants, presumably because these molecules continue to expose binding sites that are buried more rapidly in wild-type molecules. In this fashion, BiP plays a role in the ER quality control system (34), either retarding the transport of proteins (35) or even targeting them for **protein degradation** (36).

As in the case of folding in the cytosol, an important rate-limiting step in folding in the ER can be the ***cis-trans*** **isomerization** of the **peptide bonds** of certain proline residues. This reaction is catalyzed by peptidyl prolylcis/trans isomerases, and it seems to be a redundant activity that several luminal proteins, including S-cyclophilin and **FK506**-binding protein 13, can perform.

A general property distinguishing cytosolic proteins from those that fold in the ER is the presence of disulfide bonds in the latter. Cysteine residues in nascent polypeptides oxidize in the lumen because of the higher redox potential, maintained by the approximately 3:1 ratio of reduced (GSH) to oxidized (GSSG) forms of glutathione (37). Because disulfide bonds form covalent folding intermediates, they are very important in the folding process (38). Thus, a number of luminal enzymes are capable of catalyzing the rearrangement of protein disulfide bonds. The most abundant of these enzymes are the 57-kDa protein disulfide isomerase and two structurally related proteins, ERp72 and ERp58. There is currently no evidence for the existence of disulfide isomerases in any other organelle of eukaryotes.

A second general property of proteins that fold in the ER is their frequent modification by Asn-linked glycosylation, as discussed above. The state of modification of these carbohydrates can be used to monitor the folding of **glycoproteins**. The terminal Glc residues on the initial high-mannose oligosaccharide are trimmed sequentially by glucosidase I, an ER membrane protein, and glucosidase II, a luminal protein. The enzyme that can reattach terminal Glc residues, UDP-Glc:glycoprotein glucosyltransferase, can distinguish between folded and unfolded polypeptides (39). Also involved in this monitoring system are the membrane-spanning calnexin and the soluble, Ca^{2+}-binding calreticulin. They are structurally related, and both can bind to monoglucosylated glycoproteins, an intermediate stage in the processing. In this way, calnexin and calreticulin bind to a partly trimmed intermediate and serve as sensors of the glycosylation state. The final Glc is then trimmed, and the glycoprotein is then either reglucosylated by the glucosyltransferase, if its state of folding is immature, or recognized as mature enough to be packaged for transport to the Golgi complex.

Although calnexin and calreticulin have similar fine specificities of binding to the trimmed oligosaccharides, they can clearly distinguish and bind different folded forms of the same protein. The basis for this difference is not clear. Nonetheless, gene ablation of calnexin and calreticulin in both *Saccharomyces cerevisiae* and mammalian cells in culture show that their roles in protein folding are redundant. An important unresolved issue is whether the **lectin**-like activity of the two chaperones is sufficient to account for their recognition of folding species, or whether the chaperones also interact with the folding polypeptides themselves.

In addition to BiP, calnexin, and calreticulin, there are several other resident ER proteins that function as molecular chaperones. Among these are GRP94 and PDI, which have been shown to associate transiently with folding intermediates. ERp72, ERp58, and the **immunophilins** are also potential chaperones or enzymes involved in folding, based on their association with other proteins and on their sequence similarity to cytosolic chaperones. GRP94 (also known as ERp99, gp96, endoplasmin, and hsp108) is a homodimeric glycoprotein that binds Ca^{2+} and ATP and makes up 5% to 10% of the total luminal protein. It is known to bind a number of peptides (40), as well as a narrow spectrum of proteins. GRP94 is a stress protein from the hsp90 family, whose synthesis is induced upon glucose starvation, Ca^{2+} depletion, or treatments with **tunicamycin** and amino acid analogues. Physiologic demands can also induce GRP94 expression: It is up-regulated during the differentiation of resting B lymphocytes into **antibody**-secreting cells (41) and within plasma cells in response to the production of nonsecretable immunoglobulins. The regulation of GRP94 under all these conditions is coordinated with other ER proteins, most notably BiP (41), and to a lesser extent

PDI and ERp72 (42). The role of GRP94 (and those of ERp72, ERp58 and immunophilins) in protein folding *in vivo* remains unclear, however, largely because its substrate specificity and detailed modes of action are still to be elucidated.

The growing list of ER chaperones raises several questions: Do they perform redundant functions or are they functionally distinct? How do they discriminate among the various proteins that fold in the ER? How do they participate in different aspects of the folding process? Regulation of the activity of molecular chaperones is another fundamental problem that is only beginning to be addressed. Phosphorylation has been shown to regulate the activity of BiP (43). GRP94, calnexin, and calreticulin are known to be phosphorylated *in vivo*, but the relation of the modification to their function is not yet understood. Thus, an intriguing emerging possibility is that ER chaperones cycle between active and inactive states that are marked by phosphorylation. The presence of so many folding factors clearly provides an environment that promotes efficient folding of proteins that are destined for export and in many cases are produced in large amounts.

8. Degradation of ER Proteins

An inevitable by-product of an active folding compartment is the presence of misfolded proteins and the need to degrade them (see DNA Degradation In Vivo). For many years it was thought that such degradation occurs within the ER itself, but this notion was challenged by the inability to demonstrate an appropriate set of ER proteinases, equivalent to those that reside in the cytosol. Recent discoveries, in both mammalian systems (44, 45) and in yeast (46, 47), have now clearly demonstrated the presence of a conserved retrograde traffic pathway, whereby misfolded secretory proteins are presented to the cytosolic proteasome machinery for degradation (48). Misfolded soluble and membrane proteins are translocated out of the ER, probably through the same Sec61 channel used for incoming nascent chains, and are guided with the aid of cytosolic hsp70 to 26S proteasome particles, many of which are in proximity to the ER membrane. Often, as in degradation of cytosolic proteins, the misfolded proteins that are translocated out of the ER are marked for degradation by covalent addition of poly-ubiquitin chains. The proteasome is apparently highly processive, because no large degradation intermediates are seen, and the products are short peptides with a narrow size distribution. For many membrane and secreted proteins, proteasome-mediated degradation is now thought to be the major route of disposal if they fail to fold properly, although the existence of a proteolytic pathway within the ER itself is still a possibility.

9. Sorting of Itinerant and Resident ER Proteins

The transport of proteins from the ER to the Golgi complex is via **vesicles**. Cargo proteins are selectively concentrated into “exit sites” marked by 10-nm-thick electron-dense cytosolic coats that are made of two distinct biochemical complexes, called COPI and COPII (49). Under the control of a fission machinery that uses small Gtpases to regulate protein–protein interactions, COP-coated vesicles bud off the ER membrane and are targeted for fusion with the next membrane in the pathway. The mechanism of membrane budding driven by COPII shows remarkable overall similarities to that of COPI budding, the coat that is also involved in intra-Golgi transport and in retrograde transport to the ER, as well as to budding of **clathrin**-containing coated vesicles, which mediate transport from the plasma membrane and from the *trans*-Golgi network. The discrimination between cargo proteins and resident ER proteins at the level of packaging into the vesicles is thought to be mediated by a family of small 24-kDa proteins (50). Vesicle budding from the ER has been reconstituted with purified membranes and three soluble proteins from yeast: Sec13 complex, Sec23 complex, and the small GTPase Sar1p (51).

Luminal residents of the ER, like the chaperones BiP and GRP94 and the enzyme PDI, use a receptor-mediated mechanism to ensure their localization within the ER lumen. Their *C*-terminus consists of the tetrapeptide Lys–Asp–Glu–Leu (KDEL), which is recognized specifically by an intracellular receptor that resides mainly throughout the Golgi complex. Similar receptors with slightly altered tetrapeptide specificities are found in lower eukaryotes. KDEL proteins that “escape” the ER are specifically retrieved by this receptor and transported back to the ER (52, 53).

Resident ER membrane proteins often have a different type of retrieval signal that distinguishes them from itinerant membrane proteins: a dibasic amino acid (either Lys–Lys or Arg–Arg) motif in their cytosolic domain near the *C*-terminus. This motif is recognized by the COPI complex, providing the basis for specifically packaging these proteins in vesicles that transport them retrogradely from the Golgi to the ER (54).

The combination of biochemical experiments reconstituting transport vesicles with the elucidation of retention mechanisms that differentiate resident ER proteins from itinerant proteins brings us closer to solving the important problem of how proteins are selectively sorted and packaged into transport vesicles, a question that is at the heart of the compartmentalization of eukaryotic cells.

10. Biogenesis of the ER

In fibroblasts, the ER accounts for 2% to 5% of the cytoplasmic volume, whereas in "professional" secreting cells, like pancreatic acinar cells or lymphoid plasma cells, the ER is considerably expanded, its cisternae are often stacked together (4), and it occupies up to 25% of the cytoplasm (Fig. 2). For example, during the development of **B cells** into plasma cells, when synthesis and secretion of immunoglobulin increase by two orders of magnitude, the ER grows, with both the volume and membrane area increasing three- to fourfold (41), and it changes from a network surrounding the nuclear envelope to one that fills the peripheral cytoplasm. There is a coordinate increase in the synthesis of the main luminal proteins, as well as of membrane proteins involved in the translocation process.

This phenomenon is probably the normal counterpart to the induction of luminal proteins observed as a result of accumulation of unfolded proteins in the ER under a variety of metabolic stresses, the so-called unfolded protein response (UPR). The accumulation of unfolded protein in the ER causes induction of the biosynthesis of ER proteins to alleviate the situation.

A second pathway of signal transduction from the ER to the nucleus regulates sterol biosynthesis. A small family of transcription factors, the sterol response element binding proteins (SREBPs), activates sterol-regulated **promoters**, such as those of the genes for the key enzyme HMG-CoA reductase or the LDL receptor, as well as other enzymes that synthesize fatty acids (55). SREBP is synthesized as an ER membrane protein; upon sterol depletion, it is processed by two proteinases, one of them probably a thiol proteinase, releasing the active DNA-binding transcription factor and enabling its translocation to the nucleus (56). In this fashion, coordinate metabolic control over two types of lipids necessary for membrane biosynthesis is maintained and is triggered by alterations in the lipid composition of the ER membrane.

HMG-CoA-reductase is also at the center of another ER biogenesis phenomenon. When it is overexpressed as a result of compactin treatment, there is a reversible proliferation of smooth ER membranes, which pack in hexagonal arrays (57). A similar elaboration of ER-derived smooth membranes is seen in various yeast strains deficient in inositol metabolism. These may represent cases where one of the feedback mechanisms that regulate the size of the ER "overreact," leading to excessive synthesis of some components, instead of coordinate synthesis of all components, as is required to maintain homeostasis of the ER.

Endosomes

Endosomes comprise a complex series of intracellular organelles that mediate crucial functions in the endocytosis pathway (1). Ligands internalized through **clathrin**-coated vesicles are first delivered to "early endosomes." These are tubular/vesicular organelles distributed primarily in the peripheral cytoplasm of the cell. The internal pH of these structures is mildly acidic (pH ~6.0). The low pH is established and maintained by the membrane-associated vacuolar H^+bATPaseb and regulated by the Na^+K^+ATPase. The low-pH environment is essential for certain sorting functions of endosomes. For example, it facilitates dissociation of some ligands, such as **low density lipoprotein** (LDL), from their receptors, allowing the receptor to be recycled to the cell surface and reused, whereas the ligand is retained in the cell and degraded. Disruption of the endosomal pH by weak bases, ionophores, or inhibitors of the vacuolar ATPase disrupts the sorting functions of these organelles. The acidic pH within endosomes is used by certain **viruses** (eg, influenza virus) and toxins (eg, diphtheria toxin) to facilitate membrane fusion or translocation to the cytoplasm.

Early endosomes are the primary sorting organelles in the endocytic pathway, with two principal exit routes: (1) the recycling pathway to the cell surface, and (2) the pathway to late endosomes and lysosomes (1). In addition, proteins may be sorted out of early endosomes to recycling endosomes (a subset of endosomes that have nearly neutral pH and are enriched in **transferrin receptors**), the *trans* **Golgi network** (TGN), and other locations in certain differentiated cell types (for example, the GLUT 4 glucose transporter-containing compartment in adipocytes), transcytotic vesicles in polarized cells, synaptic vesicles in neurones, and MHC class II-containing vesicles in some antigen-presenting cells (2). It is believed that transport between these compartments is mediated by carrier vesicles (although these have not been characterized in detail) that fuse with their target organelles through SNARE/NSF and Rab-dependent mechanisms (3).

Late endosomes receive internalized ligands and receptors from early endosomes and provide a second sorting compartment before lysosomes. Late endosomes are again tubular/vesicular and frequently contain many membrane vesicles or lamellae. The internal pH of late endosomes is more acid (pH ~5.5) than that of early endosomes. Transport from early endosomes to late endosomes is mediated by endosomal carrier vesicles and/or multivesicular bodies that derive from early endosomes.

The different endosomal compartments are not well-characterized biochemically or morphologically. However, analyses of the distribution of Rab family of proteins have suggested that these small Gtpasesmight provide functional markers for endosomal subcompartments (4). Thus Rab 5 is primarily associated with coated vesicles and early endosomes, Rab 7 with late endosomes, and Rab 4 with recycling endosomes (1). Because these proteins have been implicated in the specific fusion involved in vesicular transport, their restricted and unique distributions may define specific transport steps and possibly unique SNARE-dependent fusion (4).

Endotoxins

The majority of bacterial toxins are proteins released by **bacteria** in the medium and are termed exotoxins. However, many gram-negative bacteria, upon lysis or during division, release toxic lipid components of the outer membrane, which are therefore named endotoxins. These molecules are lipopolysaccharides (LPS) of a complex and variable nature that are capable of inducing a variety of local and systemic effects, including fever and toxic shock (1). LPS binds directly to the CD11/CD18 molecules and 95-kDa scavenger receptor of **macrophages**(3). After fixation to a plasma protein LBP, the complex LPS-LBP is capable of binding the CD14 molecule present on macrophages, neutrophils, and platelets (2). Such binding triggers a variety of effects. Platelets release prostaglandin E_2, tromboxane A $_2$, and PAF (platelet-activating factor), and these mediators induce platelet aggregation and coagulation and trombotic phenomena. Activated macrophages and neutrophils release oxygen radicals and nitric oxide, which causes the relaxation of smooth muscles. LPS are the most potent inducer of the release of **cytokines** from macrophages. It appears that such platelet and inflammatory cells responses have developed in order to respond rapidly to the presence of potentially pathogenic bacteria (3). However, such a defensive response may turn easily into harmful, even deadly, systemic effects when larger amount of LPS are released or bacteria multiply in the blood and release LPS in a tissue so rich in target cells.

Engrailed Gene

In multicellular organisms, the induction and maintenance of a **differentiated** state during development depend on the expression of a large number of genes acting at multiple levels (1). Genetic and molecular studies in *Drosophila* have largely contributed to the elaboration of this concept. During the embryonic development of *Drosophila*, the anterior-posterior (A/P) organization is generated by the activity of several maternal and zygotic genes (2, 3). Many of these genes encode transcriptional regulators that sequentially subdivide the embryo into smaller domains (segments and compartments) along the A/P axis (Fig.1). The segmentation gene *engrailed* (*en*) is one of the components of this regulatory cascade that defines the A/P axis during *Drosophila* embryogenesis. The *engrailed* function is essential to specify the posterior cell identity, as well as the A/P compartment boundaries (4-7). *en* is involved not only in the establishment of the posterior cell's fate but also in its maintenance. Indeed, *en* expression remains essential throughout the fly's life, from early embryonic development to the larval and adult appendage development (8-13) (Fig.2).

Figure 1. Cascade of genes that form the anterior-posterior (A/P) axis during embryogenesis. *engrailed* is a segment pol formation of the segments. This gene directly regulates the expression of the homeotic genes involved in the identity of t expression of the *Polycomb Group* genes, in particular, *polyhomeotic* (58). It also interferes directly in morphogenesis ar structural genes, such as that for b3-tubulin (54).

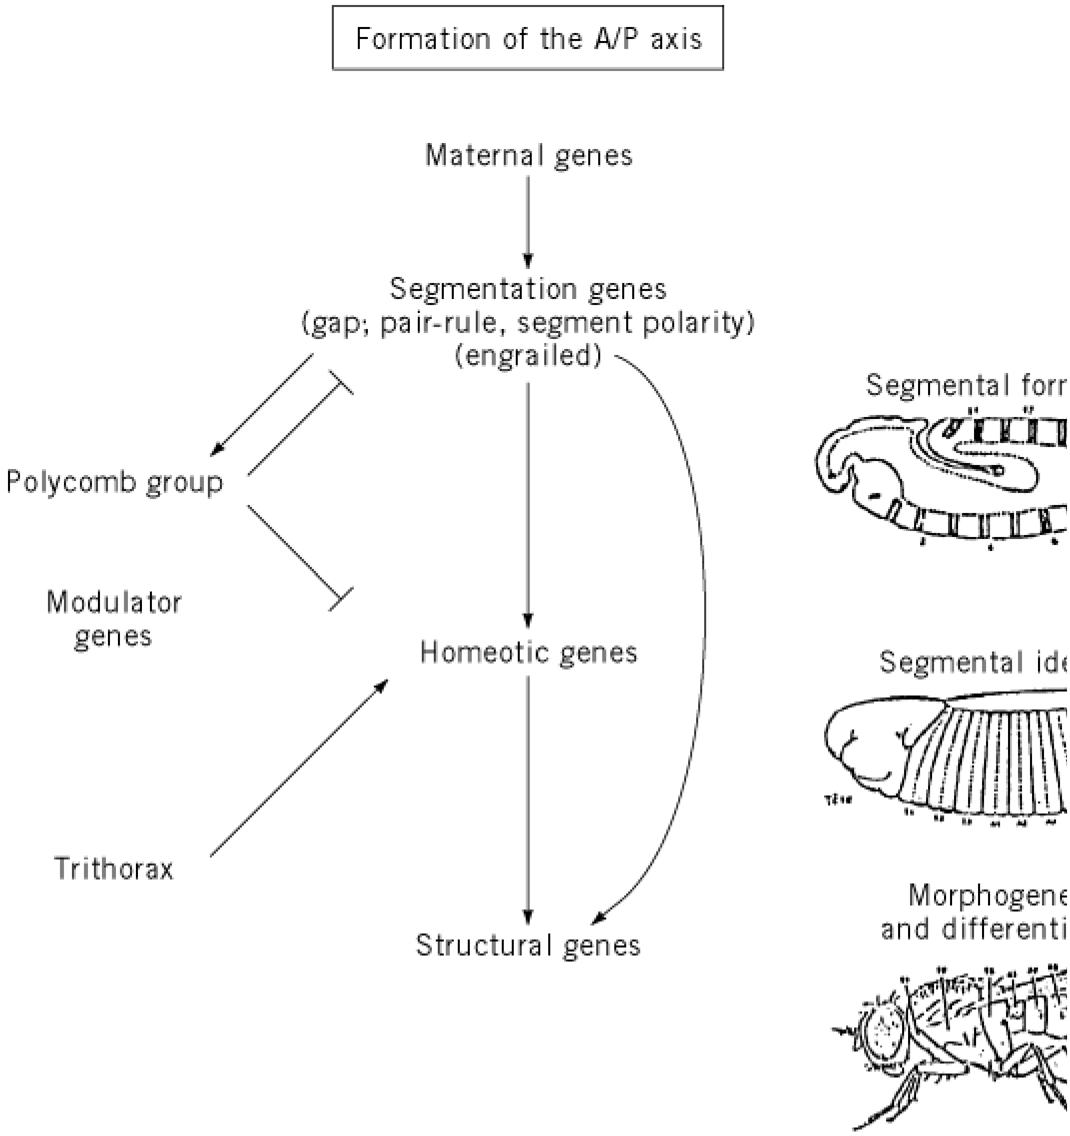

Figure 2. Expression of *engrailed* during development. In each case, the expression of *engrailed* defines the posterior cc (*en-lacZ*) producing an Engrailed–**beta-galactosidase** fusion protein has been used, and the *engrailed* gene expression f (8).

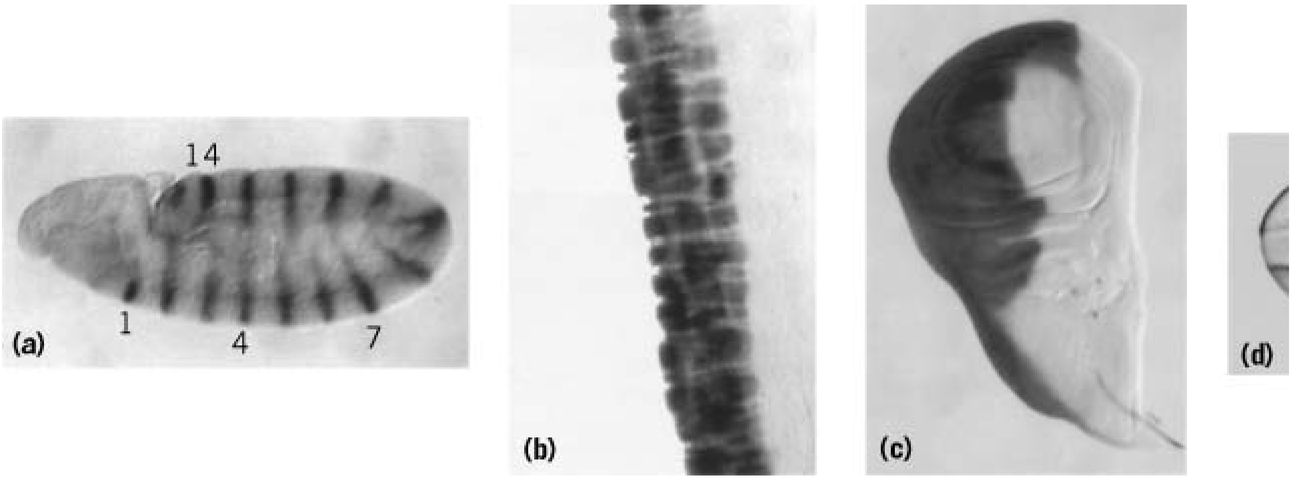
b. *engrailed* expression of third instar *en-lacZ* larval hindgut.

c. *engrailed* expression of third instar *en-lacZ* wing imaginal disk.

d. *engrailed* expression of adult *en-lacZ* wing.



The positioning of the A/P boundaries established by the segmentation genes before gastrulation is an essential step in development because these boundaries serve as a reference for the subsequent and spatially restricted expression of the homeotic genes of the ***Bithorax*** and ***Antennapedia*** **complexes** (14). Each segment is characterized by the activity of a specific subset of homeotic genes, the other homeotic genes being repressed in that segment (14). The differential expression of the homeotic genes, which is essential to confer segmental identities, is established by the segmentation genes. The segmental identities are then maintained by the ***Polycomb*** **group** (*Pc*G) and the ***Trithorax*** **genes**, the latter being required for the maintenance of the activation of the homeotic genes (15) and of *engrailed* (16). On the contrary, *Pc*G genes are required for the maintenance of the repression of the homeotic genes (17), as well as of segmentation genes, like *engrailed* (18, 19). It has been suggested that the *Pc*G proteins form multimeric complexes that maintain repression by imprinting, limiting the accessibility of transcription factors to chromatin (17, 20, 21).

engrailed is also essential in the developing central nervous system, where it is segmentally expressed (22-24). Homologues of *engrailed* have been identified in other dipteria (25) and other organisms, such as zebrafish (26), chickens (27), mice (28, 29), and humans (30). All these organisms express *engrailed* during neurogenesis. In vertebrates, the neural tube is a segmented region, where *engrailed* expression is segmentally reiterated (31). This indicates that some of the *engrailed* functions during cell determination might be conserved during evolution. For example, the genetic network regulating the development of the brain in vertebrates involves conserved genes that control segmentation in *Drosophila* (32). In particular, the *Wnt-1/engrailed* interaction was shown to be conserved from flies to mice (33).

In the *Drosophila* epidermis, *engrailed*-expressing cells also express ***hedgehog*** (*hh*) (34), which encodes a secreted protein (Hh) that influences the pattern of cell differentiation across the embryonic segments, indicating that these *en/hh*-expressing cells have organizer properties (35). In particular, interfaces between posterior cells, which express *engrailed*, and anterior cells, which do not, were shown to be required for pattern formation (36). In the embryos, just anterior to the *en*-expressing cells, cells express ***wingless*** (*wg*), which encodes a secreted protein. During early embryogenesis, interdependent regulations between *en* and *wg* occur. Later, their expression is regulated by different mechanisms and maintained by autoregulation (35-39).

Later in development, during wing morphogenesis, *en* is also involved in the specification and the maintenance of posterior patterns, as well as in creating the compartment border. *en* activity in the posterior cells directs them to express *hh*, which is secreted anteriorly (34, 40). *en* blocks the ability of the posterior cells to respond to Hh (12), whereas its absence in the anterior cells allows them to respond to Hh. Hh acts in a stripe of anterior cells abutting the A/P boundary through the Patched (Ptc) receptor, whose expression is also activated by the Hh signal (43). These anterior cells, receiving the Hh signal, express ***decapentaplegic*** (*dpp*) (a homologue of the **transforming growth factor**-b signaling molecule) which, in turn, exerts a long-range organizing activity on the growth and patterning of both compartments (44). Hence, *en* plays a major role in the control of **imaginal disk** growth, by regulating the expression of *dpp* (44, 45). Indeed, *en* has two separable roles: a cell autonomous role in defining the posterior compartment, by repressing genes that are expressed in the anterior compartment, such as ***cubitus-interruptus*** (*ci*) (46, 11), *ptc,* and *dpp* (45), and a nonautonomous role in the anterior compartment through its regulation of *hh* (34, 47). The *en*-related gene *invected* (*inv*) encodes redundant functions, even though *inv* performs only a discrete subset of the functions ascribed to *en* (40, 42). For example, *inv* does not regulate *hh* or all the genes of the *hh* signaling pathway (41).

Engrailed (En) is a homeodomain-containing protein that performs its key role during *Drosophila* development by acting as a transcription factor (48). Despite the considerable amount of research conducted on homeodomain proteins, little is known about their mechanisms of action. One issue is understanding the specificity of their action because they all bind to DNA sequences containing the same core motif 5′-TAAT- 3′, which is essential for their DNA-binding activity; the nucleotides flanking this core provide the specificity of binding (49, 50). The N-terminal residues of the homeodomain were found to contribute to this sequence-specific association. In particular, the identity of residue 50 of Engrailed affects the base preference, both *in vitro* and *in vivo* (51-53).

Because of this remarkable conservation of binding properties among all homeodomains, the discovery of their DNA target sequences *in vivo* has been difficult. Identification of their target genes is, however, an essential step in understanding their role during development. Such a study has been performed in order to understand how *engrailed* achieves its complex regulatory role throughout development (Fig. 2).

The identification of target genes for transcription factors has been undertaken using different approaches, based on two main ideas. The first approach is functional and is based on the existence of genetic interactions between two genes. Genetic experiments have shown that En is able to repress *ci* (46), *dpp, ptc* (45), and the gene for b3-tubulin (54) and to activate the expression of several other genes, such as *en* itself (35), *hh* (34), ***Ultrabithorax*** (*Ubx*) (55, 56), and *polyhomeotic* (*ph*) (13, 54), but the direct effect of En on these genes has not always been proved.

The other approaches are based on the capacity of transcription factors to bind to specific DNA sequences. Libraries have been constructed that are enriched either in sequences that bind En *in vitro* (57) or in embryonic chromatin that binds Engrailed *in vivo* (54, 58). This latter approach has also been used successfully to identify the target genes of the homeotic protein Ubx (59, 60). In this process, DNA-protein complexes that exist in embryos are stabilized by UV crosslinking. The complexes formed with the endogenous En protein are then selected by **immunoprecipitation** with an anti-En antibody, followed by cloning.

Engrailed binding sites have also been localized directly on **polytene chromosomes** of salivary glands with an anti-Engrailed antibody. The number of En binding sites was estimated to be approximately 100 (58). Among these sites, in the 2D region, the *Pc*G gene *polyhomeotic* (*ph*) was shown to be a direct target of *engrailed*, through the combined use of these different genetic and molecular approaches. In particular, the activation of *ph* by En was shown to be required for the maintenance of the posterior cell fate and the position of the anterior-posterior boundary in the wing, a role assigned to the *en* function (13).

As already mentioned, among the known target genes of En, some are repressed, whereas others are activated by *engrailed*. Transfection experiments into cultured cells have demonstrated that En can act through a consensus En binding site, referred to as the NP site (“ATTAATTGA”), as a passive repressor, by competing with specific activators for binding sites located upstream of a basal promoter (61-63). Repression by En can also occur by competition with the general transcription factor TFIID for binding to the TATA box (64). En has also been found to function as an active repressor of transcription by binding to sites distinct from those bound by activators (65). The active transcriptional repression can also be enhanced in the presence of corepressors like Groucho (66, 67). A **domain** other than the homeodomain was found to be responsible for repression by En (65, 68). In particular, this repressor domain is able to confer the capacity to repress transcription in transfected cultured cells, as well as *in vivo* when transferred to a heterologous DNA-binding domain (65, 68, 69).

Analysis of the molecular mechanism of transcriptional activation by En showed that its binding fragment responsible for activation is different from that responsible for repression. For activation, the binding segment consists of a long stretch of "TAAT" motifs, where up to ten En proteins can bind cooperatively (70). A strong activation is, however, obtained only in the presence of a cofactor, Extradenticle (Exd), another homeodomain-containing protein. In the presence of En, Exd becomes able to bind to this segment (71, 70). When both proteins are bound to DNA, between En and Exd turn En into an activator (70). Interestingly, activation occurs even when such an activator-binding fragment is localized far away from the coding sequence, as long as an En consensus sequence, related to NP ("ATTAATTGA"), is located just upstream of the gene to be activated.

Interactions between distantly located En binding fragments could also be responsible for the *en* autoactivation that occurs at germ-band extension (35). The observation that the autoactivation of *en* depends on *exd* maternal expression suggests that Exd is involved in this phenomenon, as it is in the case of the activation of *ph* by En (72). The fragment responsible for the *en* autoactivation, which is able to bind Exd, has not yet been isolated.

Other peculiar observations have been described concerning the *engrailed* gene. Among them is the "homing" phenomenon, in which P elements containing *en* DNA sequences are preferentially inserted at the *en* locus (8). Moreover, preferential insertions of *Drosophila* transposable elements containing a particular fragment of the *engrailed* regulatory DNA have been described (73). Finally, this regulatory DNA fragment from the *engrailed* gene was also found to mediate transvection of the *white* gene (74, 75). This silencing activity results from the presence of a polycomb response element (PRE) within the fragment of *engrailed* regulatory DNA, which was shown to bind *pleiohomeotic* (76). The presence of a PRE in this fragment could also explain the homing and the preferential insertion of *engrailed* sequences in the genome, even though this has not yet been formally proved.

Enhancer

1. Introduction/Summary

In the regulation of gene transcription, two aspects are of prime importance, namely the point of initiation and the rate of transcription. In bacteria, both of these are usually determined by short DNA sequence motifs, collectively called promoters, that are in close proximity to the initiation site. In mammals and other eukaryotes, the point of transcription initiation of protein-coding genes is determined by proximal promoter sequences, but the frequency of transcription is influenced by remote DNA sequences, termed enhancers, that can be located thousands, if not tens of thousands of basepairs from the promoter. Enhancers are typically 100–300 bp long and represent an array of binding sites for DNA-binding transcription factors. Binding of such proteins to an enhancer helps, in a collaboration between enhancer and promoter, to recruit components of the transcription apparatus. These include the **RNA polymerase** II holoenzyme and enzymes that loosen the chromatin packaging of DNA. Due to its specific DNA sequence, any given enhancer binds a subset of the many hundred transcription factors of a eukaryotic organism. Some of these proteins are present only in a given cell type, others become active only upon an external stimulus, such as a hormone. Accordingly, an enhancer can activate a linked gene only in the appropriate cell type, or in response to a specific stimulus. Many genes are controlled by several distinct enhancers, which ensures gene activation in response to different cues. Also, sequence rearrangements in enhancers may lead to the evolution of new patterns of gene expression in multicellular organisms. Due to their prominent role in rendering chromatin more accessible to DNA-interacting proteins, at least some transcriptional enhancers have additional overlapping functions in that they facilitate DNA replication, de**methylation** of cytosines at CpG sites, and site-specific DNA recombination, switch recombination and somatic hypermutation of immunoglobulin genes. Also, some enhancers act as a genetic switch between positive and negative gene regulation; under conditions where the linked gene has to remain silent, they serve as a platform for the binding of repressing factors/cofactors.

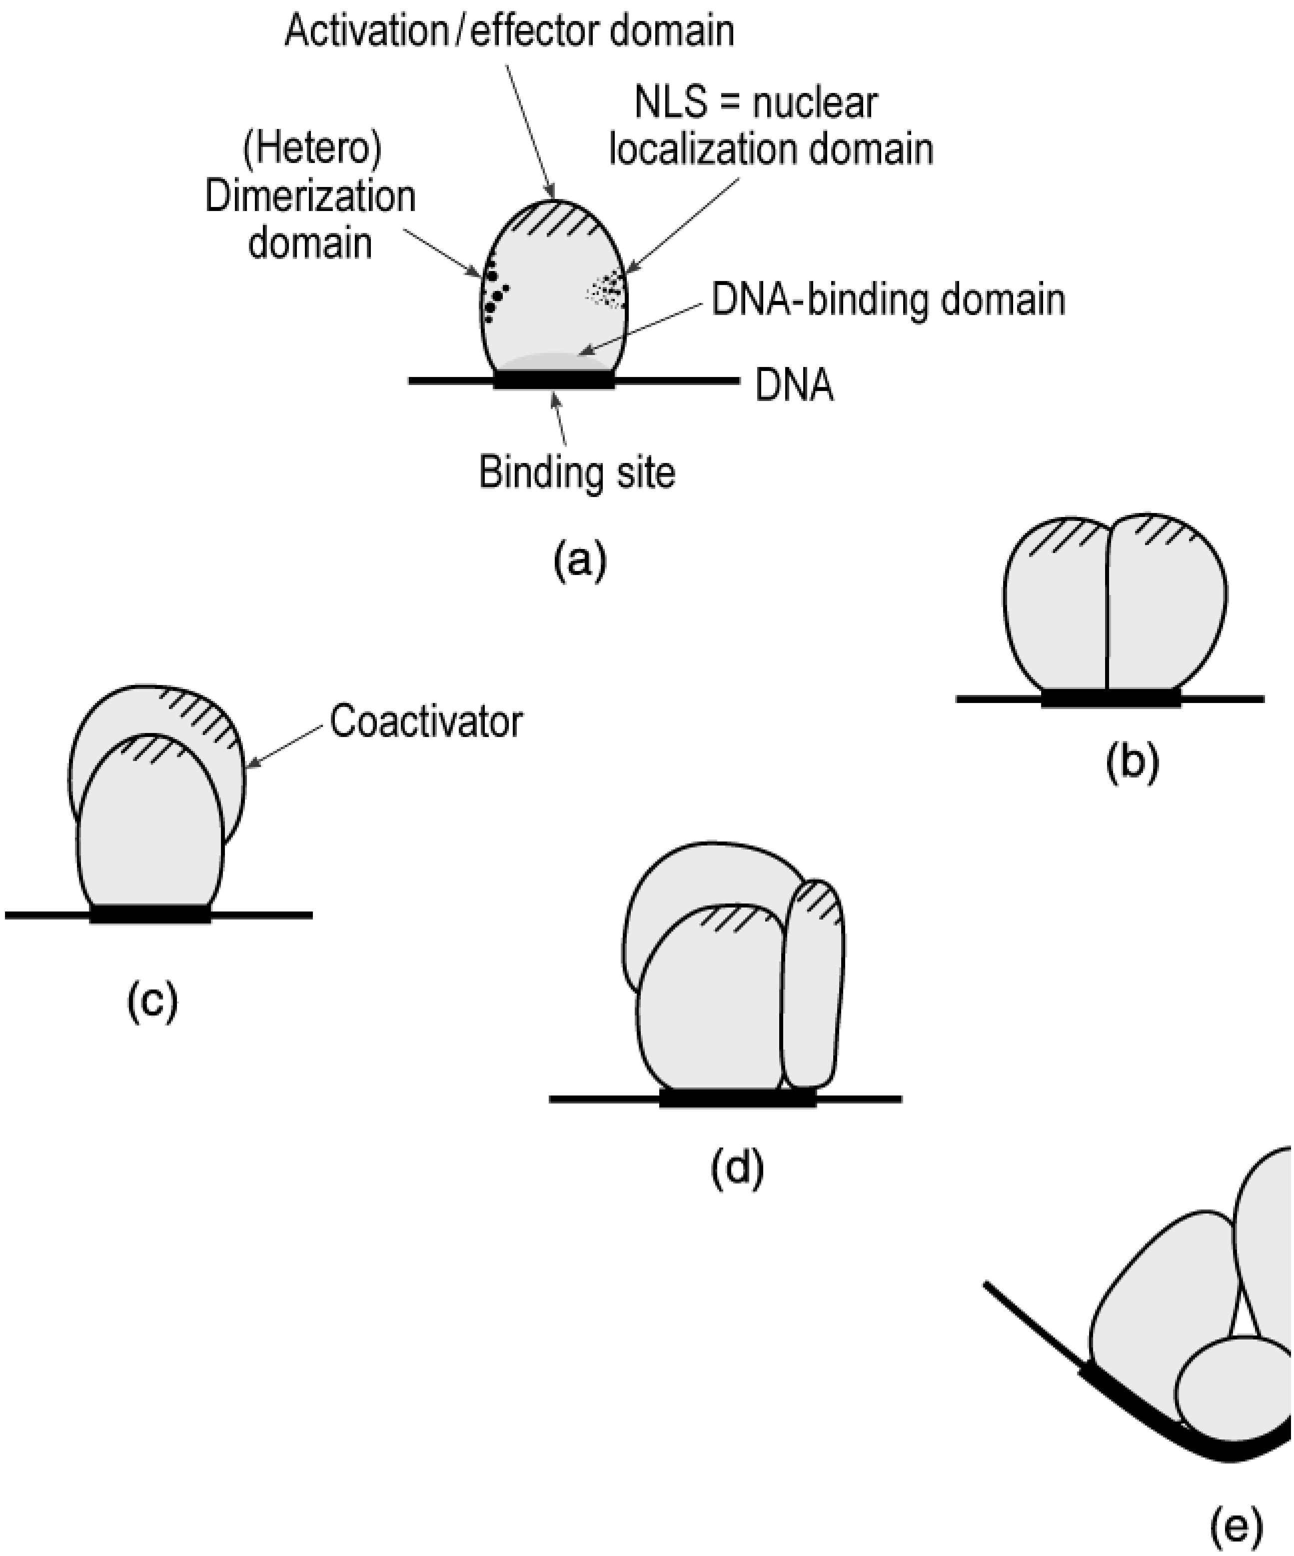
2. Discovery, Definition

In 1981, the first enhancer characterized was from the genome of simian virus 40 (=SV40) (1, 2). This enhancer sequence is naturally located between 300 und 100 bp upstream of the initiation site for early mRNAs, but could be experimentally placed at various distances from an unrelated reporter gene, which thereby was transcriptionally activated. Characterization of enhancers from SV40 and other viruses led to the following definition of a transcription enhancer: (i) a DNA sequence, typically about 200 bp in size, that strongly activates transcription of a linked transcription unit from its correct initiation site; (ii) it activates transcription independently of its orientation; and (iii) it is able to exert its function over large distances of more than 1000 bp, from a position either upstream or downstream of the initiation site (3-5).

The first cellular enhancer was discovered in the immunoglobulin (Ig) heavy chain gene (6-8). This constituted a hallmark in the understanding of gene regulation in higher organisms, because it showed that gene control by remote enhancer sequences was not a viral peculiarity. Most importantly, the Ig enhancer stimulated transcription in a cell type-specific manner, thus being the first genetic element described to have such a property. The Ig enhancer is located downstream of the initiation (5′-cap) site, within the second intron, showing that enhancers can be naturally located downstream of the site of initiation. This concept has since been widely confirmed in most eukaryotes from flies to men (Figure 1). While most of these studies were done with RNA polymerase II-transcribed genes, transcription enhancers are also associated with **ribosomal** genes that are transcribed by RNA polymerase I (9).

Figure 1. Enhancer types in different organisms. (**a-d**) Schematic representation of a mammalian gene with different
indicated (18, 3, 4). In a gene stripped of its enhancer, transcription is low or undetectable (**a**). An enhancer (array of bla
binding sites for transcription factors) can be located adjacent to the promoter, as in several viruses or metallothionein st
upstream, like in the albumin gene (**b**); or within the gene, usually as part of an intron, like in immunoglobulin (Ig) genes
also found far downstream of the transcription unit, as in T cell receptor and Ig genes (**d**). One and the same gene can als
one enhancer, to ensure activity in several cell types and in response to different stimuli (not shown here). In the baker's
(upstream activating sequences) are considered analogous to mammalian enhancer elements. They can also work in eithe

however, they are rarely, if at all, activating from positions downstream of the gene (**e**). The majority of eubacterial pron control of RNA polymerase with sigma 70 factor and cover less than 100 bp. The promoters of genes activated upon nitr driven by sigma 54 factor and show similarities to eukaryotic enhancers, in that an upstream binding site, in conjunction protein, can work from variable distances (**f**) (85-87).



In addition to the originally discovered intronic enhancer, the immunoglobulin heavy chain locus was also found to contain a second, extended B cell-specific enhancer located far downstream of the entire **locus**, as well as additional cytokine-inducible enhancers involved in Ig class switching (10).

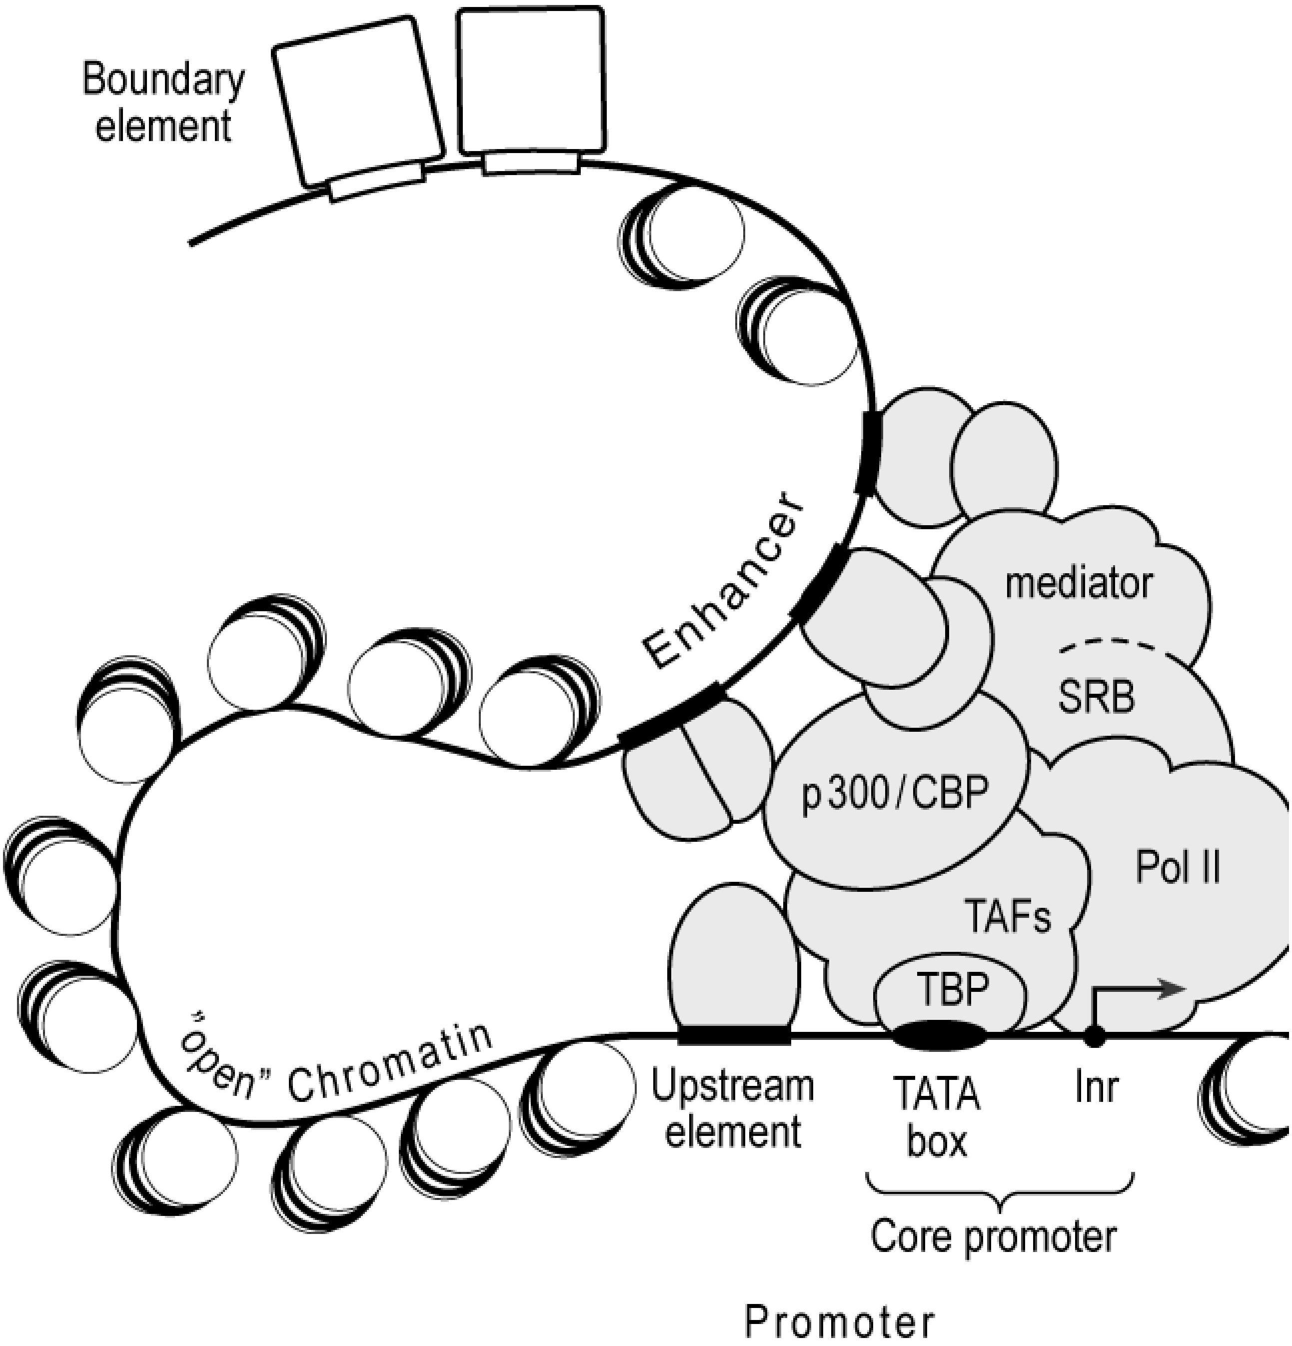
In many other instances, enhancers were established to play a crucial role in stage- and cell type-specific gene expression: In an interplay with the transcription factors that bind to them, enhancers ensure proper development of all multicellular organisms; see, for example, Refs. 11-13. Perhaps the most extensive studies have been done in Drosophila, where a gene for a developmental regulator protein is typically under the control of several separate enhancers. Depending on the stage and cell type, some enhancers can exert either positive or negative effects on transcription. For example, to establish a repetitive stripe pattern of even-skipped gene expression during early Drosophila embryogenesis, a single enhancer does not suffice, but one of several enhancers controls the expression of just one of these stripes (14, 15; see also 16).

3. Modular Structure of Enhancers

A typical enhancer is 100 to 300 bp long and essentially consists of an array of binding sites, each about 10 bp long, for DNA-binding transcription factors (17, 18). Every eukaryotic cell contains hundreds of different transcription factors, each with a DNA binding domain of characteristic specificity for DNA sequence recognition, plus an "activation domain". The latter establishes contacts to other components of the transcription apparatus and thus enhances the level of gene transcription. Since under some conditions, negatively acting proteins can be recruited, an activation domain was also referred to as "effector domain". The DNA sequence recognition specificity and affinity of many eukaryotic transcription factors does not match that of bacterial regulators. This seems to be compensated by a multitude of protein-protein interactions (see text below).

A given DNA site can, for example, be recognized by a monomer, by a homodimer reminiscent of bacterial regulators, or by heterodimers. It can also be recognized by heterodimers where only one partner binds DNA strongly, while the other makes only minor contacts to DNA and in turn may have a leading role in activation. More complex situations have also been documented (see Figure 2).

Figure 2. Enhancer-binding transcription factors. A typical transcription factor contains a DNA-binding domain, a nu signal for import into the nucleus, an activation/effector domain for contacts to coactivators/mediators and a (hetero)dim (**a**). Although shown here schematically, the three-dimensional structure of many transcription factors is known from X- or nuclear magnetic resonance (NMR) analysis. Binding to DNA can involve homo- or heterodimers (**b**) (e.g., see Ref. 8 transcription factor can associate with a coactivator that does not contact DNA. For example, the cell type-specific coact OcaB/OBF-1) binds to a ubiquitous factor (Oct-1) to bring about preferential activity in B lymphocytes (**c**) (89-91). A co DNA binding specificity and contribute a strong activation potential. For example, the herpes viral coactivator VP16 (= associates with the cellular Oct-1 factor and with an additional large protein termed host cell factor (HCF). By providing simplex virus recruits Oct-1 to a new DNA sequence motif present in viral promoters at the expense of proper host cell f "Architectural" proteins, that by themselves would neither activate transcription nor bind to DNA with high specificity, binding of *bona fide* transcription factors to DNA, as indicated here for the protein HMG I(Y) (center) that bends DNA b minor groove (**e**) (20); see also refs 93, 94. Superstructures composed of several such binding sites and DNA-bound fact referred to as an enhanceosome (22). DNA binding transcription factors of the enhancer and the promoter, the latter inclu binding protein (TBP) and the general transcription factor TFIIB, recruit via multiple protein-protein contacts, further ge factors, adaptor- and mediator/SRB-proteins which in turn recruit RNA polymerase II to the initiation site. Individual pr specific subset of factors for initiation; for example, the TBP-associated factors (TAFs) may be replaced by other multip shown here. Besides RNA polymerase, several enzymatic activities are associated with the initiation complex, including acetyl transferases. The latter mainly acetylate histones to ensure a loose chromatin structure permissive for transcription coordinated gene transcription is often flanked by boundary elements (= insulators) (**f**) (see text).



A typical enhancer has a modular structure and is composed of binding sites for several different transcription factors (17, 18), but synthetic enhancers can readily be obtained by multimerization of one and the same DNA sequence motif (19, 20). From these and other experiments, it is concluded that each binding site for a transcription factor (or factor dimer, see Figure 2) can be considered one enhancer unit that, in principle, is able to activate transcription by itself. However, single sites have poor, if any, activity, and multiple sites have to act synergistically to yield strong activation (19-21). More complex cases are also documented where a functional unit consists of some 60 bp of DNA, with several transcription factors stereospecifically aligned on it with the help of "architectural" proteins that bend the DNA, a superstructure that was termed the enhanceosome (22).

A DNA-binding transcription factor, whether bound to a distal enhancer or a proximal promoter, does not directly recruit RNA polymerase II, but instead acts via intermediary proteins to form large complexes (see below and Figure 2). Such multiprotein complexes seem to be quite forgiving towards the positioning of their DNA-binding partner, which could explain the fact that an entire enhancer, subsets of it, and in many cases even individual transcription factor binding sites in an enhancer or promoter can be inverted relative to each other without loss of activity (23, 1, 17, 24). This general property of eukaryotic regulatory DNA sequences to retain activity when inverted, was first documentend with an upstream segment of the histone H2A gene termed "modulator" (23).

4. Mechanism, Recruitment

Transcription factors may activate transcription in more than one way, but all involve some kind of recruitment process. The activation domain of a DNA-binding transcription factor binds to additional proteins (coactivators, adaptors, mediator proteins, SRB proteins), organized in multiprotein complexes that in turn establish contacts to RNA polymerase II (25, 26). The related coactivators CBP/p300, originally found to bind the mammalian DNA-binding factor CREB that is responsive to induction by cyclic AMP, contain several domains for interaction with a multitude of other transcription factors (27). Transcriptional activators are also known to contact the general transcription factor TFIIB, the TATA-box binding protein (TBP) and/or TAF proteins associated with it (28, 29).

The recruitment concept for transcriptional activation has gained credit from elegant experiments where covalent linkage of a DNA-binding transcription factor to a basal transcription factor (the TATA-binding protein TBP) rendered the *bona fide* activation domain obsolete. The same was found when a DNA-binding factor was designed to make an artificial, tight contact to the SRB complex. These findings demonstrate that linking a DNA-bound transcription factor to a component of the mediator complex is in principle sufficient to activate transcription (30-32).

The transcription factors of the enhancer are likely to bind, indirectly via cofactors, to those of the promoter to form an initiation complex, with the intervening DNA looped out. Several experiments support a looping between enhancer and promoter (eg, see Refs. 33 and 34). In spite of the compelling simplicity of the above experiments, it is unlikely that transcriptional activation is naturally brought about by a uniform mechanism. Among other evidence, this is suggested by the fact that there are different types of activation domains, when classified according to their activation properties (35, 36), and it is obvious that transcription can be controlled not only at the level of initiation but also at the level of elongation (37-39).

The coactivator and mediator protein complexes also contain several histone acetylase enzymes. Their major targets are the histones, but a number of transcription factors can also become reversibly acetylated. Acetylation of histones generally loosens chromatin structure and thus makes it more accessible to the transcription apparatus (40). Major support for this concept comes from experimental digestion of chromatin with DNaseI (41). Transcriptionally active DNA is generally DNase I sensitive, which is correlated with the presence of acetylated histones. In addition, the enhancer and promoter regions themselves are hypersensitive, due to binding of transcription factors with, at least in some cases, concomitant removal of nucleosomes (42). (Besides a genetic screen called "enhancer trap" (43, 44), the property of DNaseI hypersensitivity is the most effective method in identifying candidate enhancers from large DNA segments). Large multiprotein complexes (SRB/mediator; SWI/SNF etc.) are known to support chromatin remodelling and recruitment of the transcription apparatus (45, 25-48). Extended regions of inactive chromatin, termed heterochromatin, tend to be associated with the periphery of the nucleus (49). By fluorescence staining it was shown that a silent, peripheral gene relocalizes to a more central region upon activation of its enhancer. The general validity of this phenomen remains to be seen, and also whether such a relocalization ist the cause or the effect of transcriptional activation.

5. Evolution

In higher eukaryotes, genes regulating development are often under the control of multiple enhancers, and it was argued that enhancer shuffling was the major driving force in the evolution of new patterns of gene expression (50-53). Apart from shuffling, enhancer evolution may be facilitated by the fact that enhancer DNA sequences are more tolerant to rearrangements than protein coding sequences, which has, e.g., resulted in divergent primary enhancer sequences that nevertheless serve the same function (54). In fast-evolving viruses, a new cell type specificity is readily achieved by enhancer rearrangements, usually involving deletion-duplication of subsegments, with little alterations elsewhere in the genome (55). Duplications of enhancer subsegments, which are indicative of recent functional alterations, are also found in some cellular enhancers and in humans may even vary between ethnic groups (56). However, not every arbitrary enhancer-promoter combination can be expected to function since in any gene, promoter and enhancer(s) have co-evolved for optimal function. There are indeed documented cases of preferential, if not exclusive enhancer/promoter specificity (57-59). Nevertheless, promiscuous enhancer-promoter cooperations were found from yeast to mammals and may be the rule, rather than the exception (44, 50, 60).

6. Open Questions/Related Phenomena

Even though many aspects of eukaryotic transcription control have already been elucidated, thanks to a combination of genetics, reverse genetics and biochemistry, many questions remain. One of them concerns the mode of activation: does an enhancer allow for fine tuning of the activity of a gene within one individual cell, or can a gene only exist in two states, namely fully activated or completely switched off? In the latter case, the function of the enhancer would be to increase the probability of the gene being in the “on” state. While the first of these possibilities seems to make more sense, at least in the case of hemoglobin genes, there is evidence for the latter one (61).

Some extended enhancer regions have been referred to as LCR (locus control region). The most thorough studies were done with the hemoglobin beta chain locus, where the LCR consists of a group of at least five remote enhancers/DNase I hypersensitive regions contained within a DNA segment of 15 kb. Each LCR subdomain confers distinct activation properties in erythroid cells. The LCR, which is located some 50 kb from the most downstream beta-globin transcription unit, ensures the complete, stage-specific and cell type-specific expression pattern of the globin genes under its influence (62-64).

In spite of an ability to work over long distances, enhancer activity is confined to the same DNA molecule, i.e. to an activity in cis. In certain constellations that requires pairing of homologous chromosomes, an enhancer can also activate the promoter in the homologous locus, a phenomenon termed **transvection** (65). While well-documented in Drosophila, the relevance of transvection in mammals remains to be seen.

Perhaps due to its ability to loosen up chromatin structure, a transcription enhancer may be used for other activities besides transcriptional activation. For example, the activity of an enhancer *in cis* was also correlated with the initiation of DNA replication (66-68). Moreover, in immunoglobulin (Ig) genes, enhancers induce demethylation at CpG sites (70), site-specific gene rearrangement (VDJ joining) and also class switch recombination (71). In addition, the amazing process of localized Ig gene hypermutation in B memory cells is dependent on an active transcription enhancer (72). The Ig gene locus also harbors so-called matrix attachment regions (MARs), A+T-rich DNA segments which have little activity by themselves but in transgenic animals support long-range enhancer activity, apparently by counteracting the formation of transcriptionally inactive chromatin (73).

In a process opposite to activation, genes can be inactivated by recruitment of histone deacetylases and other proteins counteracting transcription to the promoter/enhancer region (74, 75). Non-acetylated histones tend to assume a chromatin structure that is refractory to the transcription apparatus, which is also reflected by a relative resistance to experimental DNase I digestion. A so-called silencer DNA segment can inactivate a linked gene over large distances (76-78). Again, for this purpose, DNA binding proteins recruit a number of cofactors which together block transcription (74, 75, 78, 79). Enhancers and silencers originally were described as non-overlapping DNA entities of opposite function. However, a number of enhancers, notably for developmental gene regulation in

Drosophila, also harbor binding sites for negatively acting DNA binding proteins and/or cofactors. Thus, in a cell type where the gene must not be active, an enhancer may serve a silencing purpose (80). To prevent undue spreading of an enhancer (or silencer) effect to neighboring genes, chromosomal domains of gene activity are separated from each other by so-called boundary, or insulator, sequences (81, 82)(Fig. 2).

Finally, in the process of RNA splicing, a process that bears some resemblance to transcriptional enhancement has been described. So-called splice enhancers denote RNA sequences in the primary transcript which, by means of specific protein binding, facilitate RNA processing at nearby splice sites. Unlike transcription enhancers, splice enhancers are typically located in an exon (exonic splice enhancer = ESE), consist of short sequence motifs that cannot be inverted, and act over short distances only. This process is mainly used to favor one type of splice site at the expense of another, i.e., for alternative splicing (83, 84).

Enkephalins

Enkephalins are pentapeptides with the sequence Tyr–Gly–Gly–Phe–X, which are the natural ligands of the opiate **receptors**. The two major enkephalins are [5-leucine] enkephalin (abbreviated [Leu] enkephalin) and [5-methionine] enkephalin (abbreviated [Met] enkephalin) (1). The peptides are derived from three precursors, pro-opiomelanocortin (POMC) and pro-enkephalins A and B (2). The prohormones are of similar size and contain multiple repeated units of enkephalins. The precursors are processed **proteolytically**, mostly in the Golgi apparatus, to the hormonally active products. The two proenkephalins show considerable sequence homology; they probably originated from a common ancestral gene by gene duplication.

The proenkephalin peptides and the enkephalins are distributed in many types of cells, especially brain, spinal cord, and gut. POMC is present in high concentrations in the corticotropic cells of the adenohypophysis and in many endocrine-related tissues (eg, adrenal medulla). Enkephalins have analgesic properties. They are also synthesized in neurons and are abundant in various regions of the hypothalamus, acting on the secretion of hormones of the hypothalamus and hypophysis (they stimulate secretion of prolactin, thyrotropin, and growth hormone and inhibit secretion of follicle-stimulating hormone/luteinizing hormone (folitropin/lutropin; FSH/LH), adrenocorticotropic hormone (ACTH), and vasopressin/oxytocin (3). The enkephalins are hydrolyzed by enkephalinases. Inhibitors of the degrading enzymes have been introduced as analgesics (4).

Enterokinase

Enterokinase, also known as enteroprotease (E.C. 3.4.21.9), is a key enzyme in the digestion of dietary proteins in the small intestine. It catalyzes the activation of **trypsinogen** by removing six amino acids from the amino terminus of the 229-residue protein and does so with extremely high specificity. The resulting trypsin then activates all the other pancreatic proenzymes, as part of a two-step proteolytic cascade that is essential for proper digestion.

Enterokinase is a serine proteinase of the **trypsin** family and with trypsin-like specificity (1). It is synthesized in the epithelial cells of the duodenum and appears to be an intrinsic membrane protein located on the outer surface of the intestinal brush border. In fact, it is generated from a 1019-residue precursor that is proteolytically cleaved to a 235-residue light chain, which resembles trypsin and has the serine proteinase catalytic triad, plus a 784-residue heavy chain (2); the two chains are linked by a disulfide bond (3). In this regard, its properties are like those of the blood-clotting enzymes (4).

It should be noted that the term kinase is normally used to denote an enzyme that catalyzes the transfer of a phosphate group from a donor, such as ATP, to a receptor, such as glucose. In this regard, enterokinase has been misnamed. It does not catalyze phosphate transfer at all and, hence, is more appropriately called *enteropeptidase* .

Enzyme Immobilization And Conjugation

Immobilization and conjugation refers to the covalent attachment of an enzyme to a solid support or to a soluble molecule through use of bifunctional crosslinking reagents (see Crosslinking). The use of immobilized enzymes in the medical, pharmaceutical, chemical, and food industries continues to increase dramatically. Future exploitation of immobilized or conjugated enzymes will undoubtedly result in the development of new biosensors and bioreactors for use in such areas as diagnostics (*in vivo* monitoring of metabolites, drugs, and proteins); environmental monitoring (detection of pathogens, toxins, and pollutants); separation sciences; the synthesis of complex, chiral organic compounds; and the detection of macromolecular interactions (reviewed in Refs. 1 and 2).

Among the most widely used bioconjugates are reporter enzymes covalently crosslinked to antibodies. These conjugates have been pivotal in the development of enzyme-linked immunosorbent assay (ELISA) systems, which allow detection of an immense variety of analytes through their specific recognition by appropriate antibodies. The two most commonly used reporter enzymes in ELISAs are alkaline phosphatase and horseradish peroxidase (HRP). The characteristics of these enzymes allow for different strategies in their conjugation to antibodies. For example, HRP contains saccharide groups that can be readily oxidized to aldehydes, which, in turn, are conjugation targets for free amino groups on the antibody. Alternatively, because HRP contains few **lysine residues**, it can be conjugated to antibodies by glutaraldehyde without significant formation of insoluble products. Several heterobifunctional crosslinking reagents, including ***N*-hydroxysuccinimide** ester/maleimide reagents, which selectively link **amino** and thiol groups, are also widely used in enzyme–antibody conjugation (3).

Enzymes can be immobilized by conjugation to a variety of different types of supports having different properties and uses. For instance, in aqueous solution polyethylene glycols have a large exclusion volume, which encompasses those molecules conjugated to them. Thus, proteinases and antibody molecules can be excluded from enzymes conjugated to these polymers, a property that can be beneficial for applications that require exposure of the conjugates to biological fluids (4). Reversible solubilization of an enzyme can be achieved through its conjugation to liposomes, using a reagent such as a **carbodiimide**; reversible precipitation and solubilization can be brought about by manipulation of the dielectric strength of the solution. Biosensor technology utilizes proteins that are immobilized by bifunctional crosslinking reagents to diverse supports (5), including carboxymethylated dextran-coated gold film, metal-coated nylon mesh, and carboxymethyl cellulose. Immobilization of enzymes on novel solid-phase matrices, such as porous zirconium, silicates, and colloidal gold, has been used in the construction of bioreactors for the industrial generation of numerous compounds. Many supports have functional groups that must be chemically activated prior to conjugation with protein; this allows activation to be carried out under harsh conditions that would otherwise be detrimental to the protein.

Enzyme-Linked Immunosorbent Assay (ELISA)

Enzyme-linked immunosorbent assay (ELISA) is a technique for quantifying a substance by use of an antibody specific for that substance that has been conjugated to an enzyme. The original ELISA was developed along the lines of a solid-phase radioimmunoassay, substituting an enzyme for a **radioactive** label (1, 2). Regardless of the experimental design used for the immunological reactions, the end result is that the antibody–enzyme conjugate is immobilized. Enzymatic activity is assayed in a subsequent reaction, and the activity is related to the quantity of analyte (antigen or antibody) present in a test sample by comparison to a set of controls of known concentration.

A key reagent for all ELISAs is the enzyme conjugate. In most cases, the enzyme is crosslinked covalently to an antibody, but experimental designs with enzyme-labeled antigen are also used. Indeed, the ELISA method is adaptable to any **ligand** and **receptor** pair. The most common enzymes used are alkaline phosphatase and horseradish peroxidase. These proteins are stable to the crosslinking procedures, and they catalyze reactions with highly chromogenic substrates, leading to very sensitive detection limits. Optical absorbance is the most common method of measuring enzyme activity, but other detection technologies are also used, such as **fluorescence** or chemiluminescence. Covalent linkage to a chromatography matrix was used to immobilize the first "immunosorbent," but use of plastic multiwell microtiter plates is now nearly universal, as these allow simultaneous monitoring of scores or hundreds of enzymic reactions in automated instruments.

The number of experimental formats used for ELISA is immense. This discussion is limited to the simplest and most useful assay designs.

1. Competitive ELISA

The first reported ELISA was a competition assay, in which adding an unlabeled competitor molecule reduced the amount of enzyme conjugate that could be immobilized (1). This remains an extremely common approach. The method begins with adsorption of antigen to the surface of a microtiter plate (Fig. 1). This non-specific adsorption occurs spontaneously, simply by allowing the antigen solution to stand in the wells of the plate. The linkage to the plate is noncovalent, but essentially irreversible, and the adsorbed antigen is seldom released during subsequent reactions and washing steps. Often a blocking step follows, in which a concentrated solution of a protein such as serum albumin is used to coat the remaining plastic surface, thereby preventing later adsorption of assay components. The plate is washed with a neutral buffer. The antibody solution of unknown concentration, and a series of controls, consisting of known quantities of the same antibody, are mixed with a fixed amount of the antibody–enzyme conjugate and added to different wells of the plate. The conjugate binds to the immobilized antigen, but so does the unconjugated antibody, and the binding of each is mutually exclusive. Thus, the higher the concentration of unconjugated antibody, the less the amount of enzyme immobilized. After allowing an interval for the antigen to be bound, the plate is again washed, and the addition of substrate initiates the enzymatic reaction. The rate of product release, or the accumulation of product after a fixed time, is determined for the unknown analyte and controls. Reactions to which no unlabeled competitor was added will have the highest absorbance, and are taken as a 100% response. Controls lacking conjugate, or lacking antigen, or to which a saturating amount of competitor was added, give the lowest absorbance. This value, reflecting background enzyme binding and the uncatalyzed chromogenic reaction, is taken as a 0% response. Data from the other controls are plotted to give a calibration curve, using a logarithmic concentration scale on the abscissa and an absorbance or percentage scale on the ordinate (Fig. 2a). The response from the unknown is compared to the calibration curve, and the corresponding concentration is read off the abscissa.

Figure 1. Competitive ELISA.

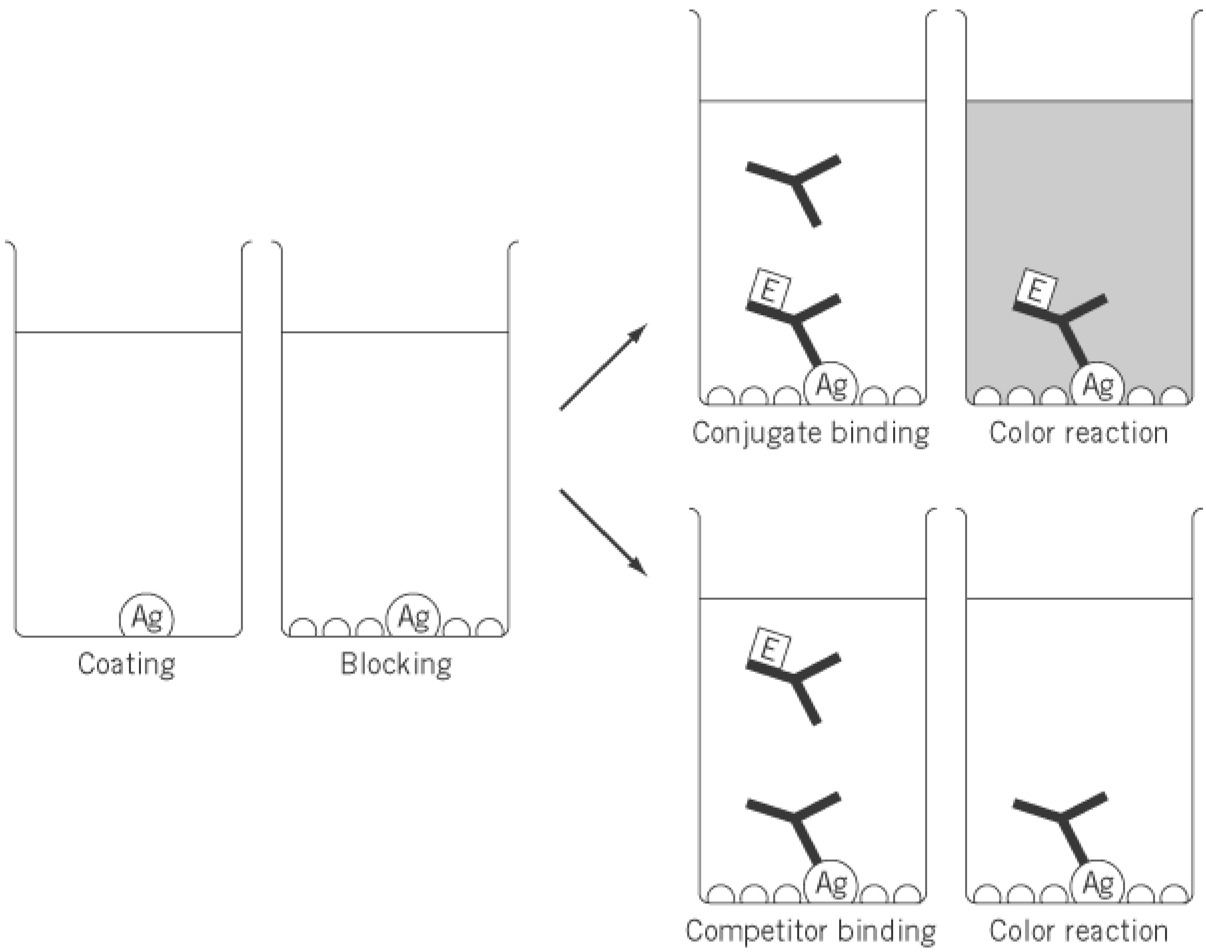

Figure 2. ELISA standard curves.

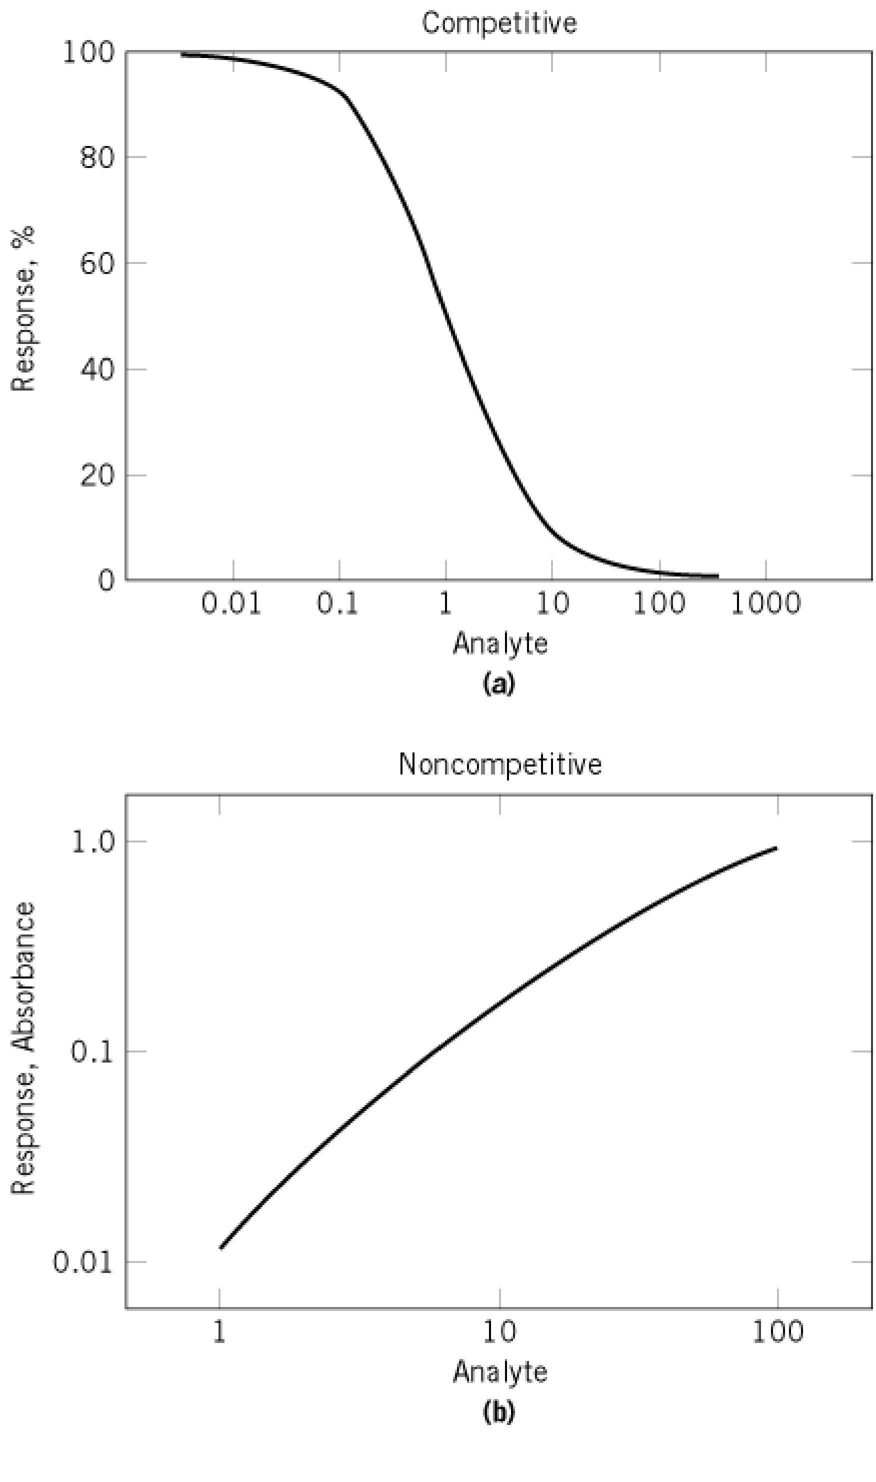
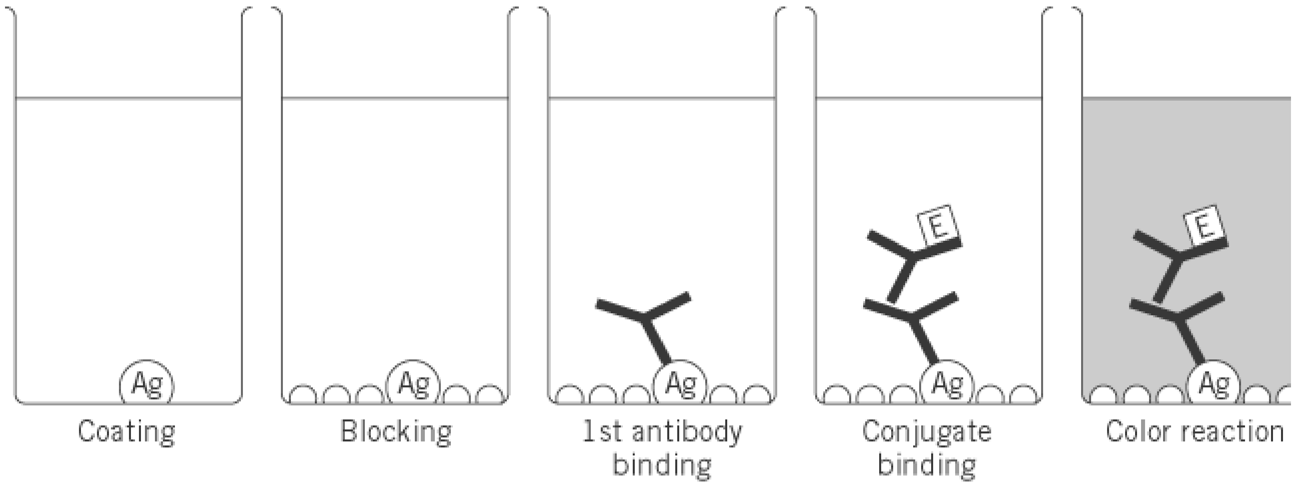


A shortcoming of this competitive design is that the response from small amounts of analyte may be almost as high as the 100% control. The change in reading due to the analyte is thus read as the difference between two large numbers. To be considered precise, the minimum readable difference must be much larger than the standard deviation of the highest point on the calibration curve, a fact that inherently limits the sensitivity of competitive ELISAs. The two noncompetitive designs that follow circumvent this limitation. The response in these assays is proportional to the analyte added; hence even a low reading may be detectable against the background level of enzymatic activity (Fig. 2b).

2. Indirect ELISA

The enzyme conjugate in an indirect ELISA (3) is an anti-antibody; the antibody that actually recognizes that the antigen is unlabeled. Quantification of the unlabeled antibody is normally the goal sought, and the indirect ELISA is most commonly used to assess the seropositivity of subjects who have potentially been exposed to pathogens. In an indirect ELISA, antigen is immobilized and the plate blocked as above (Fig. 3). The test sample is added, along with controls consisting of antibodies of the same specificity, species, and isotype as the test sample. After an interval allowed for antigen binding, the plate is washed and the conjugate added. The antibody used to make the conjugate reagent is typically a polyclonal preparation specific for constant regions of the antibody in the test sample (see Immunoglobulin Structure). Finally, enzymic activity is assayed as above. Controls are plotted on a linear or log–log scale (Fig. 2b). In this case, the response increases with increasing amount of analyte and does not necessarily reach a plateau. Reaching a plateau at high analyte concentration may indicate that the binding capacity of the unlabeled antibody in the sample exceeds the quantity of conjugate added, or more trivially, that the optical density after the color reaction is simply too great to be measured. The concentration of analyte in the test sample is interpolated from the calibration curve, as above.

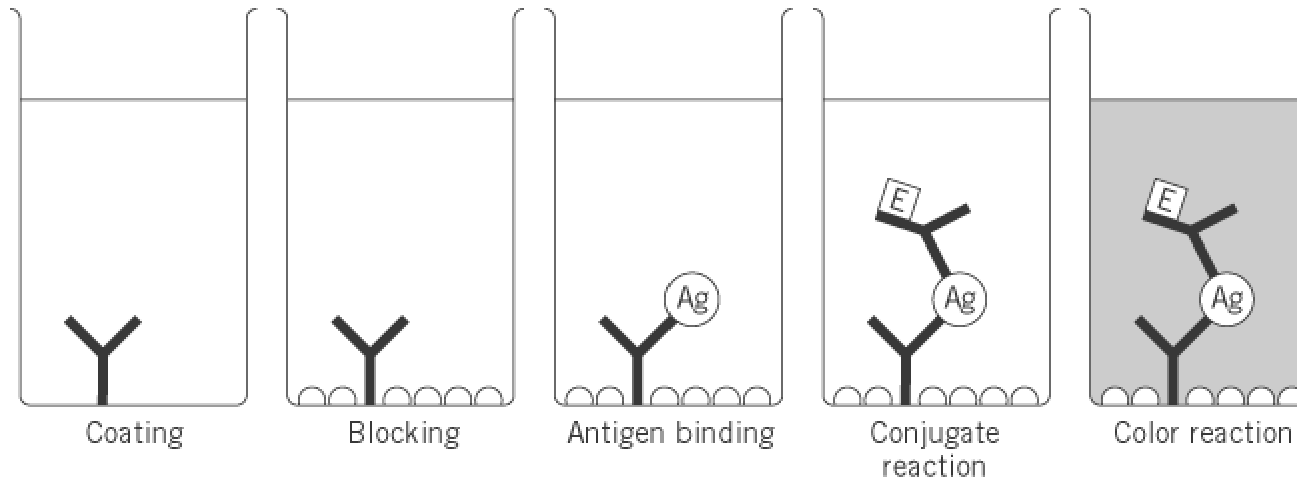
Figure 3. Indirect ELISA.



3. Sandwich ELISA for Antigen

This ELISA method (4) is conceptually similar to the indirect ELISA described above, but the analyte is usually a nonimmunoglobulin antigen that becomes “sandwiched” between an unlabeled immobilizing antibody and an antibody–enzyme conjugate (Fig. 4). The procedure begins with adsorption of a specific antibody to the surface of the assay plate. The plate is washed, and the test sample is added, along with controls consisting of known quantities of the same antigen. The plate is again washed, and the antibody–enzyme conjugate is added. This reagent binds to the immobilized antigen and hence becomes immobilized itself. A crucial aspect of the design of a sandwich assay is selection of an immobilizing antibody and a conjugate antibody that together will actually allow a “sandwich” to form. Obviously, two monoclonal antibodies that recognize the same epitope will exclude each other's binding. Use of a monoclonal immobilizing antibody is advantageous, however, since it occludes only a single epitope, leaving the remaining surface of the antigen available for deposition of the antibody–enzyme conjugate. After the conjugate is allowed to bind, the tray is washed a final time, and substrate is added to initiate the color reaction. A rising calibration curve again results, from which sample concentration is interpolated as above.

Figure 4. Sandwich ELISA.



4. Affinity Determination

Many authors have equated the analyte concentration at the 50% response point in the competitive ELISA with the equilibrium **dissociation constant** for an antibody–antigen interaction. This approximation is invalid. However, ELISA can be used to measure the equilibrium constant if the indirect ELISA method is applied after equilibrium is reached (5). The antibody and antigen in question are mixed in a series of different ratios, and the solutions are allowed to come to equilibrium. The equilibrium mixtures are then transferred to an ELISA plate that has been coated with the antigen. Standards with known amounts of free antibody are run in parallel. Free antibody will bind to the immobilized antigen. It is essential that only a small fraction of the total available amount of free antibody become bound to the plate, so that the assay does not lead to an apparent shifting of the equilibrium point (6). The plate is washed, and an antibody–enzyme conjugate that binds to the immobilized antibody is added. The plate is washed again, substrate solution added, and the amount of enzyme activity determined. The color response from the reactions with the equilibrium mixtures is compared to that from the controls, and the relative response is equated to the concentration of free antibody at equilibrium. A correction can be applied to allow for the multivalency of the antibody (7). Using the measurements of free antibody and knowledge of the total antibody and antigen present, one can infer the concentrations of free and bound antigen and antibody. These data can then be graphed on a Scatchard Plot, or numerical analysis can be used to determine the association equilibrium constant for the antibody–antigen interaction.

Enzymes

Enzymes are proteins that act as biological **catalysts**. They are produced by living cells, but are independent of those cells for their catalytic activity. Like all catalysts, they speed up the rates of chemical reactions, but their special importance lies in the fact that they can do this at neutral pH and relatively low temperatures, and do so specifically, essentially for only one chemical reaction (see Induced Fit). The rate increase, which is due to the lowering of the activation energy barrier by binding and stabilizing the transition state (see Transition State Analogue), can be as much as 10^{12}-fold (1). Under these circumstances, the uncatalyzed reaction would be barely detectable. As catalysts and under *in vitro* conditions, enzymes function at concentrations very much lower than those of the substrates on which they act. However, in the cell, the enzyme level often exceeds the substrate concentration. Enzymes increase the rate of a reaction in both the forward and reverse directions and, therefore, have no effect on the equilibrium constant K_{eq} of the reaction (see Haldane Relationship). In theory, enzymes as catalysts remain unchanged at the end of a reaction, but as enzymes are proteins, they are subject to **denaturation**, which can lead to loss of activity over the course of a reaction. Enzymes may show either absolute or broad specificity. For example, catalase acts only on hydrogen peroxide, whereas alcohol dehydrogenase oxidizes a number of aliphatic and aromatic alcohols.

Enzymes have the same general structure as all proteins (see Protein Structure). The basic structure consists of a polypeptide chain that is made up of 20 amino acid residues joined in a linear sequence by peptide bonds. The folding of the polypeptide chain gives rise to the final enzyme structure, which contains an active site at which the substrates bind to undergo reaction. It is this folding to form the active site that is responsible for the catalytic power and specificity of enzymes. The active form of an enzyme may consist of single or multiple subunits (see Oligomeric Proteins), with molecular weights ranging from about 14,000 to 4,000,000 (Table 1).

Table 1. Molecular Weights and Subunit Composition of Selected Enzymes

Enzyme	Molecular Weight	Number of Subunits
RibonucleaseA	13,700	1
Lysozyme, hen	13,900	1
Carbonic anhydrase	30,000	1
a-Amylase	50,000	2
Hexokinase	102,000	2
Alcohol dehydrogenase	150,000	4
Aspartate transcarbamoylase	310,000	12
Urease	480,000	2

Glutamine synthetase	600,000	12
Pyruvate dehydrogenase	4,000,000	1 (960,000)
		24 (90,000)
		12 (112,000)

Some enzymes bring about **energy transductions** that include the conversion of light energy to chemical bond energy in photosynthesis, as well as the conversion of chemical bond energy to mechanical energy in muscle contraction and to pumping energy for the **membrane transport** of ions against an unfavorable gradient.

The activities of enzymes are usually subject to control, not only through changes to intracellular substrate levels, but also by activation, inhibition, and covalent modification. The activity of enzymes is influenced by pH because of the presence of ionizing amino acid residues at the active site. Some enzymes require **prosthetic groups** or metal ions (see Coenzyme, Cofactor), whereas others must undergo irreversible (see Proenzyme) or reversible activation. Reversible activation is often achieved by means of **phosphorylation** or adenylylation. Glycogen phosphorylase is activated by the transfer of a phosphoryl group from ATP to a single serine residue and inactivated by a **phosphatase** that removes the phosphoryl group. By contrast, *glycogen synthase* is inactivated by the phosphorylation of a serine residue and activated through phosphatase action. The protein kinases responsible for the phosphorylation of phosphorylase and glycogen synthase are activated by 3′, 5′-cyclic AMP. The interaction of this nucleotide with the regulatory subunits on the inactive kinases causes release of the active forms of the enzymes. The reversible activation of *glutamine synthetase* involves the transfer of the AMP moiety of ATP to and from the hydroxyl group of a **tyrosine** residue. Both reactions are catalyzed by the same enzyme, *adenyl transferase* . Enzymes can be inactivated by small molecules that covalently interact with amino acid residues at the active site (see Active Site-Directed Irreversible Inhibitors) or inhibited by substrate analogues, which can behave as drugs or pesticides (see Dead-End Inhibition).

A group of enzymes that are subject to special control are the **allosteric** enzymes. The activities of these enzymes are not only more sensitive to changes in intracellular substrate concentrations, but they are also activated and/or inhibited reversibly by modifiers that are small molecules which combine at either a specific binding site on a catalytic subunit or on a special regulatory subunit. Modifiers are frequently the end-product of a metabolic pathway and have structures that differ from those of the substrates for the allosteric enzymes (see **Feedback inhibition**). The control of enzyme activity can also be achieved through their interaction with low-molecular-weight proteins, such as calmodulin.

It has been demonstrated recently that it is possible to produce monoclonal antibodies which show catalytic activity (2). The generation of catalytic antibodies, or abzymes, has occurred through the use of an antigen that resembles the transition state or an intermediate state of the reaction (see Transition State Analogue). The idea was to produce an antibody that would bind tightly to, and stabilize, the transition state complex so as to enhance the reaction rate. The rate enhancement and small number of antibodies produced with a particular antigen suggest that the analogues are not good mimics of the actual transition state, or that good catalytic activity requires more than simply the stabilization of a transition state complex. Catalytic activity is not restricted to proteins, for RNA molecules have been shown to function as enzymes. These relatively small molecules, which are generally found in viruses, have catalytic features in common with those of enzymes (3).

1. Enzyme Nomenclature

In 1956, the International Union of Biochemistry established an International Commission on Enzymes. There were several reasons why. The number of known enzymes was increasing rapidly and their naming by individual researchers was not satisfactory. Further, the names did not always convey the nature of the reaction being catalyzed and similar names were given to enzymes of different types. The first report on enzyme nomenclature was produced in 1961 and contained references to 712 enzymes. The sixth report was published in 1984 by Academic Press and contains classifications for 2,477 enzymes. The publication lists classes of enzymes as well as information about the reference number, recommended name, reaction catalyzed and other names for particular enzymes. Enzymes in this volume are categorized as Dehydrogenases, Hydrogenases, Hydrolases, Isomerases, Synthetases/Ligases, Synthases/Lyases, Oxidoreductases, Phosphotransferases, and Transferases .

Epidermal Growth Factor

The epidermal growth factor (EGF) family of proteins is defined by their sequence homology and capacity to bind and activate the EGF receptor. Also described is the ErbB receptor family, which includes the EGF receptor, which is also known as ErbB-1 and HER-1, and three sequence-related receptors. Brief mention is made of the heregulin/neuregulin growth factors, which are structurally related to EGF but do not bind to the EGF receptor, although they do bind and activate other ErbB receptors.

1. EGF Ligands

There are six known mammalian gene products that share primary sequence homology, are recognized by the EGF receptor with high affinity (**dissociation constant** in the nanomolar range), and activate intracellular signaling pathways leading to increased cell proliferation. These ligands are known as EGF, transforming growth factor alpha (TGFa), heparin-binding EGF (HB-EGF), amphiregulin, betacellulin, and epiregulin (1, 2). As noted below, two of these ligands, betacellulin and epiregulin, are able to bind not only to the EGF receptor, but also to ErbB-4, a separate member of the EGF receptor family. In addition to these ligands encoded by genes in mammalian cells, EGF growth factors are encoded by genes in the fruit fly *Drosophila* (*sptiz, gurken, vein*) (3), the nematode *Caenorhabditis elegans* (*lin*3) (4), and certain Pox-family viruses (5). The *Drosophila* gene *argos* apparently encodes an antagonist growth factor for the fly EGF receptor (3). To date, however, EGF receptor antagonists have not been found in other biological systems or created through synthetic chemistry.

Structurally, the EGF receptor ligands are small monomeric proteins of 6–10 kDa that are characterized by conserved sequence features—most notably six **cysteine** residues that, in the mature ligands, form three characteristically spaced disulfide bonds producing three loop structures within the molecule (5). Nuclear magnetic resonance (NMR) has been employed to determine the high-resolution protein structures of EGF and TGFa (see EGF Motif), while site-directed mutagenesis has revealed which amino acid residues are essential for growth factor function (6). The structures of EGF and TGFa are highly superimposable, and each is dominated by beta-sheet structure. Growth factor mutagenesis (5, 6) and an NMR study of a TGFa:EGF receptor ectodomain complex (7) implicate residues in both the amino- and carboxy-terminal domains, which are not closely packed together in the high-resolution structure. Therefore, the growth factor may use more than one surface or domain to contact the receptor binding site. This multidomain view of growth factor binding to its receptor has also provoked models in which the ligand is bivalent and capable of associating with two receptor molecules (8).

The mature proteins, especially EGF, are chemically and biologically very stable to extreme physical conditions, such as acid and heat. All the growth factors have been produced as recombinant proteins, and many are commercially available. EGF is easily derivatized with covalent probes, including ^{125}I, fluorescein, biotin, and various toxins (5). These modifications have been employed to quantify and/or visualize growth-factor interactions with receptors or, in the case of toxin conjugates, to kill cells having EGF receptors, particularly certain tumors that overexpress this receptor (9).

The mature EGF and EGF-like ligands are found in the extracellular space as freely diffusible proteins, but they are not products of the secretory pathway. The extracellular ligands are derived from the ectodomain of transmembrane precursor proteins present on the surface of cells (5). In these precursors, the EGF or EGF-like sequence is liberated into the extracellular environment as a diffusible growth factor following a series of **proteolytic** processing steps (5, 10). This means that the presence or concentration of extracellular mature growth factor is determined not only at the level of gene expression, but also by control of the extent of precursor proteolytic processing. Yet relatively little is known regarding the identity or biological control of the activity of the proteinases involved, although metalloproteinase activity is frequently implicated on the basis of inhibitor studies for the precursor processing of TGFa (11), EGF (12), HB-EGF (13), and amphiregulin (14). The existence of transmembrane precursors has raised the question of whether the precursor form of the growth factor can activate EGF receptors on adjacent cells, without the necessity for proteolytic processing. While this is not trivial to test experimentally, the available data indicate that such communication is possible (10). Whether this is biologically significant in mammals is unclear; in developmental circumstances, however, where neighboring cells obviously must communicate, such juxtacrine communication is possibly significant.

EGF and other EGF-like ligands are present in most bodily fluids (urine, milk, saliva), but they are difficult to detect in blood or serum (5). The production of these growth factors is not confined to one or two organs within the body, but it seems to occur within many tissues. Hence, the circulatory system is not essential for delivery of the growth factor to target cells. It seems likely that growth factors like the EGF ligands are examples of paracrine hormones in which the production and utilization of the ligand occurs in different cells within the same local environment of a tissue. Each EGF-like growth factor has a distinctive pattern of expression in tissues, although in certain tissues there is usually some degree of overlap with the expression of other members of this growth factor family. In the case of tumor cells, it is a frequent observation that the same cell constitutively produces and is activated by a growth factor. This is a process termed autocrine regulation and may be particularly important for TGFa, amphiregulin, and epiregulin, which are frequently expressed in tumor cells (15).

EGF is known to stimulate the proliferation of a great many cell types in cell culture, as its receptor is expressed in almost all nonhematopoietic cells (5). In the intact animal, however, enhanced proliferation of epithelial tissues is the most commonly observed response to the administration of exogenous EGF (5). Proliferation of skin and isolated epidermis have been the model system for an EGF-responsive tissue, but published data also show enhanced proliferation *in vivo* of internal epithelial tissues, such as trachea and gastrointestinal tissue. In the adult, it seems likely that the EGF family of growth factors participates in control of the relatively high level of homeostatic proliferation necessary to support epithelial tissues. Administration of EGF to fetal or newborn animals often hastens certain developmental processes, such as lung maturation and eyelid opening, respectively (5). TGFa and amphiregulin are particularly recognized as EGF family members that are expressed during gestation (16). At least one nonmitogenic biological response has been described following EGF administration to animals: the inhibition of parietal-cell acid secretion (5). It is unclear, however, whether EGF ligands normally participate in pH control within the gastric system.

In humans, the genes for EGF, TGFa, amphiregulin, and HB-EGF are localized, respectively, to chromosomes 4q25 $\rightarrow$ q29, 2p11 $\rightarrow$ p13, 4q13 $\rightarrow$ q21, and 5 (17). The genes range in size from 120 kbp and 24 exons (for EGF) to 18, 14, and 10 kb and 6 exons each for TGFa, HB-EGF, and amphiregulin, respectively. The expression of genes in this family has been demonstrated in both nontransformed and transformed cells to involve autoinduction by the homologous growth factor, or by a different member of this growth factor family (18). The autoinduction mechanism could be a significant amplification factor in autocrine tumor growth and in Poxvirus infection.

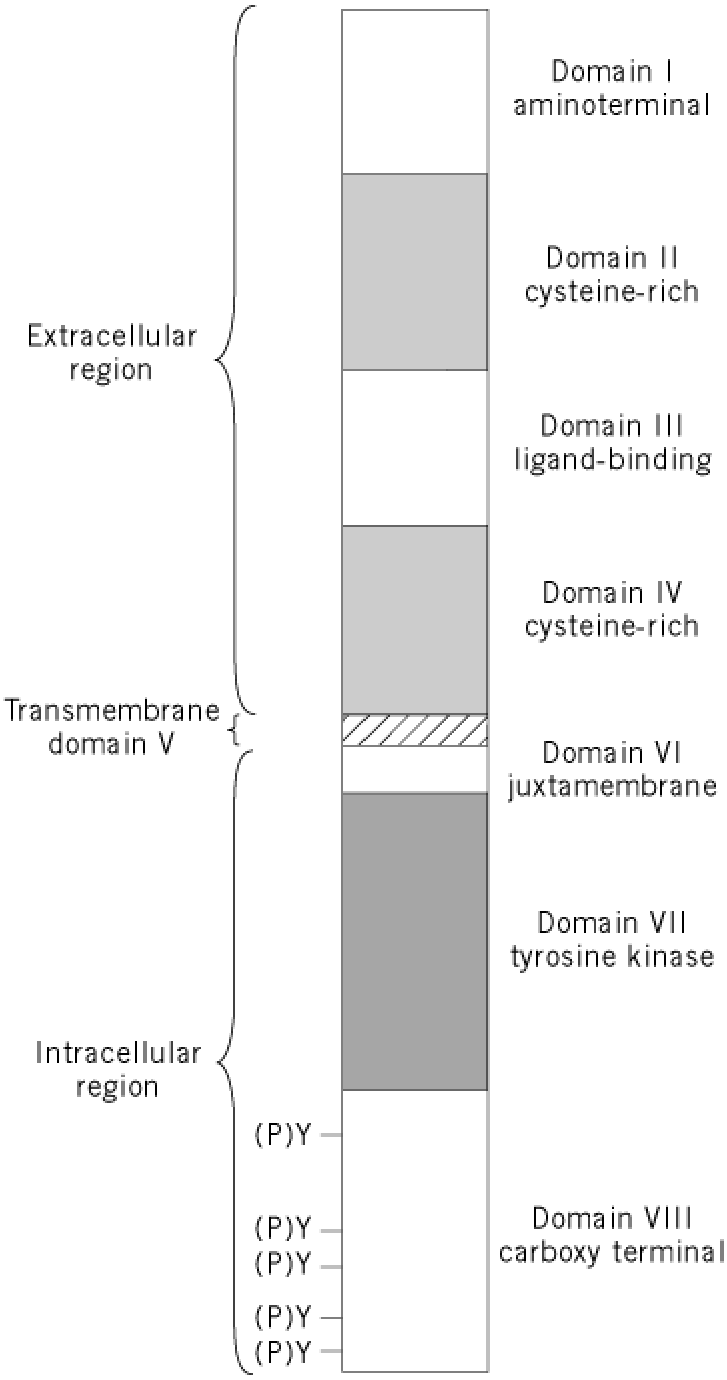
In contrast to the severe phenotype exhibited following targeted disruption of the EGF receptor gene in mice (see text below), " **knockout**" of the TGFa gene in mice produces only a mild disturbance in the function of the hair follicle and a consequent "wavy" hair **phenotype** (19, 20). While knockouts of other family members have yet to be reported, preliminary data for some also suggest mild changes in phenotype. Hence, while receptor function is indispensable in the animals, there does seem to be considerable functional redundancy within the EGF family of ligands.

2. EGF Receptors

Based primarily on sequence similarity, four members have been identified in the ErbB family of EGF receptor-related molecules (1, 2): the EGF receptor (also known as HER-1 and ErbB-1); ErbB-2 (Neu, HER-2); ErbB-3 (HER-3); and ErbB-4 (HER-4). EGF, EGF-like ligands, and heregulin (neuregulin) activate these receptors, but in distinctive and complex ways (1, 2). EGF and the EGF-like ligands (HB-EGF, TGFa, amphiregulin, betacellulin, epiregulin) recognize ErbB-1, while the heregulin growth factors bind to ErbB-3 and ErbB-4. However, some EGF family molecules can bind to the EGF receptor and another ErbB receptor. For example, betacellulin, HB-EGF, and epiregulin, but not EGF or TGFa, activate ErbB-4 as well as the EGF receptor. The heregulin isoforms bind to ErbB-3 and ErbB-4, but not to the EGF receptor. There is no known ligand for ErbB-2, which seems to function as a co-receptor with each of the other ErbB family members (21, 22).

The mature forms of these receptors contain approximately 130 kDa of protein complexed with N-linked carbohydrate (see *N*-Glycosylation) to give a molecular mass of approximately 175–185 kDa (5). Based on cloning and **sequencing** of complementary DNA for the EGF receptor prototype for this receptor family (23), the transmembrane orientation of the ErbB receptors is believed to consist of three regions, as shown in Figure 1. These are (i) an extracellular **ligand-binding** region, (ii) a cytoplasmic region, and (iii) a single **hydrophobic** transmembrane domain of approximately 24 amino acid residues. Among these ErbB family receptors, the cytoplasmic carboxy-terminal domains show similarity in size, but are the most heterogeneous domains in terms of sequence similarity. The EGF receptor is the most widely-studied and best-characterized molecule among the members of ErbB receptor family. The remaining portion of this article is, therefore, focused on the structure–function, activation, regulation, and genetic alterations of the EGF receptor.

Figure 1. Schematic representation of the EGF receptor. Based on its amino acid sequence, obtained by cDNA sequencing (23), the protein structure of the EGF receptor is subdivided into extracellular, transmembrane, and intracellular regions and into eight domains. The phosphotyrosyl residues in the carboxy-terminal domain are indicated by (P)Y.



As depicted in Figure 1, the extracellular region of the EGF receptor can be divided into four **domains** based on the presence of two cysteine-rich regions (Domains II and IV). The functions of the cysteine-rich domains are not clearly understood, although they probably provide significant structural stability, because 25 disulfide bonds are found in these two domains (24). Domain III, localized between these two cysteine-rich domains, is thought to mediate ligand binding (5). There are implications that residues in Domain I may also contribute to ligand binding (25), but there are no high-resolution data to define the receptor/ligand binding site. The ectodomain of the receptor is heavily glycosylated with 10–11 N-linked oligosaccharide chains (5). Among these carbohydrates, at least three are of the high-mannose type, while the others are complex-type oligosaccharide chains. While oligosaccharide addition is necessary for correct EGF receptor folding and processing to the cell surface, there is no evidence that carbohydrate is a determinant of ligand binding or other receptor functions at the plasma membrane.

The intracellular or cytoplasmic region of the EGF receptor is composed of three domains: the juxtamembrane domain, a **tyrosine kinase** domain, and a carboxy-terminal domain (Fig. 1). The receptor is actually an enzyme (tyrosine kinase), and the kinase activity is dependent on ligand binding to the receptor ectodomain (5). Clearly, the tyrosine kinase domain is critical to the receptor's capacity to elicit biological responses, namely mitogenesis, following ligand binding. Inactivation of the kinase domain by site-directed mutagenesis abrogates EGF responses. Five tyrosine autophosphorylation sites have been identified in the carboxy-terminal domain at Tyr992, 1068, 1086, 1148, and 1173, while modification by **phosphorylation** of **serine** or **threonine** residues by **serine–threonine kinases** has been localized to both the carboxy-terminal and juxtamembrane domains. One of these, Thr654 in the juxtamembrane region, is a substrate for protein kinase C, and its phosphorylation results in attenuation of receptor tyrosine kinase activity. Phosphorylation of the tyrosine residues of the carboxy-terminal domain results in formation of "docking sites" for many of the substrates of the receptor tyrosine kinase (26).

The EGF receptor is activated by a two-step mechanism (26). First, binding of a cognate ligand to the monomeric receptor induces the formation of noncovalent receptor dimers. Although the mechanism of dimerization is not clear, it may be due to a conformational change in the receptor external domain or to bivalent binding of EGF to the receptor. Interestingly, the EGF receptor can, in response to ligand binding, also form heterodimers with other ErbB family receptors, particularly ErbB-2 and ErbB-3 (1, 2). The second step in receptor activation occurs when dimerization of the receptors leads to juxtapositioning of the cytoplasmic domains and transphosphorylation of the two receptors present in the dimer (26). Hence, autophosphorylation is probably a mixture of inter- and intramolecular phosphorylations. At present it is unclear how autophosphorylation sites may relate to the control of tyrosine kinase activity. Unlike many other tyrosine kinase receptors, none of the EGF receptor autophosphorylation sites is within the kinase domain, where it might directly regulate the kinase active site.

Based on the studies with "dominant-negative" kinase-inactive EGF receptor mutants, it has been concluded that transphosphorylation within dimers is essential for substrate phosphorylation and concomitant EGF-mediated signal transduction (26). When a kinase-inactive EGF receptor mutant is coexpressed in the same cell with wild-type receptor, heterodimers of the two receptors (wild-type and mutant) are produced in response to EGF. Kinase activation and signaling are suppressed in proportion to the relative overexpression level of the mutant receptors. The reason for attenuation of the wild-type receptor function is that kinase-inactive receptors do form dimers with the wild-type receptors, but transphosphorylation does not occur.

The cytoplasmic substrates that are phosphorylated by the EGF receptor include: (i) enzymes, such as **phospholipase C**-g1; **Src**, a cytoplasmic tyrosine kinase; the **ras** GTPase-activating protein; and the phosphotyrosine phosphatase SHP-2; (ii) the transcription factor STAT; and (iii) the nonenzymatic adapter molecules GRB-2, the p85 subunit of phosphatidylinositol 3-kinase, eps8, eps15, Nck, and Shc (1). Also, heterodimerization leads to EGF-dependent phosphorylation of ErbB-2 and ErbB-3 (1, 2). Many, but not all, of these receptor-proximal proteins have in common the presence of a noncatalytic domain of approximately 100 residues termed a *src* homology, or **SH2**, domain (27). SH2 domains recognize phosphotyrosine-containing sequences and thereby mediate association of these molecules with activated receptors. This mechanism to promote receptor association serves two purposes. First, it facilitates subsequent tyrosine phosphorylation of the SH2-containing protein by the receptor tyrosine kinase domain. Second, it relocalizes cytoplasmic SH2 molecules to the receptor carboxy-terminus and hence close to the cytoplasmic face of the plasma membrane. Relocalization may be a significant factor for those molecules that function by modifying plasma membrane phospholipids (eg, phospholipase C-g1) or those (GRB-2 and Shc) that interact with membrane-localized signal transduction target proteins, such as Ras. Actually, the GRB-2 adaptor associates with the EGF receptor, but it is not detectably phosphorylated. Therefore, relocation of GRB-2 seems to be the only function of its receptor association.

Desensitization of the activated EGF receptor is achieved by two mechanisms. The first and best understood is endocytosis of the activated receptor, followed by its degradation in **lysosomes** (28). This provides a relatively slow rate of receptor inactivation and results in the down-regulation of the cellular level of receptor protein, when receptor degradation exceeds receptor biosynthesis. To initiate this process, ligand binding to the EGF receptor induces receptor clustering in **clathrin**-coated pits and rapid internalization. Following this internalization step, ligand:receptor complexes in endosomes are targeted to the lysosome, where both the receptor and its ligand are degraded. It should be noted that during a substantial portion of this endocytosis process, EGF remains bound to the receptor and phosphotyrosine remains detectable on the receptor. Hence, the internalized receptor remains potentially functional for some period of time. Curiously, the heregulin receptors (ErbB-3 and ErbB-4) are not subject to rapid internalization following ligand binding (29).

A second means by which activated receptors are desensitized involves the phosphorylation of serine/threonine residues within the cytoplasmic domain (30). This mechanism is not, however, well understood.

Overexpression or mutation of the EGF receptor has been reported to be associated with certain malignancies (31). For example, there is frequently detected in glioblastomas a small genomic deletion of exons encoding a small region of the EGF receptor ectodomain. This mutation inhibits ligand binding but produces a constitutively active receptor. In a sizable fraction of breast cancers, the EGF receptor is overexpressed but not mutated (31, 32). Also, the EGF co-receptor ErbB-2 is even more frequently overexpressed in breast cancer. Antibodies to the EGF receptor and ErbB-2 are being evaluated for therapeutic efficacy in breast cancer clinical trials (33).

In humans, the gene encoding the EGF receptor is localized to the p13 → q22 region of chromosome 7 (17). Expression of the EGF receptor gene produces two major species of messenger RNA: 10.5 and 5.8 kb. The 5.8-kb mRNA represents a full-length cDNA that includes 5′- and 3′-untranslated sequences (23, 34). The genesis and significance of the 10.5-kb mRNA is not clearly understood, but it probably contains a longer 3′-untranslated sequence. In certain cells, a smaller mRNA (2.0 kb) is also detected. This mRNA is formed by RNA splicing and encodes the EGF receptor ectodomain. In cells expressing this mRNA, the ectodomain fragment is fully glycosylated and secreted (35). The **promoter** sequence of the EGF receptor represents a typical "**housekeeping gene**" with extremely GC-rich sequences and the absence of TATA and CAAT boxes (36).

Targeted disruption of the EGF receptor gene in mice produces multiorgan failure and embryonic lethality in most, but not all, mouse strains (37-39). In some mouse strains, it has been reported that "knockouts" of the EGF receptor live up to 8 days after birth and suffer from impaired epithelial development in skin, liver, and gastrointestinal tract. However, neurodegeneration is the most common and strain-independent phenotype of postnatal mice that lack EGF receptors (40). Gene "knockouts" of ErbB-2 (41, 42) and ErbB-4 (43) both produce deficiencies in neurodevelopment and development of the embryonic heart, leading to lethality at 10 days' gestation. Homozygous disruption of the ErbB-3 gene in mice produces severe defects in neurogenesis, specifically in Schwann cell development and the maturation of neurons, plus abnormalities in cardiac development (42, 44). In fact, defects in neural development have been noted in all ErbB knockouts, including the EGF receptor. EGF receptor-null mice, however, have not been reported to be abnormal in heart development.

Epigenetics

Epigenetics is derived from the Greek word epigenesis, which describes the Aristotelian concept that an organism develops progressively through a series of causal interactions of various parts. During the 16th and 17th centuries, the epigenetic mode of development was held in contrast to the preformation theory, which maintained that development occurred by simple enlargement of a preformed homunculus in the germ cell (for the early history of its usage, see ref. 1). More modern definitions include the concept that, during development, cells progress through microenvironments that induce a stepwise restriction of their developmental potentialities into specialized ones via changes in gene expression (2). Based on this view of development, Holliday has defined epigenetics as the study of the mechanisms "that impart temporal and spatial control on the activity of all those genes required for the development of a complex organism from the zygote to the fully formed adult" (3). More recent usage, however, has tended to emphasize the "epi" or "beyond" aspect of the term. Strohman points out that "epigenesis is the historical alternative to genetic determinism and that it establishes the basis for a level of organizational control above the genome" (4). Accordingly, molecular geneticists use the term epigenetics for a process by which the state of gene expression is modified at a given time of development and becomes heritable at the cellular or organismal level. Molecular mechanisms underlying epigenetic phenomena are known only in a few cases. The known mechanisms include modifications of **DNA** and changes in the chromatin structure, which are thought to be propagated through templating (5).

There exist a broad variety of epigenetic phenomena in many organisms. Perhaps one of the best-studied epigenetic phenomena is **mating-type** silencing in the yeast *Saccharomyces cerevisiae* (6, 7). Yeast cells possess one of two mating types, a or a, determined by which of the alternate mating-type **alleles** is present at the mating-type locus (MAT). In addition, cells harbor two other copies of mating-type genes at the loci called HML and HMR. Despite their identical sequences, the mating-type gene located at the MAT locus is active in transcription; those at HML and HMR are silent. The molecular basis of mating-type silencing appears to lie in the specific type of chromatin structure at the HML and HMR loci.

In the fruit fly, *Drosophila melanogaster*, several phenomena have been described as epigenetic. The first example, known as position effect variegation (PEV), is observed when a chromosomal segment of euchromatin is translocated adjacent to a heterochromatic region (8). Such a translocation results in variegated spreading of repression from the heterochromatic region into the euchromatic segment, causing a metastable state of expression of the translocated genes. Because the variable spreading of gene inactivation is inherited clonally, the PEV phenomenon is considered epigenetic. The second example includes the **silencing** of homeotic genes during development (9). Homeotic genes are expressed in specific domains of the body and silenced in others. This spatially regulated silencing is established in early embryogenesis and is maintained throughout development by a group of chromatin-associated proteins known as the Polycomb group proteins.

In mammals, genomic imprinting and X-Chromosome Inactivation in females are both examples of epigenetic effects. Genomic imprinting has been observed for some 20 genes whose expression in an early embryo depends on whether the allele is derived maternally or paternally (10). Some genes are inactive when derived from maternal gametes; in other genes those derived paternally are inactive. The molecular basis of imprinting is known to be methylation of the DNA. The state of inactivity is inherited clonally through subsequent cell divisions by templating of the methylated state. Particular CpG sequences in imprinted genes are methylated in gametes of one sex but not the other (see CpG Islands). The zygote therefore becomes heterozygous at imprinted genes, carrying a methylated allele and a nonmethylated allele. During development, methylated alleles are not expressed, while **homologous** copies that are nonmethylated are expressed and provide the necessary functions. In primordial germ cells (the precursors of eggs and sperms), imprinting is erased by demethylation of appropriate residues in the imprinted genes. These residues are remethylated *de novo* in gametes in either the maternal or paternal mode.

In female mammals, one of two **X chromosomes** is inactivated, appearing cytologically as a Barr body. The X chromosome is inactivated by coating with the so-called Xist RNA (11). The Xist gene on the active chromosome is turned off by methylation of its **promoter**, while the Xist gene on the chromosome to be inactivated produces Xist RNA that coats its own chromosome. Once an X chromosome is inactivated, its inactive state is clonally inherited in its descendant cells, without the need of Xist RNA. Thus, Xist RNA appears to initiate an epigenetic state that is perpetuated, without playing a further role.

Lesser known, but equally fascinating, epigenetic phenomena are found in fungi and plants. *Neurospora crassa* and *Ascobolus immersus* seem to protect their genomes from assaults by transposable elements through mechanisms known as repeat induced-point mutation (RIP) and methylation-induced premeiotically (MIP), respectively (12, 13). Transposable elements, often present in multiple copies, trigger their mutual silencing in a process known as quelling by methylation or C to T transition mutations of repeated sequences. A paramutation, found in higher plants such as maize, tomato, or tobacco, is a mitotically and meiotically heritable change in gene expression that does not involve alterations in DNA sequences (14). At paramutable loci, some alleles, called paramutable alleles, are susceptible to paramutation, others, known as paramutagenic alleles, induce paramutation in the homologous copy of the same gene.

Epigenic Patterning

In the animal kingdom, the first developmental determination of the **germ cells** is the presence of a *polarity* . This is necessary to determine early coordinates for further development and organogenesis. In other words, there are one or more mechanisms to determine which part of the cell is supposed to form the posterior, anterior, dorsal, and ventral poles. The morphological appearance of the egg before fertilization, and also shortly after, fertilization is not uniform but shows a more or less distinct polarity, which is termed the animal–vegetal polarity. In certain species, sperm can only enter at the animal pole, indicating that there must be differences in molecular composition of the opposite poles.

There are various reasons for the development of the animal–vegetal polarity. In many cases, the feeder cells of oocytes are not uniformly located around the oocytes. Thus, they are fed from one side, which results in an asymmetrical concentration of certain molecules within the oocyte plasma. Another influence to produce polarity is probably light and gravity. However, after fertilization in space or in a fast rotating clinostate, Xenopus exhibited normal embryonic development and normal axis formation (1). In eggs containing a considerable amount of yolk, gravity forces the yolk to settle down. This event takes place in amphibia after sperm entry, which enables a free rotation of the egg **cytoplasm**. This causes the formation of the vegetal and animal polarity, in which the vegetal pole contains larger amounts of yolk than the animal pole.

The other polarity of the cell is not as easily determined in the unfertilized egg. In many cases, the posterior-anterior axis is determined by the site of sperm entry. On egg activation, a number of cytoplasmic reorganizations take place. In some species a region becomes visible, the *gray crescent*, which is located opposite to the site of the sperm entry. This is the prospective area in which **gastrulation** will take place. In amphibia, this region marks the prospective backside and distal side of the embryo. In birds, the dorsal-ventral polarity is determined by the structure of the egg, and the caudal distal polarity is assumed to be based on the influence of gravity. In mammals, there are contrary observations regarding where the inner cell mass settles. This embryonic event determines at least the dorsal side, whereas the mechanism that determines the prospective axis of the head and tail is still the subject of investigation.

Nüsslein-Volhard and others have provided more information about the situation in ***Drosophila***. In this species, the presence of a genetically determined polarity of the anterior and posterior regions of the egg was demonstrated. In the anterior region, a product of the gene ***bicoid*** was found to determine the development of the head and thorax (2, 3). In *Drosophila* bcd – / – mothers, which could not produce the bicoid gene product, larvae with no heads appeared. The product of the gene *nanos* is responsible for the formation of an abdomen and germline development (4), and its highest concentration occurs in the posterior end of the egg (5). In mothers homozygous negative for the nanos gene, no abdomen is formed. Compensation of the missing gene products by injection of *bicoid* messenger RNA or *nanos* mRNA leads in each negative variant to the development of a normal phenotype. Nanos and bicoid form concentration gradients from the anterior to the posterior and activate in a concentration-dependent manner a number of zygotic segmentation genes (6, 7). Bicoid controls transcription of the *hunchback* gene (6). In this cascade, the gene *staufen* is important for the localization of maternal mRNA to the posterior pole and for bicoid mRNA to the anterior pole in the *Drosophila* egg (8). In contrast, the nanos protein suppresses translation of *hunchback* mRNA. *Hunchback* is a gene responsible for the formation of anterior structures; on inhibition of these anterior structures, posterior ones are formed. The hunchback gradient controls *caudal* , which is concluded to be a region-specific activator of abdominal segmentation genes (9). Furthermore, injection of *nanos* mRNA into the anterior end induced the development of larvae with two abdomen and no head. Two heads and no abdomen develop in larvae on injection of *bicoid* mRNA into the posterior end of the egg.

In *Drosophila*, axis formation involves a series of interactions between the oocyte and the surrounding somatic follicle cells. The dorsal and ventral sides is determined by the localization of the oocyte nucleus and *gurken* mRNA to the dorsal-anterior corner of the oocyte. Gurken protein is believed to act as a ligand for the *Drosophila* epidermal growth factor (EGF) **receptor** (10).

It must be admitted that the naming of the above genes is somewhat peculiar. Many of the genes are not named according to their function, but instead according to the **phenotype** produced when the gene is defective. In this respect, this means that the gene *dorsal* determines the development of ventral structures, not dorsal. The dorsal protein migrates into the nuclei of the ventral side and acts, similar to nanos or bicoid, as a **transcription factor**.

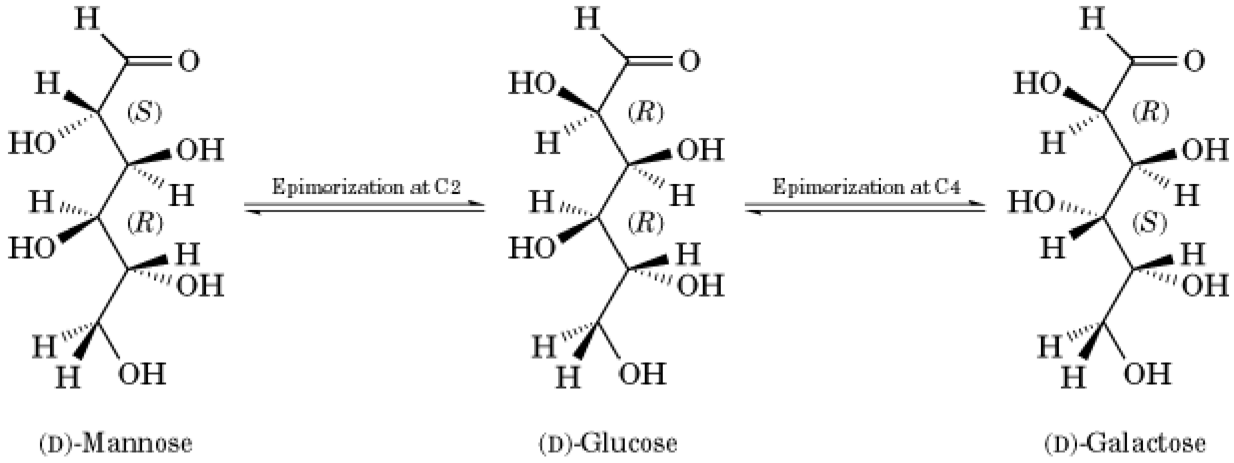
Epimers and Epimerization

Epimers are diastereomers that are related by the inversion of configuration at a single **chiral** center (1). This definition extends the original meaning of epimer, which was used to identify sugars that differed in configuration at C2 (2). This definition intentionally excludes enantiomers, such as D- and L-alanine, since they are not diastereomers. It also excludes diastereomers that are related by the inversion of more than a single chiral center. Thus, D-glucose and D-mannose are epimers, as are D-glucose and D-galactose. D-mannose and D-galactose are not epimers, however, because they are related by inversion at two chiral centers, C2 and C4 (Fig. 1)

Figure 1. Stereochemical drawings of glucose, mannose, and galactose, with their four chiral carbons. The configurations at C2 and C4 are labeled and distinguish these three sugars. Glucose is an epimer of both mannose and galactose because they differ by the configuration of a single chiral center. Mannose and galactose have different configurations at both C2 and C4 and are not epimers.



The chemical conversion of one epimer to another is called epimerization. If this interconversion is catalyzed by an enzyme, the enzyme is an epimerase. As an example, UDP-glucose-4-epimerase catalyzes the epimerization of the C4 carbon of glucose. In the reaction, UDP-glucose is epimerized to UDP-galactose. When the inversion of configuration occurs to interconvert enantiomers instead of diastereomers, the reaction is a **racemization**.

Epistasis

In Mendelian genetics, epistasis refers to the situation in which the phenotype caused by a mutation in one gene (A) masks the phenotype resulting from a mutation in another, nonallelic gene (B). Thus the individual carrying mutations in both genes A and B exhibits the same phenotype as the individual carrying a mutation in gene A alone. In this case, gene A is said to be epistatic over gene B, and gene B hypostatic to gene A. A classic example of epistasis is found among genes that determine mouse coat color. In the presence of albino mutant alleles, the mutant phenotypes of other coat-color determinants are not revealed, due to lack of pigment. Albino mutations, therefore, are epistatic over all other mutations that affect coat-color (1).

An epistatic relationship between two gene functions is often used to infer their relative order within a genetic pathway. Interpretation of such analysis depends on the type of genetic pathways. In biosynthetic pathways in which a series of genes modify a common intermediate substrate, epistatic genes are placed upstream of hypostatic ones. An example of such pathways is the morphogenetic pathway of **T4 phage** for head, tail, and tail-fiber assembly (2). In regulatory gene pathways, in contrast, where a member gene regulates the expression or activity of a downstream gene or gene product, epistatic genes are generally located downstream. A good example is found in the regulatory gene pathway that determines the dorsoventral body axis of the embryo in the fruit fly, *Drosophila melanogaster* (3). Most loss-of-function mutations that affect this pathway dorsalize the embryo. In contrast, a gain-of-function mutant allele of Toll, known as $Toll^{D}$, has been found that ventralizes the embryo. The presence of the opposite phenotypes allowed the investigators to combine a dorsalizing allele in a tester gene with the ventralizing allele of Toll and ask which of the two alleles is epistatic in double-mutant embryos. If the double mutant shows a dorsalized phenotype (ie, the tester allele is epistative over $Toll^{D}$), the tester gene is placed downstream of Toll. If the double mutant shows a ventralized phenotype, the tester gene is placed upstream. In this way, the genes in the pathway that affect the embryonic dorsoventral axis have been placed upstream or downstream relative to the Toll gene.

The logic of this type of analysis is straightforward if the pathway is a simple (ie, linear) series of genes or gene products. In such a pathway, the output depends solely on the activity of the terminal member of the pathway, and other members can be thought of as a series of on-off switches that determine the active or inactive state of the output gene. Regulatory gene pathways are not always simple, however, and there are situations in which epistatic genes act upstream. For excellent discussions of more complicated situations, as well as on assumptions and "rules" used in epistasis analysis, see Avery and Wasserman (4).

In population and quantitative genetics, epistasis refers to the genotype value for fitness contributed by gene interaction between two loci. The aggregate genotypic value of an individual (G) may deviate from the sum of the genotypic values attributable to the first locus (G_A) and the second locus (G_B). If it does, the deviation or nonadditive component (I_{AB}) is ascribed to epistasis, or interactions, between the two loci (5). Thus, $G = G_A + G_B + I_{AB}$. An example of epistasis can be seen when quantitative trait loci (QTL) from lines selected for high numbers of abdominal bristles in Drosophila are tested in pairwise combinations. In such tests, several pairs of QTLs for abdominal bristle number showed strong epistasis (interaction), resulting in abdominal bristle numbers that were beyond the additive effects of individual QTL (6).

Epitope

Epitope designates an area of an antigen that interacts with a specific antibody. It has generally replaced the former name of antigenic determinant. By symmetry, the term *paratope* has been proposed for the antibody, instead of antibody combining site (also designated as antigen binding site), but is much less widely used. An extension of this terminology is to be found as idiotopes and allotopes that designate epitopes that define **idiotypic** and allotypic (see **Allotype, alloantigen**) specificities, respectively.

Epitopes are defined functionally by the interaction of the antigen with a particular antibody, so it does not represent a preformed antigenic structure in itself; instead, it is defined by the immune system. This means that identification of epitopes will depend upon the nature and the number of **B-cell** clones that will respond to the administration of antigen. It is therefore very likely that two individuals will have a different pattern of recognition of the same antigen, although large overlaps are the rule. A consequence of this is that the best tool to define an epitope is a monoclonal antibody, which constitutes a reliable and standardized reagent. The obvious requisite for a region of the antigen to be recognized as an epitope is its accessibility—that is, that it be in contact with the solvent, which is favored by the presence of hydrophilic and/or charged amino acids.

Defining the structural basis of an epitope on natural antigens, such as proteins, is an almost impossible task, because B cells, and hence antibodies, recognize epitopes directly as native structures of the antigen. This implies that most epitopes have a complex three-dimensional structural organization that is generally lost upon cleavage of the antigen. Limited proteolysis of a protein may retain some regions that still contain native epitopes, but it is quite obvious that isolation of a “pure” epitope is most often not feasible. Interesting attempts to isolate epitopes from natural proteins have nevertheless been made with some success. This is the case of myoglobin and lysozyme, for which a loop of 20 amino acids clamped by a disulfide bond has long been a prototype of an “isolated” epitope. Because of their repetitive structural organization, polysaccharides are somewhat better tools to derive epitopes. This was the case for dextran, a polymer of glucose that allowed Kabat to demonstrate that various oligosaccharides were competing with the binding of dextran to its antibodies and indicating that they could be considered epitopes of this antigen. In fact, because the optimal inhibition was obtained by a hexasaccharide, it was concluded that the size of the anti-dextran combining site was that required to accommodate a molecule having the size of this inhibitor. Most of our knowledge of the antigenicity of proteins has been gained thus far with synthetic polyamino acids that constitute simplified models of proteins, because they can have a rather monotonous organization; for example, three or four amino acids might be linked covalently to a backbone of poly-L-lysine, like those extensively studied by the group of Sela in Israel. These models favored, however, sequential epitopes, as opposed to the conformational ones that are commonly encountered in natural protein antigens. The use of haptens was of course only a first approach to define an antigenic determinant, and they gave information of interest regarding the exquisite specificity of antibody recognition.

Monoclonal antibodies (mAbs) have proven of great value in epitope mapping the surface of an antigen. Mapping is based on inhibition of one mAb by others. When complete and reciprocal inhibition is observed between two mAbs, it is concluded that both antibodies recognize the same epitope. Although not a definitive proof, it remains an acceptable conclusion. Partial inhibition is suggestive that the two mAbs recognize overlapping epitopes. Consequently, a sufficiently large collection of mAbs permits exhaustive mapping of the epitopes, which may cover the entire surface of the antigen. One must realize, however, two important points: (*1*) Some regions are more frequently recognized than others; these are the immunodominant epitopes; and (*2*) the number of mAbs that can bind simultaneously to a given antigen molecule is necessarily limited by the steric hindrance imposed by the surface of the antibody combining site that interacts with the epitope. Having said that, it is quite obvious that the overall number of epitopes that can be detected on one antigen molecule is directly related to its surface area.

By extension, the notion of **T-cell** epitopes has been defined. From a physiological point of view, it is somewhat more complicated in that it is linked directly to the mechanism of **antigen presentation** and thus requires the interaction of the antigenic structure with two partners, the **multiple histocompatibility complex** (MHC) molecules and the T-cell receptor (TCR) itself. Because antigen processing and presentation have been defined for only proteins thus far, such T-cell epitopes are **peptides**. In a sense, the structural basis for a T-cell epitope is simpler and more directly accessible than in the case of B cells, because these peptides are short and are recognized as a sequential determinant. Strictly speaking, however, the term *epitope* is reserved to that part of the peptide that interacts with the TCR, whereas regions that interact with the MHC molecule, which are of decisive importance, because it conditions immunogenicity, are described sometimes as the "agretope." Extensive analysis by site-directed mutagenesis has clearly demonstrated which key residues contributed the epitope or the agretope. Because of the differences in the structures of the cavity that bind the peptides in various MHC molecules, the size of the peptide is limited to 9 amino acid residues for those that bind to class I MHC molecules, whereas it may be somewhat larger for those that are presented by class II. A very large number of such small overlapping peptides may be derived from one protein antigen. The problem of recognition by the MHC molecules, which are in very limited number for any given individual (a few discrete molecules), is therefore very different from the huge repertoire expected from Ig and TCR molecules. What happens is that MHC molecules will "choose" only a very few peptides from one antigen, those that fit with the minimum requirements that drive the interaction with the agretope. This is why every individual will use a different way to respond to the same antigen. Using a simplified model of antigen, such as a monotonous synthetic polypeptide, the chance is high that the molecule will be **immunogenic** only in those individuals with the appropriate MHC molecules. This was the case of the strains of mice injected with synthetic polypeptides that did or did not respond, initiating the first approach to the understanding of the genetic control of the immune response and starting the elucidation of the physiological role of MHC molecules.

Both the B-cell and T-cell epitopes raise directly the problem of the repertoire of the immune system, a central notion that is directly related to the number of potential antibodies and TCR that a given organism can potentially make (see Repertoire).

Epstein-Barr Virus

Epstein–Barr virus (EBV) is a ubiquitous human herpesvirus that is the causative agent of infectious mononucleosis and associated with several malignancies, such as Burkitt's lymphoma (BL), nasopharyngeal carcinoma (NPC), some cases of peripheral T-cell lymphoma and gastric carcinoma, and B-cell lymphoma of acquired immune deficiency syndrome (AIDS) and transplant patients. EBV has the ability to immortalize human B-lymphocytes *in vitro*.

The EBV genome is double-stranded linear DNA with an approximate length of 175 kbp and a G+C content of 59%. Reiterated direct repeat sequences at both termini (TR) and within the genome (IR) separate the EBV genome into five unique regions. The EBV genome circularizes after entry into cells, and it is maintained stably as a **plasmid** .

Although the entire EBV genome is maintained in immortalized lymphocytes, virus replication usually does not occur in these cells. During a latent infection, six nuclear antigens (EBNA1, EBNA2, EBNA3A, EBNA3B, EBNA3C, and EBNA-LP), three membrane proteins (LMP1, LMP2A, and LMP2B), and two small nuclear RNAs (EBER1 and EBER2) are expressed. EBNA-LP, 2, 3A, and 3C and LMP1 are essential or critical for primary B-lymphocyte growth transformation. EBNA3B, LMP2A, LMP2B, and EBERs are dispensable for immortalization.

EBNA1 from a typical EBV strain B95-8 consists of 641 amino acid residues. A long hydrophilic **domain** of residues 459 to 607 has a **DNA-binding** activity that is nucleotide sequence-specific. The specific EBNA1 binding sequence is located at oriP, which is the origin of EBV plasmid replication. Replication from oriP requires both the ***cis*-acting** elements (the family of repeats and the dyad symmetry elements) and the viral protein EBNA1. EBNA1 binding to oriP is also required for efficient EBNA transcription, where oriP serves as an enhancer. EBNA2 induces expression of viral genes LMP1 and LMP2 and cellular genes CD21, CD23, and c-fgr. EBNA2 responsive elements have been defined in the upstream **promoter** regions of these genes. Interaction of EBNA2 with its response element is mediated by a cell protein Jk, which recognizes a GTGGGAA sequence present in all known EBNA2 response elements. EBNA3A, EBNA3B, and EBNA3C are encoded by three genes that are tandemly placed in the EBV genome and are likely to have been derived a common origin. EBNA-LP is encoded by the leader of each of the EBNA **messenger RNAs** and is **translated** from these mRNAs when the first and second exons are spliced, so as to create the EBNA-LP initiation codon. Deletion of the EBNA-LP gene reduces greatly the efficiency of B-lymphocyte immortalization by EBV.

LMP1 consists of an amino-terminal cytoplasmic domain, six **membrane**-spanning **hydrophobic** domains separated by short reverse turns, and a carboxy-terminal cytoplasmic domain. LMP1 has the ability to transform rodent fibroblasts, and it blocks differentiation in human keratinocytes. In transgenic mice, LMP1 expression causes epithelial hyperplasia. In BL cells, LMP1 induces villous projections, growth in tight clumps, NFkB activity, and expression of activation markers (CD23 and CD40), cell adhesion molecules (ICAM-1, LFA-1, and LFA-3), IL-10, and the Bcl-2 proto-**oncogene**. There are two NFkB-activating regions in the carboxy-terminal cytoplasmic domain. One of these regions associates with members of the tumor necrosis factor receptor-associated factor (TRAF) family of proteins. CD40 is a well-known mediator of growth of B lymphocytes. LMP1, through direct interaction with TRAFs, may constitutively activate CD40 signal transduction and promote cell growth. LMP2A is a substrate for B lymphocyte **src** family **tyrosine kinases**. LMP2A expression blocks calcium mobilization in B lymphocytes. There is no known function for LMP2B.

EBERs are RNAs that are not **polyadenylated**, and they have extensive primary sequence similarity to adenovirus VA1 and VA2 and cellular U6 small RNAs.

In contrast to the EBV gene expression in immortalized lymphocytes, more limited numbers of EBV genes are expressed in EBV-associated tumor cells. BL and gastric carcinoma cells express EBNA1, but do not express other EBNAs and LMPs. NPC and T-cell lymphoma cells express EBNA1 and LMPs, but do not express other EBNAs. It is known that EBNAs other than EBNA1 become targets of cytotoxic T lymphocytes. Therefore, it is important for tumor cells not to express these antigens so as to survive under normal immunity.

EBNA2 and LMP1 are particularly important for the immortalization of primary lymphocytes. These proteins, however, are not expressed in most EBV-associated malignancies, although there is a report suggesting that malignant phenotypes are dependent on the presence of EBV genomes. These observations may be extended to the pathogenic role of EBV in other EBV-associated malignancies.

Equilibrium Dialysis

Equilibrium dialysis is a technique for analyzing the binding of a low molecular weight ligand to a macromolecular **receptor** (1) (see **Ligand binding**). Information that can be obtained from an equilibrium dialysis experiment includes the stoichiometry of the complex formed and the affinities of the interacting components (2), plus more subtle properties such as **cooperativity** . In the simplest form of an equilibrium dialysis experiment, receptor and ligand solutions are placed in compartments on opposite sides of a semipermeable dialysis membrane. The pore diameter of the membrane is chosen to allow passage of the ligand and prevent passage of the receptor. The ligand thus redistributes between the two compartments, whereas the receptor stays in its own compartment. If the receptor binds the ligand, an excess of ligand begins to accumulate in the receptor compartment. When equilibrium is reached, two conditions are met, as long as there is no nonideality in the system: (*1*) the free ligand concentration is equal on both sides of the membrane and (*2*) the ligand in the receptor compartment is partitioned between free and receptor-bound form according to the equilibrium constant for the receptor–ligand interaction. The total ligand concentration on each side of the membrane is measured after equilibration, as is the receptor concentration, if necessary. The excess ligand concentration on the receptor side is attributed to its binding to the receptor. This basic experiment is repeated for a series of receptor and ligand concentrations. Pairs of bound and free ligand concentrations may then be analyzed by a graphical method, such as a Scatchard Plot, or fit by least squares to a binding equation to derive the relevant parameters of the receptor–ligand interaction (3).

The primary advantage of equilibrium dialysis over other techniques for measuring ligand-binding equilibrium constants is that equilibrium dialysis does not rely on assumptions that a measured property, for example, a spectral change, correlates linearly with receptor occupancy. Development of microdialysis cells and of dialysis membranes made from purified material with well-defined molecular weight cutoffs have eliminated many artifacts once associated with equilibrium dialysis. Persisting sources of error include aggregation of the ligand, which will retard or prevent its passage through the dialysis membrane, adsorption of ligand or receptor to the membrane, and changes in volume and concentration resulting from an osmotic imbalance at the start of the experiment.

The assumption that the free ligand concentration is equal on both sides of the membrane at equilibrium is not always valid. Most proteins and all **nucleic acids** are charged; thus these macromolecules accumulate a set of neutralizing counterions. A ligand of opposite charge can act as a neutralizing counterion, resulting in an imbalance between free ligand concentrations in the receptor and ligand compartments of an equilibrium dialysis experiment. This imbalance, known as the Donnan effect (4), does not reflect a biologically specific ligand–receptor interaction, but occurs with whatever counter-ion is available, as a consequence of maintaining the overall electrical neutrality of the solution. The practical impact of the Donnan effect is to give spurious evidence of an association between a ligand and receptor of opposite charge. Even if a ligand is uncharged, changes in ionic strength or pH due to redistribution of buffer ions may still interfere indirectly with an experiment. The magnitude of the Donnan ratio (an ion's concentration in the receptor compartment divided by its concentration in the ligand compartment) is greatest at high receptor concentration and low ionic strength. For example, 100 μ*M* receptor containing 10 charges in the presence of 1 m*M* NaCl will yield a Donnan ratio of 1.5, meaning that a monovalent ligand will appear to be 50% enriched in the receptor compartment. If the receptor concentration is lowered to 1 μ*M*, or the salt concentration raised to 100 m*M*, the Donnan ratio drops to 1.005. Although simple addition of salt essentially eliminates the Donnan effect as an interfering factor in equilibrium dialysis, the added ions may distort the experiment in a different way, by competing with the ligand for association with charged groups in the receptor binding site. An alternative to using high salt concentration is to measure the Donnan ratio directly and apply a correction factor (5).

Equilibrium Potential

Current flows resulting from ions diffusing across a phase boundary establish an electrical potential difference across that phase boundary in opposition to the ion currents. The origin of this potential lies in the difference in mobilities of anions and cations as they diffuse across the phase boundary. The electric field slows the faster ion and speeds up the slower ion, so that no net transfer of charge occurs across the phase boundary. The magnitude of the diffusion potential will depend on the difference in chemical potentials of the electrolytes in the contiguous phases, as well as differences in ionic mobility. The *Planck–Henderson equation* provides a quantitative calculation for the diffusion potential Y_D; for a single electrolyte (eg, NaCl) we have

$$\Psi_D = -\frac{(u-v)RT}{(u+v)zF}\ln\frac{C_2}{C_1} \tag{1}$$

where *u* and *v* are the cationic and anionic mobilities, respectively, *R* is the gas constant, *T* is the absolute temperature, *z* is the valence of the electrolyte, *F* is the Faraday (96,500 C/mol), and C_i are the electrolyte concentrations in the two contiguous solutions. Two examples of the use of equation 1 are for (i) the *liquid junction potential* that arises when two electrolyte solutions with different concentrations form an interface and (ii) when a synthetic membrane with a selective permeability for one of the ions is inserted between the two solutions. For the ion-specific selectively permeable membrane, equation 1 becomes

$$\Psi_D = \frac{RT}{zF} \ln \frac{C_2}{C_1} \tag{2}$$

This is the equilibrium potential for the permeable ion (see Membrane Potentials).

Estrogen Receptors

Estrogen, together with the other sex steroid hormones, progesterone and testosterone, provokes the development and determination of the embryonic reproductive system, masculinizes or feminizes the brain at birth, and controls reproduction and reproductive behaviour in the adult, plus the development of secondary sexual characteristics. Furthermore, both an atheroprotective effect of estrogen and a protective effect against osteoporosis are well documented. The hormone probably enters its target cells by diffusion (see Steroid Hormone Receptors) and activates estrogen receptors (ERs) that are paradigmatic transcription factors in eukaryotes. ERs are members of the steroid hormone receptor family that, in turn, is a subfamily of the nuclear receptor superfamily of proteins (see Steroid Hormone Receptors). Effects of ERs on the genome are mediated through binding of the hormone–receptor complex to short, specific DNA sequences, termed estrogen response elements (EREs), located in the vicinity of approximately 100 estrogen-regulated genes in each cell, and subsequent modulation of gene expression (see Hormone Response Elements and Glucocorticoid Response Element). The ERE functions as an enhancer and the ERs as enhancer binding factors that are equipped with domains and surfaces responsible for hormone and DNA binding, activation of transcription, and interaction with other nuclear partners.

Until recently, only one oestrogen receptor had been known, which is now called estrogen receptor a (ERa or NR3A1 according to a new nomenclature proposal (see Steroid Hormone Receptors)). In 1996 a second estrogen receptor, now known as estrogen receptor b (ERb or NR3A2), was identified (1). Therefore, older literature always refers to ERa and has often to be reinterpreted in the light of at least two receptors being present in many tissues.

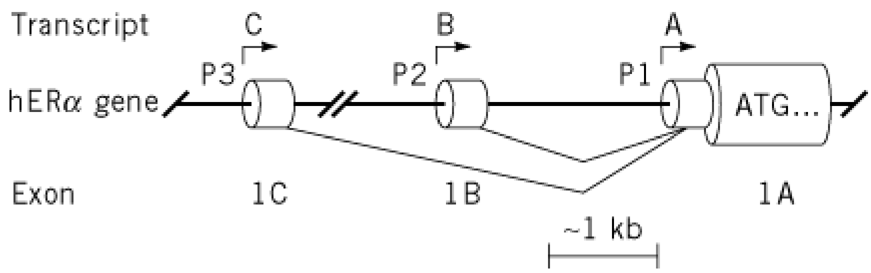
Apart from their involvement in the development of the reproductive system, estrogens are also implicated in the growth of breast cancers. Already in 1896, Beatson observed the regression of metastatic breast cancer after ovariectomy (*ce, after estrogen withdrawal*). Since that time, various surgical and pharmacological endocrine therapies have been employed (see below). Today, the determination of the concentration of sex steroid receptors in breast cancers is performed routinely and is very important for prognosis in general and the therapeutic regimen in particular.

The molecular mechanisms by which ovarian hormones stimulate growth of breast cancers are unclear, but they are likely to involve an extensive crosstalk of ERs with other signalling pathways. ERa, for example, activates the **signal-transducing** Src/p21ras/Erk pathway in human breast cancer cells via an interaction with c-Src (see Cis Configuration). In addition, ERa can integrate signals from the progesterone receptor into this signalling cascade (see Steroid Hormone Receptors). ERa is also activated when it is complexed with **cyclin** D1, which has an important role in the development of breast cancer and is required for normal breast cell proliferation and differentiation associated with pregnancy. Furthermore, such growth factors like epidermal growth factor (EGF), can activate ERa through the mitogen-activated protein, MAP Kinases pathway, which probably involves receptor phosphorylation.

1. Domain Structure

The human ERa was cloned from cDNA libraries prepared from the MCF-7 breast cancer cell line in 1985. This cDNA clone was later shown to contain an artifactual point mutation that resulted in the substitution of a valine (mutant receptor called HEO) for a glycine (wild-type receptor called HEGO). The hERa gene encompasses 10 exons spread over 140 kbp and is regulated by at least three different **promoters** (see Fig. 1). The ERa cDNA encodes a 595–amino acid residue protein of 66 kDa. The oestrogen receptor is a modular protein composed of distinct regions corresponding to functional and structural units called **domains** that are labeled A–F (see Steroid Hormone Receptors, Fig. 1B). Transcription activation functions have been detected in regions A/B (AF-1, also called q-1 or enh-1) and E (AF-2, also called q-2 or enh-2). Region C is the DNA-binding domain (DBD), and region D is often considered as a flexible hinge region between the DNA- and ligand-binding domains. The very amino terminus of region D is also an integral part of the DBD. Region E is the ligand-(hormone)-binding domain (LBD), composed mainly of 12 a-helices, and contains AF-2 that forms the core of the most carboxy-terminal helix 12 (see text below). Beyond helix 12 starts region F, which is not required for hormone binding but seems to be important for the discrimination between agonistic and antagonistic ligands.

Figure 1. The 5′ region of the hERa gene. The promoter P1 in front of exon 1A generates transcript A encompassing a 5′-untranslated region (UTR, smaller cylinder) and the start of the coding region (larger cylinder). The other two promoters, P2 and P3, generate transcripts in which the noncoding exons 1C or 1B are alternatively spliced to the same acceptor splice site within a short upstream open reading frame found in the 5′-UTR of transcript A. Depending on tissue-specific promoter utilization, different hERa transcripts can be detected in different tissues that code for the same receptor protein, but have distinct 5′-UTRs. Common to all UTRs is the presence of short upstream open reading frames that are implicated in the regulation of translation efficiency.



Regions C and E are not only responsible for DNA- and ligand-binding, respectively, but they encode other functions as well. At equilibrium the majority of ERa is in the nucleus, due to the presence of so called nuclear localization signals (NLS) that are believed to be required for **nuclear pore** recognition (see Nuclear Import, Export). A constitutive NLS is located at the border of region C to D, whereas a second NLS in the LBD is ligand-dependent.

ERb was found in rat prostate and later in human testis cDNA libraries using **PCR**-cloning strategies involving degenerate primers. With 8 exons spread over approximately 40 kbp, the human ERb gene is considerably smaller than the ERa gene. Several mRNA bands have been observed on RNA Blots

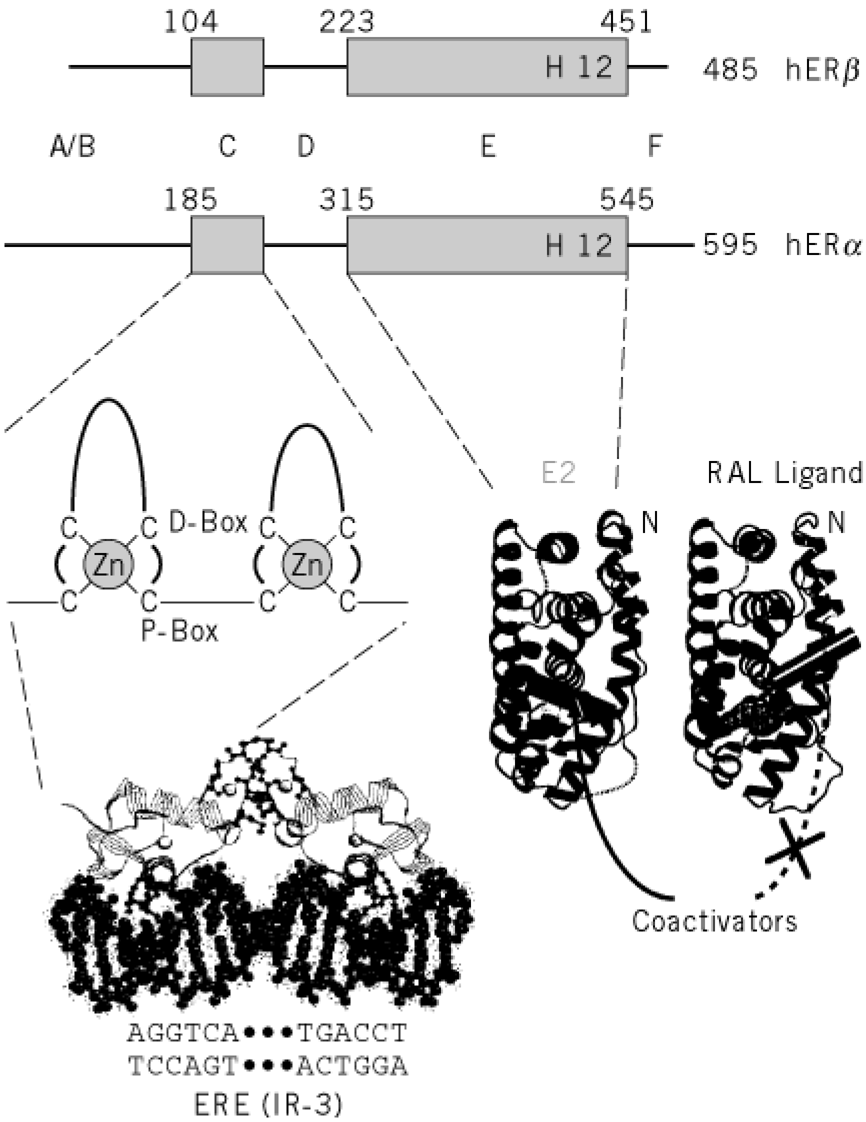
(Northern Blots), possibly indicating that the ERb gene is also characterized by multiple promoters, which is a general phenomenon within the steroid hormone receptor family. The human cDNA encodes a 485-residue protein that shows a high degree of homology to ERa within the DBD (96% identity) and the LBD (58%).

2. DNA Binding

All members of the steroid hormone receptor family were initially thought to bind to their cognate response elements as homodimers . Today the family also contains two oestrogen-related orphan receptors that bind to DNA as monomers (see Steroid Hormone Receptors). Moreover, the two closely related ERs, a and b, are known to bind to DNA as homodimers, but they can also form heterodimers which is an otherwise common mechanism within the nuclear receptor superfamily. Oestrogen receptor homo- or heterodimers bind to the estrogen response element (ERE) that is composed of two half-sites (AGGTCA) arranged as palindromic, inverted repeats (IRs), where the half-sites are separated by three nucleotides (IR-3). One ERE half-site is recognized by one receptor monomer. The half-site spacing of three base pairs is such that an ER homodimer binds both half sites on the same face of the DNA. The DNA-binding domain of the ERs comprises approximately 80 amino acid residues encoded by region C, plus some 14 *N*-terminal amino acids of region D. The domain contains two patterns that are reminiscent of, but clearly distinguishable from, the **zinc finger** motifs first observed in the *Xenopus laevis* transcription factor IIIA (TFIIIA; see **Zinc fingers**). The ER zinc fingers are also able to coordinate a zinc atom tetrahedrally but are of the type C_2–C_2 (see Fig. 2). Each ER monomer contains two of these particular zinc fingers, which are folded together to form a single structural domain (2). Characteristic of this fold are two highly amphipathic a-helices, one contributed by each finger, that cross at an approximately right angle at their midpoints (see Fig. 2). The **hydrophobic** surfaces of these helices form a rigid core decisive for the stability of the structure that is further strengthened by two zinc ions holding the base of a loop against the *N*-terminus of each helix. The specific interaction of an ER homodimer with DNA is determined by only a few amino acid residues located in two regions, the proximal box (P-box; see Fig. 2) and the distal box (D-box). The P-box lies at the amino terminus of the first fingers a-helix (its "knuckle"). Four amino acid residues within the P-box interact with base pairs, and only three of them are required for the discrimination between an ERE and a nonestrogen steroid hormone receptor response element. When these three residues are exchanged for the three cognate residues of the glucocorticoid receptor, ERE-specific binding is converted to glucocorticoid response element–specific binding. The five D-box residues form the weak dimerization domain within the DBD and are responsible for the recognition of the correct half-site spacing (IR-3). These dimerization forces are too weak for the DBD alone to form dimers in solution, but they make DNA-binding cooperative. The complete receptor protein exists as a homodimer in solution, due to a strong dimerisation domain within the LBD.

Figure 2. Structure of estrogen receptors. (**Top**) The functional domains (A/B to F) of hERa and b are illustrated at the primary structure level. The numbers refer to amino acid positions. Highlighted are the DNA-binding domain (DBD) in small boxes and the ligand binding domain (LBD) in larger boxes. The A/B and F domains are drawn to scale. (**Middle left**) In an exploded view of the hERa–DBD its secondary structure, characterized by two steroid hormone receptor-specific zinc fingers, is depicted. Four cysteines each tetrahedrally coordinate two zinc ions. The proximal box (P-box) responsible for specific DNA-recognition is shown on left; the distal box (D-box) mediating DBD-dimerization is shown on right. (**Bottom left**) The secondary structure explodes into a view of the crystal structure of the hERa's DBD bound to DNA. The four amino acid side chains of the P-box interacting with DNA bases are again shown in boldface. These residues are part of an a-helix responsible for specific DNA-sequence recognition that is positioned within the DNAs major groove (perpendicular to the paper plain). A second amphipathic a-helix can be seen to cross the recognition helix with the red P-box residues at a right angle. The D-box residues promoting DBD dimerization are located between the two helices. Underneath the DNA the sequence of the consensus estrogen response element (ERE) is shown. Both half-sites are organised as an inverted repeat with 3-bp spacing (IR-3). (**Middle right**) The crystal structure of the ligand-binding domain complexed with the natural ligand 17b-estradiol (E2, left) and the antihormone raloxifene (RAL, right). Decisive for a productive interaction with coactivators is the proper positioning of helix 12 (H12) over the ligand-binding pocket. (The authors thank R. Hubbard and A. Pike,

University of York, UK, for providing this part of the figure.)



3. Ligand Binding

Estrogenic hormones, as well as synthetic antihormones, enter the target cell by simple diffusion and bind, within the cytoplasm, to a multiprotein complex of **molecular chaperones** and ER. Hormone binding induces a transformation of the ER complexes that is associated with an increase in affinity for DNA and leads to a tight association with the nuclear compartment. In addition to DNA-binding, the bound hormone confers transcriptional competence onto ERs that is exerted by two independent **transactivation** functions (see text above). The crystal structure (3) of the hERa ligand binding domain complexed with the endogenous hormone 17b-estradiol (PDB accession no. 1ERE; see Structure Databases) and the antihormone raloxifene (PDB accession no. 1ERR) have been determined (see Fig. 2). The LBD of hERa is folded into a three-layered antiparallel a-helical sandwich that creates a wedge-shaped molecular scaffold, in which the ligand-binding cavity is located at the narrower end of the domain. This cavity is completely partioned from the external environment and is closed by helix 12 operating as a "lid" after 17b-oestradiol has entered the binding pocket (see Fig. 2, left LBD structure). In "lid-on" position, AF-2 is able to interact with co-activators that in turn connect the receptors to the transcription machinery and activate transcription (for more details, see Steroid Hormone Receptors). When an antihormone-like raloxifene is bound instead, closure of the ligand binding pocket is not possible, and AF-2 cannot be placed in a transcriptionally competent position (see Fig 2, right LBD structure).

Although the precise mechanism of this ligand induced switch between active and inactive AF-2 was not known until recently, a number of proteins have been rendered functionally estrogen-dependent by fusion with the hormone-binding domain of ERa (4).

4. Hormones and Antihormones in Breast Cancer

Since Beatson's observation of regression of metastatic breast cancer after ovariectomy, in 1896, oncologists have been searching for an ideal antihormone that will prevent the proliferative effect of estrogen on breast cancer but preserves an atheroprotective effect and protects against osteoporosis without any side effects. Approximately 50% of all breast cancers contain clearly detectable amounts of hERa and are, thus, amenable to hormone therapy. Disease prognosis is better when receptors are present, probably because their presence reflects a greater degree of differentiation of the tumor, indicative of slower growth. Only approximately 50% of these receptor-positive cases also respond positively to an antihormone treatment. Several ER sequence variants were identified in human breast cancer cell lines and tumor specimens, but it is not known if these mutations are important for breast cancer progression or interfere with endocrine breast cancer therapies.

Currently, the most commonly used antihormone is tamoxifen, which is converted to 4-hydroxy-tamoxifen *in vivo*, the actual antihormone. Tamoxifen appears to antagonize estrogen action by competing with oestrogens for receptor binding. Receptor-bound tamoxifen, like raloxifene, is postulated to be unable to position helix 12 of the LBD in such a way that AF-2 is placed in a transcriptionally competent position (see discussion above). However, tamoxifen can still act as a partial estrogen agonist depending on the tissue and response examined. This is probably due to the ligand-independent and cell-specific activity of AF-1 within the receptor's A/B domain. Tamoxifen is clearly effective in receptor-positive breast cancer patients and has very few side effects. It still retains a protective effect against osteoporosis, but does not reduce the risk of cardiovascular disease. Its effectiveness was also proved in prevention trials, although a slightly increased risk for developing endometrial cancer and thromboembolic events must be taken into consideration. Other antiestrogens with a broader spectrum of positive effects than tamoxifen, such as raloxifene, are currently being tested in clinical trials.

With the discovery of a second estrogen receptor, all clinical data on antihormone therapies of receptor-positive breast cancer patients must be reevaluated. It is already known that some breast cancers express ERb but no ERa, and some express both receptors. Differing ERb/ERa ratios could explain cases that were typed receptor-negative but still responded positively toward antihormone therapy, as well as those receptor-positive cases that were refractory toward antihormone therapy. Therefore, the presence of both receptors in tumor specimens will probably be determined routinely in the near future.

5. Results from Disruption of the Mouse Estrogen Receptor a Gene

In addition to its importance for a normal postnatal sexual development, estrogen action has always been considered as a crucial factor for prenatal development. This hypothesis is generally supported by the fact that almost no ERa mutations are known. An exceptional case, however, is a 28-year-old tall man in whom a premature stop codon in position 153 of hERa could be identified (5). The patient is homozygous for this mutation, showed no response to estrogen administration, and manifested decreased bone mineral density and increased bone turnover. This homozygous human knockout already indicates that ERa is not required for prenatal development but is very important for bone maturation and mineralization in males also. Targeted disruption of the ERa gene in mice (ERKO mice (6)) showed the same result (see Gene Targeting). Homozygous ERKO mice are viable, and the external phenotypes of both sexes are normal. Internally only the females show noticeable gross differences from normal, with hypoplastic uteri as well as hemorrhagic cystic ovaries that lack corpora lutea. In addition, the mating behavior of the females is severely compromised, because they show no typical lordosis posture or receptiveness to wild-type males, even when treated with estrogen. Consequently, all homozygous ERKO females are infertile, as are the male mice. The latter show normal motivation to mount females, but they achieve less intromissions and virtually no ejaculations. Aggressive behaviors were dramatically reduced, and male-typical offensive attacks were rarely displayed by ERKO males. In addition to an altered mating behavior, spermatogenesis is disturbed, as manifested by low sperm numbers and defective sperm function. Therefore, expression of the ERa gene appears to be necessary not only for the development of the female and male reproductive systems but also for the full development of both female and male sex behavior repertoires.

With the discovery of ERb, the question of the importance of estrogen receptors for prenatal development is open again and has to await the production of ERb single- and ERa/ERb double-knockout mice.

6. Functional Differences between ERa and ERb

In light of the high homology between ERa and ERb, the question arises as to whether one receptor is a mere "backup" of the other, or whether each receptor has its own set of specific functions. ERb was shown to have DNA-binding specificity overlapping with that of ERa and activates transcription of reporter gene constructs containing EREs in transient transfections in response to estradiol. The response of both receptors to a number of estrogen agonists and antagonists has been determined in such a way, and numerous differences have been observed. Furthermore, the tissue distribution of both receptors is clearly different. Whereas some tissues contain both receptors, as does the human mammary gland, others contain only a single receptor type. One prime example are the granulosa cells of the ovaries, which contain only ERb and are devoid of ERa. Previously, the granulosa cells had been identified as a target for oestrogen action, although they were shown not to contain ERa. This puzzling finding can now be explained by the presence of ERb. Other examples are the Leydig cells of the testis, which contain ERa but no ERb, whereas the developing spermatids express ERb and ERa is absent. Therefore, with the advent of a second estrogen receptor, at least two more important parameters have to be considered when analyzing the regulation of gene expression by estrogen: the ERa/ERb- ratio and the presence of ERa/ERb-heterodimers and their distinct functions dependent on the agonist/antagonist and promoter context investigated.

Estrogens

Estrogens are female sex steroid hormones derived from cholesterol. The most potent estrogen is 3,17b-estradiol (estradiol 1,3,5-estratriene-3,17b-diol). The 16a-hydroxylated derivative of estradiol, estriol, is a weak estrogen, whereas the 17b-oxidized compound, estrone, is hormonally inactive. Synthetic nonsteroid estrogens, such as diethylstilbestrol, have been introduced as therapeutic drugs in various endocrine diseases. Estrogen antagonists (eg, tamoxifen) have also found use in therapy, particularly of breast cancer.

Estradiol is synthesized in the ovary, the placenta, the adrenal cortex, and the testis. In the theca cells of the ovarian follicles, cholesterol is metabolized to progesterone and to androstendione, which in the granulosa cells is subsequently transformed to estradiol by aromatization of the A ring by the aromatase complex. This process is stimulated by FSH (folitropin).

During fetal and early postembryonic development, estrogens are responsible for inducing female characteristics and for the formation of the female genitals (oviduct, uterus, vagina). In the adult, estrogens act on the development of the secondary female sexual characteristics—for example, on the growth and differentiation of the breast glands, on the appearance of pubic and axillar hair, and on fat deposition in the skin. Estrogens affect the central nervous system and can modify sexual behavior. They also act positively on bone mass. In collaboration with progesterone, estradiol regulates the menstrual cycle. Specifically, in the first half of the cycle, estradiol stimulates proliferation of the epithelial and stromal cells of the endometrium, in preparation for ovulation.

The molecular action of estrogens, like that of the other steroid hormones, is by modulation of gene transcription (see Response Element). The hormone first binds to the estrogen receptor, a member of the superfamily of nuclear receptors, which then homodimerizes and binds to specific nucleotide sequences, the estrogen response elements. This triggers activation of gene transcription. Among the genes regulated by estrogens are **protooncogenes** of endometrium cells encoding transcription factors involved in cell replication (c-fos, c-jun, c-myc) (1-3), those encoding the progesterone receptor, growth factors, and various structural and adhesion proteins (4). In the liver, estrogens stimulate the synthesis of steroid- and thyroxine-binding proteins. The molecular effects of estradiol on the synthesis of phosphoproteins in the chick oviduct, such as ovalbumin, have been studied in detail and were instrumental in developing concepts on the mode of action of steroid hormones (5).

Ethidium Bromide

Ethidium bromide (phenanthridinium, 3,8-diamino-5-ethyl-6-phenyl-, bromide) is a heteroaromatic cationic dye (an aminoacridine) with the molecular formula $C_{21}H_{20}BrN_3$ and a relative molecular mass of 394.31 (Figs. 1, 2). It exists as a dark red crystalline or amorphous powder at standard temperatures and pressures. It has a melting point (and decomposition temperature) between 533 and 535 K, moderately high solubility in water (5 g/100 mL), and is essentially odorless. Ethidium bromide is a powerful mutagen, extremely toxic by inhalation, ingestion (LD_{50} 1503 mg/kg oral, rat), and skin contact, and a suspected carcinogen and reproductive toxin.

Figure 1. Ball-and-stick representation of the ethidium bromide molecule (phenanthridinium, 3,8-diamino-5-ethyl-6-phenyl-, bromide). RMM = 394.31.

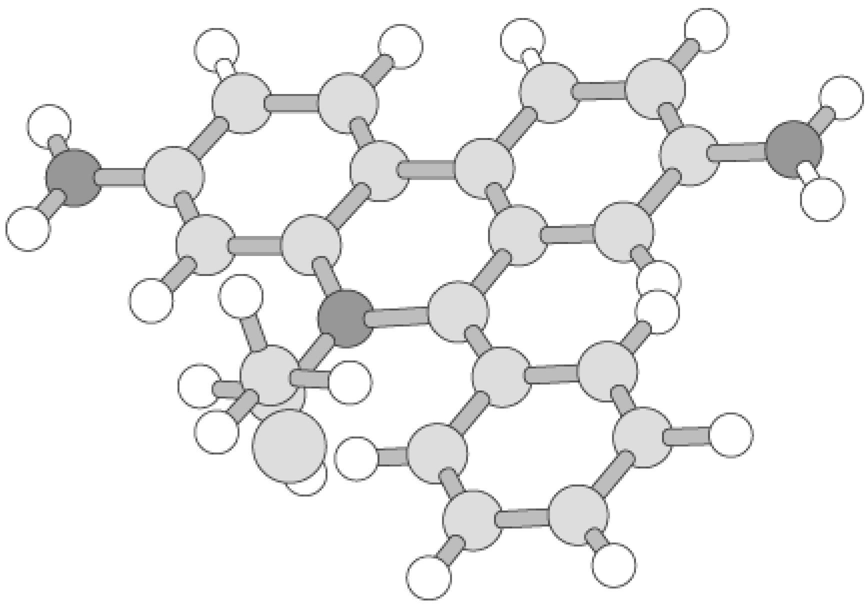

Figure 2. The intercalation of ethidium bromide into a portion of a DNA double helix. The intercalated dye increases the spacing of successive base pairs, distorts the regular phosphate backbone, and reduces the pitch of the helix.

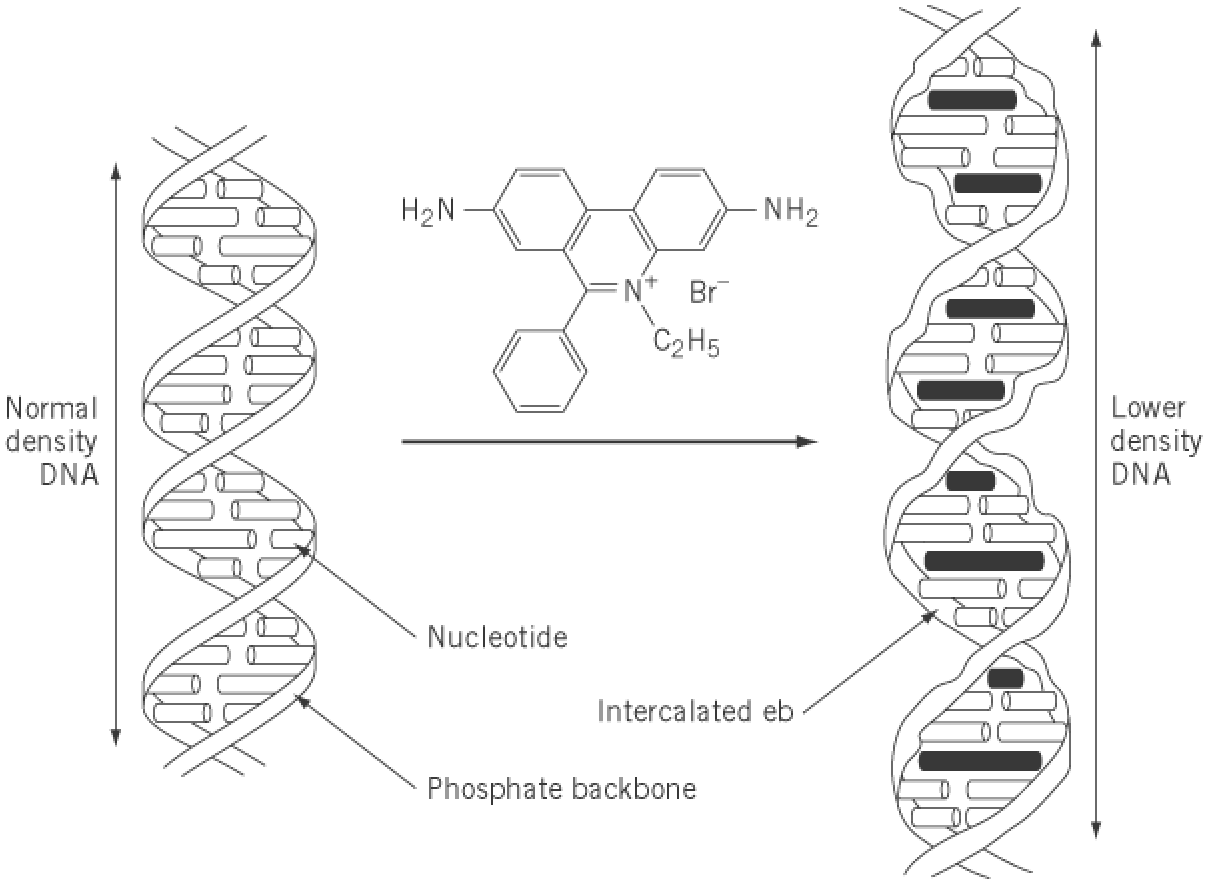

Originally, ethidium bromide (EB) found fame in the late 1940s as an antitrypanosomal, antimicrobial, antibacterial, and antiviral agent (1). It is generally agreed that these biological effects are a direct consequence of the inhibition of nucleic acid synthesis, which in turn is related to the specific binding of the drug to DNA. EB inhibits **DNA polymerase** and binds *in vitro* to both RNA and DNA. Investigation into the precise nature of the DNA-EB binding mechanism led to the discovery that the drug (and many other related molecules) binds by a mechanism termed intercalation. This process has been studied extensively during the past three decades, and the photophysical changes that accompany intercalation have been successfully applied to quantitate and structurally elucidate DNA. The nature of the DNA-EB interaction and subsequent analytical applications are the focus of this article.

1. Photophysical Characteristics of EB

EB is dark yellow in aqueous solution and possesses a broad structureless absorption spectrum (l_{max} ~ 480 nm). Increasing EB concentration leads to a red shift in the absorption maximum, accompanied by hypochromism. The existence of an isobestic point reflects a simple equilibrium between monomeric and dimeric species (2).

EB is weakly **fluorescent** in aqueous solution and possesses a broad structureless emission spectrum (l_{max} ~ 617 nm). The low fluorescent quantum yield and short fluorescent lifetime (3) in aqueous solution are attributed to efficient quenching of the excited state by the transfer of a proton to an adjacent water molecule (4, 5). Moreover, the EB dimer is not fluorescent and consequently provides an efficient mechanism for fluorescent quenching when EB is complexed in the dimeric form. Both of these phenomena prove important when EB interacts with DNA.

2. Intercalation of Dyes with DNA

Modification of DNA by binding with dyestuffs suspected to have possible chemotherapeutic effects was noted as early as the 1940s in the pioneering work of Michaelis (6). The classic intercalation mechanism for the physical interaction between drugs and DNA is discussed elsewhere in this volume, but the characteristics of dye intercalation with DNA were established primarily with reference to aminoacridones (7) and EB (1). Consequently, the fundamental attributes of classic intercalation are outlined. Very simply, intercalation describes the insertion of planar heteroaromatic molecules between adjacent nucleotide base pairs of a DNA duplex (see DNA Structure). Intercalative binding follows the neighbor exclusion principle, where every second site along the helix remains unoccupied, and thus EB intercalation occurs through interaction of the phenantridinium ring with the duplex (8). This leads to a very elegant binding model (Fig. 2). More specifically, the EB–DNA complex involves **hydrogen bonding** between the 3,8 amino substituents of the EB molecule and the phosphate groups across the two DNA strands. These hydrogen bonds maintain the orientation of the EB cation with respect to the polymer frame (9). The simplicity of this model was naturally extended to explain the interaction of other molecules with DNA. These included antitumor antibiotics whose mode of action involves interference with nucleic acid synthesis (1). The intercalation mechanism of EB with double-stranded DNA can be thought of as consisting of three fundamental features: [1] helix extension (Fig. 2); [2] local, helical unwinding during binding; and [3] insertion of EB so that the plane of the aromatic chromophore is perpendicular to the helical axis. This binding process has been confirmed by various experimental approaches including, X-ray crystallography (10), autoradiography (11), NMR spectroscopy (12), equilibrium studies (13), **viscosity** measurements (14), and calorimetry (15). Nevertheless, optical measurements have played the dominant role in the use of the EB to DNA interaction. Consequently they are discussed in detail here.

3. Intercalation of EB with DNA

The formation of a metachromatic complex between EB and DNA can be simply observed by measuring the absorption spectrum. As the DNA to EB ratio increases, the absorption spectrum shifts to longer wavelengths (3, 16, 17). The formation of such complexes causes a shift due to the stabilization of the excited state upon binding (9). The shift is observed only at high DNA to EB ratios because an excess of free dye normally masks the absorbance contribution of bound EB. Importantly, a binding constant of $2.1\times10^{6}M^{-1}$ demonstrates the high affinity of EB of DNA (18).

More relevant to the use of EB in molecular biology are the observed variations in its fluorescent characteristics on binding to polynucleotides. Broadly, both the time-integrated fluorescent intensity and the average molecular fluorescent decaytime increase dramatically on interaction with DNA (eg, the fluorescent decay time of EB in water is about 1.8 ns, compared to 23 ns in DNA) (3, 8, 19, 20). This variation can be explained by reference to Figure 2. When EB intercalates with the double helix, it sits in the **hydrophobic** pocket of the base pair system and is shielded to a large extent from solvent molecules. Consequently, the rate of excited state quenching (via proton transfer to solvent molecules) decreases, leading to an increase in both the fluorescent decay time and the fluorescent quantum yield. Because the fluorescent intensity of EB in aqueous solution is very small (due to a low fluorescent quantum yield), measuring the fluorescent signal when bound to DNA provides the most common method for DNA detection in the molecular biology laboratory (e.g., in slab gel electrophoresis and capillary zone electrophoresis) (21-23). Furthermore, the fluorescent enhancement has resulted in extensive use of EB as a probe of the topological (24, 25) and dynamic (26-29) properties of DNA.

EB is widely used as a probe in clinical DNA assays. The selective binding of EB to double-stranded DNA, combined with the exquisite sensitivity of fluorescent spectroscopy, provides an obvious route to DNA quantitation on a nanogram scale (30). With excitation at 520 nm and emission at 600 nm, EB fluorescence is enhanced approximately 30-fold in upon binding to duplexes. Moreover, the use of fluorescence detection for quantitative purposes is favorable because fluorescent enhancement is practically independent of base composition (31-33).

Nevertheless, care must be taken when using EB as a quantitative probe of DNA. Numerous studies have demonstrated a modification in the classic intercalative behavior of EB with high dye concentrations. In addition to conventional intercalation, there is also EB binds secondarily through an external site (most likely along the phosphate backbone). Binding to this secondary site occurs most readily at low ionic concentrations (<0.1 *M*), after binding at primary sites has been saturated (3, 14, 19, 21). Secondary binding is most clearly evidenced by the heterogeneous nature of fluorescent decay profiles originating from high EB to DNA ratios (3, 19). The true nature of secondary binding is still poorly understood. It must be accounted for, however, when relating time-integrated fluorescent intensities to the amounts of double-stranded DNA. In addition, variations in the fluorescent quantum yield of EB intercalated into heterogeneous natural DNA (eg, calf thymus DNA) as a function of salt concentration and temperature suggest that the detailed features of the EB to DNA complex are inextricably linked to the overall structural properties of the binding sites on the duplex chain (9).

The huge interest in the clinical use of compounds that bind strongly to DNA as antitumor agents at low concentrations has led to the study of a related class of EB compounds. Appropriately designed dimers of EB have binding affinities and fluorescent enhancements much higher than those of the monomer (18, 34, 35). Glazer and co-workers synthesized an ethidium homodimer, illustrated in Figure 3, that bisintercalates at a ratio of one dimer per four to five base pairs and is stable on electrophoresis gels. The system was used successfully to detect and quantify DNA fragments with picogram sensitivity subsequent to an electrophoretic separation (36). Current applications of bisintercalators of this kind include multiplex detection of DNA restriction fragments (37), high sensitivity detection of the products from the polymerase chain reaction (**PCR**) (36), sizing of individual double-stranded DNA fragments by flow cytometry, and the study of **DNA–protein interactions** (38). Furthermore, DNA probes that have a double-stranded region (for intercalation sites) and a single-stranded region (for recognition of specific target sequences) offer an exciting application for this generation of versatile fluorescent probes.

Ethylene

1. History

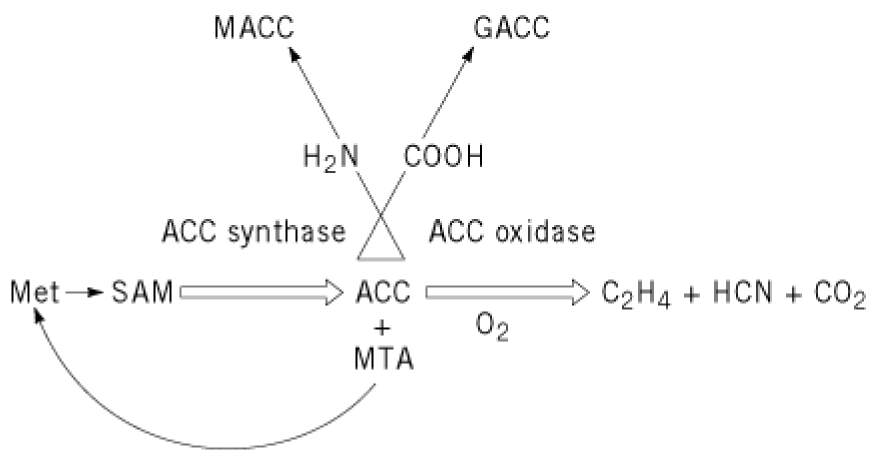
For a long time, people have recognized the ability of certain gases to stimulate fruit ripening. The ancient Chinese used to burn incense to accelerate ripening. In 1910, Cousins (1) advised the Jamaican Agricultural Department to ship oranges and bananas separately, because some emanation from the oranges (originating from fungal contamination) induced ripening of the bananas. In 1934, Gane (2) proved that ethylene is synthesized by plants and initiates fruit ripening.

The first report of effects of ethylene on vegetative growth dates from 1901, when the Russian physiologist Dimitri Neljubow (3) demonstrated that ethylene in illuminating gas causes the “triple response” in dark-grown pea seedlings: inhibited epicotyl elongation, radial swelling, and a horizontal growth habit, because of loss of geotropism (3). Deleterious effects of illuminating gas had already been observed in the previous century, when leaks in gas pipes caused precocious leaf abscission of surrounding trees.

2. Biosynthesis and Metabolism

Ethylene is a unique gaseous signaling molecule with a simple molecular structure (C_2H_4). It is active at concentrations as low as 10 nL/L of air (10 ppb). The biological precursor of ethylene in higher plants is L-methionine. By the action of S-adenosyl-L-methionine (AdoMet) synthetase, methionine and ATP are conjugated to form AdoMet (Fig. 1). Subsequently, AdoMet is converted to 1-aminocyclopropane-1-carboxylic acid (ACC) and 5′-methylthio-adenosine (MTA) by the enzyme ACC synthase. MTA is recycled to methionine. ACC is converted to ethylene, HCN, and carbon dioxide by ACC oxidase. Alternatively, ACC can be conjugated to malonyl-ACC and g-L-glutamyl-ACC (4, 5). These inactive derivatives are formed to prevent precursor accumulation and conversion to ethylene. In certain cases, however, malonyl-ACC can also serve as a source of ACC (6).

Figure 1. The ethylene biosynthesis pathway in higher plants. ACC, 1-aminocyclopropane-1-carboxylic acid; GACC, glutamyl-ACC; MACC, malonyl-ACC; MTA, 5′-methylthio-adenosine; SAM, *S*-adenosyl-L-methionine.



Control of ethylene biosynthesis has been observed at the level of ACC synthase and ACC oxidase activities and includes an important aspect of autoregulation (7, 8). In most cases, the ethylene levels are directly correlated with the ACC synthase activity, which is known to be highly regulated during plant development and in response to a complex array of environmental stimuli (9). Data have accumulated, however, that also indicate the importance of ACC oxidase for the regulation of ethylene synthesis (7). The synthesis of ACC does not always translate immediately into ethylene production. Interestingly, ACC is a soluble and translocatable hormone precursor, in contrast to ethylene, which, as a gas, is most probably not suited for targeted translocation processes. Translocation of ACC as a mechanism of interorgan signaling has been proposed for the regulation of plant responses to flooding stress (10, 11).

Because of its low abundance and high lability, ACC synthase proved very difficult to purify. Cloning of ACC synthase **genes** was achieved independently in several laboratories (12-14). The first nucleotide sequences of ACC synthase cDNA clones were reported by Van Der Straeten et al. (13) and Nakajima et al. (14). The former group obtained peptide sequences after 5000-fold purification of wound-induced pericarp tissue of ripening tomatoes, followed by oligonucleotide-directed screening of a cDNA library (13). Nakajima et al. (14) used an immunological approach to clone ACC synthase from a winter squash cDNA library. Sato and Theologis (12) isolated an ACC synthase clone by screening a cDNA expression library from zucchini with an antibody generated against purified ACC synthase, and the sequence was reported by Sato et al. (15). To date, clones encoding ACC synthase have been isolated from a large array of plant species. The enzyme is encoded by a highly divergent multigene family, and the expression of each gene is differentially regulated by a different subset of inducing or repressing conditions (16). Arabidopsis *thaliana* was shown to have at least five ACC synthase genes (17, 18). The *AT-ACS1* gene expression pattern was analyzed in detail using promoter-b-glucuronidase reporter gene experiments (19). It was shown that *AT-ACS1* expression was high in young and immature leaf tissues, lower in stems and in senescing tissues. The transcript levels of most ACC synthase genes are inducible by cycloheximide (16, 17), which suggests either that the messenger RNAs are labile or that transcription of ACC synthase genes is under the control of a labile repressor molecule (17). In either case, it can be concluded that ACC synthase activity is regulated predominantly at the transcriptional level. In addition, the regulation of some ACC synthase genes by various inducers may involve protein kinase activity, which in turn may be controlled through inositol-1,4,5-triphosphate (IP3)-mediated Ca^{2+} mobilization (20) (see Calcium Signaling).

A better understanding of the mechanisms involved in the transcriptional regulation of ACC synthase genes will create the possibility to control ethylene formation in a highly specific manner. To date, two strategies have been successfully applied to lower the level of ACC available for ethylene synthesis. In one experiment, the overexpression of the ACC deaminase gene of *Pseudomonas* sp. strain 6G5 in tomato plants resulted in a reduction of ethylene synthesis (21). Another approach was followed by Oeller et al. (22): expression of a tomato ripening-specific ACC synthase gene in an antisense orientation repressed ethylene synthesis almost completely. These antisense tomato fruits never get ripe until they are treated with ethylene or propylene.

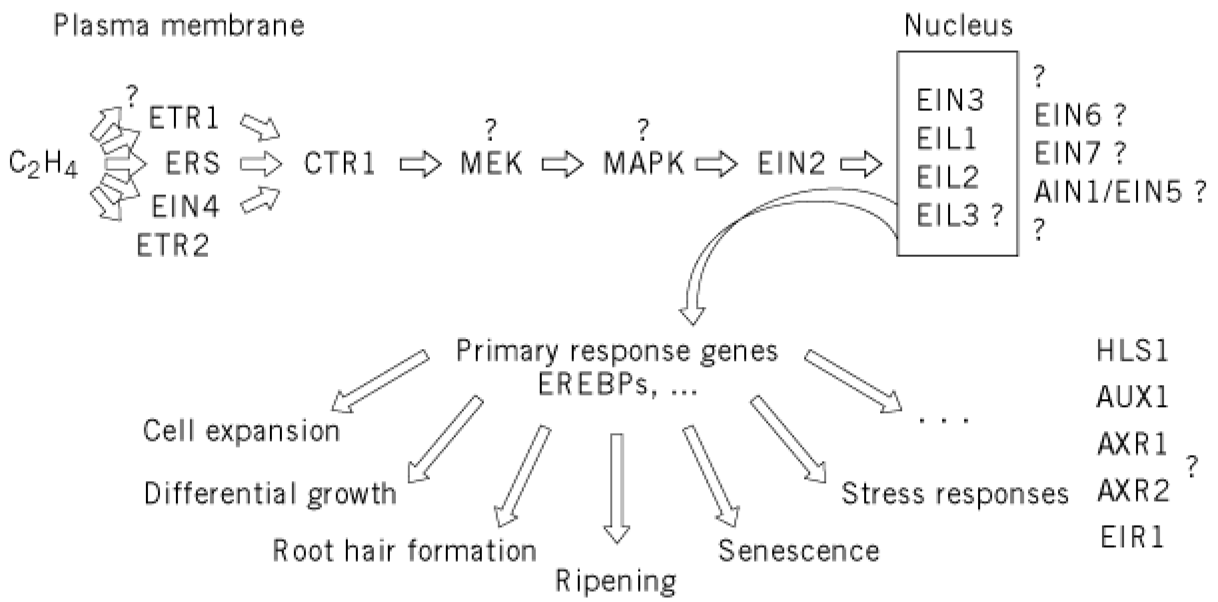
Numerous attempts were made to purify the enzyme downstream of ACC synthase, namely ACC oxidase, or ethylene-forming enzyme. A clone encoding this enzyme was finally isolated in a reverse genetics approach (23). As a first step, ripening-related clones from a tomato cDNA library were isolated. For one of these clones, induction of the corresponding mRNA was tightly correlated with increased ethylene synthesis (24). **Transgenic** tomato plants expressing the cDNA in an antisense orientation were constructed, resulting in a reduction of ethylene synthesis in a gene dosage-dependent manner. In addition, these plants were delayed in fruit ripening and leaf senescence, and ethylene synthesis was also substantially reduced in wounded leaves (23, 25). Finally, the cDNA was proven to encode ACC oxidase by heterologous expression in yeast and in *Xenopus laevis* oocytes (26, 27).

With the exception of preclimacteric fruits and flowers, it was generally believed that ACC oxidase is present constitutively in plant tissues and, therefore, would not contribute to the regulation of ethylene synthesis (28). However, Grierson et al. (7) have pointed out that the rapid induction of ACC oxidase transcripts upon wounding, when assayed in dissected plant organs, may have contributed to the false belief that this enzyme is present constitutively in all tissues. To date, we know that the expression of ACC oxidase genes can be highly regulated throughout plant development (29). As for the expression of ACC synthase genes, the transcriptional regulation of ACC oxidases was also found to be controlled by **phosphorylation** and dephosphorylation events (30). Whereas ACC synthase expression was both **feedback-inhibited** and stimulated by ethylene (8), ACC oxidase was rapidly induced by ethylene treatments (31). Finally, it should be mentioned that ethylene can be metabolized to ethylene oxide (32).

3. Signal Perception and Transduction

Using the triple response for isolating ethylene mutants, and subsequent double-mutant analysis, the ethylene signal was found to be perceived through several receptors (ETR1, ERS, and maybe also EIN4 and ETR2) and was transduced via a linear pathway to the nucleus, where the expression of a set of primary ethylene-response genes is regulated (33, 34) (Fig. 2). Characterization of the *ETR1* gene suggested an explanation for the fact that different ethylene concentrations, which give different responses, can act through a common signal transduction pathway. The *ETR1* gene has significant homology with bacterial two-component regulators (35). This kind of receptor systems is known to be able to operate over a wide range of ligand concentrations, resulting in an output that is graded with stimulus intensity (36). The amino-terminal region of the protein contains **hydrophobic** stretches, each of which is predicted to span the membrane. ETR1 is a membrane-associated, **disulfide bond**-linked dimer in extracts of *Arabidopsis* and when expressed in yeast (37). Ethylene was shown to bind to the amino-terminal hydrophobic region (38), and all of the known *etr1* mutations were also located in this domain. In addition, the *etr1-1* mutation was shown to disrupt ethylene binding. These data are consistent with the chemical properties of ethylene, which is more soluble in lipids than in water and therefore will bind preferentially in a membrane environment (39). The dominant nature of *etr1* mutations, together with the redundancy of receptors, suggests that ETR1 inhibits the ethylene response in the absence of ethylene. This characteristic implies that *etr1* mutations are gain-of-function mutations, where the enzyme is locked in a catalytically active state. When ethylene binds to the receptor, this inhibitory activity is expected to be disrupted, allowing the ethylene response to occur. Accordingly, mutations preventing the binding of ethylene would then cause a constitutive inhibition of all ethylene responses.

Figure 2. Order of action of components of the ethylene response pathway in *Arabidopsis*. The pathway was established by double-mutant analysis. EIL3 is homologous to EIN3, EIL1, and EIL2; however, it has not yet been shown to be functional in ethylene signal transduction. The position of AIN1/EIN5, EIN6, and EIN7 in the pathway is unclear. AUX1, AXR1, AXR2, EIR1, and HLS1 control a subset of ethylene responses and may act in parallel to the response pathway defined by the ETR1, CTR1, and EIN2 genes.



Recently, another putative *Arabidopsis* ethylene receptor, ERS (*ethylene response sensor*), was cloned (40), supporting the finding that the *Arabidopsis* genome encodes a complex family of these signal transduction proteins (35). The *EIN4* (*ethylene-insensitive 4*) gene has not yet been isolated. However, as for *etr1* mutations, *ein4* was dominant, and *ein4 ctr1* double mutants had a Ctr1 **phenotype**, indicating that EIN4 also acts upstream of CTR1 (41). Therefore, it is possible that *EIN4* belongs to the same gene family as *ETR1* and *ERS*. It should also be noted that biochemical evidence supports the existence of several ethylene-binding sites that can be classified in two types according to their rate constants for binding (42).

Downstream, the signal is transduced via CTR1, which encodes a Raf-like protein kinase (43). This observation confirms that ethylene induces a transient phosphorylation of several proteins in tobacco (44). All of the *ctr1* mutations found are predicted to disrupt the kinase activity (43). Furthermore, the homology of CTR1 to Raf-1 suggested that a MAP kinase cascade is located downstream (45). A similar combination of a “bacterial” histidine kinase and a Raf-like kinase was found for the high osmolarity glycerol pathway in yeast (46, 47). Signal transduction pathways that include Raf normally contain a MEK protein kinase, which is activated by Raf through phosphorylation (48). Subsequently, activated MEK phosphorylates a MAP kinase that, in turn, phosphorylates several downstream components. Such a MAP kinase was identified for the yeast high osmolarity glycerol pathway (49) and is also expected in the ethylene response pathway (45). To date, ethylene mutants identifying components of a putative MAP kinase cascade have not been isolated; however, screening for triple-response mutants has not yet saturated the genome (34). Given that *ctr1-1* mutations are recessive, it is expected that CTR1 is an inhibitor of the ethylene response in the absence of ethylene. If this were the case, CTR1 may be directly activated by ETR1, which in turn would be active in the absence of ethylene (34).

After CTR1, the ethylene response pathway proceeds with EIN2, followed by EIN3, EIL1, and EIL2. The order of action was based on the fact that *ein2* mutations tend to result in strong insensitivity, in contrast to *ein3* mutants, which remain more responsive to ethylene even in the case of null **alleles** (33, 41). This characteristic was confirmed by the cloning of *EIN3* and the related genes *EIL1*, *EIL2*, and *EIL3*. Overexpression of *EIN3* and *EIL1* in an *ein2* background resulted in a constitutive ethylene response phenotype (33), which can only be explained when EIN3 and EIL1 act downstream of EIN2, so that mutations in EIN2 do not inhibit the overexpression phenotype. *EIN3*, *EIL1*, and *EIL2* encode a novel class of nuclear proteins; and they seem to be regulating the same downstream components, because overexpression in each case complemented *ein3*. These proteins may be directly regulating gene transcription or may interact with transcription factors that have ethylene-regulated genes as targets (33).

A number of weakly insensitive mutants identified genes *AIN1/EIN5*, *EIN6*, and *EIN7*, which act downstream of CTR1, but their position relative to *EIN2*, *EIN3*, *EIL1*, and *EIL2* could not be determined (41, 50). In addition, certain mutations affect a specific part of the ethylene response. For example, the *HLS1* (*HOOKLESS1*) gene controls ethylene-regulated differential growth in the apical hook of etiolated seedlings (51), and the *EIR1* gene specifically regulates the ethylene sensitivity of roots (41).

The genetic analysis of ethylene signal transduction in *Arabidopsis* has been very successful and has resulted in the isolation of several components of the pathway. This research will now have to be complemented by biochemical studies and by detailed analysis of the various protein activities in relation to the existing physiological data on ethylene signaling. Additionally, progress is also expected from the use of new screening procedures to isolate novel ethylene mutants (52, 53). The analysis of light-grown populations of mutant seedlings can be complementary to the triple response screening, especially when considering the close interaction between light and ethylene during plant development (39).

4. Downstream Targets

Downstream from EIN3 and EIL1-3, the signal transduction pathway is expected to diverge into several branches that lead to specific ethylene responses. This view is corroborated by the existence of different cis-acting elements that confer ethylene inducibility in response to different inducing conditions. At least two separate mechanisms exist, one of which involves a *cis* element designated GCC box. In defense-related genes, such as chitinase (54), b-1,3-glucanase (55), and the basic pathogenesis-related (PR1) protein, a common motif was found, with the **consensus sequence** GCCGCC conserved between the *Nicotiana*, *Arabidopsis*, and *Phaseolus* GCC boxes (56). In addition, a GCC box was found in the **promoter** of the *HSL1* gene (51). Strong evidence for a key role of the GCC box in ethylene-induced transcription was given by coupling a 47-bp fragment from a tobacco b-1,3-glucanase gene containing two GCC box elements to the minimal cauliflower mosaic virus 35 S promoter and by demonstrating that it conveys ethylene responsiveness in transgenic tobacco plants (57). Four different cDNAs encoding GCC box-binding proteins were isolated by southwestern screening of a tobacco cDNA expression library with labeled GCC fragment as a probe (57). The predicted *trans* factors were named ethylene-**response element**-binding proteins (EREBPs) and defined a novel class of plant-specific transcriptional regulators. The DNA-binding domain was identified in a region of 59 amino acid residues that was fully conserved in the four EREBPs. Expression of the corresponding genes was ethylene-inducible. Several factors that play a role in development turned out to be members of the EREBP class of transcription factors, including APETALA2 (58), AINTEGUMENTA (59), and TINY (60). More recently, a DNA-binding protein involved in low-temperature expression was shown to be an additional member (61).

A mechanism independent of EREBPs appears to act during senescence of flowers and fruit ripening (62). A detailed analysis was made of the ethylene-regulated transcription of the **glutathione-*S*-transferase** gene *1* (*GST1*) during carnation petal senescence (63). A cDNA encoding a DNA-binding protein that interacts with a region of *GST1* and protects it upon footprinting using deoxyribonuclease 1 was obtained by southwestern screening (64). In tomato ripening, cooperative *cis* elements are required for ethylene regulation of *E4* gene transcription (65).

Finally, it should be noted that all the genes mentioned above are secondary response genes. Primary ethylene-responsive genes, activated within minutes after ethylene induction, remain to be identified.

5. Effects

Ethylene has been shown to participate in a diverse array of plant developmental processes, including seed germination, cell expansion, root initiation, senescence, leaf abscission, and fruit ripening in climacteric fruits (39). In addition, it controls sex determination in some monoecious species. In mango and Bromeliads, it induces flowering. Finally, ethylene is implicated in the control of biotic as well as abiotic **stress responses** (39).

Ethyl Methane Sulfonate (EMS)

EMS is a mutagen and a monofunctional alkylating agent of structure CH_3–CH_2–O–SO_2–CH_3, which reacts with nucleophilic sites on DNA by both S_N1 and S_N2 mechanisms. The S_N1 process involves slow generation of a very reactive intermediate that alkylates DNA with only some discrimination for nitrogen atoms. Thus treatment of DNA or whole cells with EMS leads to many

DNA products. The most significant for mutagenesis is probably O_6-ethylguanine, which base-pairs readily with thymine (1). Using bacteriophage systems, Loveless (2) showed that EMS is capable of producing high mutation frequencies, with little cell killing. The mutations produced were primarily G.C → A.T transitions, and to a lesser extent transitions containing A.T base-pairs at the mutated site, as well as frameshift mutations (3, 4). These latter events may relate to effects on DNA repair processes, while the initial events may be due to the base-pair miscoding potential of the O6-alkylguanine residues (1). EMS has often been considered the mutagen of choice for induced mutagenesis studies, being potent, easy to use, and having a well-documented mutational specificity.

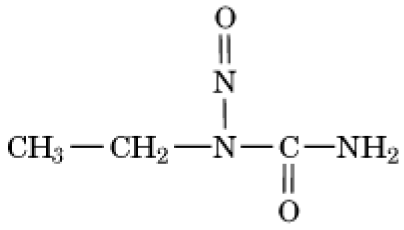
Ethyl-Nitrosourea

1-Ethyl-1-nitrososurea (ENU) is an ethylating and carbamoylating agent that is used as a potent mutagen in the mouse. ENU is widely used in mutagenesis of male (stem cell spermatogonia; differentiating spermatogonia; post-spermatogonial stages) and female (oocytes) mouse **germ cells**, where it introduces intragenic mutations. However, it has also been used for mutagenesis in sperm and embryonic and primordial germ cells, as well as **zygotes**. Because of its germ cell potency, ENU is the most suitable chemical mutagen for the generation of desired new mutations in the mouse. A variety of ENU-induced mouse mutants have been used as animal models for human genetic diseases. To close the **phenotype** gap in the mouse, several ENU mutagenesis programs have been initiated. The phenotype gap describes the fact that, although a great number of mouse mutants exist, there is still little known about the specific phenotypes of these mice.

ENU is a yellow-pink crystalline substance, with a melting point of 103° to 104°C and a molecular mass of 117.10. The structural formula is shown in Figure 1. ENU is not stable under physiological conditions, having a **half-life** of 34.1 min at pH 7.0 and 37°C. Because ENU is sensitive to humidity and light, it is stored below –10°C.

Figure 1. Structural formula of 1-ethyl-1-nitrosourea (ENU).



ENU produces mainly GC/AT transition mutations and, to a smaller extent, AT/GC, AT/CG, AT/TA, GC/CG, and GC/TA base substitutions. These effects are induced by ethylation of different positions within the four bases adenine, cytosine, guanine, and thymine, plus the phosphate groups of the DNA backbone. Additionally, ENU alkylates transfer RNA by the formation of 1,7-diethylguanosine. On removal of the ethyl group from O6-ethylguanine by the O6-alkylguanine-DNA alkyltransferase (AGT), S-ethylcysteine is formed. ENU also reacts with chromosomal proteins (histones) to an even greater extent than other mutagens, eg, 1-methyl-1-nitrosourea or 1-*n*-propyl-nitrosourea. Proteins are carbamoylated by the degradation product of ENU, isocyanic acid. It is likely that carbamoylation of the nuclear proteins influences DNA–histone interactions.

In mouse mutagenesis studies, ENU is the preferred mutagen in spermatogonia, with a linear relationship between the induction of mutations and doses greater than 100 mg ENU/kg. At concentrations lower than 100 mg/kg, mutation induction is nonlinear, as a result of DNA repair processes in stem cell spermatogonia. The major mutagenic lesion is the formation of O6-ethylguanine. However, analysis of mouse hemoglobin mutants Hbb and Hba induced by ENU has shown that base substitutions at A and T can also occur. This contrasts with findings in other systems and emphasizes the complexity of *in vivo* mammalian germ cell mutagenesis. ENU is considered to be a supermutagen in mouse stem cell spermatogonia, inducing recessive mutations with a very high frequency. This mutation rate is maximized by repeated intraperitoneal injections of at least 100-mg ENU/kg at weekly intervals to a total dose of 300- to 400-mg ENU/kg.

Chemical mutagens have also been used to induce mutations in arrested and maturing **oocytes** of female mice. However, the mutation rate is significantly lower than for treated male germ cells. In addition, a high proportion of mutants derived from treatment of oocytes are mosaics, resulting from lesions affecting only one strand of the DNA. Treatment of oocytes also generates approximately 30% of large (multilocus) lesions. Only treatment of post-spermatogonial stages results in a higher percentage (65%) of such large lesions. The differences in the mutagenic potential of ENU on oocytes and stem cell spermatogonia occur mainly because oocytes are nondividing cells until fertilization. Consequently, mutagenesis of zygotes by an exposure of 50-mg ENU/kg at the time when the female genome enters metaphase II results in much higher mutation rates than in stem cell spermatogonia.

Different approaches have to be taken to recover a mutant mouse **genotype**. Dominant mutations can be screened directly in offspring of mutagenized males, whereas recessive mutations can be analyzed using a three-generation breeding protocol. Gene mutations in mouse germ or somatic cells by mutagens have been detected by the specific locus test, dominant cataract method, mouse spot test, micronucleus test, or new test systems like the MutaMouse or Big Blue mouse [see Mouse].

Euchromatin

Euchromatin, which can be distinguished from heterochromatin contains the majority of transcriptionally active DNA. Euchromatin, initially identified cytologically during interphase, appears less condensed and stains less intensely with dyes than heterochromatin. Features of euchromatin may be usefully summarized by comparing the active X-chromosome with the inactive X-chromosome (see Barr Body, X-Chromosome Inactivation).

The euchromatin of the active X-chromosome contains hyperacetylated histones, which indicate potential for transcriptional activity. The active X-chromosome also contains reduced levels of methylated DNA and replicates early in S-phase. Euchromatin is also likely to be globally sensitive to digestion with nucleases such as DNase I (see DNase 1 Sensitivity).

Existence in either the euchromatic or heterochromatic states is not irreversible. This is best demonstrated by experiments in which cells containing nuclei that are predominantly heterochromatic are either transplanted into eggs or fused with other cells that are predominantly euchromatic, to generate a heterokaryon. Experimental results with heterokaryons in which two different somatic cells are fused, so that two different nuclei share a common cytoplasm, and nuclear transplantation experiments using *Xenopus* eggs have been interpreted as providing evidence for continuous regulation of a plastic differentiated state. Implicit in this model is the idea that all genes are continually regulated by *trans*-acting factors that can either activate or repress genes (1). For certain genes this is clearly true. It has also been shown, however, that considerable remodeling of chromosomal structure occurs in *Xenopus* egg and oocyte cytoplasm, during which heterochromatin is converted to euchromatin (2). A similar, albeit less impressive, remodeling of chromosomes occurs in heterokaryons. For example, the nuclei of chicken erythrocytes consist predominantly of heterochromatin containing the specialized linker histone H5. In heterokaryons formed by the fusion of chicken erythrocytes with proliferating mammalian cells, the chicken erythrocyte nuclei once again become transcriptionally active, leading to the appearance of euchromatin (3). This process is accompanied by decondensation of chromatin, enlargement of the nucleus, and the appearance of nucleoli. Transcription and replication of these nuclei are also activated.

Enlargement of the chicken erythrocyte nucleus is caused by a massive, but selective, uptake of mammalian nuclear proteins, including RNA polymerases. The specialized linker histone H5 is partially lost from the chicken erythrocyte nucleus and partially taken up by the mammalian nucleus in the heterokaryon. Histones H2A and H2B also exchange under these circumstances, but not histones H3 and H4. These results might reflect the relative affinity of the histones for DNA and their organization in the nucleosome. This reorganization is independent of DNA replication. Therefore, it is clear that chromosomal structure is quite dynamic, and some histones (H1, H2A, H2B) continually exchange with a free pool of proteins in the cytoplasm.

Several experiments suggest that at physiological ionic strength the linker histone H1 rapidly exchanges into and out of the chromatin fiber (5, 6). Histone H1 is a specific repressor for several eukaryotic genes. Presumably this dynamic property of the chromatin fiber and the nucleosome would eventually allow many *trans*-acting factors to gain access to their cognate DNA sequences. An important and unresolved question is whether this access is unlimited or whether access is restricted by chromosomal organization. It has not yet been quantitatively determined whether the level of transcriptional activity following de novo activation of a gene in a heterokaryon is identical to the transcription of the same gene in a differentiated cell. Of course, in *Xenopus* egg cytoplasm, such equivalent activation must occur for correct development to proceed through to the tadpole stage. Nuclear reprogramming, however, is more rapid here and is likely to be facilitated by DNA replication (4), although massive nucleus-wide remodeling can occur without concomitant DNA synthesis (7, 8).

Euploid

A euploid cell is a cell that has the basic haploid number of chromosomes characteristic of that species or any exact multiple of this haploid number. Contrary situations are explained in Aneuploidy and **Polyploidy**.

Evolution

Darwin defined evolution in the *Origin of Species* as “descent with modification” (1). Although there have been various interpretations, modifications, and additions, the concepts of this definition continue to be repeated as biology develops. It seems likely that Darwin's definition will never fade away. Therefore, it is reasonable to state that evolution is the process in which the structures and functions of organisms are inherited from generation to generation, along with changes at both the morphological and molecular levels.

In his theory, Darwin treated species as populations, and he recognized several features of populations that explain the process of evolution (1). In particular, he noticed that among individuals having variation in characteristics, those having advantageous characteristics, or “fitness,” can survive by producing more offspring of their own. This is the process of natural selection. Darwin already had advanced the concept that organisms have intrinsically inherited material labeled “genetic elements” (and later found to be DNA) and the idea that the variation found among individuals in a species was random, but these were not widely accepted. De Vries proposed the mutation theory, which states that mutations appear suddenly in a population and that species will experience periods of rapid mutation (2). His mutation theory and Mendel's law on inheritance, as well as Darwin's natural selection,were synthesized to create th e synthetic or neo-Darwin theory of evolution (3). The synthetic theory of evolution views evolution in the following way. First, mutation occurs to the genetic material, namely, DNA, in a random fashion. It is a source of genetic variation. and it is heritable to the next generation by Mendelian law. Natural selection then takes place so that individuals having advantageous characteristics can survive in a population, and the offspring have the same type of mutation, which becomes spread in a population. In this way, the genetic composition changes with the time.

The study of molecular evolution is essentially based on the synthetic theory of evolution. However, the development of molecular biology has introduced more detailed and new information on molecular mechanisms for producing genetic variation, which have accelerated the advancement of evolutionary studies. The genome projects currently in progress will give insights to the evolutionary changes of genomes, structures, and functions.

Evolutionary Distance

Evolutionary distance is a distance by which evolutionary closeness or remoteness can be measured quantitatively. Evolutionary distance may be separated into two distinctive levels; one morphological; the other, molecular. In the case of evolutionary distance at the molecular level, the number of nucleotide and amino acid substitutions, as well as immunological cross-reactions, are the most popular measures for evolutionary distance.

The number of nucleotide substitutions is estimated by making pairwise comparison of nucleotide sequences and correcting for multiple substitutions at the same site (see). For correction of multiple substitutions, one needs a model of nucleotide substitution; for example, the one-parameter method invented by Jukes and Cantor (1) assumed that the rates of nucleotide substitutions between all possible pairs of different nucleotides are equal to each other. In this case, the nucleotide substitution is estimated by the equation $K_n = -\frac{3}{4}\ln(1-\frac{4}{3}p)$, where p is the fraction of nucleotide differences. There are many modified and extended versions of this formula. For example, Kimura's two-parameter method was developed under the assumption that the rates of transition mutations and are different (2). In this way, four-parameter method and the six-parameter methods were also developed. The method of maximum likelihood was invented.

The number of amino acid substitutions is also used as a measure of evolutionary distance. Under the assumption that the substitution rates between any pair of amino acids are equal, the number of amino acid substitutions can be given by formula $K_a = -\ln(1-p)$, where p represents the fraction of amino acid differences. It is well known, however, that the substitution rate between a pair of similar amino acids is much higher than that between a pair of nonsimilar amino acids. Although Dayhoff (3) developed the algorithm to estimate the number of amino acid substitutions taking into account the similarity matrix of amino acids, the formula given was very complicated. To minimize this, Kimura (2) invented an empirical formula by adding one simple term, $K_a = -\ln(1-p-\frac{1}{5}p^2)$. Even though Kimura's formula was derived empirically, the substitution number estimated by this formula is very close to Dayhoff's estimate.

Immunological distances can be also used as a measure of evolutionary distance. The measurement of immunological distance uses as a measurement the intensity of immunological crossreaction between antigens and antisera that were prepared from different species (see). It has now become less popular, however, because the numbers of amino acid or nucleotide substitutions contain much more quantitative information.

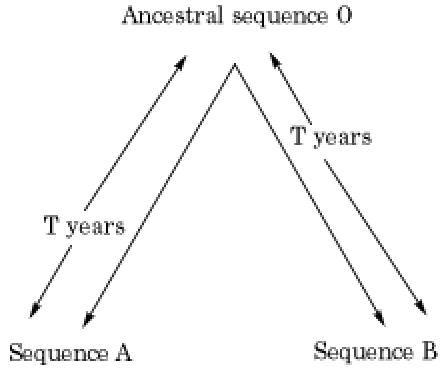
Evolutionary Rate

In the studies of molecular evolution, the rates of nucleotide or amino acid substitutions (per site per year) are usually used as the evolutionary rate (see Sequence Analysis). Compare two nucleotide sequences, A and B, as an example. Denote K_n as the number of nucleotide substitutions between sequences A and B. When the ancestral node, O, of the two sequences A and B is considered, it follows that nucleotide substitutions should have accumulated during the time of lineages OA and OB (Figure 1). If the divergence time between sequences A and B, which is measured by years, is denoted T, K_n is the number of substitutions that have taken place during $2T$. This is because the divergence time of OA plus OB should be equal to $2T$. Thus, the rate of nucleotide substitution (v_n) can be computed by the formula $v_n=K_n/(2T)$. The rate of amino acid substitution (v_a) can be obtained in a similar way: $v_a=K_a/(2T)$. Note that the number of nucleotide and amino acid substitutions can be estimated by a number of different methods (see Evolutionary Distance).

Figure 1. Estimating the rate of evolutionary change in nucleotide or amino acid sequences from the difference between two present-day homologous sequences. Rate of nucleotide substitution: $v_n=K_n/(2T)$; rate of amino acid substitution: $v_a=K_a/(2T)$



Excision Repair

Excision repair (1, 2) is a form of DNA repair involving the removal of a damaged nucleotide from DNA by dual incisions bracketing the damage (3, 4). The multisubunit enzyme system that makes the dual incision is referred to as *excision nuclease* or *excinuclease* (3). The damaged nucleotide is released in the form of an oligonucleotide, and the resulting single-stranded gap is filled in by **DNA polymerase** and sealed by a DNA Ligase. This repair mechanism, which is also referred to as "nucleotide excision repair," is a universal repair system. Excinuclease has been found in all free-living organisms, including Mycoplasma *genitalium*, which is considered a model system for "minimal cell." Although both prokaryotes and eukaryotes carry out excision repair, there are distinct differences in the mechanism in the two systems.

1. Substrate

In most organisms, excision repair is the sole mechanism for repairing bulky DNA lesions. These include the vast number of base adducts formed by polyaromatic hydrocarbons and by chemotherapeutic agents such as cisplatin, mitomycin C, and psoralen, plus the cyclobutane pyrimidine dimers and the [6–4] photoproducts induced by ultraviolet light (see Photolyase/Photoreactivation). Nucleotide excision repair is not, however, restricted to bulky adducts. Alkylated bases including O^6-methylguanine and 3-methyladenine, oxidative base lesions such as 8-oxoguanine and thymine glycols, and even apurinic/apyrimidinic sites (AP sites) are removed from DNA by excision repair (5-7). Mismatched bases are also removed with low efficiency by this enzyme system; unlike mismatch repair, however, the excinuclease cannot discriminate between the correct base and the mismatched base, and this may result in fixation of a mutation (5). The most impressive aspect of the substrate repertoire of excinuclease is that it encompasses essentially all abnormal DNA structures. It must be noted, however, that, with the exception of bulky lesions, all other lesions can be repaired by alternative repair mechanisms, including repair by O^6**-methylguanine DNA methyltransferase, DNA glycosylases, AP endonucleases**, and the mismatch repair systems. It is most likely that excision repair plays a critical backup role for these other repair systems, by repairing nonbulky DNA lesions when the normal repair enzymes are poorly expressed in a certain tissue or when a sudden burst of DNA damage exceeds the repair capacity of the specific repair mechanisms. It has been suggested that the neurological symptoms of xeroderma pigmentosum patients are caused by metabolism-induced nonbulky oxidative damage in brain cells, which overwhelms the main repair system for DNA damage caused by oxidative stress, base excision repair (7).

2. Genetics

Excision repair encompasses three basic enzymatic steps: (i) dual incisions on both sides of the damage, (ii) repair synthesis to fill in the excision gap, and (iii) ligation of the repair patch. Mutations in genes controlling any of these reactions interfere with normal functioning of excision repair. The enzymes carrying out repair synthesis and ligation are not, however, dedicated solely to repair; they also perform DNA synthesis and ligation functions during replication, recombination, and transposition. Strictly speaking, therefore, excision repair genes are the genes encoding the subunits of the excinuclease, which is the enzyme system that removes the damaged nucleotide by dual incisions bracketing the lesion. In *E. coli* and other prokaryotes, three genes—*uvrA, uvrB*, and *uvrC*—are necessary and sufficient for the excision reaction (3). In the yeast *Saccharomyces cerevisiae*, genes in the RAD3 epistasis group (RAD1, 2, 3, 4, 10, 14, 25) are required to reconstitute excinuclease (8). In humans, defects in excision repair cause xeroderma pigmentosum (XP). In this hereditary recessive disease, patients are hypersensitive to sunlight and develop skin cancers, including melanomas, at an early age. In addition, the majority of XP patients exhibit neurological signs and symptoms caused by neuronal death. There are eight XP complementation groups, XP-A through XP-G, plus the XP-variant (XP-V). Patients in complementation groups XP-A to XP-G are defective in removing pyrimidine dimers and other bulky adducts from DNA; in other words, they are defective in excision repair. In contrast, XP-V-deficient individuals exhibit normal excinuclease activity, but are defective in a process called postreplication repair. The XP complementation groups define only seven of the proteins involved in the excision reaction. In addition to these proteins, the replication protein RPA, the recombination protein ERCC1 (which makes a complex with XPF), and the transcription factor TFIIH (which includes the XPB and XPD DNA helicases and four to six additional polypeptides) are also required for dual incisions (9, 10).

There is a one-to-one correspondence between the human and yeast excinuclease genes, and similar homologous genes have been identified in all other eukaryotes tested (11). Hence, it appears that the excision repair genes and mechanism have been conserved throughout the eukaryotic kingdom. In contrast, there is no homology between the excinuclease genes of eukaryotes and prokaryotes. Certain species in the third form of life, the Archaea, appear to have XPD, XPF, and XPG homologues, and certain others have *uvrA, B, C* homologues. Hence, it appears that species in this kingdom might have either the prokaryotic or eukaryotic form of excinuclease.

3. Biochemistry

The mechanism of the excision repair reaction is quite similar in prokaryotes and eukaryotes, even though there is no structural homology between the enzyme systems: Damage is recognized by the enzyme in an ATP-independent manner, forming an unstable DNA–protein complex; then ATP hydrolysis by the proteins within the complex promotes formation of a long-lived preincision complex. Binding of a nuclease subunit triggers dual incisions, which are concerted but nonsynchronous; that is, the 33′ and 5′ incisions nearly always occur in the same DNA molecule, but the 3′ incision occurs first, followed within a fraction of a second by the 5′ incision. Following both incisions, the excinuclease proteins are replaced by replication proteins. In *E. coli*, DNA polymerase I and DNA helicase II (UvrD protein), working together, displace the excised oligomer and the subunits of the excision nuclease that remain in the postexcision complex, and they then fill in the gap (12, 13). In yeast and humans, the replication polymerase d or ε, working together with the polymerase **clamp loader** replication factor C (RF-C) and the polymerase clamp, the proliferating cell nuclear antigen (PCNA), fill in the excision gap (14). The last step is ligation of the repair patch to the parental DNA. A more detailed description of excision repair in *E. coli* and humans is given below.

3.1. Excision Repair in *E. coli* (Fig. 1)

Three subunits, UvrA, UvrB, and UvrC, are necessary and sufficient to carry out the dual incision. Their properties are summarized in Table 1. UvrA and UvrB make a heterotrimer of A_2B_1 composition that, guided by the intrinsic affinity of UvrA for damaged DNA (15, 16), recognizes subtle or gross abnormalities in the duplex structure as damage. Upon binding to the damaged DNA, ATP hydrolysis by UvrA and UvrB leads to local unwinding of the DNA and formation of a stable UvrB–DNA complex, concomitant with dissociation of UvrA from the complex (16). Here UvrA plays the role of a molecular matchmaker (17): Utilizing the energy released by ATP hydrolysis, it brings together DNA and UvrB (a protein with rather weak affinity for DNA), promotes formation of a complex between the two, and then leaves so that the complex can engage in productive reactions. Following dissociation of UvrA, the UvrC subunit binds to the UvrB–DNA complex, and the 3′ incision is made at the fourth or fifth phosphodiester bond from the damage by UvrB, perhaps with the contribution of active-site residues of UvrC (18). After the 3′ incision, the complex undergoes another conformational change that enables UvrC, perhaps aided by residues on UvrB, to make the 5′ incision at the eighth phosphodiester bond 5′ to the lesion (18). After the dual incision, UvrB, UvrC, and the “excised” dodecamer remain in a complex with the duplex. Helicase II (UvrD) binds to this complex and releases the excised oligomer and UvrC. Then, DNA polymerase I binds to the 5′ incision site and displaces UvrB, while simultaneously filling the excision gap. When the gap is filled to the 3′ end, the repaired patch is ligated to the parental DNA. There is no **nick translation** in filling in the gap and, as a consequence, the repair patch size matches precisely the size of the excision gap (13).

Figure 1. Excision repair in *E. coli*. UvrA and UvrB make up the A_2B_1 heterotrimer that, guided by the affinity of UvrA to helical distortion, recognizes DNA damage. Upon recognition, the DNA is locally unwound by the helicase action of the complex and kinked by 130°. Having performed its molecular matchmaking function, UvrA dissociates, leaving behind a stable UvrB–DNA complex that is recognized by UvrC. Upon binding of UvrC, UvrB makes the 3′ incision at the fifth phosphodiester bond and UvrC makes the 5′ incision at the eighth phosphodiester bond. Helicase II (UvrD) releases the excised dodecamer and UvrC; DNA pol I displaces UvrB and fills in the gap, which is ligated.

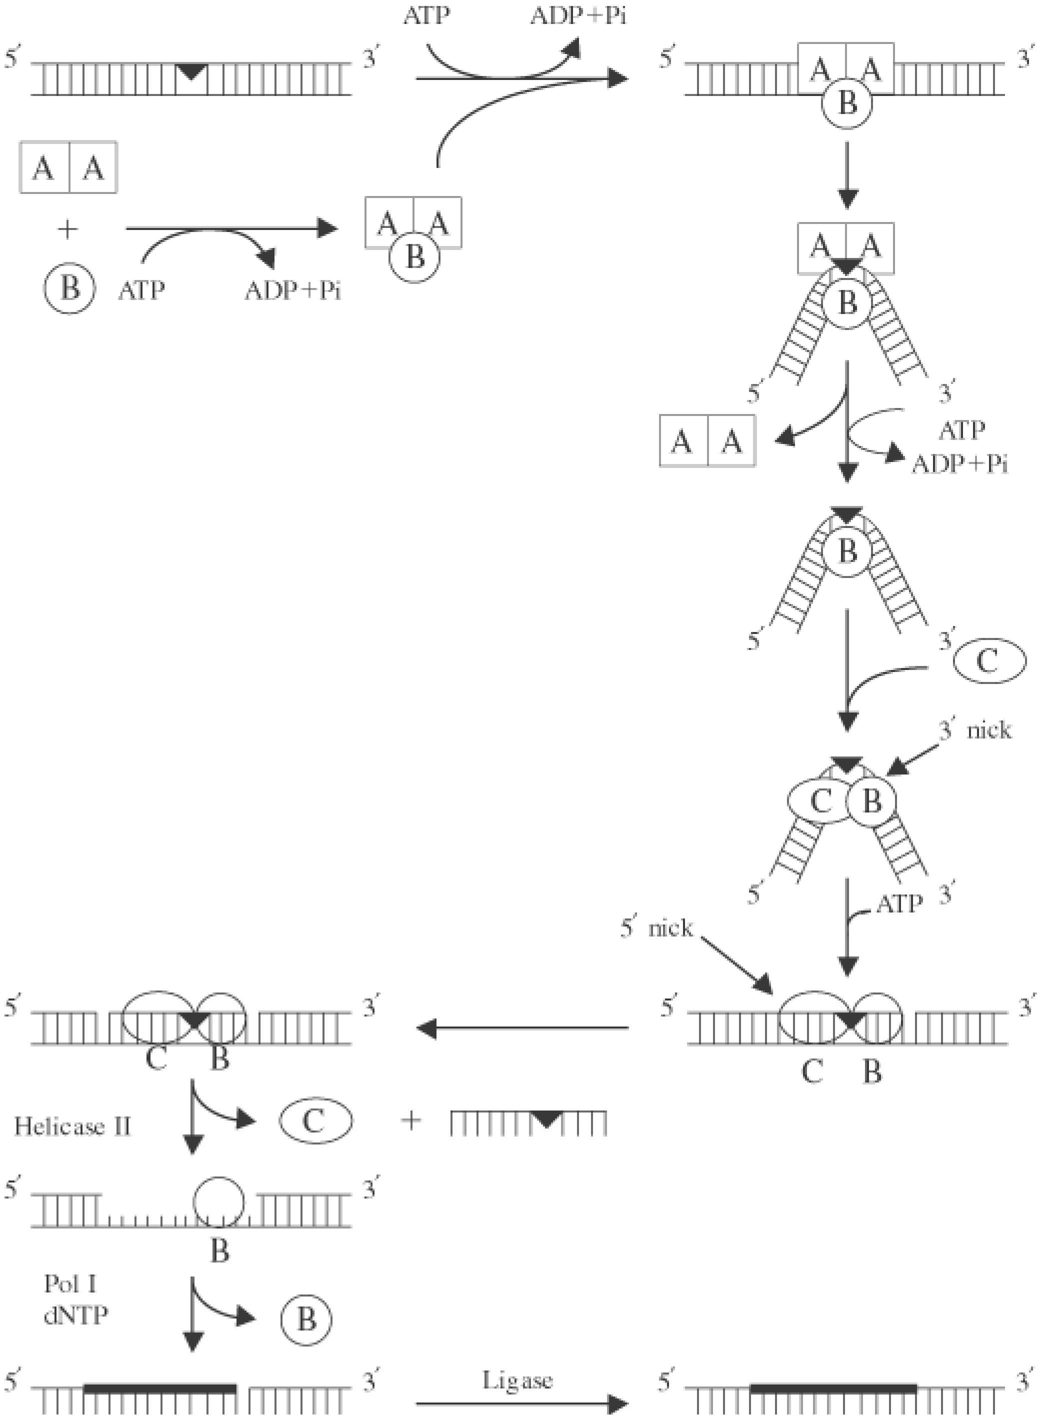


Table 1. Subunits of *E. coli* Excinuclease

Protein	M_r	Sequence Motifs	Activity	Role in Repair
Excision Nuclease Subunits				
I. UvrA	(104)	(a) Walker ATPase (2)	(a) ATPase	(a) Damage

	2			recognition (proximal)
		(b) Zinc finger (2)	(b) Damage-specific DNA binding	(b) Molecular matchmaker

		(d) UvrA superfamily	(d) TRCF binding	
II. UvrB	78	(a) Helicase motif	(a) Latent ATPase	(a) Damage recognition (ultimate)
		(b) Homology to TRCF	(b) Latent “helicase”	(b) Unwinding duplex
			(c) Damage-specific ssDNA binding	
			(d) Binds UvrA	(c) Makes 3′ incision
			(e) Binds UvrC	
III. UvrC	69	(a) Limited homology to UvrB	(a) Nonspecific DNA binding	(a) Induces 3′ incision
		(b) Limited (40 amino acid) homology to ERCC1	(b) UvrB binding	(b) Makes 5′ incision

3.2. Excision Repair in Humans (Fig. 2)

In humans, the excinuclease activity of producing dual incisions results from the coordinated action of 16 polypeptide chains in six repair factors, listed in Table 2 (9, 10). The basic reaction carried out by human excinuclease is the incision of a phosphodiester bond that is 6 ± 3 nucleotides 3′ to the damage and 20 ± 5 nucleotides 5′, followed by release of the resulting 24- to 32-nucleotide oligomers carrying the damaged base (4, 11). The reaction proceeds as follows (19): XPA, RPA, and XPC · HHR23B (20) proteins form a transient complex at the site of the damage. This complex interacts with TFIIH, which is both a transcription factor and a repair factor (21), via XPA and XPC · HHR23B and recruits this multisubunit factor to the lesion site. TFIIH unwinds the duplex by about 5 nucleotides on the 3′ side and 10 nucleotides on the 5′ side of the damaged nucleotides (19); as a consequence, it promotes new DNA–protein interactions that lead to formation of a stable preincision complex (22). XPG has high affinity for TFIIH and enters the preincision complex, either simultaneously with TFIIH or subsequently after being recruited by TFIIH, to form a very stable DNA–protein complex in which the DNA is unwound by 15 to 20 nucleotides. Entry of XPG to the preincision complex is dependent on, and concomitant with, departure of XPC from this complex. Hence, XPC plays the role of molecular matchmaker in human excinuclease. Within this complex, the 3′ incision is made by XPG (23, 24) at the sixth ± 3 phosphodiester bond 3′ to the damage. Thus, in contrast to *E. coli*, the 3′ incision can be made in humans before binding of the subunit that makes the 5′ incision. The XPF · ERCC1 complex is recruited to the repair assembly by the strong interaction between XPA and ERCC1, which is promoted by the presence of XPG within the complex. The XPF · ERCC1 complex makes the 5′ incision at the 20th ± 5 phosphodiester bond 5′ to the damage (24). Assembly of the excision nuclease is a highly concerted reaction, so that under physiological conditions the 3′ incision is rapidly followed by the 5′ incision; therefore, uncoupled 3′ incisions do not accumulate in the cell. The dual incision generates a single-stranded DNA fragment of 24 to 32 nucleotides, which is released from the duplex (excision) (10). This is in contrast to the bacterial system, in which the “excised” oligomer remains in the postincision complex until it is released by a DNA repair auxiliary helicase (10, 12, 13). Following release of the excised oligomer, the gap is filled by DNA polymerases d and ε in a reaction that is dependent on the polymerase clamp, the proliferating cell nuclear antigen (PCNA). The size of the repair patch precisely matches the size of the excision gap, with no gap enlargement on the 5′ side or nick translation on the 3′ side of the gap (25).

Figure 2. Excision repair in humans. XPA, RPA, XPC, and TFIIH recognize damaged DNA. TFIIH unwinds the DNA by about 20 nucleotides, and a transient DNA–protein complex forms. This structure is recognized by XPG, which enters the complex concomitant with dissociation of XPC (molecular matchmaker). XPG makes the 3′ incision at the sixth phosphodiester bond and recruits the XPF · ERCC1 complex, which makes the 5′ incision at the 22nd phosphodiester bond. The excised 27-mer is released along with some of the excinuclease subunits. The excision gap is filled in by DNA Pol ε and ligated.

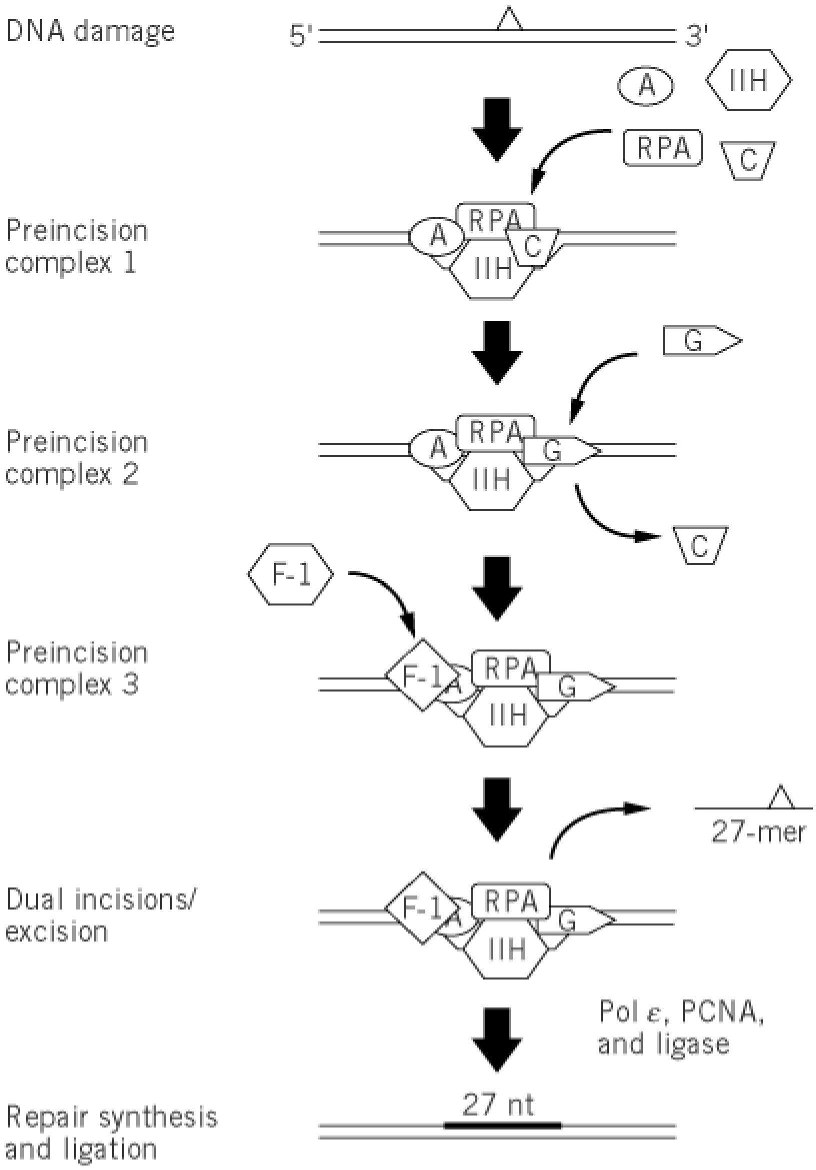

Table 2. Subunits of Human Excinuclease

Factor	Number	Proteins[a]	Sequence Motif	Activity	Role in Repair
I. XPA	1	XPA/p31	Zinc finger	DNA binding	Damage recognition
II. RPA	2	p70		DNA binding	Damage recognition
	3	p34			
	4	p11			

III. TFIIH	5	CPB/ERCC3/p89	Helicase	(a) DNA-dependent ATPase	(a) Formation of preincision complex
	6	XPD/ERCC2/p80	Helicase		
	7	p62			
	8	p44	Zinc finger	(b) “Helicase”	(b) Transcription-repair coupling
	9	Cdk7/p41	S/T kinase

	11	p34	Zinc finger	(d) CAK	
IV. XPC	12	XPC/p125		DNA binding	(a) Stabilization of preincision complex
	13	HHR23B/p58	Ubiquitin		(b) Protection of preincision complex from degradation
V. XPF	14	XPF/ERCC4/p112		Nuclease	5′ Incision
	15	ERCC1/p33			
VI. XPG	16	XPG/ERCC5/p135		Nuclease	3′ Incision

[a] The relative molecular weights of the polypeptides are indicated, for example, by p31 for M_r = 31 kDa, and so on. GTF, general transcription factor; CAK, cyclin-dependent kinase activating kinase.

4. Transcription-Repair Coupling

Transcribed sequences are repaired more rapidly by excinuclease than are nontranscribed sequences, both in prokaryotes and in eukaryotes (26, 27). The open chromatin conformation of transcribed DNA in eukaryotes contributes to the accessibility of the DNA to repair enzymes, and hence it has a faster rate of repair compared to regions of condensed chromatin conformation. The main driving force of preferential repair of transcribed DNA, however, is the mechanistic coupling of transcription to repair. The best manifestation of this active process of coupling is the fact that, although both strands of the DNA in the gene are more accessible because of the open conformation, the transcribed strand is repaired faster than the nontranscribed (coding) DNA strand, which is repaired at essentially the same rate as the rest of the genome (28, 29). Hence it appears that the main cause of repair coupled to transcription is the recruitment of the excinuclease complex to the site of damage (30). Indeed, in both prokaryotes and eukaryotes, the damage-recognition step is the slowest step of excision repair. In the act of transcription, lesions in the template strand block the progression of **RNA polymerase**—hence the stalled complex marks the site of the lesion. In other words, RNA polymerase functions as a surrogate damage-recognition protein for lesions in the template strand. Because specific binding of repair proteins to the damage itself is very slow, due to the fact that lesions removed by excinuclease have very little in common, a stalled RNA polymerase provides a fast damage-locating mechanism and a common structural element (RNA polymerase in elongation mode) for the excision repair system. It appears both in prokaryotes and eukaryotes that a specific protein called transcription-repair coupling factor (TRCF) recognizes both the stalled RNA polymerase and a subunit of the excision nuclease and recruits the repair enzyme to the site of the lesion (30). As a result of high-specificity protein–protein interactions, rather than the low-specificity **DNA–protein interaction**, the rate of repair is accelerated. The transcription repair coupling factor is encoded by the *mfd* gene in *E. coli*, the RAD26 gene in yeast, and the *CSB* gene in humans. The molecular mechanism of transcription-repair coupling is relatively well-understood in *E. coli*, but not in eukaryotes.

4.1. Transcription-Repair Coupling in *E. coli*

The *E. coli* TRCF is a monomer of 130 kDa, and it has helicase motifs, a UvrA binding site in the NH_2-terminal half, and a RNAP-binding region in the middle (31). The protein recognizes RNA polymerase stalled at a lesion and displaces the stalled polymerase, while simultaneously recruiting the A_2B_1 complex to the damage site. The net result is the discarding of the truncated transcript and a substantial increase in the rate of damage recognition. Furthermore, because TRCF and UvrB share the same binding site on UvrA, the TRCF also helps dissociate UvrA from the A_2B_1–DNA complex and facilitates rapid formation of the UvrB–DNA complex (31), which is a prerequisite for binding of UvrC. This is followed by dual incision and the remaining steps of excision repair, which are not rate-limiting. Therefore, acceleration of the damage recognition reaction and facilitation of the dissociation of UvrA by the TRCF results in overall enhancement of the excision repair rate by nearly a factor of 10 relative to excision repair unaided by RNA polymerase and TRCF. The coupling of transcription to repair results in a decline in mutation frequency of ultraviolet-irradiated cells incubated in a medium lacking amino acids prior to plating, compared to cells plated immediately on rich medium (32). In the minimal medium, the mutagenic lesions in the transcribed genes are repaired before giving rise to mutation by DNA synthesis and replication of the lesion. Hence the gene for the *E. coli* TRCF is called *mfd* (mutation frequency decline) (32).

4.2. Transcription-Repair Coupling in Humans

The phenomenology of transcription-repair coupling in humans is similar to that in *E. coli*, although there are some important differences. Humans defective in transcription-repair coupling are afflicted with Cockayne's syndrome, a disease characterized by growth and developmental abnormalities and mild sensitivity to sunlight. Mutations in two genes, *CSA* and *CSB*, give rise to Cockayne's syndrome. Both genes have been **cloned**. The *CSB* gene is a 160-kDa monomer with helicase motifs and appears to be the functional homologue of the *mfd* gene of *E. coli*. The *CSA* protein is a 55-kDa protein with the WD sequence motif, a protein–protein interaction motif. The CSB protein is a weak ATPaseand binds to RNA polymerase II either free in solution or stalled on DNA. Significantly, in contrast to the *E. coli* TRCF, the CSB protein, even in combination with CSA protein, does not disrupt the ternary complex of RNA polymerase II stalled at a lesion (33). CSB does bind to XPA and XPG subunits of the human excinuclease, however, and may play a role similar to that of the *E. coli* Mfd protein in recruiting the repair complex to the site of damage. The mechanistic details of coupling transcription to repair are not known at present.

Both in *E. coli* and in humans, it is the nucleotide excision repair that is tightly coupled to transcription. Recently it was found, however, that transcription also stimulates removal of thymine glycols by base excision repair in a reaction that depends on the XPG protein, but not other subunits of the human excision nuclease system. The mechanistic aspects of this coupling remain to be elucidated.

5. Regulation of Excision Repair

There is a steady-state level of damage production and removal by nucleotide excision repair under physiological conditions. It would be advantageous for the cell if, upon any sudden increase of the genotoxic load, it could increase its repair capacity. Three such regulatory systems have been characterized in *E. coli*: the SOS response, the adaptive response, and the adaptive response to oxidative stress. The SOS response increases the nucleotide-excision-repair capacity of the cell by increasing the level of UvrA and UvrB subunits of excinuclease. Although DNA damage induces a dramatic stress response reaction in human cells, increased repair capacity is not part of this reaction. Human excinuclease genes are not induced at the transcriptional level by DNA damage, nor is the repair activity increased as a consequence of post-transcriptional events. In particular, DNA damage causes hyperphosphorylation of the RPA p34 subunit, but this has no effect on excision repair. Similarly, certain types of damage increase the level of p53 protein by post-transcriptional mechanisms. It has been reported that this increase stimulates repair in certain cell types, but not others. The mechanism of the p53 effect on repair is not known.

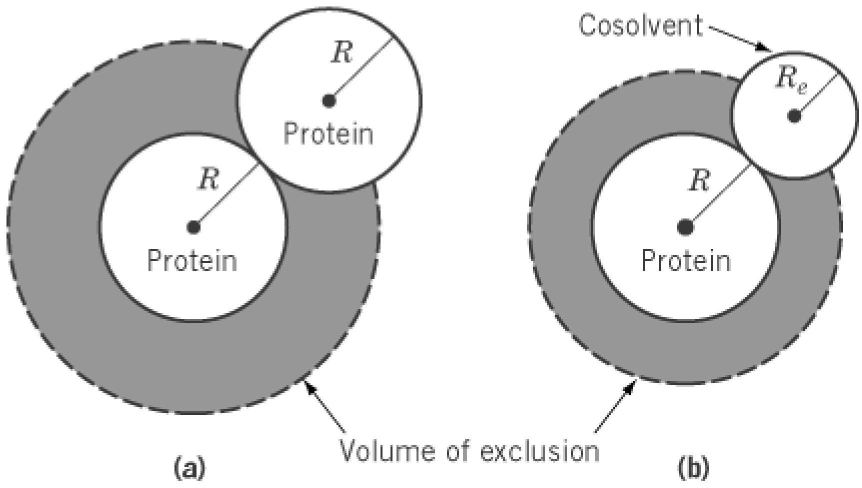
Excluded Volume

No solute molecule in a solution can be present in the same space as any other molecule in the solvent. This volume of occupation is called the excluded volume V_e. The excluded volume clearly depends on the shape and conformation of the solute molecule. In a dilute solution, the centers of two identical rigid spheres cannot be placed closer to each other than a distance twice as great as their radius (Fig. 1a). Thus, any spherical molecule excludes similar molecules from a volume eight times greater than that it physically occupies. However, the excluded volume due to the interaction of any pair of particles is counted twice, so the volume excluded by all the spherical particles in the system is four times greater than their physical volumes.

Figure 1. Schematic illustration of the excluded volume of spherical molecules. (a) Each solute molecule is excluded from the space occupied by other solute molecules in solution. In very dilute solutions, each molecule of radius *R*

contributes a spherical volume of radius 2 R. (b) A cosolvent of radius R_e much greater than that of water statistically cannot be close to a protein molecule due to a steric exclusion principle, resulting in the preferential hydration of protein. [Taken from T. Arakawa and S. N. Timasheff (1).]



The partial specific (or molar) **volume** v_2 is usually taken as the physical volume, so $V_e = 4v_2M_2$ for a spherical solute molecule of molecular weight M_2. This should be a good approximation for globular proteins. A rigid rod-shaped solute is regarded as a cylinder, so its V_e is proportional to the length–diameter ratio of the cylinder. The excluded volume of a flexible polymer depends on its radius of gyration, which is sensitive to the polymer–solvent interaction. In a good solvent, solvent molecules are preferably accessible to a polymer, which extends the chain segment and increases the excluded volume. On the contrary, V_e is small in a poor solvent, which enhances interactions between different parts of the polymer.

Many polymer solution theories have been developed for the excluded volume of flexible polymers. It is important that the excluded volume be directly related to the second virial coefficient of polymer solutions, so this is an apt criterion for the ideality of the solutions. The excluded volume effect is more significant for nucleic acids at lower salt concentration, where the stiffness or persistence length of the chain segment is influenced by polyelectrolyte effects. The excluded volume effect is also the primary basis for the ability of water-soluble polymers, such as polyethylene glycol, to **precipitate** proteins. Preferential Hydration is partly due to steric exclusion, in that a larger cosolvent is more effectively excluded from protein surface than water (Fig. 1b).

The excluded volume effect favors any chemical reaction in which the volume decreases. This includes **ligand binding** by a protein and the association of protein subunits to form oligomers. The equilibrium constant for such a reaction is increased with the increasing concentration of macromolecules in the solution. At high concentrations, such as occur normally in the **cytosol** of cells, such effects can be very large (2).

Exocytosis

Exocytosis occurs in eukaryotic cells when the membrane of a cytoplasmic **vesicle** fuses with the plasma membrane, exposing the contents of the vesicle and the lumenal layer of the phospholipid bilayer to the outside world.

1. Examples of Exocytosis

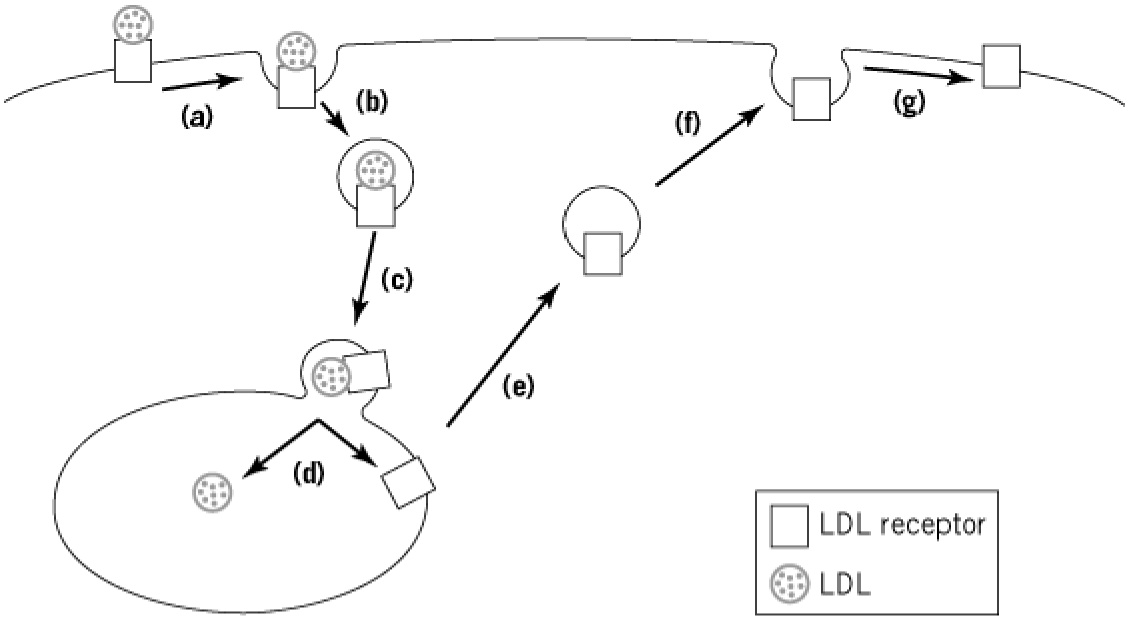
Most cells can secrete proteins (see Protein Secretion). In bacteria, the proteins can be unfolded and then threaded, or translocated, across the plasma membrane. Eukaryotes translocate newly synthesized proteins into an intracellular organelle, the endoplasmic reticulum. Proteins travel from the endoplasmic reticulum by way of the **Golgi complex**, to the plasma membrane. Transport is effected by packaging the newly synthesized proteins in secretory vesicles, which must fuse their membrane with that of the plasma membrane to release their contents to the extracellular space. Thus eukaryotic cells that secrete proteins must have the molecular machinery to allow exocytosis at the cell surface. Exocytosis must be highly efficient, since few secretory vesicles are seen in most cells.

Sometimes newly synthesized proteins passing through the Golgi complex are diverted selectively into cytoplasmic storage vesicles, usually called dense core secretory granules (1). To allow cytoplasmic storage, exocytosis of such secretory granules is inhibited, causing the accumulation of granules in the cytoplasm or along the plasma membrane. Accumulation of storage or secretory granules usually gives cells a characteristic morphology; examples are the granulocytes of the **hematopoietic** system, endocrine and exocrine cells, prefertilization eggs filled with cortical granules, and protozoa such as *Paramecium* and *Tetrahymena* . A signal to the outside of such protein-storage cells can remove the inhibition to exocytosis and trigger a massive efflux of protein, a process referred to as regulated secretion.

Some endocrine cells, such as chromaffin cells or neurons, actively transport small molecules from the cytoplasm into the lumen of the dense core secretory granules, giving them high internal concentrations of both protein and the small molecules (2). The energy for the active transport comes from a proton gradient across the secretory granule membrane (3). This property is also found in bone marrow-derived cells. Mast cells, for example, package histamine to high concentrations inside their secretory granules. When cells of this type undergo exocytosis, along with the stored proteins they release massive quantities of the small molecules, which usually are identical, or are related to, neurotransmitters.

In addition to having a biosynthetic pathway for protein secretion, many eukaryotic cells have an endocytosis pathway that internalizes plasma membrane components and returns most of them to the cell surface (4). This membrane recycling pathway allows a cell to move membrane to a site where it might be more needed; for example, a region of cell growth or migration (5). The recycling pathway also allows a cell to internalize nutrients bound to receptors, to remove the nutrients, and to send the receptors back to the cell surface for more. In the final step, a membrane vesicle on the recycling pathway must fuse with the plasma membrane (that is, it must undergo exocytosis). Thus, the exocytosis machinery is essential for endocytotic recycling, as well as for protein secretion (Fig. 1).

Figure 1. Example of exocytosis in endocytosis. Exocytosis is used in other processes besides delivery of secretory proteins to the cell surface. Here, using the trafficking of low-density lipoprotein (LDL) receptor as an example, we see how exocytosis is an integral part of endocytic trafficking. (**a**) Cholesterol-containing LDLs bind to their receptors and (**b**) are internalized by endocytosis. (**c**) The endocytic vesicles fuse with an endosome (**d**) where LDL dissociates from its receptor. While LDL is eventually broken down for utilization of the cholesterol (**ef**), the LDL receptor is recycled back to the cell surface by exocytosis (**g**) so that it can be reused.



As with protein secretion, there appear to be constitutive and regulated exocytotic steps associated with membrane recycling. Membrane vesicles carrying nutrient receptors, such as the **receptors** for transferrin and low-density **lipoprotein**, fuse rapidly with the plasma membrane, independently of an external signal. In specialized cases, exocytosis is inhibited, causing an accumulation of endocytotically derived membrane vesicles (6). Two examples of such storage vesicles are synaptic vesicles and vesicles storing intracellularly a special type of glucose transporter, GLUT4 (glucose transporter 4) (7). Regulated exocytosis of the endocytotically derived vesicles can occur when the inhibition is removed, by an electrical signal in the case of the nerve cell, and by insulin in the case of GLUT4-storing fat and muscle cells.

Fortunately, similar molecular machinery seems to be used by all forms of exocytosis, regulated or constitutive, biosynthetic, or plasma-membrane recycling. Furthermore, the molecules that regulate exocytosis appear to be conserved, as are the transporters that put neurotransmitters into dense core secretory granules and into synaptic vesicles.

2. Measurements of Exocytosis

A common but crude measure of exocytosis is the appearance in the extracellular medium of the contents of a secretory vesicle that has undergone exocytosis. Thus exocytosis of synaptic vesicles (see Secretory Vesicles/Granules) at the nerve terminal causes release of neurotransmitter, and exocytosis of secretory granules from b-cells of the pancreatic islets of Langerhans releases insulin. Extracellular neurotransmitters and hormones can be measured biochemically, as can the constitutive secretion of enzymes such as invertase by yeast or proteinases by mammalian cells. Biochemical measurements are usually incapable of measuring the kinetics of exocytosis with accuracy.

The release of neurotransmitters, however, can be measured electrophysiologically with much greater precision. Most neurotransmitters activate the postsynaptic target cell by binding to closed **ion channels** and causing them to open. Measurement of current flow through the postsynaptic ion channels gives an almost instantaneous assay of the exocytosis rates in the presynaptic nerve terminal. The precision and sensitivity of electrophysiological measurements, pioneered by Dr. Bernhard Katz and his coworkers at University College, London, allowed detection of a quantum of neurotransmitter release, lasting a millisecond or so, generated by exocytosis of the contents of a single synaptic vesicle. Electrophysiology revealed that exocytosis is very rapid, occurring within 100 µs of a stimulus to the nerve terminal, and that the concentration of the neurotransmitter in the synaptic vesicle is very high, greater than 100 m*M*.

Postsynaptic currents generated by presynaptic release of neurotransmitter accurately measured the exocytosis because the receptor channels were 10 to 20 nm from the exocytosis site. Release of biogenic amines from cells such as chromaffin cells can likewise be measured rapidly and quantitatively by placing a carbon electrode close to the cell and detecting the biogenic amine by its **redox** potential (8). This technique was first applied to exocytosis by Wightman's group and is called amperometry.

Another technique widely used to study exocytosis uses the cell-surface capacitance. The electrical capacitance across the plasma membrane of a cell is proportional to its area. When exocytosis occurs, the capacitance increases because of the addition of membrane (9, 10). The sensitivity of capacitance measurements is such that it can measure the addition of the membrane of a single secretory granule. It cannot yet detect the addition of a single synaptic vesicle, since they are too small (50 nm diameter). When the capacitance signal is big enough, however, the capacitance changes give an instantaneous measurement of exocytosis.

To measure capacitance, a cell must be attached to a “patch electrode,” which allows electrical communication between the salt solution inside the electrode and the cytoplasm of the cell.

Video techniques for quantifying fluorescent markers in cells and recording changes in **fluorescence** intensity as a function of time are becoming increasingly sophisticated. Video-microscopy techniques are used to study exocytosis by loading synaptic vesicles with a membrane-impermeable fluorescent dye (11, 12). Each synaptic vesicle can contain about 30 dye molecules. When the membrane of a synaptic vesicle fuses with that of the plasma membrane, the intensity of the fluorescence decreases by a fixed amount, which can be measured using sensitive detection devices. The dye technique for studying exocytosis was pioneered by William Betz and his colleagues at the University of Colorado.

When the secretory vesicle is big enough, it is possible to observe exocytosis in the light microscope. Some protozoa, such as *Paramecium* or *Tetrahymena*, have large cytoplasmic vesicles, packed with protein, that are docked at the plasma membrane. When the light microscope is used (13), the dense contents of the secretory granules can be seen to disappear when exocytosis is triggered. The convenience of a visual assay for exocytosis has made it possible to screen for secretion mutants in organisms of this type. Exocytosis of secretory granule content can also be detected visually in sea urchin eggs and in some classes of mast cell.

3. Mechanism of Exocytosis

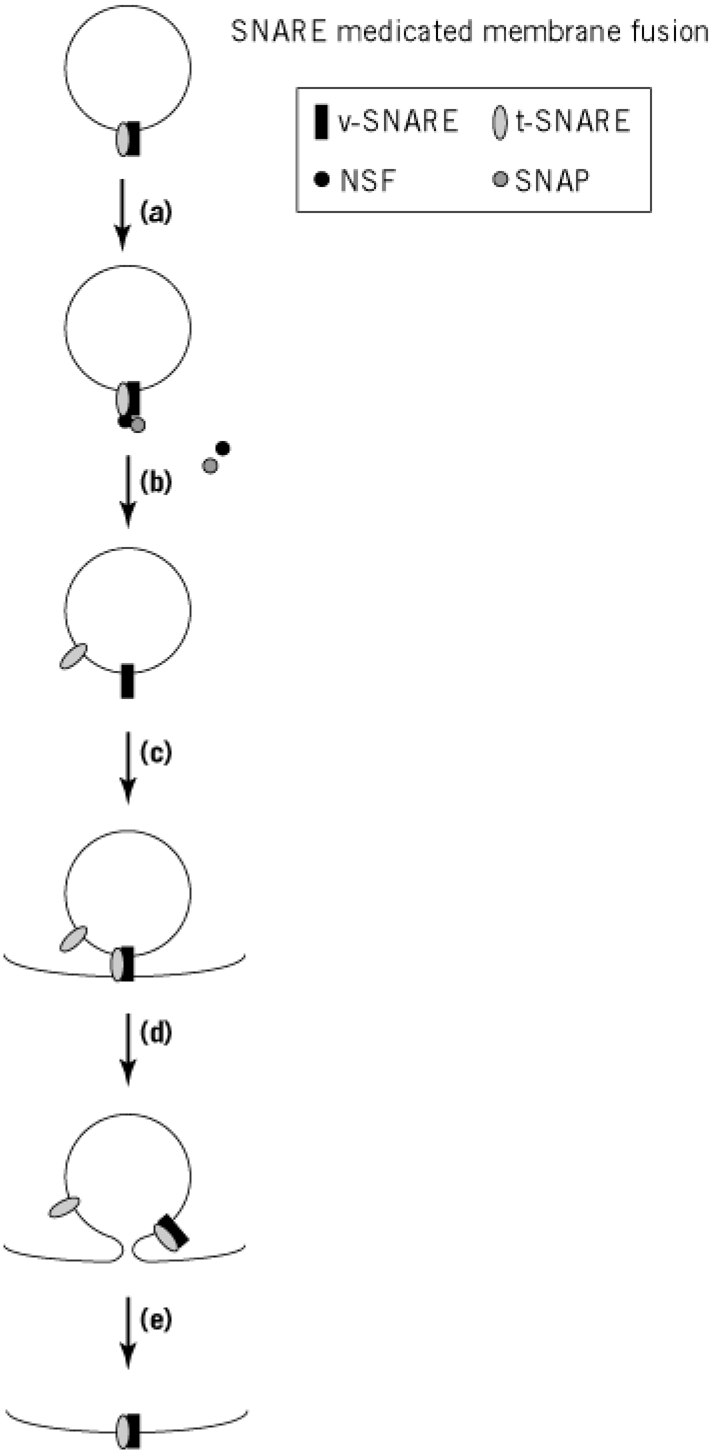
Exocytosis takes place in several stages. First the membrane of the vesicle recognizes the plasma membrane and forms a close association with it. Then the phospholipid bilayers are rearranged so that the membranes of the vesicle and those of the plasma membrane become continuous. Finally, the curved vesicle membrane flattens out, adopting the curvature of the plasma membrane.

Association of the cytoplasmic vesicle with the membrane is sometimes called docking . There are two types of vesicle docking, which sometimes get confused. Since exocytosis is not a random event but requires docking specifically between a vesicle and plasma membrane, the two membranes must recognize each other, presumably through protein–protein interactions. The recognition and fusion steps must be rapid processes in most cells, because few vesicles are seen adjacent to the plasma membrane or in the process of fusion. In contrast, in regulated secretory cells, such as neurons and endocrine cells, the secretory and synaptic vesicles (see Secretory Vesicles/Granules) are in a stable association with the plasma membrane. The long-lasting docking in neurons and neuroendocrine cells is presumably an adaptation that allows very rapid exocytosis in response to an extracellular signal. To avoid confusing the two forms of docking, we discuss first the generic, short-term docking, present in all eukaryotic cells.

Many of the molecular insights into exocytosis derive from mutations that affect protein secretion in yeast (see Sec Mutants/Proteins). Such mutants can have defects in all stages of the protein export pathway. Particularly relevant to exocytosis are the mutations that accumulate post-Golgi secretory vesicles in their cytoplasm. Of the three sets of gene products that affect exocytosis, the ones that are understood in most detail are the SNARE proteins (14). The name SNARE (SNAp REceptor) derives from one of the ways the proteins were discovered (discussed later) and is useful to describe their function. A v-SNARE protein on a vesicle targeted for exocytosis interacts with a t-SNARE on the target plasma membrane. The first identified member of the v-SNARE family was the synaptic vesicle protein initially called VAMP (Veside Associated Membrane Protein) (15) and later synaptobrevin (16). The characteristics of v-SNAREs on secretory vesicles include (*1*) a vestigial lumenal or extracytoplasmic domain at the **C-terminus**, which can be as small as two amino acid residues; (*2*) a single conserved transmembrane domain; (*3*) a highly conserved juxtamembrane region that has the predicted sequence of a coiled coil, and (*4*) a variable **N-terminal** domain. At the cell surface, the v-SNARE is believed to interact with two t-SNAREs. One is a member of the syntaxin family (17), which also has a small lumenal *C*-terminal **domain**, a single transmembrane domain, and a coiled-coil region. The third, a member of the SNAP (synaptosomal-associated protein)-25 family (18), is a cytoplasmic peripheral protein, also with a coiled-coil domain, and is held to the plasma membrane by covalently attached **palmitoyl groups**. The three proteins are believed to form a ternary complex via their helical domains, which facilitates fusion (19). All well-studied exocytotic events, from yeast to mammalian cells, also appear to involve close **homologues** of these three SNARE proteins (20). Even synaptic-vesicle exocytosis, where the fusing vesicle is endocytotically derived, uses SNARE proteins. This has been shown using mutations in Drosophila that affect the neuronal SNAREs VAMP/synaptobrevin or syntaxin (21, 22). The involvement of SNAREs can also be verified by use of bacterial neurotoxins. Tetanus toxin and the botulinum neurotoxins A to G are endopeptidases that specifically hydrolyze the SNARE molecules (23). Exocytosis from nerve terminals and endocrine cells is blocked by these neurotoxins, providing evidence for the involvement of the SNARE complex even in regulated exocytosis (24).

SNARE complexes form readily, even with purified components in the presence of detergents. Given their high proclivity for spontaneous interaction, it is no surprise that the SNAREs appear to be sequestered in complexes that limit their reactivity. The v-SNAREs in synaptic vesicles (VAMP/synaptobrevin) is sequestered by the synaptic-vesicle protein synaptophysin, which has four transmembrane segments (25). The corresponding t-SNARE, syntaxin, is strongly bound to a cytosolic protein, which is called the *sec*1 gene product in yeast and nsec1, for neuronal sec1, in the nervous system (26, 27). Since SNARE complexes are so energetically stable, energy must be expended to separate the SNAREs. Separation of the complex involves the ATPase NSF (*N*-ethyl maleimide sensitive factor) and two accessory proteins, called a- and b-SNAP (28). For NSF to bind, the SNAPs must bind the SNARE complexes. Thus the SNARE complexes received their name, SNAP receptors. The acronym SNAP stands for soluble NSF-acceptor protein in this case. For the t-SNARE SNAP-25, the acronym denotes synaptosomal-associated protein. The identity of the acronyms is coincidental but confusing. Currently, it is thought that NSF might act to dissociate the SNARE complex before fusion, but this is controversial (29, 30) (Fig. 2).

Figure 2. SNARE-mediated membrane fusion. (**a**) NSF and SNAP proteins bind to v-SNARE/t-SNARE complexes on membranes. (**b**) ATP hydrolysis by NSF causes dissociation of the SNARE complex so that (**c**) the v-SNARE can form a complex with a t-SNARE on a target membrane. (**d**) By an unknown mechanism complexes formed with SNAREs on opposing membranes are thought to promote membrane fusion (**e**), ending with the SNARE complex on the same membrane. NSF/SNAP must dissociate the complex again before either of the SNAREs can be reused.



Exocytosis in yeast is also inhibited by a mutation in a small, ras-like, GTPase, the *sec*4 gene product (31). The *sec*4 protein is a member of a large class of small GTPases, the rab proteins. All secretory vesicles have a rab protein. In the case of synaptic vesicles, it is *rab*3A. Rab proteins appear to interact with a complex of proteins, of which the rabaptin complex is the prototype (32). The *rab* system seems to parallel the SNARE system in docking secretory vesicles at the plasma membrane. Thus, yeast mutations in the *rab* pathway can be rescued by overexpression of genes in the SNARE pathway (24). Another protein complex that appears to determine the site of exocytosis in yeast and mammalian cells is the exocyst (33, 34).

The final class of players in exocytosis appears to be related to actin-binding proteins, because mutations in such proteins block protein secretion (see Sec Mutants/Proteins.) The link between membrane traffic and the actin cytoskeleton is currently obscure.

4. Regulated Exocytosis

Regulated exocytosis is found in cells that have a large cytoplasmic pool of secretory vesicles. In the presence of a suitable external stimulus, the probability of exocytosis per secretory vesicle increases manyfold. In neurons and endocrine cells, the external stimulus commonly triggers in regions of the cytoplasm near **calcium channels** a rise of intracellular calcium ions from its normal low level of about 0.1 μM to levels that can range up to 100 μM and greater (35). A common conjecture is that calcium ions bind to an inhibitor of exocytosis, removing the inhibition. Good candidates for calcium sensors in neurons are members of the synaptotagmin family (36). Synaptotagmins have two **calcium-binding** domains on their cytoplasmic regions and can oligomerize. Mutations in synaptotagmin cause loss of calcium-dependent exocytosis (37). Despite the conjecture that the calcium sensor is inhibiting exocytosis, its absence in mutant organisms does not lead to high levels of exocytosis in the absence of stimulation.

Another calcium-binding protein implicated in regulated exocytosis is the CAPS protein (38). Its addition to cell-free preparations of secretory granules docked at plasma membranes restores calcium-dependent release. The CAPS protein binds to the negatively charged phospholipids, the phosphorylated forms of phosphatidyl inositol. Consistent with CAPS having a role in exocytosis is the finding that secretory granules must be primed with adenine triphosphate (ATP) in cell-free systems before exocytosis can occur (39). The ATP is required to phosphorylate the 4′ and 5′ positions on the inositol ring, catalyzed by specific phosphatidylinositol kinases. The phosphorylation state of phosphatidyl inositol is found to determine the efficiency of several membrane trafficking steps (40), but the reason is not yet clear.

The inside surface of the plasma membrane is frequently coated with a layer of cross-linked actin filaments. To allow exocytotic vesicles access to the plasma membrane, it may be necessary to remove or rearrange the subcortical actin layer. Many reports of such rearrangements have been recorded for stimulated endocrine cells. Solubilization of the actin array may be facilitated by an actin-severing protein (41).

5. The Fusion Pore

Electrophysiological measurements of exocytosis have predicted that the merging of secretory-vesicle membrane with plasma membrane is preceded by the formation of a channel, the so-called fusion pore (42). One line of evidence for such a pore comes from amperometry. When the release of a biogenic amine from a secretory granule is measured, the massive efflux of granule content is preceded by a small "step" of amine release like that predicted if the inside of the secretory granule were connected to the outside by a small channel or hole of nanometer diameter (43). A second indication of the reversible formation of a channel is "capacitance flicker." Exocytosis can be detected as a sudden increase in membrane capacitance; occasionally, however, a sudden increase is followed by a sudden decrease of exactly the same amplitude. These data are consistent with a transient and reversible fusion of secretory granule and plasma membranes. A third line of evidence supporting the idea of a fusion pore is that the current that flows through the fusion pore as the secretory-granule membrane discharges its membrane potential. From measurements of the conductance of the channel, estimates of its size can be made. When it first forms, the fusion pore seems to form a channel of about the size of a large ion channel.

The molecular nature of the fusion pore, if it exists, is unclear. Fusion between a membrane-covered virus and the plasma membrane has been studied extensively for influenza virus. The viral protein triggers fusion by undergoing a conformational change that extends a 16- to 23-amino acid residue "fusion peptide," a **hydrophobic** sequence that is essential for fusion (44). Extension of the fusion peptide requires a helical hairpin to be converted to a triple-stranded coiled-coil domain (45). The three SNARE proteins, VAMP/synaptobrevin, syntaxin, and SNAP-25, have coiled-coil domains that initiate oligomer formation. VAMP also has a small alpha-helical domain that resembles a fusion peptide. There is no experimental evidence, however, that the SNAREs form a fusion pore. Nor is it clear whether the initial hole is exclusively due to rearrangement of the lipid bilayer or to a proteinaceous channel. In influenza virus-mediated fusion, a hemifusion state is formed if the transmembrane tail of the fusion protein is replaced by a glycophosphatidylinositol anchor (46). This was interpreted to mean that the hemifusion state is an intermediate in virus-induced fusion.

Logically, membrane fusion must be initiated by the formation of one or several small holes through the membrane of both the exocytotic vesicle and the cell surface. Electrophophysiologically, the evidence for the reversible formation of such a hole is excellent. As yet, molecular knowledge lags far behind the physiology.

Exon Shuffling

When intervening sequences were discovered to split eukaryotic **genes** into segments coding for protein, the intervening sequences were named *introns* and the coding regions, exons (1) (see **Introns/exons**). Since then, heated discussion has ensued concerning the evolutionary origin and biological significance of introns in eukaryotes, because almost all of the prokaryotic genes lack introns, and the introns have no known role.

Gilbert (1) proposed a scenario in which introns simply connect neighboring exons to each other in the genome; consequently, genetic recombination would not harm the coding portions of genes if it took place within the intron regions. Such recombination within introns would facilitate the shuffling of exons, to create new exon combinations and lead to the emergence of new genes with new functions. This is the “exon shuffling” theory (see also Gene Splicing).

Exon shuffling is related to the present controversy regarding the “early” versus “late” intron theories. The early-intron theory maintains that introns existed in the ancestor genomes of prokaryotes and eukaryotes, but that all those in prokaryotes were deleted by some unknown mechanism. On the other hand, the late-intron theory contends that introns could have been inserted, similar to transposable elements, into eukaryotic genomes quite recently, at least after the **divergence** of eukaryotes and prokaryotes. This theory is based on the observation that there are many genes in which the locations of introns are not conserved among vertebrates, invertebrates, and plants (2).

If the early-intron theory is correct, exon shuffling probably had a significant role in the creation of new genes. If the late-intron theory is right, however, exon shuffling might have been significant only after the introns were inserted. The controversy remains to be resolved.

The **domain** shuffling theory is similar to the exon shuffling theory, but in sharp contrast, maintains that the unit of shuffling during evolution is a functional protein domain, not an exon. The functional domain does not necessarily correspond to the exon. Although there are some cases where it does, most functional domains consist of more than one exon or occupy only part of a large exon. For example, the Kringle domain is known to have been shuffled as a unit during evolution. The Kringle domain is a characteristic supersecondary structure frequently found in the serine proteinases involved in the blood clotting system. Even though the Kringle domain is, in most cases, split into three exons by two introns, those found in various proteins are almost always complete forms and never found as parts corresponding to the exons. At present, however, there is no known genetic mechanism for facilitating domain shuffling, and domain shuffling seems to have taken place in prokaryotes as well (3).

Expansibility

The expansion of a protein molecule with increasing temperature reflects its atomic packing and flexibility, as does its compressibility with increasing pressure. X-ray crystallography studies indicate that both the crystal lattice and protein structure expand with increasing temperature. For myoglobin, a volume expansion of 5% of the crystal lattice and 3% in the protein molecule occurred as the temperature increased from 80 to 300 K, which corresponds to a thermal expansion coefficient of 1.15×10^{-4} K^{-1} (1). **Ribonuclease A** exhibited a smaller expansion 0.9% for a temperature increase from 98 to 320 K (2). It is likely that a more compressible protein will also be more thermally expansible. It is believed that the observed expansions of proteins with temperature are due to motions of secondary structure and exposed surface loops and to a decrease in local atomic packing density (see van der Waals Surface, Volume). Thermal expansion of a protein is not uniform over the molecule, just as in the case of contraction by pressure.

It is known that the apparent and partial specific volumes (v_2) of proteins in aqueous solution are linearly dependent on temperature in the range of 4 to 45°C. Positive values for $d\,v_2/dT$ of (2.5 to 10×10^{-4} $cm^3\ g^{-1}\ K^{-1}$ have been reported, with the majority lying between (3.5 to 5) $\times 10^{-4}$ $cm^3\ g^{-1}\ K^{-1}$. These values are greater than the expansion coefficient found for the X-ray crystal structure.

If the thermal expansion of crystal structure is caused by the cavities, the positive values of dv_2/dT for folded proteins would be dominantly attributed to the hydration effect, ie, a volume increase due to dehydration of protein molecules on elevating the temperature (see Partial Specific (Or Molar) Volume). The temperature effect of v_2 is still pronounced for amino acids and small **peptides**, probably due to a large dehydration effect: dv_2/dT is 1.3×10^{-3} cm^3 g^{-1} K^{-1} for glycine and 7.3×10^{-4} cm^3 g^{-1} K^1 for triglycine. In this sense, an unfolded protein is expected to have a larger dv_2/dT value than a folded one because the accessible surface area (amount of hydration) increases on denaturation. Hawley reported that dv_2/dT increases by 0.18×10^{-4} cm^3 g^{-1} K^{-1} and 0.51×10^{-4} cm^3 g^{-1} K^{-1} on pressure denaturation of ribonuclease A (pH 2.0) and chymotrypsinogen (pH 2.07), respectively (3). However, the temperature effects on v_2 at high pressures and high concentration of denaturants, above where conformational changes or denaturation take place, are complex since the volume change of hydration Dv_{sol} may involve the contributions of changes in water structure and preferential solvent interactions.

Expressed Sequence Tag

An expressed sequence tag (EST) is a short stretch of **DNA** sequence that is used to identify an expressed **gene**. Although EST sequences are usually only 200 to 500 nucleotides in length, this is generally sufficient to identify the full-length **complementary DNA** (cDNA). ESTs are generated by sequencing a single segment of random **clones** from a **cDNA library**. A single sequencing reaction and automation of DNA isolation, sequencing, and analysis have allowed the rapid determination of many ESTs. Now, the majority of the sequences in sequence databases are ESTs. Although most ESTs have been isolated from humans, a large number of ESTs have been isolated from model organisms, such as *Caenorhabditis elegans* (1), *Drosophila*, rice (2), and *Arabidopsis* (3). ESTs are also being isolated from more exotic organisms, such as *Entamoeba histolytica* (4) and *Leishmania major promastigotes* (5). ESTs have numerous uses, from **genetic mapping** to analyzing gene expression, and the number of ESTs isolated from different organisms will continue to rise rapidly.

1. Generation of ESTs

The most important step in generating of ESTs is producing a cDNA library. First, messenger RNA (mRNA) is extracted from the material being studied and is used as a template by **reverse transcriptase** for cDNA synthesis. Then the DNA is **cloned** into a suitable **vector** to produce a cDNA library. Random clones are isolated from the library, and one or both ends are sequenced by single-pass sequencing.

The source of the mRNA is an organism, tissue, or cell line grown under normal conditions or treated with hormones, drugs, heat, etc. The source of the starting material depends on the type of genes to be identified and the reason for generating the ESTs. EST analysis is used to find previously undiscovered tissue-specific **genes** or to tag as many different expressed genes as possible. It is also used to examine the relative abundance of expressed genes. Libraries used for the first two types of studies are often normalized, so that highly-expressed genes and rare genes are represented more equally in the library or subtracted to reduce or eliminate the number of highly abundant clones (see Subtractive Hybridization). An alternative to normalizing or subtracting libraries is to sequence a small number of ESTs from as many different tissue types and treatments as possible because different types of genes are highly expressed under different circumstances.

It is useful if the cDNAs in the library are cloned directionally, so that ESTs are isolated specifically from either the 5′- or the 3′-end of the cDNA. 3′-ESTs often represent the 3′-untranslated region of the mRNA and are used to separate members of gene families that have similar coding sequences, whereas 5′-ESTs generally represent coding sequence and give a better idea of the type of gene being expressed.

If the starting material for mRNA isolation is limiting, cDNA minilibraries suitable for EST analysis are generated by arbitrarily primed RT-PCR (6).

2. The Multitudinous Uses of ESTs

2.1. Obtaining Full-Length cDNAs from ESTs

An EST is useful because it represents an expressed gene. Once an EST has been identified, it is usually straightforward to obtain the full sequence of the "tagged" cDNA. Some sources provide EST DNA that is used in further studies. Alternatively, the EST sequence is used to design PCR primers or hybridization probes for cloning the full-length cDNA (see Cloning). Another strategy is "virtual cloning", where computer analysis is used to array **homologous** ESTs and any other sequences from the same gene (7). Once isolated, then the full-length cDNA is used in mutagenesis, **transgenic**, and expression studies to analyze the gene function.

2.2. Genome Analysis and Mapping with ESTs

Many organisms, for example, humans, *Arabidopsis*, and *C. elegans*, will have their entire genomic DNA sequenced in the relatively near future, and certain genomes, such those of *Saccharomyces cerevisiae* and various **bacteria**, have already been entirely sequenced. In the meantime, EST analysis provides a rapid way to identify expressed genes. Now, it is not possible to predict coding sequences in genomic DNA reliably from sequence information alone. Even when complete genomic sequences are available, ESTs are useful in analyzing the genomic sequence, for example by verifying putative coding sequences and confirming **intron** and exon boundaries. They are also helpful in distinguishing pseudogenes from real genes and in identifying **alternatively spliced** transcripts, which could never be predicted from the genomic sequence alone.

ESTs are also used to provide markers for genomic mapping by converting them into "sequence tagged sites" (STS). An STS is a set of PCR primers that identifies a single gene, and STS primers are designed from the EST sequence (8). An STS can be mapped to a specific region of the genome, and if DNA contigs are available for the genome under study, the STS can specify a genomic clone. Mapping of ESTs to genomic clones will provide a map of expressed genes for each clone and, in humans, these maps can be used to identify candidate genes for inherited human diseases that have been mapped to chromosomal regions by pedigree analysis.

2.3. Gene Expression Studies Using ESTs

As mentioned previously, gene expression in different organisms, tissues, or cells, before or after different treatments, can be studied by surveying ESTs isolated from libraries created from different mRNA sources. If nonnormalized and unsubtracted libraries are used to isolate ESTs, the frequency of isolation of a particular EST indicates the relative message abundance of the tagged gene (9). It is also possible to isolate novel tissue-specific genes by merely searching EST databases (10).

2.4. Rapid Identification of New Genes and Gene Families

As of 1998, the majority of ESTs in the databases represent genes that have not been previously identified. Traditionally, gene sequences have been obtained one at a time, first by isolating a protein, by identifying a mutant and cloning the mutated gene by complementation, or by positional cloning (see Cloning). Compared with these methods, generating ESTs is a very rapid method for identifying new gene sequences.

EST database searches also provide a rapid method for finding genes similar to a gene of interest. Methods, such as PCR, using degenerate primers, or **hybridization** at low stringency also enable the identification of similar genes, but these methods are often not as successful as database searches. Databases can be searched by using either nucleic acid sequences or protein sequences. Protein comparison searches are often more fruitful because protein sequences are better conserved. Additionally, databases can be used to search for similar genes among all the represented organisms simultaneously, thus facilitating comparative studies. Once similar genes have been identified, they can be translated into protein sequences and the database searched again to find the sequences most similar to this second set of genes. Thus it is possible to identify large families of related genes rapidly by EST database analysis.

2.5. Using ESTs to Clone Specific Genes

In humans, one main goal of genomic research and EST analysis is to aid in identifying and cloning human genes related to diseases. Various groups have begun to look between species to find candidate human disease genes. One group used an EST database search to identify human cDNAs homologous to previously cloned *Drosophila* genes that have an interesting developmental mutant **phenotype** (11). Then the human sequences were mapped by several methods, and the positions of the cDNAs compared with the map positions of human disease genes. Some of the cDNAs mapped to regions containing human disease genes that cause symptoms similar to the defects in the corresponding *Drosophila* mutant genes. Thus these cDNAs are candidates for the disease genes, and further studies can be undertaken to determine whether the cDNAs and the disease genes are one and the same. Another group is systematically identifying novel human ESTs related to known genes in a variety of model organisms (12). Then the ESTs are mapped to both human and mouse maps. Again, such genes can provide candidates for human disease genes, thereby potentially speeding up their cloning and aiding in their analysis by providing a model system for further studies.

ESTs are extremely useful tools for gene analysis in organisms besides humans, although to date most effort has been spent identifying human ESTs. In any organism where a mutation has been mapped to a certain genomic region or to a genomic clone, ESTs mapping to the same region identify candidate genes. In more unusual organisms, where few genes have been previously isolated, EST analysis provides a rapidly generated survey of the types of genes expressed by the organism and is used, for example, to isolate novel genes from pathogenic organisms (4, 5). In **plants**, the weed *Arabidopsis* is often used as a model system for gene isolation. EST database searches provide a rapid means of isolating similar genes from important crop plants, in much the same way that interesting genes from model systems are used to isolate corresponding genes from humans and mice. STSs from ESTs representing important plant genes could be used as markers in selective breeding programs.

3. Some Recent Twists on EST Generation

A technique termed *serial analysis of gene expression* (SAGE) has recently been developed to perform some of the functions of EST analysis (13). Short diagnostic sequence tags (9 to 10 bp) are randomly isolated from a tissue, concatenated, cloned, and sequenced. This method allows extremely rapid identification of thousands of genes and is used either to identify new genes or to analyze relative levels of gene expression. SAGE may prove quite useful in rapid surveys of gene expression differences between tissues or between developmental and disease states. ESTs still have many advantages over this method, however. The production and concatenation of the tags are somewhat cumbersome, and the small amount of sequence information in the tags precludes many of the interesting uses that have been found for ESTs.

An ingenious method has been developed to tag promoter-proximal sequences in mouse embryonic **stem (ES) cells** . Using a gene-trap retrovirus shuttle vector (14). A large number of ES cells were selected for neomycin resistance, indicating that the retrovirus containing a promoterless neomycin-resistance gene had inserted next to the promoter of an expressed gene. These neomycin-resistant ES cells were cloned. Some cloned cells were frozen and others used to extract DNA. The DNA flanking the retrovirus was isolated and sequenced to provide a *promoter-proximal sequence tag* (PST). PSTs are ESTs derived from genomic DNA rather than cDNA, and they are used similarly to screen sequence databases and to make STSs for mapping. However, they also have an additional advantage. Each PST represents a specific ES cell line harboring a potentially disrupted gene, and mutant ES cells are used to generate mutant mouse strains (15). PSTs thus allow rapid progression from sequence analysis of a gene to analysis of its function in a mutant mouse.

4. The Future of ESTs

ESTs have already proved useful in rapidly identifying novel genes, providing markers for mapping, providing candidate disease genes, and for analyzing gene expression. Because the generation of ESTs proceeds faster than the functional identification and analysis of the genes that they represent, much future research will be directed toward determining functions for the newly identified genes and gene families. The cDNAs identified by EST analysis can be used in standard experiments designed to elucidate their cellular and developmental functions. As so many novel genes have been and are being identified, some researchers are looking for more rapid ways to analyze function or expression of large numbers of genes. A recent innovation is the use of cDNA (16) or oligonucleotide (17) microarrays that represent large numbers of genes or whole genomes. Hybridization to microarrays of labeled mRNA samples isolated from different tissues, mutant backgrounds, or developmental or growth states allows analysis of changes in gene expression for a large number of genes simultaneously. Other researchers have developed a system for monitoring the effects of gene disruption on growth in yeast for many genes simultaneously (18). The development of additional techniques for global analysis of gene expression and function will be essential for rapidly characterizing the wealth of new genes identified by EST studies.

Expression Libraries

An expression library is a collection of DNA molecules that can be expressed *en masse* through enzymatic methods to yield a population of DNA, RNA, or protein products that can be screened for individuals displaying desirable properties. The DNA sequences within the library can be of natural or synthetic origin. The advantage of screening expression libraries constructed from the genome or complementary DNA (see Genomic Libraries and cDNA Libraries) is that the expression products derived are usually biologically relevant. In contrast, synthetic DNA expression libraries may yield expression products that are not found in nature. However, there are two major advantages to screening synthetic DNA expression libraries. First, the expression products that are selected for a particular purpose may perform better than natural biopolymers. Second, a great deal of information is obtained by screening synthetic libraries of known composition, because the distribution of sequences selected compared with those not selected provides structure–activity relationship (SAR) data describing molecular interactions characteristic of the target being screened.

Expression libraries contain genomic or cDNA sequences cloned into expression vectors, which are plasmids or bacteriophage genomes that have been engineered to contain regulatory elements governing expression of foreign DNA inserts. For example, vectors containing a **promoter** sequence of **T7 phage** will initiate RNA transcription at a fixed position and direction. Once transcription is initiated, the T7 **RNA polymerase** will continue making an RNA copy of the DNA coding strand, including any foreign DNA that is encountered, in progressive fashion until a T7 terminator sequence is read (by convention, the coding strand is the top strand in a 5′ to 3′, left to right, double-stranded gene depiction). The resulting polymer that is formed is thus an RNA transcript of the DNA template. Such a DNA library can only be expressed in cells that also contain the enzyme T7 RNA polymerase. Typically, the gene encoding the T7 RNA polymerase is engineered to be inducible by the addition of a soluble sugar analogue, such as **IPTG**, so that library RNA expression can be co-induced at appropriate times in the screening process. RNA expressed from DNA libraries may be the intended chemical entity to be screened, or the RNA molecules may serve as templates for the translation of protein products. If the expressed RNA molecules contain suitable prokaryotic and/or eukaryotic ribosome recognition sequences, ribosome-mediated **protein biosynthesis** will initiate at an AUG start codon. The result will be a protein molecule encoded by the original DNA template. In general, it is easiest to screen protein expression libraries when the transcription and translation occur *in vivo* using a suitable host cell. However, in certain circumstances it may be advantageous to perform the protein expression *in vitro*, using cell-free translation extracts that contain the requisite protein synthesis machinery. In either case, the population of expressed proteins can be screened for any of a range of phenotypic properties, including antibody reactivity, affinity to a target molecule, or catalysis.

The ability to engineer, at the DNA level, additional useful sequences into protein reading frames provides a powerful means of generating **fusion proteins** with desirable properties. Modern expression libraries contain many types of tags or fusion domains that facilitate **library** screening and downstream manipulation of individual clones. There are at least four types of protein fusion moieties commonly available. This list is not intended to be exhaustive but instead to illustrate the power of the technology. First, epitope tags are typically short amino acid segments fused to either the *N*- or *C*-terminus of the cloned protein. An epitope tag provides ready-made immunoreactivity to the cloned gene product through commercially available antibodies. Epitope tags are useful in both detection and purification of cloned gene products. Second, like epitope tags, affinity tags are amino acid sequences fused to either terminus of the cloned protein. The most common use of affinity tags is in affinity purification, although detection can also be performed through the tag. One commonly used affinity tag is the 6-His tag, which is simply a sequence of six **histidine** residues that bind with high affinity and specificity to nickel; therefore, 6-His fusion proteins can be purified from all other cellular proteins by affinity chromatography over nickel-agarose (1). Third, domain tags are independent units of structure and function that maintain or enhance certain activities of the proteins from which they were derived. Domain tags are useful for protein purification and detection. Common examples include **glutathione-*S*-transferase** (GST), which enables facile purification over glutathione-agarose resins (2), and **green fluorescent protein** (GFP), which is an autofluorescent protein that can be monitored in both quantitative and localization assays (3). Fourth, cleavage sequences are commonly introduced between the fusion tags and the cloned genes so that the tags can be removed following affinity purification. Cleavage elements are most commonly **proteinase** recognition sequences, although self-cleaving protein domains called inteins are becoming increasingly available (4) (see Protein Splicing).

A special type of cDNA expression library called the **two-hybrid system** (5) deserves special mention because it illustrates a powerful coupling of molecular engineering with combinatorial approaches to investigating protein function. The purpose of screening two hybrid libraries is to discover proteins that interact with a protein of interest. The system is termed “two-hybrid” because two separate plasmids have been engineered to express hybrid versions of transcriptional activators such as the yeast GAL4 protein. Normally, the GAL4 protein contains both a **DNA-binding** domain and a transcriptional activation domain. When intact GAL4 binds to its DNA recognition sequence, the transcriptional activation domain promotes transcription of adjacent gene sequences. In the two-hybrid system, the GAL4 DNA binding domain is expressed as a hybrid with the protein of interest, termed the “bait”. A second vector containing the GAL4 transcriptional activation domain is used to construct a library of cDNAs such that each cDNA is expressed as a hybrid protein fused to the GAL4 transcriptional activation domain. Neither of the hybrid GAL4 domains alone can promote transcription of a reporter gene, nor do they interact spontaneously. However, if one of the proteins expressed as a fusion with the GAL4 transcriptional activation domain happens to form a **protein-protein interaction** with the bait protein, the two GAL4 domains are brought into proximity where they can activate expression of a reporter gene. Many variations of this powerful method have since appeared, including two-hybrid systems for mammalian cells (6) and three-hybrid systems for detecting protein-nucleic acid interactions (7).

The other major type of expression library uses synthetic DNA to express DNA, RNA, or protein products for screening. Expression of RNA and protein can be mediated through cloning vectors in similar fashion to the cDNA expression libraries. Examples of cloned synthetic DNA expression libraries include **phage display** and protein engineering projects in which portions of a protein-coding sequence are randomized synthetically to derive novel proteins with altered properties. Alternatively, the synthetic DNA library may be maintained as oligonucleotides that are replicated through **PCR** or some other enzymatic amplification strategy. Expression of these types of libraries always occurs *in vitro* and usually employs a synthetic phage T7 promoter to mediate expression of RNA. Thus, RNA copies of the DNA library are produced upon incubation with purified T7 RNA polymerase and ribonucleoside triphosphate (rNTP) building blocks. The resulting single-stranded RNA can be screened for affinity to specific molecular targets (RNA aptamer libraries) or for catalytic activity (ribozyme libraries). Similarly, single-stranded DNA copies can be prepared from DNA aptamer libraries by removing one of the two DNA strands, which has been previously tagged with biotin, by **denaturation** and affinity chromatography over a streptavidin matrix. DNA aptamers are similar in many ways to RNA aptamers, but they are more resistant to chemical and enzymatic degradation. Finally, peptide aptamers can in principle be prepared by *in vitro* translation of RNA transcripts from oligonucleotide libraries, although this method is not commonly employed.

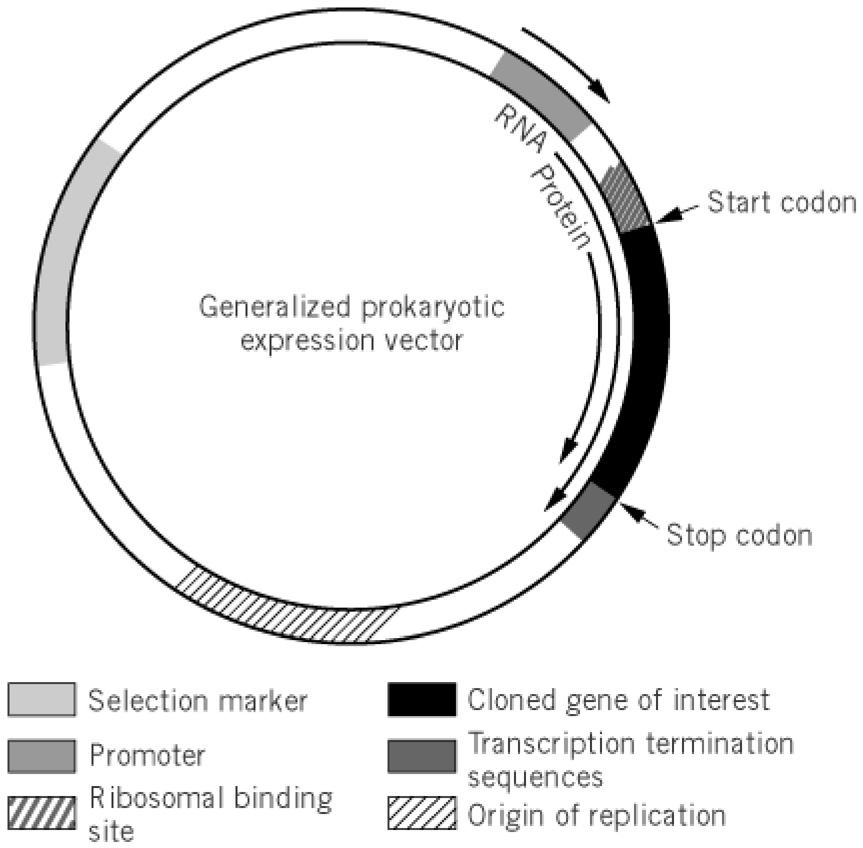
Expression Systems

Expression systems are used for the production of protein from recombinant DNA molecules (see Recombinant Proteins). They are of widespread use in industry, health care, and scientific research because of their flexibility and ability to achieve production levels exceeding those of the native source of the protein. An expression system consists of a **vector** carrying the gene encoding the protein of interest, along with the sequences necessary for transcription of the DNA into messenger RNA and translation of the mRNA into protein, plus a host providing the **enzymatic** machinery for carrying out these processes. In a homologous expression system, the gene to be expressed derives from the same species as the host whereas, in a heterologous expression system, the gene to be expressed and the host are of different origin.

1. Design of the expression vector

An expression vector not only provides the components necessary for cloning, transfer, stability, and multiplication of recombinant DNA but it also delivers the elements required for correct transcription of DNA into functional mRNA and efficient translation of mRNA into the desired protein. However, the importance of the basic elements controlling gene dosage and selection should not be ignored in the design of an expression system. A generalized **prokaryotic** expression vector is shown in Figure 1.

Figure 1. Generalized prokaryotic expression vector. The figure shows a typical prokaryotic expression vector, with a selection marker gene allowing stable maintenance of the plasmid, an **origin of replication** controlling the **copy number** of the vector, and a promoter and a ribosomal binding site positioned upstream of the gene of interest. One or more transcriptional termination sequences are positioned downstream. Furthermore, a eukaryotic expression vector would contain an extra origin of replication and an extra selectable marker to allow replication and maintenance in both *E. coli* and the eukaryotic host. The transcriptional termination signal would include a polyadenylation signal.



A **promoter** is a region of DNA recognized by an **RNA polymerase** and is the prerequisite for initiation of transcription. Promoters consist of characteristic sequence elements. In general, promoters from prokaryotes and **eukaryotes** differ, and a common organization pattern can be given for each. However, there can be pronounced differences between species, and more subtle variations are found within the same species, giving rise to promoters with different strengths and control mechanisms.

The strength of a promoter determines the frequency with which a gene is transcribed by controlling the rate at which the RNA polymerase and the promoter form the initiation complex. However, the strength is governed not only by the interaction with the RNA polymerase. Other proteins, so-called transcriptional activators and repressors, bind to the promoter region and regulate the process of transcriptional activation. Often, eukaryotic expression vectors provide transcriptional enhancer elements as well.

The ideal promoter for the expression of a recombinant protein not only generates the synthesis of high levels of mRNA but, even more important, it should be inducible, ie, the experimenter should be able to control its activity. However, only a few inducible promoters are tightly controlled, so that some transcription occurs even in the uninduced state. The overproduction of a protein will most often influence the cell in a negative manner and can be detrimental in the most severe cases, where the protein of interest is toxic to the host (see Poison Sequence). If this seems to be a problem, it may prove advantageous to use a weaker promoter under tighter control. Also, when overexpression seems to outstrip the host's post-translational modification, **molecular chaperone**, and proofreading systems, the use of a weaker promoter may be beneficial. For most expression systems, both constitutive and inducible promoters are available. The "on" state of the best inducible promoters can be regulated, thereby providing a means of optimization (1).

Some prokaryotic expression vectors contain antitermination elements, which stabilize the RNA polymerase on the DNA template to ensure optimal elongation of the transcript. Transcriptional terminators positioned at the 3′-end of the expressed gene restrict the size of the mRNA, minimize the sequestering of RNA polymerase, and isolate the plasmid's replication functions, thereby stabilizing the **plasmid**. Eukaryotic mRNAs are processed more extensively than prokaryotic mRNA, including such processes as **splicing** and the addition of **poly-A** tails. The signals for these steps are provided by eukaryotic expression vectors at positions downstream of the cloned gene.

The degradation of mRNA allows a biological system to adapt to changes in the environment (see RNA Degradation In Vitro). Yet the aim of the gene expression systems is to maintain a high level of mRNA for the gene of interest during its expression. The stability of mRNA can, in some cases, be increased by insertion of sequences that fold into stable **secondary structures** at the ends of the mRNA, thereby "capping" the mRNA.

The initiation of the translational process requires a **ribosomal** binding site, where the small subunit of the ribosome binds to the mRNA to form the initiation complex. The first triplet of nucleotides to be translated is the start codon, which usually has the sequence AUG. In prokaryotes, a Shine–Dalgarno sequence is positioned 4 to 13 nucleotides upstream of the start codon. This purine-rich sequence base-pairs with the 3′-end of the 16 S ribosomal RNA (rRNA) and thereby regulates the specificity of ribosomal binding. So-called specialized ribosome systems can be constructed that direct ribosomes specifically to the mRNA of interest. Site-directed mutagenesis is applied to both the Shine–Dalgarno region and the rRNA to change their sequence, while maintaining the base pairing. In eukaryotes, the formation of a translational initiation complex is directed by the **5′-cap** -structure, 7MeG(5′-5′)pppNp (N is the first nucleotide of the mRNA), at the 5′-end of the mRNA. However, several eukaryotic mRNAs have been found to be translated in a cap-independent manner (2).

Secondary structures in the 5′-untranslated region of the mRNA and around the start codon may hamper recognition of the start site. If potential secondary structures seem to be any problem, they can be eliminated by introduction of silent mutations at the third positions of the initial **codons** or by random mutagenesis in the region upstream of the start codon. Another approach to overcome the problem of secondary structures is to express the protein of interest as a **fusion protein** or to use a two- **cistron** system. In the first approach, a nucleotide sequence encoding a protein or peptide that is known to be well expressed is introduced in-frame between the start codon and the gene of interest. The resulting N-terminal fusion partner most often provides other advantages as well, such as increased stability or simplified purification (see Fusion Gene, Fusion Protein). In the second approach, a strong ribosomal binding site and the 5′-end of a well-translated gene, followed by a stop codon, is positioned immediately upstream of the gene of interest. Translation of the protein of interest will then be reinitiated immediately after the first gene.

The degeneracy of the genetic code implies that most of the 20 amino acids are encoded by two or more codons called synonymous codons. The synonymous codons are not used with equivalent frequencies by different strains or even throughout the genome of a single organism (3, 4) (see Codon Usage and Bias). Weakly expressed genes are characterized by the occurrence of infrequently used codons, which are typically recognized by rare tRNA species. It is advisable to avoid the use of rare codons when possible in systems for high-level expression.

The three stop codons UAG, UAA, and UGA differ in their efficiency in terminating translation. UAA seems to be favored in highly expressed genes and [should be used in] expression systems.

If a heterologous expression system is used, the gene of interest should preferably be devoid of **introns**, which may not be properly processed by a host of different origin than the gene. However, the presence of introns has, in some cases, been required for successful expression. In such cases, the intron can be provided by the expression vector downstream of the gene of interest.

2. Choice of host

Considerable knowledge about expression in *Escherichia coli* has accumulated over the years, and *E. coli* is often the first choice of host when a new protein has to be expressed. Furthermore, *E. coli* grows fast in inexpensive media, allowing scale-up for industrial purposes. However, proteins containing disulfide bonds are unlikely to fold correctly in the cytosol of bacteria, which is relatively reducing. Misfolding may lead to the formation of inclusion bodies, which can be both an advantage and a disadvantage. The advantages are that the protein is protected from proteolytic degradation and that the purification strategy can be simplified. However, the protein needs to be denatured and refolded, a task that can cause difficulties (see Protein Folding In Vitro). The coexpression of folding factors such as molecular chaperones, thioredoxin, or protein disulfide isomerase, which assist the folding of protein, can be beneficial in some cases. A secretion strategy may represent another solution to the problem [see Secretion Vector]. Even though *E. coli* is able to secrete proteins, the outcome of such an approach is highly unpredictable. *Bacillus* species will often be a better choice of host in such a case. Furthermore, *Bacillus* has the advantage that it does not produce endotoxins (lipopolysaccharides) and has been classified as a GRAS (which stands for *generally regarded as safe*) organism. The range of promoters available for *Bacillus* is more limited than the range for *E. coli*. Some other prokaryotic hosts, eg, *Lactococcus lactis* (5), also are gaining popularity as expression hosts.

On the other hand, bacterial systems have this limitation: they are unable to provide many of the post-translational modifications often found in eukaryotic proteins. If these modifications are needed for obtaining proper structure or activity, a eukaryotic host should be chosen.

Yeast, the simplest eukaryotic expression host, offers many advantages of both prokaryotic and eukaryotic systems. Yeasts grow rapidly in inexpensive media and are easy to manipulate genetically. Furthermore, yeasts provide an environment for carrying out secretion and providing post-translational modifications that are more similar to those found in proteins from the higher eukaryotes. The yeast strain traditionally used as a host for protein expression, *Saccharomyces cerevisiae*, is regarded as safe, given its long history of use in the production of food and beverages. More recently, the methylotrophic yeasts *Pichia pastoris* (6) and *Hansenula polymorpha* have gained popularity because of their higher production levels. However, yeast shows a tendency to hyper**glycosylate** the overexpressed protein, and the resulting high-mannose polysaccharide structures may affect the activity or folding or both, and they are potentially **immunogenic**. The filamentous **fungi**, *Aspergillus* and *Trichoderma*, are becoming increasingly popular as expression hosts, not least because of the very high amounts of protein that can be obtained with secretion systems (7).

Another eukaryotic expression system of high popularity is the baculovirus/insect cell system, which is relatively easy, cheap, and fast to use. The first generation of systems utilized the strong transcription signals for expression of the polyhedron protein of the **virus** . The baculovirus system provides more, although not all, of the features characteristic of mammalian cells, and the yields are often high. However, the high yields sometimes lead to the formation of inclusion bodies. Interestingly, the baculovirus system can be used for **phage display** of large, complex disulfide-containing proteins, thereby overcoming the limitations of the original bacterial system.

If the protein of interest is of mammalian origin and if authenticity is of utmost importance, a mammalian expression system should be chosen. It may also enable the study of an engineered protein in its natural environment; for example, a biological assay could be coupled to the expression system for the evaluation of functional effects. The basic technology is now available, but these expression systems are not very cost-efficient and are sometimes difficult to scale up. Often, it takes a long time to establish a stable system with high expression levels.

Eukaryotic expression systems can be divided into two groups: those that involve transient or stable expression of recombinant genes from transfected DNA molecules, and those that involve helper-independent viral expression vectors. Vectors used for stable expression contain a complete eukaryotic transcriptional unit inserted into a bacterial replicon. The DNA integrates at a low frequency into the host genome and usually directs the expression of the desired protein at low levels. Recombinant virus systems represent powerful tools for the expression of recombinant proteins in cultured cells, animals and man. A comparison of five different eukaryotic expression systems can be found in reference 8.

There are several factors to take into consideration before setting up an expression system. How much protein is needed? What is its application? Is authenticity important? Can the presence of heterogeneity be accepted? Are the technologies available? The choice of an expression system will depend largely on the desired use of the expressed protein; for example, even microheterogeneity can be a problem if the protein is to be used for **X-ray crystallographic** structural analysis, as these heterogeneities may hamper the crystallization process (9).

Proteolysis of heterologous proteins is another problem that should be considered in the choice of a host for expression. Bacteria and lower eukaryotes use proteolysis as a primitive immune system, which attacks and eliminates “nonself.” Different proteinase-deficient strains have been constructed to overcome this problem, but these strains grow at a lower rate, and their usefulness for solving a particular problem is often unpredictable. If proteolysis is a problem, it is advisable to test a selection of these hosts. Alternatively, a secretion strategy or a fusion protein strategy can be chosen. In the first case, the gene product is removed from the cytoplasm, where most proteinases are located. In the second case, the fusion partner can have a stabilizing effect. The method of induction of expression should also be considered when proteolysis appears to be a problem. Some induction methods (eg, heat induction) activate the **heat-shock** system of the cell, which includes a whole range of proteolytic enzymes.

In particularly difficult cases, where the protein of interest is toxic or prone to form inclusion bodies, the use of a cell-free protein biosynthesis system may be beneficial. In such a system, the enzymes needed for transcription and translation are present in a cell extract instead of a live organism. One further advantage is the possibility of introducing unnatural amino acids into the protein of interest (10, 11).

Finally, when a suitable expression system has been established, the growth and eventual induction conditions need to be optimized to obtain the maximal yield of product. It is often advisable to decrease the growth rate below the optimal by reducing the temperature, aeration, or nutrition content of the media. The risk of overloading the protein synthesizing machinery, leading to inclusion body formation or misfolded proteins, is thereby avoided. Furthermore, the expression vector is stabilized. Also, the strategy of recovering the expressed protein will influence the product yield and thus deserves optimization.

The vast number of vectors and hosts available should be able to satisfy the demands of any protein to be expressed. Yet protein expression is a somewhat empirical process, making it difficult to foresee which system should be chosen for optimal success. Advances in the understanding of how expression systems work will undoubtedly make for a higher degree of predictability than is currently the case.

12. P. Gacesa (1997) *Vectors: Expression Systems (Essential Techniques Series*), John Wiley & Sons, New York. A laboratory manual that enables the reader to make the best choice of method, conditions, and equipment for working with expression vectors. A troubleshooting guide is included.
13. D. V. Goeddel (ed.) (1990) *Methods in Enzymology*, vol. **185**, Gene Expression Technology, Academic Press, San Diego, California. The reader is provided with a basic understanding of the problems that may occur while trying to express a protein in various expression systems. Furthermore, more sophisticated solutions to the problems are provided. Strongly recommended.

Many of the books suggested under the entry "**Protein engineering**" contain several chapters about different host systems.

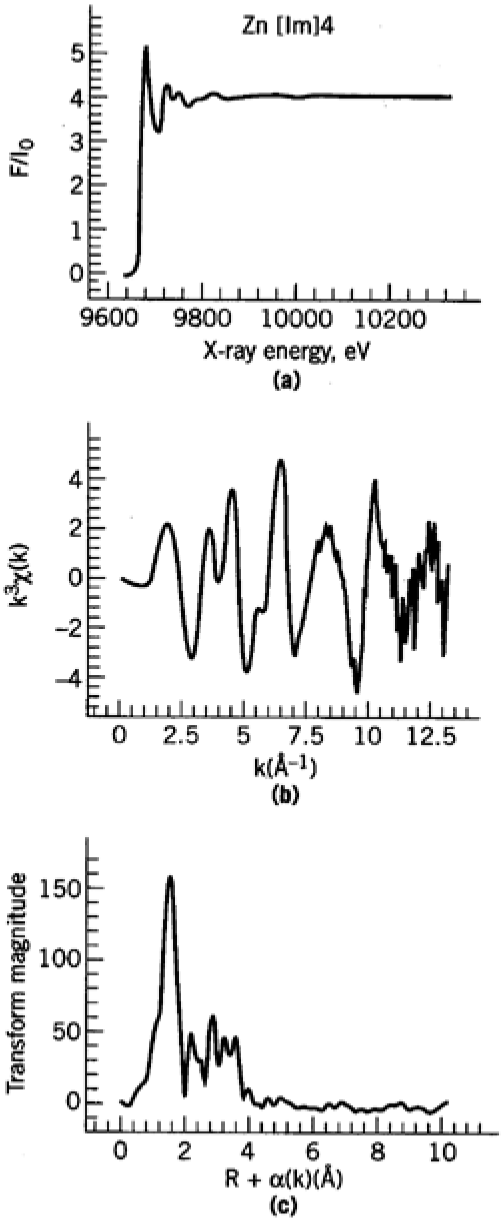
14. In the journal *Current Opinion in Biotechnology*, one issue per volume (usually issue 5) is dedicated to reviewing the latest advances in the field of expression systems, enabling the reader to become fully updated.

Extended X-Ray Absorption Fluorescence Spectroscopy (EXAFS)

X-ray absorption spectroscopy is particularly useful for investigating the electronic structure and local environment of the metals in metalloproteins (1). It is not limited by the physical state of the sample (e.g., gel, crystal, tissue) and, unlike X-ray crystallography, the entire structure of a crystalline molecule need not be determined to understand the local structure of the metal site. Obtaining data from light atoms, however, is very difficult. Atoms lighter than sulfur cannot be studied routinely because high vacuum is required. Most of the work reported to date has been with samples containing transition-metal ions. An intense, tunable X-ray source is required, and making measurements at a synchrotron facility must be done on a competitive basis. The ideal sample has a volume of 20 to 100 µl and a concentration of at least 1 mM. It must be maintained at low temperature while the data are being collected, so as to minimize radiation damage.

Like visible photons, X rays are absorbed by matter according to the Beer–Lambert law (see Spectroscopy) and cause changes in the energy levels of the electrons of the absorbing atom. Because the energies of X-ray photons are considerably greater than those of visible light, however, the electrons affected are those in the lower shells, principally the K- and L-shell electrons. Therefore, X rays whose energies are near those of the atomic or molecular energy levels of the metal can be used to probe the electronic structures of the metal sites. The edge region of the absorption spectrum in the top panel of Fig. 1 contains information relating to the valence state and coordination geometry of the absorbing metal atom and the chemical identities of the neighboring atoms.

Figure 1. X-ray absorption data for $\mathrm{Zn[imidazole]}_4^{2+}$ (a) Data collected as fluorescence (*F*) normalized by the initial intensity I_0. (b) EXAFS data derived from the data in (a) after subtracting a background, corresponding to the metal ion without neighbors, and multiplying by the factor k^3, where k is proportional to $E_{\mathrm{electron}} = E_{\mathrm{X-ray}} - E_{\mathrm{ionization potential}}$. (c) Fourier transformation of the EXAFS data in (b), showing the coordination shells around the Zn^{2+} ion. The first shell contains four imidazole N atoms at 2.40 Å, and the higher shells contain the other C and N atoms of the imidazole rings.



When the X-ray energy exceeds the ionization potential or threshold of the metal, which is the energy at which the inner shell electrons are promoted to the continuum, the absorption spectrum is characterized by an oscillatory structure (top panel of Fig. 1) at energies greater than the absorption edge, which is known as the extended X-ray absorption fine structure (EXAFS). This structure results from interference in the ejected photoelectron wave from the metal atom and the photoelectron wave backscattered from neighboring atoms. This interference phenomenon provides a very precise measurement of the distance to the neighboring atoms (typically ± 0.02 Å). In addition, the EXAFS oscillations contain information relating to the number of neighboring atoms of a limited range in atomic number (rows in the periodic table can generally be distinguished). Because this ejected photoelectron wave is spherical, the position in three dimensions is lost on average. In a simplified form, an equation describing these oscillations can be written as

$$k^3\chi(k) = \sum_j N_j A_j(k) \sin(2kr_j + \alpha_j(k))$$

where *k* is the wave vector, which is related to the X-ray energy, c is the oscillatory part of the X-ray absorption spectrum, N is the number of neighbors at distance r, $A(k)$ is the backscattering amplitude, which depends on the chemical identity of the neighboring atoms, and a(k) is the phase shift due to the potentials of both the absorbing metal and the neighboring atoms. The summation is over all coordination shells j, but in reality data can be collected only at distances less than about 5 Å for biological samples. The previous equation is written in this interference form to facilitate describing the data analysis necessary to determine the structural parameters.

Although X-ray absorption can be measured by observing either the transmission of X rays through the sample or the fluorescence emitted as a result of absorption, the latter is used almost exclusively for biological samples, because of its enhanced sensitivity. To obtain information about the number and average distances of the neighboring atoms, the data must be analyzed to isolate these parameters in the previous equation. Figure 1 shows the results for $Zn(imidazole)_4^{2+}$ during each step of the analysis. First, a simple linear background is subtracted from the data to normalize to zero the data below the edge region (top panel). Then, a background resembling the spectrum of the metal without neighbors (ie, a free atom) is subtracted, the energy scale is converted to wave numbers ($Å^{-1}$), and the data are multiplied by k^3. The results are displayed in the middle panel of Fig. 1. Now, the y-axis corresponds to the left side of the previous equation. Fourier transformation is used to isolate the contributions of the individual coordination shells, which converts the x-axis to r + a(k). This is similar to a radial distribution function that describes the radial electron density around the absorbing metal set at the origin. The first peak of the bottom panel of Fig. 1 is the first coordination shell, and those at greater x-axis values are further from the metal. The x-axis can be converted to r if one knows the chemical identity of the scatterers in each shell. For example, the average distance of the first shell peak is r + a(k) = 1.52 Å. It is composed of four nitrogen atoms, however, and it is known from investigating model compounds of known structure that a(k) = 0.88 Å for Zn–N coordination. This makes the average distance of those four nitrogen ligands 2.40 Å, with an estimated error of ±0.02 Å. Using model compounds, one can also determine that there are four nitrogen ligands in the first coordination shell. A more elaborate analysis, considering the higher shells of scattering atoms, would also lead to the conclusion that the ligands are imidazole. This example illustrates the need for model compound data or theoretical determination of the amplitudes and phases for each chemical type of ligand.

This example also demonstrates one limitation of EXAFS. In the absence of information about the metal-coordination environment, the data simply give an average of the number of ligands and their distances. In the best of circumstances without other biophysical or biochemical information, this method can determine only the difference between elements in the rows of the periodic table (e.g., C/N/O, S/Cl, or Se). Additional limitations occur as a result of uncertainties in the data analysis. For example, it is rarely possible to distinguish between one and two coordinated histidine residues in the presence of thiol group ligands without further information (such as knowledge of the protein primary structure). Rigorous analysis of X-ray absorption data for a complex coordination environment (e.g., metal clusters) in proteins can be impossible without methods to isolate each metal site, for example, by metal substitution.

Extracellular Matrix

Extracellular matrix (ECM) is a general term for extracellular networks of fibrous glycoproteins, proteoglycans, and carbohydrates that are secreted by cells. There are a wide variety of matrix types that fulfill many important functions in developing and mature animals and plants. ECM can be categorized as strong connective tissue ECM or loose connective tissue ECM. In strong connective tissue, such as bones, teeth, antlers and horns, a meshwork of fibrous protein is strengthened by deposition of calcium phosphate. Loose connective tissue includes specialized structures such as tendons, ligaments, fascia, cartilage, cell walls, and cuticles. Also in this category are the basal laminae (or basement membranes) that underlie epithelial cell layers and surround muscle cells, fat cells, and Schwann cells, and the collagenous interstitial matrix that is secreted by fibroblasts and lies beneath the basal laminae.

ECM contributes to the structure of organisms, acting as a scaffold for building strong connective tissue, and organizing cells into specific patterns in loose connective tissue. Tendons and ligaments contain molecules that give them their unique structural features in connecting bone and muscle. ECM in the joints provides cushioning, and elastic layers around blood vessels allow control of blood flow. The basal lamina in the kidney glomerulus acts as a molecular filter, allowing smaller molecules to pass from the blood to the urine. ECM can form important barriers in tissues to coordinate cellular movements and organization of cellular layers. For example, the basal lamina underlying endothelial cells in blood vessels prevents cells from leaving the circulation, except for certain cells that have the ability to pass through. This barrier is especially important during inflammation and metastasis.

While the important structural roles played by ECM have been recognized for a long time, recent research has uncovered crucial instructive activities that direct cellular movement and regulate cellular differentiation and gene expression. Individual molecules have now been purified, and their activities have been characterized. Many ECM molecules have been shown to support adhesion of cells, and some (such as tenascin) display anti-adhesive activities that may be important in establishing tissue boundaries or pathways of migration. Early in development, neuroblasts and myoblasts contact ECM as they migrate to their final destinations. ECM is also important in axon pathfinding and synapse formation. The basal lamina surrounding muscle cells has specialized regions in the synaptic cleft at the neuromuscular junction that contains molecules important for synapse function, such as acetylcholinesterase. In addition, synaptic basal lamina contains molecules that help guide synapse formation and regeneration, such as laminins containing the b-2 subunit and agrin. *beta*-2 laminins are also important in photoreceptor development and synapse formation. ECM also acts as a reservoir of positively charged growth factors, many of which bind to negative charges in ECM molecules. Growth factors and ECM molecules act in concert to direct a wide variety of cellular traffic during tissue morphogenesis. For example, fibroblast growth factor must bind to heparan sulfate chains from proteoglycans to be stable and active. In addition, the activity of some growth factors is enhanced when cells are bound to ECM, due to a synergy of their respective intracellular signaling pathways. Finally, some ECM molecules are proteolyzed to generate smaller soluble factors. Collagen XVIII is cleaved to generate endostatin, an antiangiogenic motility factor that can prevent tumor progression in mice. It has become clear that the ECM is in part the mortar that holds cells together in tissues, but it also acts as the brick mason, guiding the development and deposition of cells within the organism.

Cells interact with and respond to specific matrix molecules via cell surface receptors such as the Integrins, which bind matrix on the outside of the cell, and send signals across the plasma membrane to regulate intracellular events. Some cells make identifiable, stable junctions with ECM via integrins. These include focal adhesions which link to the actin cytoskeleton and hemidesmosomes, which connect to intermediate filaments. Other cell interactions with ECM are more transient. Contact with the matrix can alter the polymerization dynamics of the cytoskeleton to bring about changes in cell shape important in cell adhesion, migration and polarity. Adhesion to ECM is important in cellular responses to physical/mechanical forces, such as shear stress caused by blood flow over endothelial cells. ECM can activate signaling cascades involving tyrosine kinases which control cell growth, differentiation and apoptosis (see Integrins). Other receptors may also play roles in interacting with the ECM, including proteoglycans and galactosyl transferases.

The molecular complexity of the ECM is formidable, and many components are polymerized and then interwoven by covalent and noncovalent cross-links. The specific molecular attributes of ECM components give rise to their specific functional roles. For example, collagen I, the most abundant protein in animals, forms covalently cross linked fibrils with the tensile strength of steel that are found in skin, tendon, ligament, and bone. In contrast, Collagen IV forms sheets that polymerize with heparin sulfate proteoglycans and laminin-1 to give rise to the basal lamina. The presence of negatively charged, unbranched carbohydrate polymers called glycosaminoglycans (GAGs), both as free molecules and attached to protein backbones in proteoglycans, form a cushion-like hydrated gel important in the function of joints. For example, hyaluronan, a free GAG molecule that can be as long as 20 mm if stretched from end to end, forms a viscous random coil that provides turgor pressure in spaces between cells. Aggrecan, a proteoglycan, is a key cushioning element in cartilage. The elastic properties of cross-linked elastin arrays allow lung bronchial sacs to expand and arteries to change their diameter. Many ECM proteins are composed of repeated motifs that arise from individual exons, suggesting that new proteins evolved by shuffling various exons. Electron micrographs of purified ECM molecules have revealed striking geometries, from cross-shaped structures like laminin-1, to centipede like arrays of proteoglycans in an aggrecan aggregate, to pentameric and hexameric asterisks like thrombospondin-4 and tenascin, respectively. Some ECM proteins have many different isoforms arising from both alternative splicing and multiple genes that encode homologous families of subunits. For example, there are over 20 varieties of collagens made from 38 distinct polypeptides. At least 15 types of laminin have been identified. Other ECM components such as vitronectin and fibronectin are made in one form and deposited in matrices, and a second form is an abundant component of blood plasma.

The macromolecules that make up the ECM are synthesized by cells that reside within the matrix. This includes fibroblasts in the interstitial matrix, chondroblasts in cartilage, and osteoblasts in bone. Some fibril forming ECM proteins such as collagen are made initially with N- and C-terminal extensions called propeptides that prevent polymerization until the propeptides are cleaved outside the cell. Collagen also contains posttranslationally modified hydroxyproline and hydroxy lysine, which are important for hydrogen bonds that stabilize fibrils. The enzymatic addition of the hydroxyl groups requires ascorbic acid (vitamin C), and deficiencies lead to weakened blood vessels and loose teeth characteristic of the disease Scurvy. Outside the cell, triple helical collagen monomers are cross-linked via covalent bonds to form 50 nm extracellular fibrils. Cells can assemble complex ECM arrays on their surface via the activity of integrin and dystroglycan receptors.

Once assembled, ECM is insoluble and fairly stable. For example, a collagen I molecule in bone might last 10 years before it is replaced. However, in some cases the degradation and turnover of matrix does occur, and it is carefully regulated. White blood cells must degrade the vascular basal lamina to leave blood vessels and enter inflamed tissue, and metastatic cancer cells can migrate to distant sites by violating ECM boundaries. Matrix is also degraded at certain times during development and wound healing, such as in the sprouting of new blood vessels (angiogenesis). In these cases most matrix is degraded by a family of over 20 secreted proteases called Matrix Metalloproteinases (MMPs), which require bound Zn^{2+} or Ca^{2+} for activity. MMPs are secreted as inactive precursors which are activated by proteolytic cleavage. Activity is also regulated by a family of secreted protease inhibitors called tissue inhibitors of metalloproteinases (TIMPS). The process of matrix degradation is of great importance to medical researchers interested in controlling inflammation, tumorgenesis, and metastasis.

The importance of ECM is underscored by the consequences of mutations that ablate or alter matrix components. For example, human mutations in collagen I can result in osteogenesis imperfecta (weak bones) or Ehlers-Danlos Syndrome (defective joints), or even death. Over 1,000 mutations have been identified in 22 different collagen genes, and these lead to a variety of diseases characterized by defective connective tissue. Mutations in fibrillin results in Marfan's syndrome, a disease characterized by defects in elastic tissue such as the aorta, which is subject to aneurysms. Mutations in laminin genes can lead to congenital muscular dystrophy and junctional epidermolysis bullosa, a skin blistering disease. More recently, genetic studies in model animal systems have also demonstrated the importance of ECM. For example, loss of laminin in the worm *Caenorhabditis elegans* results in defective mesodermal cell migration and axonal pathfinding under the epidermis. Mice with null (knockout) mutations in the fibronectin gene fail to develop notochord, somites, neural tube, and heart and die by embryonic day 10.

There is still a great deal to learn about the ECM. New molecular components continue to be discovered, and their functions are not yet known. Furthermore, alternatively spliced variants of known molecules, and isoforms derived from separate genes have been discovered which differ in structure and function. Proteolytic fragments of ECM molecules, such as endostatin, angiostatin, and tumstatin, are being investigated as possible anticancer treatments. The exact molecular structure of complex ECMs such as the basal lamina are not yet clear, and how cells adhere to, migrate on, and move across matrices is still not completely understood. As more genomes are sequenced, we should get a better idea of ECM complexity and evolution. Developing better treatments for important human diseases such as arthritis, cancer, and macular degeneration may be made possible by a better understanding of the ECM.

Extrachromosomal Inheritance

“Extrachromosomal inheritance” is a term to be avoided. It is used sometimes as a synonym for cytoplasmic inheritance, which usually arises from the genetic information on mitochondrial or chloroplast genomes. Using the term **chromosome** in the broad sense of any DNA or RNA molecule capable of autonomous replication, the term *extrachromosomal inheritance* has a very limited content (see **Maternal effects**).

If the term chromosome is restricted to the complex structures in the **nuclei** of the eukaryotes, then *extrachromosomal inheritance* covers both cytoplasmic inheritance and the inheritance of plasmids that replicate autonomously in the nuclei of the cells. Because their distribution patterns differ from those of the major chromosomes, their inheritance diverges from Mendelian rules (see Mendelian Inheritance).

Most nuclear plasmids are phenotypically silent and can only be detected by identification of their molecules. This is the case of the “two-micron circle,” a nuclear plasmid of *Saccharomyces cerevisiae* . Although it does not confer any phenotype to the yeast, it has been useful in the development of **vectors** for **genetic engineering**.

In bacteria, *extrachromosomal inheritance* could designate the inheritance of autonomous plasmids separate from the main chromosome (see F Plasmid).

Eye (Bubble)-Form Intermediate

In general, DNA replication of a **chromosome** starts from a genetically fixed site and proceeds bidirectionally. At the initial stage of replication, the replicated regions form structures like an eye (or a bubble). This form is important, as it represents the origin region of the chromosome (see Replication Origin); various methods to detect eye-form intermediates have been developed. Electron microscopy (**EM**) of the replicating DNA can detect eye-forms as large as several kilobases (1). Using a combination of digestion by appropriate restriction enzymes and electron microscopy, the origin of replications of **plasmids**, **bacteriophage**, and **virus** DNA has been identified (2). Recently, the two-dimensional gel electrophoresis method was developed to detect various forms of replication intermediates (3). Chromosomal fragments produced by digestion with restriction enzyme are separated by electrophoresis by agarose gel electrophoresis, first by size and then by shape. The distribution of intermediates on the two-dimensional (2D) gel is detected by **hybridization** with a **radiolabeled** probe of a cloned DNA fragment from or near the replication origin. Since the correlation between the size and complexity of shape of eye-forms is different from that of Y-fork intermediates (see Replication Fork (Y-Fork Intermediate)), the former can be distinguished from the latter by the shape of arcs on the 2-dimensional gel (Fig. 1). In particular, when the origin of replication is not located at the center of the fragment, the change from eye- to Y-form occurs as replication proceeds on the fragment, which results in a discontinuous distribution of arc from eye- to Y-form. This method has been used successfully to detect the chromosomal origins of **eukaryotes**, in particular of *Saccharomyces cerevisiae* (4), *Schizosaccharomyces pombe* (5), and *Drosophila* chromosomes (6). Detection of eye-forms from mammalian chromosomes is technically difficult, due to the large amount of background DNA, and this method generally produces ambiguous results as to the site of origin of replication (7).

Figure 1. Two-dimensional gel electrophoresis method to detect eye-form (bubble-form) and Y-form replication intermediates. (**a**) Examples of patterns of Y-form (left) and Eye-form (right) intermediates of the replication of *Saccharomyces cerevisiae* chromosome are shown. Intermediates were detected by hybridization with the ^{32}P-labeled probe of cloned DNA within the fragments shown in (**c**). (**b**) The photos in (**a**) are drawn schematically. Dotted lines indicate the location of linear DNA fragments of corresponding size. (**c**) The population of the intermediates detected in (**a**) and (**b**) Left panel: Replication fork moves from the left (or right) side of the fragment and proceeds to produce Y-forks of variable size. Theoretically, a Y-fork with equal branch lengths is structurally most complex and shows least mobility in the second dimension. Right panel: Replication initiates from the center of the fragment and proceeds bidirectionally, producing various sizes of bubble intermediates. The largest bubble is like a circular DNA and shows least mobility in the second dimensions. The locations of the probe used for detection in (**a**) are indicated by dotted lines. Dark spots in the photos in (**a**), and drawn schematically in (**b**), indicate that the majority of DNA detected by

the probe is nonreplicated (or completely replicated) linear molecules.

F Plasmid

In 1953 a new type of genetic element was postulated in order to account for the sexual behavior of *Escherichia coli* K-12 (1, 2). This determinant spread rapidly and independently through recipient cell populations, indicating considerable autonomy, but it was completely dispensable and conferred no **phenotype** on its host other than maleness. Nevertheless, it was stably inherited by the cells it invaded. It behaved, in essence, like a small, infectious chromosome, and it was baptized the fertility (F) or sex factor. The nature of the proposed new element was amply confirmed: F turned out to be the prototype of the circular, double-stranded DNA **plasmid**.

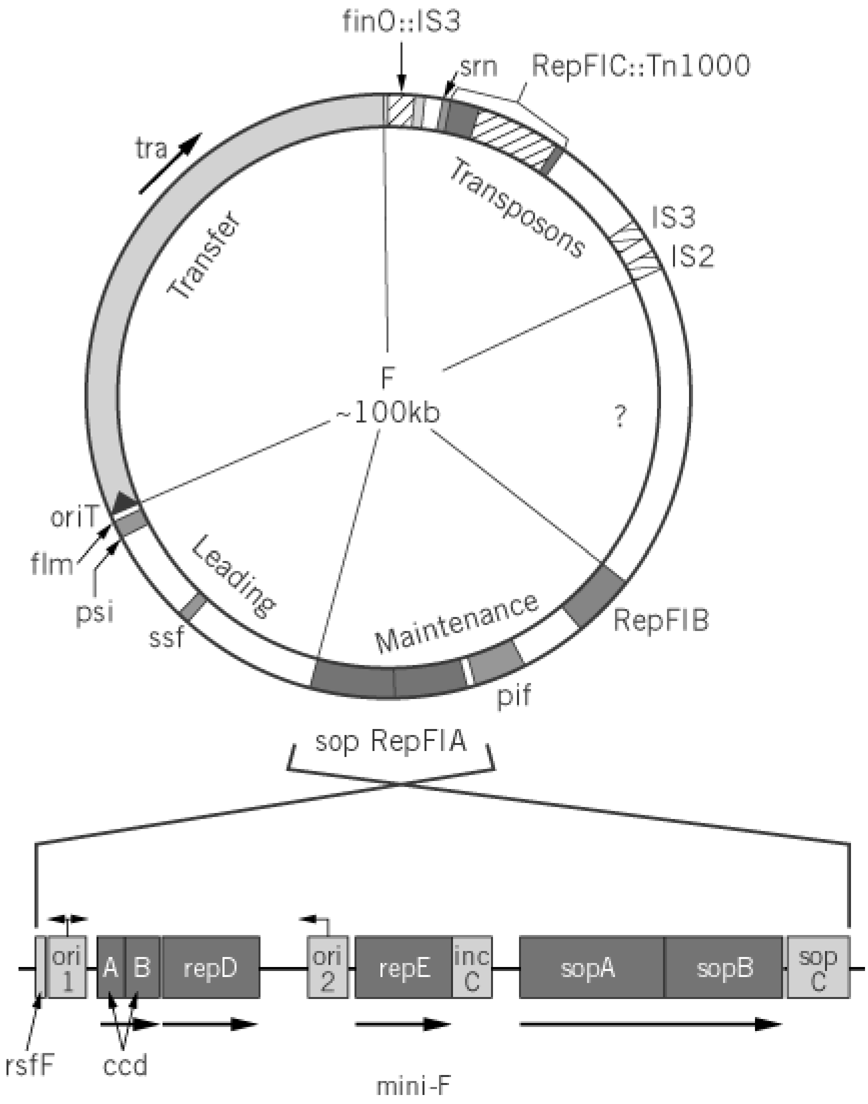
F was immensely important to the development of molecular genetics. By promoting transfer of chromosomal genes, it opened the way to large-scale mapping of the bacterial genome; and by acquiring and transferring small portions of the host chromosome, it could create partial **diploid** conditions that enabled analyses of bacterial **gene** function and control of **gene expression**. The nature and consequences of F-specified maleness are generally understood and are described in the entry Hfr's and F-primes. F has also been at the forefront of investigations into how low-copy number replicons are maintained stably; the mechanisms that regulate F's maintenance will be the major focus here.

Early studies of F were greatly aided by the discovery of derivatives that carry chromosomal genes (F-primes). For example, isolation of F′ lac^+ mutants (in a *lac* mutant strain) that remained Lac^+ at 30°C but segregated Lac^- at 42°C demonstrated that F carries its own replication determinants (3). The selective inhibition of F maintenance by acridine dyes (4) also pointed to the autonomy of F replication. Measurements of b-galactosidase in F^-/lac^+ and $F'lac^+/lac^+$ strains gave the first indication that the copy number of F is about the same as that of the chromosome. The strict regulation of copy number was reflected in the phenomenon of incompatibility, the inability of two F plasmids (eg F′*lac* and F′*gal*) to be coinherited. The F replication system enables integrated F to assume control of chromosome replication in strains unable to initiate it themselves, a phenomenon known as “integrative suppression” (5, 6). Beyond the initiation of replication at the origin, however, F replication becomes strictly dependent on host functions.
The term “episome” was coined to denote plasmids like F with both autonomous and passive (integrated) modes of propagation. This property turned out not to reflect a fundamental distinction from other plasmids, and the term is no longer considered useful.

1. Anatomy of F, A Mosaic

F consists of four functional blocks and a region of unknown composition (Fig. 1). The 33-kbp *tra* operon encodes the essential components of donor ability, the mating apparatus and the DNA manipulation enzymes responsible for transmitting F into recipient cells, as shown by the self-transmissibility acquired by plasmid vectors into which it, along with the origin of transfer (*oriT*), has been inserted. The ~ 13-kbp leading region that follows *oriT* is the first to enter recipient cells during transfer; only a few genes within it are known, and their involvement in transfer has not been demonstrated. The region at the other end of the *tra* operon contains a defunct replicon and appears to have acted as a trap for transposable elements; the latter contribute indirectly to mating activity, because one of them is inserted in the *finO* regulator gene, causing constitutive expression of the *tra* operon and high transfer rates, and (ii) also because homologous recombination with similar elements in the chromosome is the major route of F integration to form Hfr donors. The fourth region carries all the significant determinants of F maintenance. When isolated and joined to an antibiotic resistance gene to permit selection, it behaves as a normal plasmid (mini-F) with the same replication, partition, and stability properties as its parent F (7, 8). It is, therefore, the form most often used for studies of F maintenance.

Figure 1. Genetic map of the F plasmid. The circular F plasmid has been divided into five sectors, roughly according to function. Gene symbols are explained in the text. The **tra** arrow indicates the direction of transcription of the *tra* operon. The **oriT** arrow indicates the direction of conjugal transfer. Unshaded blocks of the circle correspond approximately to unsequenced regions. Below is the *repFIA* mini-F; note that it is shown inverted relative to F, by convention. Arrows above *ori1* and *ori2* show bi- and unidirectional replication, respectively.



A closer view reveals F to be a mosaic of replicative determinants. Three have been identified: *repFIA*, *repFIB*, and *repFIC*. The first two can be isolated as miniplasmids, although replication of *repFIB* is partly defective, so that replication of F itself is predominantly governed by *repFIA*. The *repFIC* locus, identified as such by comparison with the *rep* sequences of other plasmids, is inactive due to insertion of Tn*1000* in a progenitor of F. Portions of F as yet unsequenced may prove to contain other replicons. The presence of multiple replicons has proved to be a common feature of large plasmids, and it suggests that many such plasmids may have arisen by the fusion and rearrangement of a limited number of ancestral plasmids (9, 10). The fact that only *repFIA* is fully functional may account for the fact that F is stably maintained in only a narrow range of hosts: *E. coli* and similar Enterobacteria.

1.1. RepFIA

The *repFIA* locus is itself an ensemble of essential and accessory maintenance functions (Fig. 1). **Electron microscopic** examination of replication intermediates showed that replication forks emanated bidirectionally from a site termed *ori1* [also called *oriV* (11)]. However, miniplasmid deletion derivatives that lack this site, but show similar replication behavior, were obtained readily (12). These replicate unidirectionally from *ori2* [*oriS* (13)], both *in vivo* and *in vitro* (14, 15). It is not known why the *ori1* site is preferred in the original mini-F. In any event, the smaller mini-F, replicating from *ori2*, has been used in most investigations.

The basic *repFIA* replicon is made up of three components. One is *ori2*. The others are the single essential replication gene, *repE*, whose product regulates all aspects of initiation, and the copy control region, *incC* (13, 16, 17). A plasmid comprising only these elements replicates normally, but is nevertheless unstable. Stable inheritance requires a mechanism to ensure that plasmid copies are directed into each of the daughter cells, and this function is provided by the adjacent *sop* locus (18). *Sop* is essentially a partition module that can act independently of the *rep* locus to which it is normally linked, to stabilize plasmid vectors in which it is inserted. Together, the *rep* and *sop* loci constitute the basic F maintenance system. This arrangement is remarkably similar to that found in the P1 prophage plasmid [a detailed level, *RepFIB* is probably a more exact analogue of the mini-P1 replicon]. Studies of mini-F and mini-P1 have been reciprocally informative.

2. F in the Cell Cycle

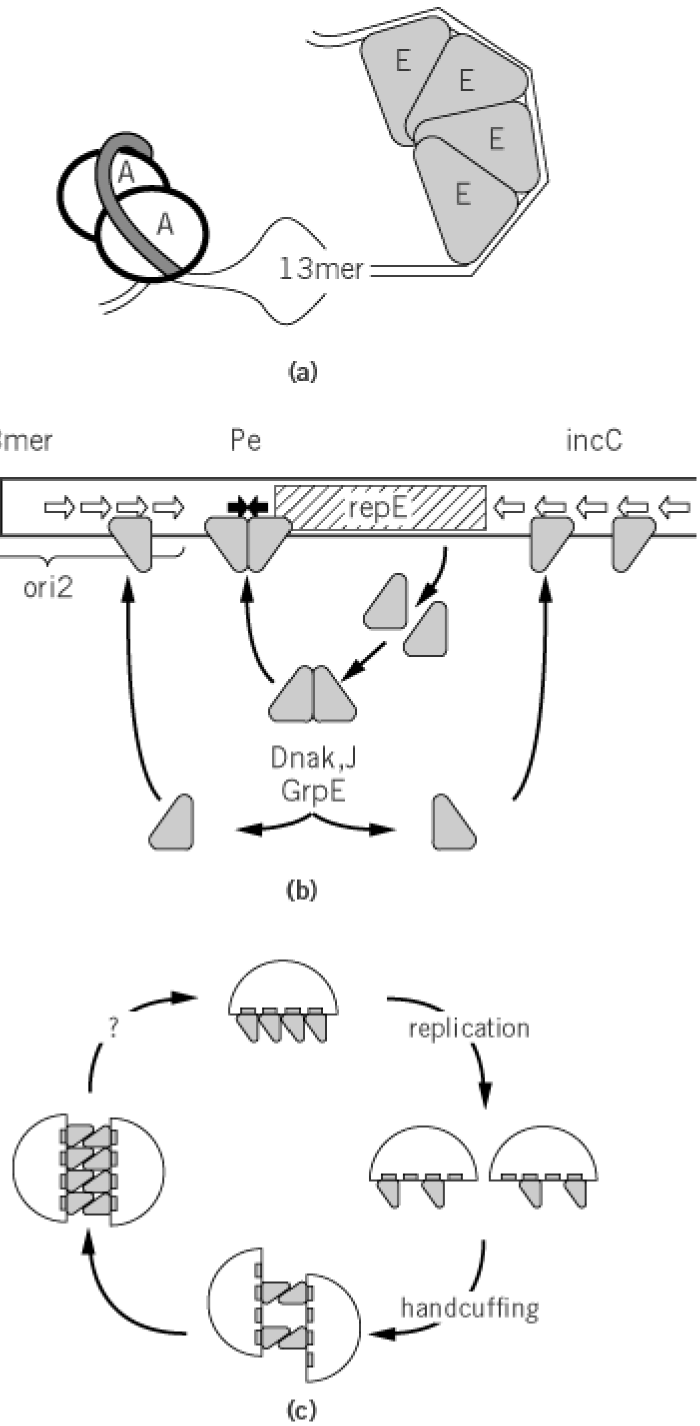
To ensure that F makes replicas available for both daughter cells at division, in spite of its low copy number, it would appear necessary for replication to be coordinated with the cell cycle. Viewed simply, this would imply that F replication take place at a specific time in the cycle for given growth conditions, as does the initiation of chromosome replication. However, a number of careful studies have indicated that both F and mini-F replicate in cells of all ages, without delaying cell division (eg, Refs. 19 and 20). Despite some dissenting opinion (21), it appears reasonable at present to view replication of F as more loosely coordinated with the cell cycle than that of the chromosome. How F could achieve high hereditary stability in the absence of cell cycle coordination remains unclear.

3. Replication Control

F provides the regulator of its replication, while the chromosome contributes essential components to the mechanism of initiation at *ori2*. Thus, the host DnaA initiator protein binds on one side of the origin to enhance opening of an AT-rich region (Fig. 2**a**). Initiation itself, however, requires binding of the F RepE protein to specific sites (iterons) on the other side (22), so that the duplex becomes sufficiently deformed to allow entry of **DnaB helicase** and assembly of a replication complex (23, 24) (see DNA Replication).

Figure 2. Aspects of mini-F replication. (**a**) Opening of *ori2* at initiation; **A** is DnaA protein, bound at tandem DnaA boxes (shaded DNA), **E** is RepE monomer bound to the iterons of *ori2*; together they cause melting of the AT-rich region at a 13-mer sequence similar to those that are opened at an early stage of initiation in *oriC*. (**b**) Regulation of RepE synthesis and activity. Each arm of the operator (filled arrows) contains an 8-bp subsequence of the 19-mer iteron binding sites (open arrows), suggesting that initiation, negative control, and autoregulation all depend on interaction of the same RepE binding domain with DNA. Limiting RepE synthesis by autoregulated transcription, along with limiting RepE availability through binding to *incC*, could constitute a copy-control mechanism. But how

can competitive binding be effective if an autoregulatory mechanism exists to replenish the pool of free RepE? One solution is that RepE exists in two forms: It is first synthesized as a repressor, which binds to the operator but not to the origin, and part of it is then converted to an initiator form that binds to *incC* and *ori2* . In this way, titration and autoregulation become to a large extent independent of each other (30). Indeed, the complex formed by RepE with the operator is structurally distinct from that formed with *ori2* (31). The model is further supported by the finding that most RepE is present in a dimer form with operator-binding and repressor activity. The initiator is made when the dimer is converted by the DnaK–DnaJ–GrpE chaperone machine to a monomer, which binds to the *ori2* and *incC* iterons (29). These chaperones are thus needed for normal levels of mini-F replication (32). Certain mini-F mutants that have escaped chaperone-dependence make RepE that has lost the ability to dimerize, resulting in high copy numbers (29, 33). (**c**) Principle of handcuffing and the cycle of initiation and inhibition; the interactions shown are intermolecular, but intramolecular coupling is also possible. After replication, the RepE remaining at *ori2* pairs with RepE remaining either at *incC* or at *ori2* on a second plasmid. As more RepE is made, it also pairs, inhibiting initiation by hindering access to replication proteins or impeding the structural transition needed for initiation. Failure to pair is a feature of certain copy-mutant initiator proteins of plasmids P1, RK2, and R6K (35-37). An unknown event (question mark) ruptures the coupling to allow initiation.



The *incC* control region acts as a brake on the formation of RepE-*ori2* initiation complexes. Additional copies of *incC* in ***trans*** inhibit replication, while deletion of *incC* causes about a fivefold increase in copy number (16, 17, 25). Because *incC* binds RepE (Fig. 2**b**), it was easy to imagine that it competes with *ori2* for RepE, controlling replication by titrating the initiator. An alternative copy-control mechanism sprang from studies of plasmids P1 and RK2 (26, 27), in which it was found that initiators bound to iteron sites can also bind to each other. The iteron regions *ori2* and *incC* could thus pair, either intra- or intermolecularly, to block initiation. This model, termed "handcuffing," would explain regulation of the frequency of initiation by a dual activity of RepE: initial reinforcement of the handcuff to prevent initiation, followed by formation of an initiation complex to start replication (Fig. 2**c**). A subtle modulation of RepE synthesis would seem necessary to allow the transition.

In fact, production of RepE initiator is finely regulated. First, RepE represses transcription of its own gene, by binding to the *repE* **promoter** (28), accounting for the limited quantities of RepE initiator. Second, newly made RepE has only this activity and is unable to initiate replication. This is because newly synthesized RepE forms dimers, which bind to the inverted repeat operator sequence in the *repE* promoter region but not to the iterons in *ori2*. To become an initiator, RepE must be converted to a monomer form (29-31). This conversion is catalyzed by the **DnaK-DnaJ** -GrpE **molecular chaperone** machine, a host function that is needed for normal levels of mini-F replication (29, 32, 33).

Despite the identification of these elements of F replication control, a satisfactory explanation of this process is still beyond us. The discovery of the essential role of the chaperone machine has served only to push the question of the key regulatory process one step further back: What determines the rate at which RepE dimer is converted to active monomer? If the handcuffing model is correct, how is the pairing broken to allow replication? Motor forces of the partition system have been proposed as keys (or boltcutters) for removing the handcuffs (34). But if handcuffed plasmids are pulled apart by the partition apparatus, how does unpairing occur in the case of partition-defective mini-F mutants, which replicate at a normal rate? The true status of *ori1* is unclear: If it is really the major origin in wild-type F, why is DnaA-assisted strand-opening over 2 kbp away essential for initiation?

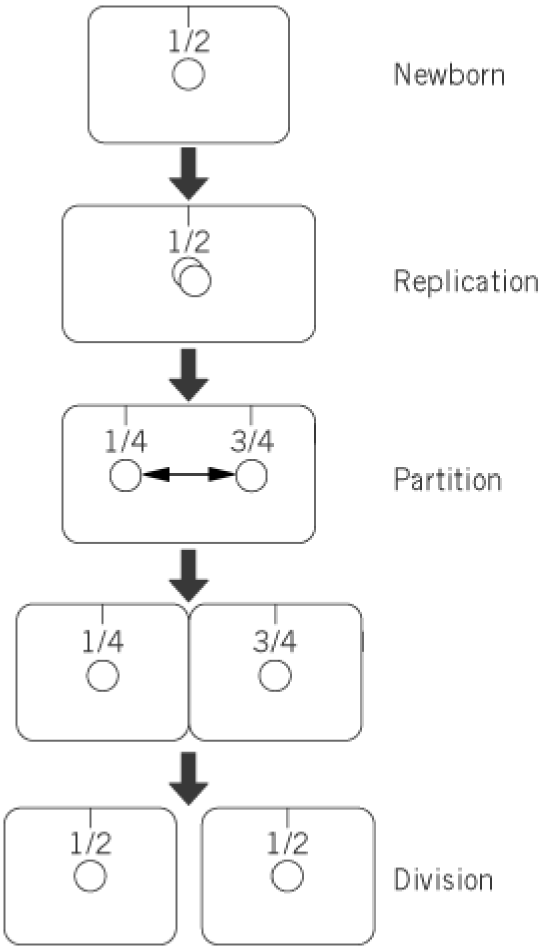
4. Partition

Deletion of the *sop* region causes loss of mini-F at the rate expected for random distribution of a small number of plasmid copies to daughter cells prior to division, consistent with the disruption of an active partitioning mechanism. The *sop* region consists of three elements (Fig. 1), all essential for partition (18, 38). Two partition proteins, SopA and SopB, are encoded by the *sop* operon. SopA is the main regulator of the operon; it binds to a series of short repeated sequences in the promoter to repress transcription (39). SopB may also assist this repression, because *in vitro* it enhances the affinity of SopA for its promoter (39). The major role of SopB, however, is the formation of a partition complex with *sopC*, a series of 12 tandem repeats of 43 bp that act in ***cis*** to ensure partition, much like a eukaryotic centromere. SopB appears to bind as a dimer to an inverted repeat sequence in each 43-mer, and to wrap *sopC* DNA in positive *supercoils* to form a characteristic complex (40, 41).

How this complex acts in partition is still unknown. Current models suppose that plasmid replicas attach as paired molecules to a host structure, such as the membrane or the division septum, and that some force then splits the pairs, pulling one copy toward each pole. SopA has an ATPase activity and is presumed to have a function in partition beyond its regulatory activity. It may link the SopB-sopC complex to the host structure, where its ATPase activity could drive the separation of paired plasmid copies (42). Our ignorance of the host components with which the Sop complex interacts is presently the major barrier to understanding partition. Host mutations that influence mini-F stability have been located in the *gyrA*, *topA*, and *ugpA* genes (43-45). While the DNA topology function or membrane localization of these proteins is suggestive, there is as yet no good explanation for their roles in partition.

Recent refinements in cytochemical methods applied to bacterial cells have made possible the localization of plasmid molecules as fluorescent foci, allowing the movement of mini-F and other plasmids to be followed in individual cells and populations (20, 46). The data thus far published indicate a preferential location at mid-cell (the site of the next division septum) for mini-F (Fig. 3). After the focus doubles, presumably reflecting replication of the plasmid, the two new foci appear to move to the 1 / 4 and 3 / 4 positions, the midpoints of the emerging daughter cells, at a speed suggestive of an active, directed mechanism. Partition-defective mini-F shows a more random distribution and is often present close to the cell poles (20). These results are consistent with old observations of the paucity of sop^{+} F plasmids in anucleate cells (" minicells") created by division near the cell poles and with the contrasting abundance of *sop* mutant plasmids (47).

Figure 3. Positioning and displacement of mini-F during the cell cycle, based on microscopic examination of cells labeled with fluorescent probes (20, 46). The 1 / 4 and 3 / 4 positions in older cells become the 1 / 2 positions in new cells. Note that the smallness of the interval between the appearance of two mini-Fs and their appearance at the new cell mid-poles implies active displacement (double-headed arrow).



5. Resolution

The stability of DNA species that replicate as q-shaped molecules is under continual threat from the formation of dimers by homologous recombination, because this decreases the number of separate molecules available for partition and reduces initiation frequency in dimer-carrying progeny. Most such replicons have solved this problem by acquiring a site-specific recombination system that resolves dimers back to monomers. *RepFIA* is one of these. The product of the *resD* gene is necessary for the resolution, which takes place within a sequence containing an inverted repeat of 10 bp, the rfsF site (48, 49). ResD is presumed to be the **resolvase**, though *in vitro* evidence is lacking.

6. Addiction

F possesses another type of stability function that, instead of ensuring that each daughter cell inherits a plasmid copy, kills those that fail to. The host population is thus coerced into maintaining the plasmid, a situation likened to addiction (50). The *ccd* (controlled cell death) system turned out to be the first of many examples of a widespread "stable-toxin-unstable-antidote" strategy (51). The CcdB protein inhibits an essential cellular function, DNA gyrase, but in F^+ cells it is kept in check by complexing with the relatively unstable antidote protein, CcdA (52, 53). In an F^- segregant cell, the CcdA is lost by rapid **proteolysis** and cannot be replaced, and the CcdB liberated can attack gyrase and thereby kill the cell.

Two other toxin–antidote systems, *srn* and *flm*, are carried by F. SrnB promotes the degradation of **ribosomal** RNA and transfer RNA by damaging the inner membrane and allowing entry of **ribonuclease I** (54), but its synthesis is normally inhibited by an unstable **anti-sense** RNA, SrnC (55). As with the Ccd system, loss of the plasmid causes a rapid decline in the antidote SrnC, and the liberated and stabilized *srnB* messenger RNA is then translated to produce the toxin. The locus is situated next to *repFIC::*Tn*1000* and was undoubtedly once part of a viable replicon, similar to the R1 plasmid whose *hok*/ *sok* killer system it resembles. *Flm* is another *hok*/*sok* analogue. Its toxin (*flmA*) and antidote RNA (*flmB*) genes are located in the leading region (56). It is tempting to suggest that a burst of FlmA synthesis in the recipient modifies the membrane to facilitate conjugational transfer, but the actual relevance of *flm* is unknown.

Easy isolation of F^- and mini-F^- segregants suggests that these toxin–antidote systems are inefficient. This may, however, be the result of unintended laboratory selection for tolerant strains during decades of genetic experimentation. The significance of such addictive systems in the wild remains to be assessed.

7. Conjugal Aids

Two other loci in the leading region encode functions for which a role in conjugation can be envisaged. The *psiB* gene product is transiently expressed following transfer to a recipient cell, where it inhibits the SOS response, probably by preventing the activation of **RecA** protein (57). Its role might be to prevent induction of inappropriate SOS functions in the recipient. The *ssf* gene, an analogue of *E. coli ssb*, encodes a single-stranded DNA binding protein that might protect DNA entering the cell prior to its replication (58). The absence of leading region functions does not, however, impede DNA transfer or recombinant formation, at least in laboratory conditions, and their significance is thus unclear.

8. Phage Exclusion

Following infection of an F^+ cell by certain phages dubbed "female-specific", (eg, T7 and FII), expression of phage genes begins and the cell dies, but phage development is arrested. The F locus responsible is *pif* (phage inhibition by F), an operon consisting of two genes, *pifC* and *pifA*, located between the *repFIA* and *repFIB* regions. The phenotype is not understood. It appears to be due largely to interactions between PifA and the products of phage genes 1.2 and 10, but it does not seem to be related to the normal activities of these genes. These interactions somehow interrupt entry of phage DNA and cut short expression of its late genes (59). PifC represses *pif* operon transcription by binding to a short inverted repeat sequence overlapping the *pif* promoter –10 region (60). The participation of PifC in mini-F replication initiated at *ori1* has also been proposed, on the basis of the defective replication phenotypes of *pifC* **amber mutants** (61). It is also possible, however, that the phenotype is an indirect effect of PifC amber fragments binding to the *pif* promoter.

9. Perspectives

The F plasmid as a tool has largely retired from the front line of molecular genetics, to be replaced by sleeker, more powerful technologies. Nevertheless, its properties continue to be exploited, eg, its stability and low copy number make it suitable as a **vector** for cloning large fragments of eukaryotic DNA [the BAC vectors (62)]. As a biological entity, on the other hand, F has retained its mystery. We understand only dimly the control of its replication, its mechanism of partition, and the relationship of both processes to the host cell cycle, not only for F, but for all low-copy-number replicons. Finally, although whole-genome sequencing has not yet proved equal to the task of completing the sequence of F, this project is underway (R. Skurray and L. Frost, personal communications) and may well provide some surprises.

Factor Xa

Factor X is a component of the blood clotting system. It circulates in blood plasma (8 µg/mL) as an inactive precursor of a serine proteinase (1). When the blood coagulation process is initiated, factor X is converted to factor Xa (activated factor X), which forms part of a complex that converts another serine proteinase precursor, pro-thrombin, into the active enzyme thrombin. Clotting occurs when thrombin converts fibrinogen to **fibrin**.

Factor X is synthesized in the liver as a 488-amino-acid residue precursor protein, pre-pro-X, the primary translation product of the factor X gene (2). Forty amino acids are cleaved from the amino terminus of pre-pro-X. The resultant 448-residue protein is modified by the attachment of sugars and, in a vitamin-K-dependent process, by the carboxylation of certain glutamic acid residues to form g-carboxy glutamic acid residues. It is cleaved by a specific proteinase that removes residues 140 to 142, so factor X circulates as a two-chain, **disulfide bond**-linked, enzymatically inactive protein. This heavy-chain–light-chain dimeric structure is typical of the blood coagulation proteins (3).

As might be expected, activation of blood coagulation is a carefully controlled process involving many clotting factors (see Blood Clotting). All the details of this process are not fully understood as yet, but it is known that factor X can be converted to an active enzyme by two distinct pathways, the *intrinsic* and the *extrinsic* (4). The former pathway involves activation by factor IXa, which together with factor VIIIa forms a **receptor** on the phospholipid surface of blood platelets. When factor X binds to this receptor complex, a 52-residue peptide is cleaved from the amino terminus of its heavy chain to form factor Xa. The latter pathway involves activation by factor VIIa which, in an analogous fashion, forms a platelet-bound complex with tissue factor. When factor X binds to this complex, the same peptide is cleaved from the heavy chain to give factor Xa. Calcium ions, which bind to the g-carboxy glutamic acid residues of the light chain (and also to the other clotting factors), are essential for factor X activation.

Once factor X is activated, it binds along with factor Va on the surface of platelets, where it interacts with pro-thrombin to convert this zymogen into thrombin, the end product of the so-called coagulation proteinase cascade. Factor X was first recognized as an essential part of this cascade when it was shown that it could restore coagulability to the plasma of individuals who had a specific hemorrhagic disorder. It was given the name *Stuart factor*, which was subsequently changed to factor X in an effort to systematize the nomenclature of the clotting factors.

Facultative Heterochromatin

Facultative heterochromatin is the term describing regions of chromosomes that appear **heterochromatic** at certain times in the cell cycle but are not always this way. This is contrasted with constitutive heterochromatin, which is always condensed and stains strongly throughout the cell cycle (1). Facultative heterochromatin represents domains of euchromatin that are condensed and inactive in a particular cell. An excellent example of the assembly of facultative heterochromatin is found in the inactive X-chromosome (see Barr Body, X-Chromosome Inactivation). In the inactive X-chromosome, the histones are hypoacetylated, DNA is **methylated**, and the chromosome replicates late in **S-phase**. All of these traits are characteristic of inactive chromatin. Importantly, these are not irreversible modifications and can be reversed at certain points in development (see Random X-Inactivation).

The various characteristics of facultative heterochromatin effectively work together to stabilize a **transcriptionally** repressed state. The generation of antibodies against **acetylated** histones has allowed a number of general correlations concerning the possible functional roles of histone acetylation. There is also a strong correlation between histone acetylation and the transcriptional activity of chromatin. In *Saccharomyces cerevisiae* most of the genome is transcriptionally active and contains hyperacetylated core histones. Transcriptionally inactive **domains** of chromatin in **yeast**, such as the silent **mating type** cassettes and **telomeric** sequences, contain histone H4 that is hypoacetylated, except at one position, Lys12 (2). In higher eukaryotes, acetylation of histone H4 increases during the reactivation of transcription in the initially inactive chicken erythrocyte nucleus, following fusion of the erythrocyte with a transcriptionally active cultured cell, to form a heterokaryon (see Euchromatin). Histone acetylation is particularly prevalent over the specific b-**globin** genes that are actively transcribed in reticulocytes. More recent studies have demonstrated convincingly that histone hyperacetylation is actually restricted to the domain of chromatin that contains the potentially active chicken b-globin gene locus (see Domain, Chromosomal). This result indicates very specific targeting of histone acetyltransferase activity. **Immunolabeling** of polytene chromosomes in *Chironomus* and *Drosophila* also reveals a nonrandom distribution of histone H4 acetylation that correlates with transcriptional activity. Within female mammals, the transcriptionally inactive X-chromosome is distinguished by a lack of histone H4 acetylation (3). Therefore several independent experimental approaches have shown that actively transcribed and potentially active chromatin domains are selectively enriched in hyperacetylated histones, whereas transcriptionally inactive chromatin contains hypoacetylated histones.

A role for specialized chromatin structures in mediating transcriptional silencing by methylated DNA, like that found in the facultative heterochromatin of vertebrates, has been suggested by several investigators. High levels of methyl-**CpG** correlate with transcriptional inactivity and **nuclease** resistance in vertebrate chromosomes (4). Methylated DNA transfected into mammalian cells is also assembled into nuclease-resistant structures within the assembled minichromosomes, indicating the existence of unusual **nucleosomal** particles (5). These unusual nucleosomes migrate as large nucleoprotein complexes in agarose gel electrophoresis. These complexes are held together by higher order protein–DNA interactions, despite the presence of abundant **micrococcal nuclease** cleavage points within the DNA. Individual nucleosomes assembled on methylated DNA interact together more stably than on unmethylated templates.

The accessibility of chromatin to nucleases could also be affected directly by the stability with which the histones interact with DNA within the nucleosome. DNA methylation does not influence the association of core histones with the vast majority of DNA sequences in the genome. However, for certain specific sequences, such as those found in the Fragile X mental retardation gene 1 promoter, methylation of CpG dinucleotides alters the positioning of histone–DNA contacts and the affinity with which these histones bind to DNA (see Acentric Fragment). The exact chromatin structure found *in vivo* can also result from gene activity. Linker histones, such as H1, are relatively deficient in the transcribed regions of genes. So it is not surprising that transcriptionally inactive facultative heterochromatin containing methyl-CpG should show an increase in the abundance of histone H1, whereas DNA sequences lacking methyl-CpG are deficient in H1. *In vitro* studies indicate that histone H1 interacts preferentially with methylated DNA under certain conditions.

There are also features of transcriptional repression dependent on methylated DNA that can be explained by methylation-specific repressors that operate more effectively within a facultative heterochromatin environment. Transcriptional repression is strongly related to the density of DNA methylation. A non linear relationship exists between the lack of repression observed at low densities of methyl CpG and repression at higher densities. These results led to the demonstration that local domains of high methyl-CpG density confer transcriptional repression on unmethylated **promoters** in *cis*. The importance of a nucleosomal infrastructure for transcriptional repression dependent on DNA methylation is shown by the observation that immediately after injection into *Xenopus* oocyte nuclei, methylated and unmethylated templates both have equivalent activity (6). As facultative heterochromatin is assembled, however, the methylated DNA is repressed with the loss of DNase I hypersensitive sites and the loss of engaged **RNA polymerase** . The requirement that nucleosomes exert efficient transcriptional repression dependent on DNA methylation can be explained in several ways. Methylation-specific repressors might recruit a corepressor complex that directs the modification of the chromatin template into a more stable and transcriptionally inert state. One potential candidate corepressor for MeCP2 is the SIN3-histone deacetylase complex, because inhibition of histone deacetylation reverses some of the transcriptional repression conferred by DNA methylation (7). Alternatively, like histone H1, methylation-specific repressors might bind more efficiently to nucleosomal rather than to naked DNA. Any cooperative interactions between molecules could propagate their association of methylation-specific repressors along the nucleosomal array even into unmethylated DNA segments. This latter mechanism is analogous to the nucleation of heterochromatin assembly at the yeast telomeres by the DNA-binding protein RAP1, which then recruits the repressors SIR3p and SIR4p that organize chromatin into a repressive structure (8) (see Telomere). All of these potential mechanisms could individually or together contribute to assembling of a repressive facultative heterochromatin domain.

A final relevant issue is the significance of the timing of replicative initiation on facultative heterochromatin in **S-phase**. Facultative heterochromatin is normally replicated late in the S-phase. If replication disrupts both active and repressed chromatin structures, then the entire nucleus has to be remodeled after each replication. The accessibility of immature chromatin on newly replicated DNA provides a means to accomplish this remodeling. The reformation of nuclear structures, however, has other implications. If the transcription factors available in a cell are limiting, then a gene that is replicated early in the S-phase has more opportunity to assemble an active transcription complex than a gene that replicates late simply because the gene that replicates early is available for transcription factors to bind to it before all of the early replicating portion of the genome has sequestered these factors. Therefore a late-replicating gene in facultative heterochromatin experiences a relative deficiency in transcription factor availability. Transcriptionally active genes in euchromatin replicate early in the S-phase (see Euchromatin). The reason for this early replication is unknown, but possibilities include the local disruption of chromatin structure by transcription complexes, which makes that DNA more accessible to the replication machinery (9) and the observation that many transcription factors are in fact also replicative factors. An attractive variation of this model is that the type of chromatin assembled early in the S-phase is more accessible to transcription factors than chromatin assembled late in the S-phase. Early replicating chromatin may sequester histones that are more highly acetylated and consequently more accessible to the transcription factors that maintain continued transcriptional activity. The CENP-A protein that replaces histone H3 in the mammalian centromere within heterochromatin is synthesized at the very end of the S-phase, providing an example of how the cell cycle-dependent compartmentalization of **protein biosynthesis** might contribute to assembling a specialized chromatin structure (10). Although a general test of the significance of this model has not been made, it remains an attractive mechanism for explaining both the maintenance of specific patterns of gene expression in a proliferating cell type and the maintenance of domains of facultative heterochromatin.

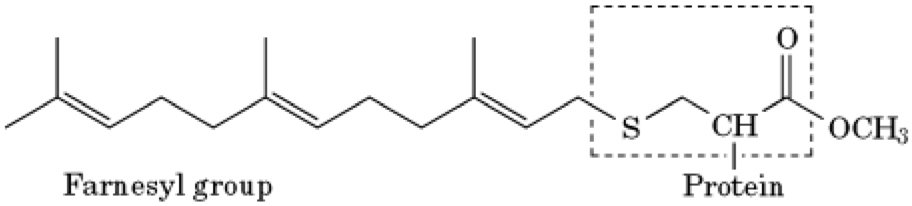
Farnesylation

Farnesylation is the process by which a cysteine residue in the C-terminal region of some eukaryotic proteins is **posttranslationally modified** with an isoprenoid lipid (the 15-carbon farnesyl group) and the exposed carboxyl group is methylated (Fig. 1). The farnesylation and carboxylmethylation increase the affinity of the protein for the membrane and have important functional consequences. The farnesyl group is one of several lipids that act as a membrane anchor for proteins. The role of the farnesyl group and other lipids in membrane anchoring is described in more detail elsewhere [see Prenylation; Membrane Anchors]

Figure 1. Modification of a C-terminal cysteine residue by a farnesyl group.



Farr Assay

The Farr assay (1, 2) is a precipitation-based immunoassay that is especially appropriate for analysis of certain antibody–antigen interactions that do not lead to an insoluble lattice of crosslinked antibody–antigen complexes (see Precipitin Reaction). Failure to crosslink is frequently encountered with haptens, small antigens, and monoclonal antibodies. The Farr assay takes advantage of a common solubility property of immunoglobulins. Ammonium **sulfate** at 50% saturation causes antibodies and immune complexes to precipitate, whereas free antigens and haptens often remain soluble. Measurement of the antigen-binding capacity of an uncharacterized antibody preparation can be achieved by mixing a fixed amount of antigen with serial dilutions of antibody, allowing the binding reaction to reach equilibrium, precipitating free and complexed antibody with ammonium sulfate, and then measuring the antigen content of the precipitate. Antigen is precipitated quantitatively until a subsaturating dilution of antibody is reached, whereupon the antigen content of the precipitates progressively decreases. Observation of a constant amount of precipitate at saturating antibody concentrations differs from the precipitin reaction, in which excess antibody actually inhibits formation of a precipitate. The Farr assay is now obsolete, but is cited frequently in older literature.

Fate Map

1. Classical Fate Maps

A fate map is a graphic representation of the cells or regions within the embryo at one point during development that will develop into specific tissues and organs at subsequent developmental stages. The concept of the fate map may be one of the earliest abstract ideas in embryology, one that is implicit, for example, in the "homunculus" imagined by seventeenth century microscopists to be a miniature adult human that is "preformed" within the sperm. The concept of preformation was generally favored by scientists until the last half of the eighteenth century, when Caspar Friedrich Wolff, through observation of chick embryo development, postulated that embryos develop through a process he termed "**epigenesis**," whereby unpatterned tissues of the early embryo reorganize and expand to form the tissues and organs of the adult. As the cellular basis for tissue organization came to be understood by the mid-nineteenth century, it eventually became clear that embryonic development could be characterized by four cellular phases common to all vertebrate and most invertebrate embryos: (i) formation of the single-celled, diploid zygote (or fertilized egg) through union of haploid sperm and egg; (ii) **cleavage** , in which the fertilized egg undergoes mitotic division without increase in size to form the multicellular **blastula** (mammalian: blastocyst); (iii) **gastrulation**, in which blastula cells rearrange and expand to form the three **primary germ layers** (ectoderm, mesoderm, and endoderm) that are organized into the basic body plan (concepts developed in the early nineteenth century by von Baer); and (iv) **organogenesis**, in which the cells within the the three primary germ layers of the embryo form the organ and tissue primordia that develop into the tissues and organs of the *fetus* . The fetal stage of development is distinguished from the embryonic phase in that the fetus is indeed a preformed miniature of the adult that contains all of the organ and tissue rudiments (in the right places and containing differentiated cells and stem cells) that need only to expand and mature to function as adult tissues and organs. The transition from embryo to fetus occurs at about the eighth week of human development.

In the late nineteenth and early twentieth centuries, embryologists began to take an experimental approach to the study of development. Fate maps of relatively simple embryos, such as ascidians, were initially established by directly observing the fate of blastula cells during gastrulation (1). The emergence of dyes that could be applied to living tissues without damaging them ("vital dyes") permitted selective staining of parts of blastula embryos and subsequent tracing of the tissues of the embryo that developed from these stained parts. Systematic application of this procedure to trace the fate of different regions of amphibian blastulas through gastrulation led to the construction of the first detailed and comprehensive fate map of a vertebrate embryo (2, 3). Subsequent work by many individuals led to the construction of fate maps for organ rudiment primordia of a variety of chordate embryos (amphioxus, fish, amphibians, birds) (4-9). These maps continue today as the primary basis for our present day understanding of **morphogenetic** movements (2) that blastula cells undergo during gastrulation. Nevertheless, these maps are constantly being revised and refined by applying more modern techniques. For recent examples, see fish (10, 11); birds (12-15); and amphibians (16-18).

Although fate maps, such as those described previously, give a general idea how regions of the blastula give rise to the primary organ primordia of the embryo, they do not yield precise details of the way cells within those primordia give rise to the more complex tissues and organs of the fetus and adult. These events could not be adequately followed by direct observation because of the massive expansion of cells during the embryonic phase of development. Moreover, during the ensuing cell expansion and migrations, vital dyes became diluted beyond the level of detectability. The latter problem was only partially circumvented by using microscopic carbon particles to follow cell movements and rearrangements (19, 20).

In the late 1960s, however, Nicole Le Douarin developed a powerful method for embryonic fate mapping that allowed following the mapping of embryonic tissues indefinitely, even into full adulthood. Briefly, she discovered that quail cells could be distinguished from chicken cells by a nucleolus in the quail cell that developed a brilliant magenta color when stained with the Feulgen reagent (21, 22). By transplanting homologous tissues from quail embryos into chick embryos, the fate of the transplanted quail cells could be established unequivocally by histological methods. Through broad application of this method, the development of the avian embryo has been mapped in detail (see Ref. 23 for many examples) Much of this newer map supports and confirms earlier work. Nevertheless, this new method brilliantly illuminated the many limitations and previous inaccuracies of earlier methods. This is particularly true for migratory mesenchyme cells within the embryo, such as the neural crest, which, as revealed by LeDouarin and co-workers, populate a previously unknown variety of tissues and organs (24-28). In addition, the embryonic development of other mobile cell populations, such as blood cell lineages (29-34) and muscle precursor cells (35-37) and many other other tissues, were extended and clarified in ways not possible previously.

2. Mammalian Embryo Fate Maps

Fate mapping in mammalian embryos progressed much more slowly because of the relative inaccessibility of these embryos within the mother's uterus. Therefore, the fate maps in most existing textbooks are derived from the avian embryo based on assumption that mammalian development is essentially identical. Because of the recent development of methods for *in vitro* culture of early mammalian embryos, fate mapping of early mammalian development has begun. One such fate map experiment was conducted by transplanting fragments of tissue from early mouse embryos **radiolabeled** with tritiated thymidine in unlabeled embryos, followed by localizing the labeled tissues by autoradiography (38). The recent development of highly **fluorescent** dyes that can be injected into cells has greatly facilitated fate mapping of early mouse embryo tissues (39-43) To date, the most important outcome of such studies has been to establish that existing mammalian fate maps based upon the avian model are indeed valid by and large. Therefore, it is no exaggeration to state that the methods and strategies developed by Le Douarin and the resulting detailed fate maps of the avian embryo provide the most accurate and comprehensive information garnered during the twentieth century about the cellular movements underlying vertebrate embryonic development, including mammalian and human development.

3. Embryonic Fate and Developmental Potential

At the onset of development, the single-celled zygote can form all of the cell and tissue types of the adult, and this potential is apportioned during embryogenesis. The relationship between developmental potential and developmental fate is the central question that developmental biologists have been trying to understand for more than a century [the reader is directed to a recent and excellent review and discussion by Viktor Hamburger of the early experiments in this area (44)]. Wilhelm Roux first addressed this problem experimentally in 1883 by ablating one blastomere of an amphibian embryo. He found that the surviving blastomere formed an incomplete embryo, leading him to conclude that fate and potential were apportioned in concert. Although this initial conclusion was flawed, Roux's novel and experimental approach laid the foundations for what came to be known as **experimental embryology**. It was not long until it was experimentally established that developmental potential is generally more widely dispersed within the early embryo than developmental fate. Thus, a specific region of the early embryo can develop into several different tissues and organs, even though its fate represents only one of those possible outcomes. As the embryo matures, the range of potentiality of these regions becomes restricted until, ultimately, potential and fate become equal, and the tissue is deemed determined (45). The mechanism(s) that control fate and potential constitute one of the central mysteries of developmental biology. The seminal experiment that established the profound depth of this mystery was reported in 1924 by Hilda Mangold, a graduate student in the laboratory of Hans Spemann. She showed that fragments of specific regions from one amphibian gastula could induce formation of a complete second embryo when transplanted into the prospective belly region of a host gastrula (46) (an English translation of this article can be found in Ref. 47). The fact that the transplanted fragment could reprogram host tissue, fated to form abdominal structures, to form head tissues, including brain, led to the "organizer" hypothesis, in which some embryonic tissues play central roles to induce and direct the development of neighboring tissues. That discovery provided the conceptual basis for virtually all developmental biology in the twentieth century. Despite the advances in the cellular and molecular analysis of development in the last two decades of this century, the mechanistic bases for organizer function, morphogenesis, and cell determination in vertebrates remain mysteries.

4. Genetic Control of Developmental Fate

By contrast, however, research into mechanisms by which genes control embryonic development has progressed most rapidly, using the fruit fly *Drosophila*, because of the advanced state of genetic analysis in this organism. Although a fate map of the early *Drosophila* embryo was available by mid-twentieth century (48), a coherent hypothesis regarding the role of specific genes in establishing the Drosophila fate map was first proposed in 1980 (49-51) (see Ref. 52 for a broad discussion of the underlying embryological issues). This breakthrough in studying the relationship between embryonic fate maps and genetics has revolutionized the developmental biology of *Drosophila*. A large proportion of the **genes** that act developmentally in flies have vertebrate **homologues** that play key, but typically different, developmental roles. Thus, a definitive model for the genetic control of embryonic fate maps and pattern formation in vertebrates remains to be established.

5. The Difficult Relationship Between Fate Maps and Vertebrate Genetic Expression Patterns

Molecular probes for the expressed products of genes developed during the last half of the twentieth century have allowed superimposing fate maps and gene expression maps. The first use of such a technique can be traced back to at least 1957, when Holtzer and Detwiler used a fluorescent antimyosin antibody to localize the earliest appearance of differentiated muscle cells within the somite myotomes of chick embryos (53). This general approach expanded enormously in recent years and now includes in situ hybridization, which allows detecting the **RNA** products of genes. Thus the developmental expression maps of a large number of genes of both known and unknown function are now known for development of a wide range of organisms. In instances in which the patterns derived from these two types of maps coincide, it is often assumed that the molecular expression accurately reflects that of cells whose fate is known. Although this may be generally true, the assumption carries potential pitfalls of which one should be wary, at least when unaccompanied by appropriate experimental validation. Migratory cells, for example, often intermingle transiently with and are indistinguishable from nonmigratory cells. The signal from the migratory cells in such situations can be discerned if they carry an independent lineage marker, such as the quail nucleolus referred to previously, that allows distinguishing them from their nonmigratory counterparts (54). On the other hand, some gene products (particularly RNA) can appear and be degraded extremely rapidly in patterns that reflect transcriptional waves passing through specific tissues. Pourquie and co-workers discovered such transcriptional waves and distinguished them from cell migration by demonstrating discordance over time between the pattern of injected fluorescent dyes and gene expression signals (55). Finally, cells may transiently express one gene product at one period of development and then switch to expression of another. Cepko and co-workers have developed techniques in which infective retroviruses are used to follow transient expression patterns of individual cells and their progeny through complex developmental pathways (56-59). These examples serve only to illustrate that gene expression patterns can only be assumed to reflect cell lineage or fate maps until experimentally verified by independent means.

6. Transgenic Strategies for Fate Mapping

Molecular techniques are now being used to map developmental fate and potential and also to manipulate them experimentally. Retroviruses are widely used to deliver bioactive genes to influence development positively or negatively through the expression of exogenous gene products (for examples, see Refs. 60, 61). The emergence of methods for creating germ-line **transgenic** mice has led to a variety of new and imaginative approaches to analyzing of the relationship between cell fate and gene expression in mammalian development. Buckingham and co-workers have “knocked-in” a **beta-galactosidase** marker gene into a gene locus, which that controls the onset of myogenesis, to locate newly "born" muscle precursor cells in the mouse embryo (62, 63). Recently, transgenes that must undergo recombination signals to be expressed in a cell- or tissue-specific fashion have been used by Nicolas and co-workers to track cell lineage progression in early mouse development (64-66). It is important to keep in mind that, because each of these techniques depends on cell- or tissue-specific gene regulation (which is itself only beginning to be understood), each is subject to the caveats alluded to previously for the relationship between cell fate and gene expression. Nevertheless, the power of these new techniques augers well for the future analysis of mechanisms underlying the apportionment of cell fate and potential during embryonic development.

Fatty Acids

The major fatty acids of plants and animals contain even numbers (14 to 26) of aliphatic carbon atoms in straight chains, with a terminal carboxylic acid group. The acids may contain up to six nonconjugated *cis*-double bonds, generally separated by two single bonds and a single methylene group. Several shorthand nomenclatures are in use to indicate the number of carbon atoms they contain and the number and position of the double bonds; for example, linoleic acid may be written either as 18:2($n-6$) or 18:2w6, where the number of carbon atoms in the chain ($n=18$) is followed by a colon and the number of double bonds (two). The position of the double bonds is set by the number of carbon atoms from the last double bond to the terminal (or w) methyl group (6); in this example, the two double bonds are between carbons 12–13 and 9–10.

Fatty acids appear as the free acids only when bound to serum albumin in blood. They occur in cell membranes primarily as the hydrophobic moiety in phospholipids and other membrane lipids as esters (see Lipids). Linoleic acid is one of a family of *essential* fatty acids (EFAs) that are required for growth and development in mammals. The EFA all contain the ($n-6$) terminal structure, which cannot be synthesized by mammalian cells because they are unable to introduce *cis*-double bonds beyond carbon 9 in fatty acids. The EFA must therefore be obtained from plants whose enzyme systems do synthesize the ($n-6$) terminal structure. Some of the more abundant fatty acids in cells are listed in Table 1.

Table 1. Some of the More Abundant Fatty Acids in Animals

Systematic Name	Common Name	Shorthand Notation
Saturated		
Dodecanoic	Lauric	12:0
Tetradecanoic	Myristic	14:0
Hexadecanoic	Palmitic	16:0
Octadecanoic	Stearic	18:0
Eicosanoic	Arachidic	20:0
Docosanoic	Behenic	22:0
Tetracosanoic	Lignoceric	24:0
Monoenic		
cis-9-Dodecenoic	Lauroleic	12:1($n-3$) 12:1w3
cis-9-Tetradecenoic	Myristoleic	14:1($n-5$) 14:1w5
cis-9-Hexadecenoic	Palmitoleic	16:1($n-7$) 16:1w7
cis-9-Octadecenoic	Oleic	18:1($n-9$) 18:1w9
cis-11-Octadecenoic	*cis*-Vaccenic	18:1($n-7$) 18:1w7
cis-9-Eicosenoic	Gadoleic	20:1($n-11$) 20:1w11
cis-13-Docosenoic	Erucic	22:1($n-9$) 22:1w9
cis-15-Tetracosanoic	Nervonic	24:1($n-9$) 24:1w9
Polyunsaturated (PUFA)		
9,12-Octadecadienoic	Linoleic	18:2($n-6$) 18:2w6
6,9,12-Octadecatrienoic	g-Linolenic	18:3($n-6$) 18:3w6
8,11,14-Eicosatrienoic	Homo-g-linolenic	20:3($n-6$) 20:3w6
5,8,11,14-Eicosatetraenoic	Arachidonic	20:4($n-6$) 20:4w6

9,12,15-Octadecatrienoic	a-Linolenic	18:3($n-3$)	18:3w3

Female

The female is one of the two possible **sexes** in nature, the other being the male. Characteristically, mature females produce **oocytes**. In species with intracorporal fertilization, the most predominant feature of a female is the limited number of **gametes** that can be produced. For example in mammals, primordial **germ cells** divide by **mitosis** in females until a certain number (200,000) of oocytes is reached. After birth, these mitotic divisions come to a standstill, and **meiosis** and further maturation of oocytes occurs after puberty at ovulation. Ovulation is not a continuous production of eggs, but involves a selection process in which certain ones are able to become dominant and cause atresia in others. These events typically occur in cycles, with a duration of 21 to 28 days. However, spontaneous or inducable ovulations can also take place, as in the cat or rabbit. Although the number of oocytes produced seems to be more than sufficient, it is apparent, for example, in humans, that the fertile period in the life span of a female is, unlike in males, restricted to a certain age and, within this age, to certain days periodically. This fact is probably the most typical feature of females with regard to **reproduction**.

Considering that each individual strives to transfer its genes to the next generation, the limited number of gametes with a chance to be fertilized causes females to take greater care of each individual gamete than males do. In females, natural selection therefore proceeded in a different way than in the male. Reproductive success in females is optimized when the offspring are actually raised and attain the ability to reproduce in the next generation. As a consequence, females not only use substantial resources in producing a single gamete, by adding nutrition (yolk) (1) and all necessary substances for initial cell divisions and growth of the cells, but, especially in higher chordates, they also provide basic nutrition for the offspring born (2). This is especially the case in mammals, where nutrition and protection is provided for a prolonged time after birth during childhood by the mammary glands, which are a typical female feature. Also, as can be seen in primates, raising of the offspring is done mostly by the female, although there are exceptions (3). Natural selection does not occur in a competition in which genes must be spread, but the most successful female is the one that is best able to protect and raise the offspring. In this respect, it is evident why females in the animal kingdom are better adapted to the environment with regard to hair or feathers, because this serves as a protection against predators. The appearance of this kind of sexual dimorphism depends on the degree of specialization among the two sexes.

In species with extracorporal fertilization, such as frogs and fishes, differences between the two sexes are smaller than in mammals. In these species, both the male and female produce a vast number of gametes to form numerous new individuals. In these species, parental care for the offspring is not the rule. As a consequence, the **phenotypically** visible differences between the sexes vanish. Nevertheless, for the sake of reproductive success, females invest more than males, because the cost of producing eggs is greater than that of producing sperm.

The common biological necessity in females of a greater investment in reproduction has evolved common characteristic features among females of different species. For example, the genitalia of the female consist of **germ-cell** conducting parts (tubes) as well as of germ-cell preserving parts (uterus). Although both male and female genital cells have the same origin in the primordial urogenital tract and in the primordial germ cells, the lack of male hormones due to the absence of the testis-determining factor allows the development of mullerian ducts (see Sex). The fate of these organs is to develop finally to an uterus and a vagina during embryogenesis. Also, the hormonal situation is different in females and males. After puberty, cyclic hormonal actions take place in the female. The expression of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are directed by FSH-releasing hormone and LH-releasing hormone, respectively. FSH and LH induce ovulation and the expression of estrogen and progesterone, which occurs in the follicle.

In the cascade of sex determination and in adults, hormones are also responsible for the expression of the female phenotype. This includes psychological behavior. Hormones in the female direct fertilization events like ovulation and behavior, eg to indicate the mating time for males.

In higher organisms, the female is the homogametic sex XX, the male the heterogametic XY. Sex determination occurs by the dependence of the presence or absence of the testis-determining factor (SRY), a gene located on the Y-Chromosome in mammals. In these species, therefore, sex determination is dependent on the sperm that successfully fertilizes the oocyte. In birds, some amphibians, and insects, the situation is reversed: The homogametic sex is male, the heterogametic sex is the female. Instead of two X-chromosomes, the chromosomes in the female are ZW, and sex determination occurs during ovulation (see Sex).

Parthenogenesis is possible only with eggs and occurs in some genera of lizards. In some species of fish, spermatozoa are necessary only for the induction of the egg, not for a genetic contribution.

Ferguson Plot

Measuring the **electrophoretic** mobility of a macromolecule at several gel (polymer) concentrations (see Gel Electrophoresis) provides information about its size and surface net charge density. In the ideal case, a plot of the logarithm of the mobility versus the gel concentration is linear and known as a Ferguson plot . The slope of such a plot gives the retardation coefficient , which is a measure of the size, shape, and conformation of the macromolecule. The intercept at zero gel concentration provides a measure of the free electrophoretic mobility, the mobility it would have in the absence of gel, which is related to the net charge on the molecular surface. In contrast, the mere inspection of one electrophoretic pattern or measurement of the mobility of one band gives no information whatsoever concerning the size or net charge of the migrating species; even a comparison with standard macromolecules is usually unreliable.

To generate a Ferguson plot, several gel (or polymer) concentrations are used simultaneously in a multitube or multichannel electrophoresis apparatus. Alternatively, a **transverse gradient** of gel concentration can be used in a single-slab gel. The slopes and intercepts of the Ferguson plot are computed and translated to parameters descriptive of the size and net charge, including their statistical limits, using relevant computer programs (1). Even without such translation, the Ferguson plot can be used to recognize qualitative relationships between the size or net charge of related bands of an electropherogram, or to test the possibility that two species are identical. Recognition of the nature of the relationships between bands helps to decide whether to use separation methods based primarily on size (see Gel Electrophoresis; Capillary Zone Electrophoresis) or charge (see Isoelectric Focusing; Isotachophoresis).

A linear Ferguson plot is expected from a simple mathematical model of a rigid ball passing through an inert random fiber network of the gel matrix (the Ogston model); it is observed experimentally with relatively rigid and spherical proteins passing through gels electrophoretically. In contrast, Ferguson plots derived with agarose gels are convex, presumably due to the progressive supercoiling of double-helical agarose with decreasing concentration. They are concave when used with DNA fragments, presumably due to the progressive stretching of the DNA molecule with increasing gel concentration.

Ferredoxins

Ferredoxins (Fds) are simple iron–sulfur proteins; that is, they do not contain other **prosthetic groups** beside one or two iron-sulfur (FeS) clusters. The first Fd to be discovered was that from *Clostridium pasteurianum* in 1962, immediately followed by the one from plant chloroplasts (1). Fds are ubiquitous, small, generally very acidic proteins, diverse in structure and function, that are involved mainly as electron carriers of low oxidation/reduction potential in fundamental metabolic processes like photosynthesis, nitrogen fixation, and assimilation of hydrogen, nitrogen, and sulfur. Recently, functions other than **electron transfer** have been discovered for some members of the very large class of FeS proteins. Indeed, it has become clear that most bacteria and plants contain not just one Fd, but a variety, distinguished by amino acid sequence, FeS cluster type, redox potential, and function. The Archaebacteria are particularly rich in Fds: *Methanococcus jannaschii* has 8 Fds and 6 polyFds, and *Archeoglobus fulgidus* has 8 Fds; as are the diazotroph bacteria (there are 8 to 9

Fds in *Azotobacter vinelandii*), followed by higher plants, from which at least six soluble Fds have been isolated. In bacteria, the number of Fds varies widely: just one Fd in *Bacillus subtilis*, but four in both *Mycobacterium tubercolosis* and *Escherichia coli*. In the first completed eukaryotic genome, that of the yeast *Saccharomyces cerevisiae*, only one Fd is present, which is similar to Fds found in mammalian mitochondria (adrenodoxin/renodoxin) that function in the hydroxylations catalyzed by cytochrome P450 for formation of steroid hormones, vitamin D metabolites, and bile acids.

Fds contain iron and sulfur atoms, organized in three different types of iron–sulfur clusters that are defined as 2Fe–2 S, 4Fe–4 S, and 3Fe–4 S (see Iron–Sulfur Proteins). These proteins absorb light in the 300- to 500-nm wavelength region: their solutions are brownish in color and become paler upon reduction. Typical **electron para-magnetic resonance** signals are shown by Fds in either the oxidized or reduced states. These proteins are sensitive to acids, oxidants, mercurials, and alkylating agents, but they show fair stability in the pH range 6 to 9 and to heat **denaturation** in the absence of oxygen. Fds are best divided into two classes: 2Fe–2 S Fds and 4Fe–4 S Fds, that may include the 3Fe–4 S clusters.

1. 2Fe–2 S Ferredoxins

These Fds are ubiquitous hydrophilic proteins of 11 to 15 kDa containing one 2Fe–2 S cluster that function as one-electron carriers. The iron-binding amino-acid sequence motif is Cys–X_4–Cys–X_2–Cys, which provides three of the four Cys ligands to the cluster; the fourth Cys ligand is distant in the primary structure. In some bacterial Fds of the hydroxylating dioxygenases (2) and in adrenodoxin, the spacing between the two first Cys residues is X_3 and X_5, respectively. The reduction potential varies in the range –400 to –100 mV (relative to the hydrogen electrode). The prototype of this class is the plant-type Fd (3), which has the role of distributing electrons received from the photoreduced photosystem I to several ferredoxin-dependent enzymes. The protein structure motif characteristic of these proteins is called "b-grasp" (a five-stranded **b-sheet** with an **a-helix** lying on top of the sheet). Adrenodoxin and putidaredoxin have additional small interaction **domains**.

2. 4Fe–4 S and 3Fe–4 S Ferredoxins

The prototype bacterial ferredoxin (4, 5) contains FeS clusters of the so-called "cubane" type, in which the four iron and four sulfide atoms are placed alternatively on the corners of a somewhat distorted cube. Coordination to the protein typically occurs through four cysteine thiolate groups to the four iron atoms. The most common bacterial ferredoxins contain two such clusters in a polypeptide chain of 50 to 60 residues. These proteins are typically found in anaerobes, where they are involved in one-electron transfer in low-potential systems, collecting reducing equivalents from a wide variety of substrates and metabolic cycles. A structural distinction has been made between the above classes of ferredoxins, which have been divided into "clostridial-type" and "photosynthetic bacterial and nif-related" ferredoxins. The former contain two Cys–X_2–Cys–X_2–Cys–X_3–Cys–Pro motifs, while the latter contain one motif of that type and the more unusual Cys–X_2–Cys–$X_{7–9}$–Cys–X_3–Cys–Pro motif. All these proteins are low-potential electron carriers, with typical reduction potential in the –390 to –450 mV range.

Some of the clostridial-type ferredoxins found in *Desulfovibrio spp* and in extreme **thermophiles** such as *Pyrococcus furiosus* contain a Cys–X_2–Asp–X_2–Cys binding motif, with a remote Cys residue as the fourth ligand and the Asp available to take the place of the missing central Cys residue of this sequence. These proteins contain a 3Fe–4 S cluster, which can be converted reversibly to a 4Fe–4 S cluster upon addition of iron and which may bind to exogenous ligands, such as thiol groups and cyanide. Cornerless cubanes containing the 3Fe–4 S clusters may be formed upon oxidation (by oxygen or ferricyanide) of regular 4Fe–4 S clusters, in a possibly reversible process.

Ferritins

Ferritins and transferrins are nonheme iron-transport proteins that provide the crucial link between dietary iron and organismal heme-iron pools (hemoglobin, myoglobin, and hemosiderin) in maintaining iron homeostasis in mammals. Ferritin is a large protein (ca. 500 kDa) that consists of an aggregate of so-called heavy and light chains, which form a hollow shell in the apo form. Each apoferritin molecule can take up 4500 iron atoms, effectively shielding them from harmful reactions with peroxide and superoxide.

Transferrins are much smaller proteins that take up iron by binding to the transferrin receptor (TfR) at the cell surface. The complex is subsequently internalized by endocytosis, and then the iron dissociates into the cytoplasm, where it is free to be taken up by ferritin and other cellular proteins.

The messenger RNAs for transferrin receptor and for both ferritin subunits contain so-called iron-response elements (IREs), which are RNA structures containing a stem and a loop that has the consensus sequence CAGUGX (1). This regulates the translation of the mRNAs.

Fertilization

In the animal kingdom, fertilization is a unique event in which a male and female haploid **gamete** join and follow a cascade of highly regulated events that results in the production of a new individual (Fig. 1). During the early stages of fertilization, the two morphologically disparate gametes, the **oocyte** and the sperm, follow a very specific process of recognition and fusion. The interactions between the two gametes and with their tubal environment are mediated by highly specialized molecules located on the outer surfaces of membranes of the gametes and on the surrounding epithelia. The molecular interactions between the oocyte and spermatozoon are also unique with regard to gene function. Both gametes are haploid, and furthermore the nucleus is greatly condensed in the spermatozoa. Thus, no gene transcription takes place; consequently, all biochemical and molecular biological interactions must be done by proteins and, to some extent, by pretranscribed RNA of the oocyte. This means that regulation of the nucleus does not take place; instead, proteins and RNA involved in the fertilization process act autonomously. On the spermatozoon, the adhesion molecules are divided into primary and secondary ligands (see Acrosome). Primary ligands are involved in initial gamete binding, whereas secondary ligands, such as proacrosin, come into action after the acrosome reaction has taken place. In the oocyte, interactions with the other gamete are mediated by an extracellular matrix, the *zona pellucida* (see Egg). This organelle consists of three **glycoproteins**, ZP1, ZP2, and ZP3, of which ZP1 is responsible for structural integrity, whereas ZP2 and ZP3 have been shown to have sperm receptor activity (1). In the mouse, primary ligands interact with ZP3, whereas secondary ligands like proacrosin also bind strongly to ZP2. Only after completion of all complementary signals and responses is penetration of the spermatozoon through the zona pellucida possible, which directs the transfer of the male genetic information to the oocyte. The fertilization process has been divided into individual steps by Wassarman (1), in a widely accepted scenario:

1. **Capacitation**. In the female genital tract, ejaculated spermatozoa undergo a process called *capacitation*. This maturing process of spermatozoa is necessary to gain full fertilization capacity, but the basic mechanisms are not fully understood. Lectins from the seminal cytoplasm adhering to the surface of the acrosomal cap undergo a change in conformation and adopt structures that enable coupling of primary receptors.
2. **Attachment**. *In vitro* fertilization experiments demonstrated that the oocyte and spermatozoa initially are attached only loosely. This loose attachment is not species-specific, and the spermatozoa can be removed easily from the egg by small turbulences.
3. **Primary binding**. After the initial contact, the sperm bind tightly to the zona pellucida. This species-specific interaction is mediated by primary receptors and ligands. Now the spermatozoa cannot be removed easily from the egg by physical means.
4. **Acrosome reaction**. Triggered by the contact with the zona pellucida, spermatozoa undergo exocytosis, known as the *acrosome reaction*. This involves hyperactivation of the motile spermatozoa, multiple point fusion of sperm cytoplasm and the outer acrosomal membrane, formation of hybrid vesicles, and exposure of the inner acrosomal membrane. Enzymes (mainly proacrosin) and inner acrosomal components that are necessary for binding, local lysis, and penetration of the zona pellucida are released and come into action.
5. **Secondary binding**. After the acrosome reaction, secondary ligands and receptors maintain the affinity between the two gametes. The forces are strong enough to keep the spermatozoa tightly attached to the zona pellucida. Adhesive proteins like proacrosin play an important role in high affinity binding.
6. **Penetration**. After exposure of the inner acrosomal membrane, the predominant molecule of the acrosome, *acrosin*, has been generated from the precursor proacrosin. It acts as a binding molecule and also a proteinase; these two phenomena together enable the sperm to bind and lyse the zona pellucida locally. The spermatozoon is driven through the zona pellucida, forced by the motile sperm tail.

7. **Fusion**. The spermatozoon that first reaches the perivitelline space then fuses with the egg plasma membrane to form a zygote. On entry of the spermatozoon, the egg is activated, which leads finally to the unification of the male and female **pronuclei**.
8. **Primary block to polyspermy**. In order to prevent several spermatozoa fusing with the oocyte, a rapid depolarization of the egg plasma membrane occurs within seconds after gamete fusion.
9. **Cortical reaction and zona hardening**. The cortical granules of the egg, which can be regarded as **lysosome**-like **organelles**, release a variety of lytic enzymes on the fusion of a spermatozoon with the egg plasma membrane. The cortical granule contents are then deposited into the perivitelline space; when they enter the zona pellucida, the ZP2 and ZP3 glycoproteins are converted into ZP2f and ZP3f, the respective inactive forms of the receptor. This modification of the zona pellucida glycoproteins constitutes a permanent secondary block to polyspermy.

Figure 1. Sperm–egg interaction. Capacitated spermatozoa bind to the zona pellucida via primary ligands and receptors. This event triggers the acrosome reaction of the spermatozoa and activates secondary ligands on the sperm. (With the friendly permission of Dr. H.-W. Michelmann.)

Fiber Diffraction

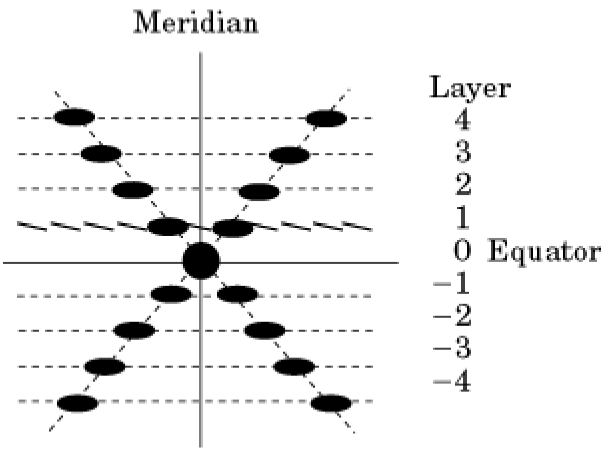
Fiber diffraction is a method of using X-ray diffraction to obtain structural information from a fibrous preparation of the material, rather than a three-dimensional crystal (see X-Ray Crystallography). Fibers consist of elongated molecules that are aligned parallel to each other along the fiber axis. In biological fibers, such as hair, collagen and **muscle**, the molecules are naturally aligned. In others the molecules must be forced to align by drawing them from a concentrated solution or by flow through a capillary. Magnetic and electric fields also have an effect.

The relatively weak X-ray scattering from fibrous specimen means that long exposures are necessary to record the diffraction pattern, and special cameras have been developed for the purpose. A fiber X-ray diffraction pattern shows series of lines of intensity perpendicular to the fiber axis, called layer lines. If the fiber axis is vertical, the layer lines are horizontal. Their distance is related to the periodicity along the fiber axis. The middle line is called the zero layer line or equator. The meridian is an imaginary line running vertically through the center of the diffraction pattern. The quality of the pattern depends on the degree of alignment of the molecules, but an X-ray fiber diffraction pattern is rarely of sufficiently high quality to determine a structure at atomic resolution. The best results are obtained with synchrotron radiation of cryocooled specimens.

In the 1930s, Astbury used fiber diffraction to group protein fibers into three types: a-fibers, b-fibers, and collagen. For a structural determination from fiber data, chemical information about the fiber is needed to postulate a model and to refine this model, obeying any symmetry constraints, until it predicts the observed intensities reasonably well. In this way, Watson and Crick arrived at the structure of **DNA** (1) and Pauling at the model for the a-helix (2). For larger structures, this is not so easy, and then isomorphous replacement is applied, as in protein crystal structure determination.

Fibers usually consist of helical arrangements of the building units. Cochran, Crick, and Vand found that the intensity diffracted by a continuous helix on the *n*th layer line is proportional to J^2_n (2p*Rr*) (3). The intensity distribution is cylindrically symmetrical around the reciprocal axis parallel to the fiber axis. *R* is the distance in reciprocal space to this axis, and *r* is the radius of the helix. J_n is a Bessel function of order *n*. These Bessel functions are oscillating functions that fade away with the distance from the origin. Therefore, the highest values are found close to the origin, which here is the meridian in the diffraction picture. But with increasing order *n*, these maximum values are found at a greater distance from the origin and become smaller. The combination of these properties creates the X-shaped diffraction picture characteristic of a helical structure (Fig. 1).

Figure 1. Schematic depiction of the typical diffraction pattern of a continuous helix.



Actual helices are not continuous, and the effect is that the intensity on a layer line depends on the structural repeat. If *P* is the pitch of the helix and *p* the axial rise from building unit to building unit along the helix axis, layer line numbers ℓ obey the equation $\frac{\ell}{c} = \frac{n}{P} + \frac{m}{p}$, where *c* is the structural repeat distance along the helix axis, n is the order of a Bessel function, and m is (like n) a whole number. This is illustrated by the following example. For the a-helix, $P = 5.4$ Å, and $p = 1.5$ Å. The structure repeats itself along the helix axis over a distance $c = 27$ Å. Therefore,

$$P = \frac{c}{5} \qquad p = \frac{c}{18} \qquad \frac{\ell}{c} = \frac{n}{P} + \frac{m}{p} = \frac{5n}{c} + \frac{18m}{c}$$

For layer line $\ell = 0$, this can be reached with the following combinations:

$n =$	–36	–18	0	+18	+36
$m =$	+10	+5	0	–5	–10

and for layer line $\ell = 1$ with

$n =$	–25	–7	+11	+29	+47
$m =$	+7	+2	–3	–8	–13

The intensity on every layer line is determined by a large number of Bessel functions J_n, but they have a nonnegligible value only for small n. Therefore, strong reflections occur on the zero layer line ($\ell = 0$) in the a-helix diffraction pattern, but not on the first one ($\ell = 1$). Layer line18 also has a strong reflection.

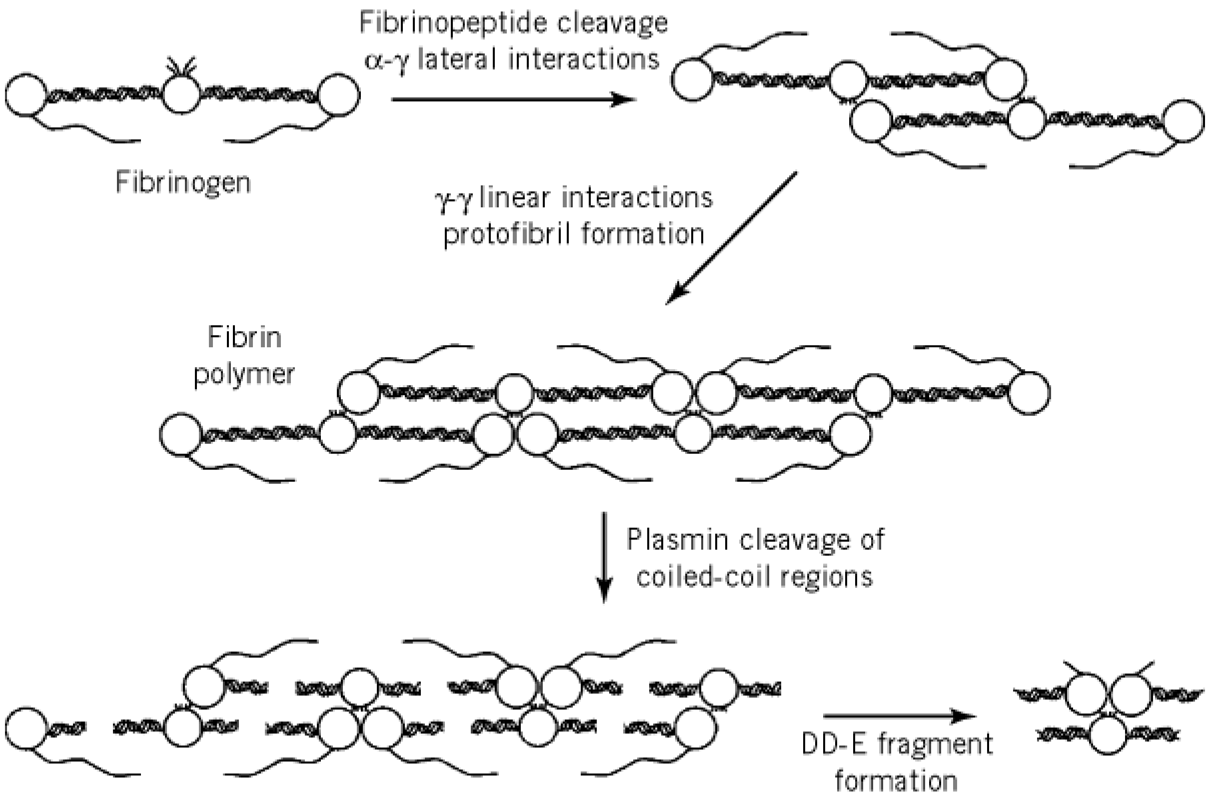
Fibrinogen

Blood clots when soluble fibrinogen is cleaved by thrombin to generate fibrin monomers which polymerize spontaneously, non-covalently and rapidly to form the insoluble fibrin clot, which is further stabilized by covalent cross-linking catalyzed by the transglutaminase, factor $XIII_a$ [see Blood Clotting]. This remarkable property is dependent on the symmetrical multi-chain structure of fibrinogen, the proteolytic exposure of cryptic binding sites, and the high concentration of fibrinogen in blood plasma (2–4 mg/mL). The cessation of bleeding is further enhanced by fibrin acting as a cofactor in blood platelet aggregation. The fibrin clot further acts as a provisional matrix for the subsequent repair of the wound.

Fibrinogen is a disulfide-bonded hexameric protein, arranged as a dimer of Aa, Bb and g chains.

These are the products of three distinct, but related, genes located in close association on human chromosome 4. The mature chains are 625, 461 and 411 residues, respectively, resulting in a molecular weight of 350 kDa for the hexamer. The gross topological structures of fibrinogen and fibrin have been deduced by both biochemical and biophysical methods. The overall appearance of fibrinogen is a linear trinodular structure 475 Å in length, with each nodule separated by an intervening rod-like region (1) (Figure 1). The N-terminal regions of all six chains are contained in the highly disulfide-bonded central nodule, the N-terminal disulfide knot. The N-termini of the Aa and Bb chains protrude from the nodule, while the g chains have shorter N-terminal sequences. Triple-chained coiled coils connect the central to the distal nodules, each of which is composed of two homologous globular domains comprising the C-terminal regions of the Bb and g chains. The longer Aa chain folds back along the axis of the molecule, to end in a globular domain that interacts with the N-terminal disulfide knot.

Figure 1. Schematic model of fibrin polymerization and its subsequent dissolution.



Structures have been determined by X-ray crystallography for various C-terminal proteolytic fragments of human fibrinogen (2, 3) and, although intact human fibrinogen has yet to be crystallized, the structure of native chicken fibrinogen has been resolved at a resolution of 2.7 Å (4). The triple-chained connecting regions are susceptible to proteolysis, generating two major fragments: fragment E corresponding to the central N-terminal nodule (approximately 15% of the molecule) and fragment D containing the distal globular domains (the two identical fragments accounting for approximately 50% of the molecule). Both of these fragments contain substantial portions of the cleaved coiled coil regions with the remainder of the protein accounted for by the C-terminal regions of the Aa chains.

Fibrin polymerization essentially occurs in three sequential steps. Firstly, thrombin cleaves the N-terminal regions of the Aa and Bb chains at Arg16-Gly17 and Arg14-Gly15, respectively, releasing fibrinopeptides A and B. The N-terminal sequence of the fibrin a chain (Gly17-Pro-Arg-Val) is the major determinant of fibrin polymerization which proceeds efficiently without further modification to the fibrin(ogen) structure, and synthetic peptides corresponding to this sequence can inhibit the polymerization of fibrin monomers (5). By contrast the b-chain sequence (Gly15-His-Arg-Pro), which is generated more slowly, although binding to fibrinogen and fragment D, cannot inhibit polymerization. Secondly, the new N-termini of fibrin monomer spontaneously interact with binding sites in the two homologous distal globular domains, with the g-chain site particularly implicated (3). Both sites are large cavities that bind a-chain Gly-Pro-Arg ligands, but the g-chain cavity is the more specific and does not bind b-chain Gly-His-Arg ligands. It is also the more distal of the two C-terminal domains and is able to intermolecularly associate in a specific “end-to-end” manner (2). Thus adjacent g-chain sites are closely situated for optimal binding of the dimeric a-chain N-terminal residues and the efficiency of polymerization derives from both a-g lateral and g-g linear interactions. The symmetry of fibrin(ogen) allows oligomerization to proceed in both directions, generating a two-molecule thick protofibril with a half-staggered overlap (Figure 1). Finally, the fibrin fibrils are reinforced by the transglutaminase activity of factor $XIII_a$. The g-g linear interactions are the major sites for the introduction of intermolecular g-glutamyl-ε-amino-lysine isopeptide crosslinks, subsequently the globular C-terminal domains of the a chains of adjacent laterally aligned protofibrils are also crosslinked, resulting in the mature, covalently stabilized fibrin mesh. Under physiological conditions these fibers are of the order of 1 µM in diameter and thus several hundred fibrin units wide.

The assembly of fibrin also reveals epitopes that are involved in its subsequent dissolution by plasmin. Conformational changes in the vicinity of the C-terminal globular domains are thought to reveal the binding sites for tPA that are responsible for the fibrin-specific potentiation of its activity [see Plasminogen Activators]. These sites are g312-324 in the C-terminal globular domain and Aa148-160, a region interacting with the Bb-chain C-terminal globular domain. The initial binding sites for plasminogen also reside in fragment D, but subsequent plasmin degradation of fibrin reveals C-terminal Lys residues that act as supplementary sites for plasminogen binding, thereby propagating plasminogen activation. Once generated plasmin can attack 50-60 of the 358 Lys and Arg residues present in each fibrin molecule, although only 10% are cleaved rapidly. The initial cleavages release the C- and N-termini of the a and b chains, respectively, followed by the cleavages in the extended coiled-coil regions that lead to dissolution of the organized fibrin structure (see Figure 1).

1. Fibrin Polymerization

The generation of fibrin from fibrinogen and its polymerization essentially occur in three sequential steps.

1. Thrombin cleaves the *N*-terminal regions of the Aa and Bb chains of fibrinogen at the peptide bonds Arg16–Gly17 and Arg14–Gly15, respectively, releasing fibrinopeptides A and B. No further covalent modification to the fibrin(ogen) structure is necessary for polymerization to proceed efficiently. The new N-terminal sequence of the fibrin a chain (Gly17–Pro–Arg–Val) is the major determinant of fibrin polymerization; synthetic peptides corresponding to this sequence can inhibit the polymerization of fibrin monomers (4). By contrast, the new b-chain *N*-terminal sequence (Gly15–His–Arg–Pro), which is generated more slowly, cannot inhibit polymerization, even though it binds to fibrinogen and to fragment D.

2. The new *N*-termini of the fibrin monomers spontaneously interact with binding sites in the two homologous distal globular domains, with the g-chain site particularly implicated (3). Both sites are large cavities that bind the a-chain-like peptide Gly–Pro–Arg, but the g-chain cavity is the more specific and does not bind g-chain Gly–His–Arg peptides. It is also the more distal of the two *C*-terminal domains and is able to associate intermolecularly in a specific end-to-end manner (2). Thus adjacent g-chain sites are closely positioned for optimal binding of the dimeric a-chain *N*-terminal residues. The efficiency of polymerization derives from both a–g lateral and g–g linear interactions. The symmetry of fibrin(ogen) allows oligomerization to proceed in both directions, generating a two-molecule thick protofibril with a half-staggered overlap (Fig. 1).

3. The fibrin fibrils are reinforced by the transglutaminase activity of factor $XIII_a$. The g–g linear interactions are the major sites for the introduction of intermolecular isopeptide crosslinks between g-glutamyl carboxyl and lysine-e-amino groups. Subsequently, the globular *C*-terminal domains of the a chains of adjacent laterally aligned protofibrils are also crosslinked, resulting in the mature, covalently stabilized fibrin mesh. Under physiological conditions, these fibers are of the order of 1 µm in diameter, and thus several hundred fibrin units wide.

2. Dissolution of the Fibrin Clot

The assembly of fibrin also makes accessible epitopes that are involved in its subsequent dissolution by plasmin, after its activation from plasminogen by tissue-type plasminogen activator (tPA). The activity of tPA is potentiated specifically by fibrin, and conformational changes in the vicinity of the *C*-terminal globular domains of fibrin are thought to reveal the binding sites that are responsible. These sites are residues 312–324 in the *C*-terminal globular domain of the g chain and 148–160 of Aa, a region that interacts with the Bb-chain *C*-terminal globular domain. The initial binding sites for plasminogen also reside in fragment D, but subsequent plasmin degradation of fibrin uncovers *C*-terminal lysine residues that act as supplementary sites for plasminogen binding, which thereby propagate plasminogen activation. Once generated, plasmin can attack 50–60 of the 358 Lys and Arg residues present in each fibrin molecule, although only 5 or 6 are cleaved rapidly. The initial cleavages release the *C* and *N* termini of the a and b chains, respectively, followed by the cleavages in the extended coiled-coil regions that lead to dissolution of the organized fibrin structure (see Fig. 1).

Fibroblast Growth Factors

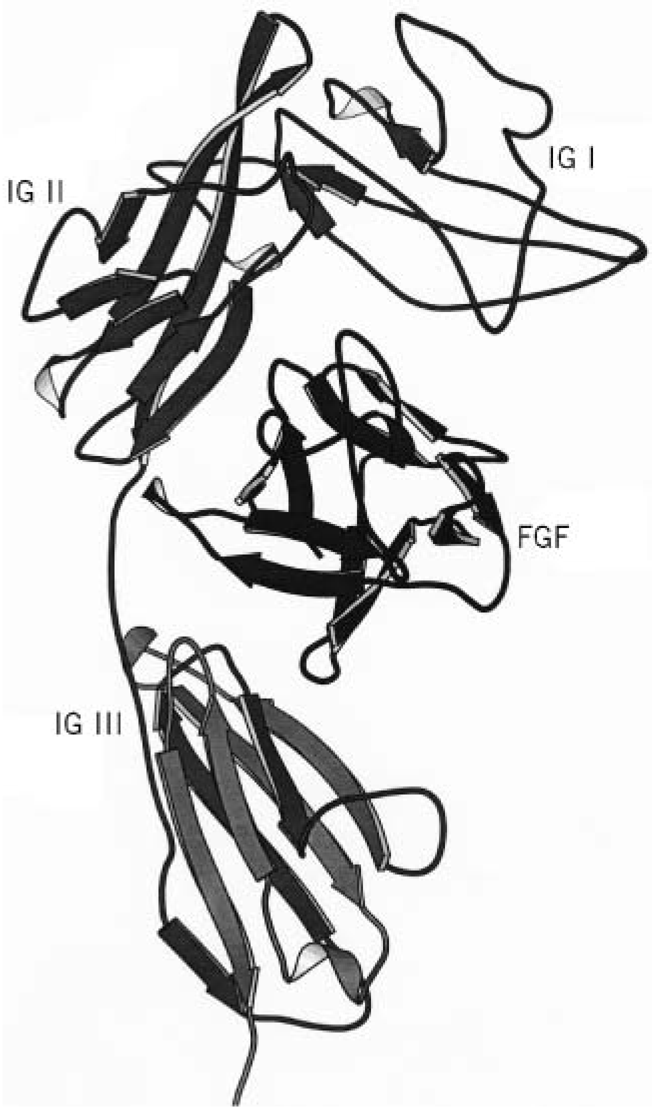
The fibroblast growth factors (FGFs) are a family of polypeptide growth factors that control many different biological processes *in vivo*. Their biological effects are mediated by association with specific cell-surface receptors of the intrinsic **tyrosine kinase** class (see Tyrosine Kinase Receptors). Their activity is modulated by association with cell-surface heparan sulfate containing glycosoaminoglycans and other cofactors.

1. Fibroblast Growth Factor Ligands

The FGF family in mammals currently comprises 14 different polypeptide chains that act as ligands, FGF1–FGF10 and FGF15–FGF18, and share an overall sequence identity of about 40%. The FGF family is highly conserved in animals: **homologues** have been isolated from a wide variety of species, including birds, amphibians, fish, insects, and nematodes (reviewed in Ref. 1). In addition to the defined family of FGF ligands, four related genes, FHF1–FGF4 (also known as FGF11–FGF14), have been isolated from expressed sequence tag (EST) projects that exhibit sequence similarity to canonical FGF ligands, but whose biological function is currently unknown (2). It is very possible that further FGF family members remained to be identified.

The protein structures of both FGF1 and FGF2 have been determined by X-ray crystallography (3). The two structures are remarkably similar and exhibit a novel 12-stranded b-trefoil topology (Fig. 1). This characteristic structure is shared with a biologically unrelated growth factor, **interleukin** -1 (IL1).

Figure 1. A molecular model of the interaction between FGF and the extracellular domain of FGF-R. The model was created by docking the crystal structure of FGF-2 (3) in place of the homologous IL1 in the crystal structure of the IL-1/IL1-R complex (9). The model shows only one half of the active complex, which is composed of two molecules of FGF and two receptors.



FGF family ligands exhibit distinct and characteristic patterns of tissue-specific gene expression during development and adulthood, suggesting that, despite their diversity, each may exhibit distinct biological functions *in vivo*. Although in most cases FGFs are expressed as a secreted molecules and elicit their biological effects in the extracellular milieu, an intriguing feature of two FGF family members, FGF1 and FGF2, is that they lack classic secretory signal peptides and, in most cases, appear to remain in an intracellular location (see Protein Secretion). This suggests that these FGFs may either require cell lysis to act or that they are released under certain conditions by a nonstandard protein export mechanism.

2. FGF Receptors

The biological effects of the FGF family of ligands are mediated by association with a family of related cell-surface receptors of the intrinsic tyrosine kinase class. The FGF family of receptors is encoded by four related genes, FGF-R1–FGF-R4. FGF-R genes have been isolated from mammals, birds, fish, amphibians, Drosophila. and nematodes (1). Individual FGF-R genes exhibit significant conservation between species and conserved features shared between the entire family. Individual FGF ligands exhibit defined patterns of receptor specificity (4), whereby some ligands interact with all FGF-R family members and others exhibit significantly more restricted affinities.

The extracellular region of the FGF-Rs comprises three domains, IgI, IgII and IgIII, which contain immunoglobulin motifs of the immunoglobulin superfamily (IgSF). Each Ig domain is encoded by two exons. In FGF-R1–FGF-R3, the IgIII domain is generated by alternative splicing of a common IgIIIa exon onto a variant IgIIIb or IgIIIc exon. The expression of FGF-R IgIII splice variants is subject to developmentally regulated gene-specific alternative splicing mechanisms (5). The selection of IgIII exons by alternative splicing mechanisms is of major functional significance because it dictates ligand specificity of FGF-Rs (6). The analysis of chimeric FGF-Rs containing variable regions from each splice variant has revealed that the interaction of an FGF ligand with its cognate receptor involves regions of both IgII and IgIII (7). Molecular models of the FGF-R ectodomain (Fig. 1) have been generated, on the basis of relationships to other IgSF family members and the crystal structure of the structurally related ligand IL1 (8, 9). These suggest that the active complex is composed of two molecules of ligand and two molecules of receptor. The ligand interacts with epitopes in both the second and third Ig domains of the receptor. These studies also reveal the existence of an extended linker domain between the IgII and IgIII domains of IL1-R. This leads to a general scheme for FGF/receptor engagement in which two independent epitopes in the ligand interact with cognate sites in IgII and IgIII. This interaction may involve interdomain reorientation on ligand binding, facilitated by the linker domain.

3. FGF Cofactors

The biological actions of FGF ligands may involve a variety of cofactors, apart from the transmembrane tyrosine kinase receptors. The most prominent of these is the sulfated oligosaccharide heparan sulfate (HS), which has been shown in many studies to interact with FGF ligands with high affinity. The crystal structure of FGF2 complexed with a linear hexasaccharide (10) reveals that this interaction occurs via binding of sulfated groups of HS to a cluster of basic residues exposed on one face of the FGF ligand. The biological role of HS in FGF action is still the subject of controversy. It has been shown that HS is, in some cases, required for FGF action (5). This has been argued to result from either HS-mediated ligand dimerization, or interaction of HS with both ligand and receptor. Others have proposed that the role of HS is simply to concentrate FGF ligand in the vicinity of the receptor (reviewed in Ref. 11).

A second FGF-binding protein is the cysteine-rich FGF receptor (12) that has been identified in many tissue types. This is a transmembrane protein, unrelated to FGF-Rs, which binds FGF ligands with high affinity. The cysteine-rich FGF receptor has been identified recently as a cell adhesion ligand of E-selectin, an inducible cell adhesion molecule that mediates the binding of neutrophils to endothelial cells and functions as a Ca^{2+}-dependent lectin. The signaling potential of this receptor, and the relationship between the interaction with E-selectin and FGF ligands, remain to be determined.

Several agents exist that interact directly or indirectly with FGF-Rs. Two proteins have been isolated by interaction screens in yeast that are unrelated to FGF ligands in sequence but appear to potentiate FGF-R signaling when overexpressed in Xenopus embryos (13). Genetic analysis of FGF signaling in *Drosophila* has revealed the existence of a conserved family of proteins, Sproutys, which, on genetic grounds, act to antagonize FGF receptor-mediated signaling pathways (14). Finally a variety of lines of evidence suggest that some effects of the homotypic cell adhesion molecules L1 and N-Cam may be mediated by direct, or indirect, activation of FGF-R signaling (15). Together these findings indicate that FGF signaling mediated by receptor–ligand interactions may be tightly constrained by the presence of specific cofactors *in vivo*.

4. Biological Actions of FGF Ligands

Genetic evidence, from gain-of-function or loss-of-function experiments, shows that the FGF family of ligands in higher vertebrates exhibits a diversity of biological functions at different times and places during embryonic and postnatal development. These include mesoderm induction, patterning of the nervous system, limb induction and outgrowth, and the development of various tissues and organs, such as the hair, ear, lungs, and teeth (reviewed in Ref. 16). The analysis of mice harboring null mutations of FGF receptors reveals that each FGF-R has distinct biological roles *in vivo* and, in particular, that FGF signaling is required at early stages of embryonic development. Thus genetic inactivation of FGF-R1 leads to early postimplantation lethality resulting from aberrant mesodermal patterning (17). Genetic inactivation of FGF R2 leads to preimplantation lethality (18), with a phenotype similar to that of homozygous null FGF-4 mice. Homozygous null FGF-R3 mice exhibit severe and progressive bone dysplasia with enhanced and prolonged endochondrial bone growth, indicating that signaling mediated by FGF-R3 acts as a negative regulator of endochondrial ossification (19).

The FGF/FGF-R axis also has considerable significance for clinical disorders of craniofacial and limb development. One of the commonest forms of inherited dwarfism, achondroplasia, arises from specific mutations in the transmembrane domain of FGF-R3 (20). This results in activation of FGF-R signaling and premature termination of long-bone extension. Moreover, mutations in the FGF-R1–FGF-R3 genes have been identified in dominantly inherited human craniofacial malformation syndromes (reviewed in Ref. 21) such as those of Crouzon, Pfeiffer, and Apert. These syndromes are all characterized by craniosynostosis (abnormal development and/or premature fusion of the cranial sutures) and additional phenotypic features such as syndactyly (digit fusion) in the Apert syndrome. The majority of these mutations described are clustered within a specific region of the extracellular domain of the receptor. In the case of Crouzon–Pfeiffer syndromes, mutations are predicted to disrupt the pattern of **disulfide bonding** in the extracellular domain (22), leading to activation of signaling via intermolecular disulfide bonding of mutant receptors. In Apert syndrome, all cases characterized to date involve specific amino acid substitutions of two adjacent amino acid residues, Ser252 and Pro253, predicted to lie in the linker region joining Ig domains II and III. The consequence of these mutations appears to be enhanced affinity for specific FGF ligands (23), which results in activation of FGF signaling in the developing suture.

5. Conclusions

The FGFs exemplify many generic features of growth factors. There are multiple ligands and receptors, each of which executes specific functions in development and adult physiology. Individual FGFs can also exert several different functions, which are not limited to the control of cell multiplication. In particular, FGFs seem to play important roles in patterning tissues of the developing embryo. FGF signaling is strictly local in action and modified by the concurrent activity of various cofactors. Finally, the dynamics of signaling elicited by FGF-R activation seems to play a critical role in the development of specific tissues.

Fibronectin

Fibronectin is a fibrillar extracellular matrix (ECM) **glycoprotein** that binds to cells and other matrix molecules, thereby contributing to the organization of the matrix and providing important adhesive sites for cells. Fibronectin is found throughout the vertebrate body, including the brain, which lacks a recognizable ECM but expresses ECM molecules like fibronectin transiently in early development. Fibronectin is a dimer of 240-kDa monomers linked at the C-terminus by a pair of disulfide bonds. The protein is made of similar but nonidentical repeating domains (types I, II, III), most of which are derived from a single exon (see Introns, Exons). The type III repeat, about 90 amino acid residues in length, occurs 15 times in each monomer and is a structural element found in other proteins as well. While the protein is encoded by a single gene, multiple splicing variants give rise to diverse **isoforms** that differ in their cell binding sites and functions. One isoform is found as an abundant protein in blood and is thought to participate in wound healing, phagocytosis by white blood cells, and blood clotting. Other forms are incorporated into fibrils in the ECM. The regions of the protein that bind to matrix molecules and cells have been uncovered by using mild proteinase digestion and column chromatography to isolate and characterize the fragments. The fibronectin monomer has two binding sites each for heparin and **fibrin**, and a single binding site for collagen. Further analysis of small synthetic peptides has led to the identification of the sequence -Arg-Gly-Asp- (RGD), which is bound by many cells via integrin receptors alpha-5/beta-1, alpha-3/beta-b1, alpha-v/beta-1, and alpha-v/beta-3. The RGD site occurs in a type III repeat on a loop extended above the surface of the domain, which is thought to provide easy access to cells. The RGD sequence is also found in other matrix proteins recognized by integrins, such as vitronectin. An **alternatively spliced** region (type III connecting segment or V) contains a second binding motif -Leu-Asp-Val- (LDV), which is the main part of the binding site for another integrin (alpha-4/beta-1) (see Integrins).

Fibronectin is one of the best-characterized ECM glycoproteins. *In vitro*, it supports adhesion of many cell types, and it can also stimulate cell proliferation, differentiation, and migration. Cells in culture often flatten and develop prominent actin arrays in response to fibronectin. The response depends on the particular cell type and its array of fibronectin receptors. The importance of fibronectin in migration of cells has been demonstrated for neural crest cells in birds and gastrulating embryonic cells of frogs, where injected antibodies and RGD-containing peptides will block cell migration. In genetically engineered mice lacking fibronectin, death occurs early in embryogenesis in part because of a failure of mesodermal cells to develop, resulting in defects in the development of the notochord, somites, blood vessels, and heart.

Fibrous Proteins

Although the fibrous proteins represent a diverse collection of structures, they can nonetheless be grouped conveniently into four classes: (i) the a-fibrous proteins, (ii) the b-fibrous structures, (iii) the collagen proteins, and (iv) those proteins that assemble into filamentous arrays but are individually globular in form. In general, all fibrous proteins contain strong repeating elements in their structures, often in the form of tandem sequence motifs. These motifs not only specify the **secondary structure**, but also play a recognizable and identifiable role in the assembly to higher levels of order. Fibrous proteins have often been used as model systems to provide insights into the structures of the more complex globular proteins.

1. a-Fibrous Structures

a-Fibrous proteins can exist *in vivo* either as individual elongated molecules (such as laminin in basement membranes and fibrinogen in blood plasma) or as filamentous assemblies (such as **myosin** in **muscle** thick filaments, **desmin** in Type III intermediate filaments, and fibrin molecules in **blood clots**). The protein sequences of all members of this family have a high propensity to form a-**helices**, which are stabilized by hydrogen bonds that lie approximately parallel to the helix axis. In addition, the a-fibrous proteins contain a characteristic heptad repeat (see also Coiled-Coils and Cytokeratins) in which nonpolar residues alternate three and four residues apart. The apolar stripe on the surface of the right-handed a-helix becomes internalized when several such a-helices aggregate and assemble into a left-handed ropelike structure (1). Although **hydrophobic** forces are very important in driving the assembly, interchain electrostatic interactions contribute significantly to determining the relative chain orientations and axial stagger, as well as the stability (1-3). In these filament-forming structures, the amino acid sequence contains a highly regular linear disposition of acidic and basic residues. The periods are usually 180° out of phase, which generates a simple rod structure with alternating bands of positive and negative charge. Consequently, assembly into the filamentous form is specified in large part by maximization of intermolecular ionic interactions, rather akin to an ionic zipper. Those a-fibrous proteins lacking periodicities in charged residues do not form regular filamentous assemblies, as judged by data currently available. In these cases, the molecules exist as separate entities, or assembly occurs in a less regular manner via non-helical domains elsewhere in the molecule, most typically at the *N*- and *C*-terminal ends.

2. b-Fibrous Structures

The b-fibrous structures were first observed in silk proteins. The fundamental structure is that of an extended array of b- strands held together in a b-sheet by a regular disposition of hydrogen bonds perpendicular to the axes of the chains (see Beta-Sheet). Two or more such sheets then aggregate into a b-crystallite. Relatively few sequence data on silks are available, but it is likely that many of them have repeating amino acid sequence motifs. This is based on the observation that the amino acid compositions are generally very simple, with perhaps only a small number of amino acids, such as glycine, alanine, serine, and glutamine, represented in any significant number. On this basis it is thought that many silks contain a dipeptide repeat (or possibly a multiple), although there are non-b-forming examples, such as *Nematus ribesii and Apis mellifera*, that almost certainly have three- and seven-residue repeats, because they give rise to a collagen and a-fibrous X-ray fiber diffraction pattern, respectively. Those silks with a dipeptide repeat, however, automatically give rise to a b-sheet with the two residues in the repeat spatially separated on opposite sides. This can give a sheet with an apolar face, for example, which can then readily assemble with the same face in a second sheet. It has been assumed that the b-sheets are planar in the silk structures, but this may not be the case *in vivo*. In fact, it is known that the b-sheets are twisted, probably in a right-handed manner, for both feather and scale keratins. In all fibrous proteins, the b-sheets are composed of antiparallel chains: in globular proteins both parallel and antiparallel b-sheets are found.

3. Collagen Class

The collagen class of fibrous proteins is characterized by a triplet repeat of the form (Gly–X–Y) $_n$, where X and Y are often proline and hydroxyproline (see Collagen). Type I collagen molecules, each of length 300 nm, aggregate with an axial stagger of distance D (67 nm) or a multiple to generate fibrils. Collagen types II, III, V, and XI also form D-periodic fibrils, but type VI collagen forms fibrils with a different periodicity. Other collagen types (IV, VII, VIII, IX, X, XII, XIII, and XIV) are non-fibril-forming but can be classified further as either basement membrane collagens (IV, VII), short-chain collagens (VIII, X), or fibril-associated collagens (IX, XII, XIV).

4. Filamentous Arrays

The last group of fibrous proteins comprise proteins that are globular in shape but assemble either helically or as a long string to form, respectively, a regular or semiregular filamentous structure. A good example of the former system is actin, in which G-actin (globular) assembles into F-actin filaments (fibrous). These, together with other proteins such as **tropomyosin** and **troponin**, form the thin filaments of **muscle**. **Titin**, a protein from muscle, consists of a series of globular domains strung together and is thus an example of the second type of filament-forming fibrous protein. The short arms in laminin are likewise composed of globular regions strung together in a near linear manner.

Fill-In Reaction

DNA fragments with 5′-overhanging ends are converted to **blunt-ended** molecules by reacting with the **Klenow fragment** of *Escherichia coli* DNA polymerase. This makes the overhanging ends double-stranded and is called the fill-in reaction. The fill-in reaction is often used to join fragments with different **cohesive ends** by converting the cohesive ends to blunt ends. This reaction is also used to introduce a frameshift mutation into a **gene**. A **plasmid** containing the gene is cut within the gene using a restriction enzyme to produce ends with a 5′-overhang. The overhang is filled in and the ends are re**ligated**. As long as the length of the overhang is not divisible by three, this procedure changes the reading frame of the gene downstream of the restriction site (see **Protein biosynthesis**).

Filter Binding Assays

The term *filter binding assay* is used to describe a variety of different techniques in biochemistry, immunology, virology and molecular biology. In molecular biology a filter binding assay is used to characterize **DNA–protein interactions**. This particular technique is also referred to as a *filter assay* or a *protein binding assay*, and it can be used to identify and characterize both DNA-binding proteins and the DNA sequences that interact with these proteins. The filter binding assay is based on the observation that proteins, but not double-stranded DNA molecules, bind to the surface of nitrocellulose membrane filters (1, 2). Therefore, if a DNA-binding protein is incubated with a specific DNA sequence before analysis in the filter binding assay, the resulting DNA–protein complex and any excess protein will bind to the membrane filter, while uncomplexed DNA will pass through. The amount of the DNA–protein complex retained on the membrane filter can be determined by using **radiolabeled** DNA to form the DNA–protein complexes and to quantify the amount of radioactivity retained on the nitrocellulose membrane by scintillation counting. The filter binding assay can be very quick if a multifilter vacuum filtration unit is used.

The filter binding assay offers a simple, rapid, sensitive, and versatile assay capable of providing information about the interactions between a DNA-binding protein and a specific DNA sequence. The use of radioactive DNA makes low concentrations of DNA and protein feasible. A typical experiment involves the titration of a constant amount of radiolabeled DNA with the DNA-binding protein of interest. The amount of radioactivity retained on the membrane increases with increasing protein concentration until all the radioactive DNA that can bind to the specific DNA-binding protein is depleted from the incubation mixture. Binding affinities can be determined by observing the level of specific complexes formed in the presence of a nonradioactive competitor DNA. The kinetics of association and dissociation of a specific DNA–protein complex can also be studied in the filter binding assay. However, filter binding assays cannot differentiate between dissimilar DNA–protein complexes, so this assay is effective only when one DNA–protein complex is formed. In addition, the DNA-binding protein must not be denatured during the purification process, because the filter binding assay is dependent on the interaction between the DNA-binding protein and a specific DNA sequence.

Because various membrane filters differ in binding specificities, the ability of nitrocellulose membranes to bind proteins and not native DNA is critical to the success of the filter binding assay. However, the molecular basis for this discrimination is not well understood. Both **electrostatic** and **hydrophobic** interactions have been suggested to be involved in the binding of macromolecules to nitrocellulose, but hydrophobic interactions are assumed to play the dominant role in the binding process (see Nitrocellulose). Although native DNA does not bind to nitrocellulose, heat-denatured DNA will (3) and should not be used in this assay. In addition, the native DNA tested in the assay must be free of contaminating proteins that could bind the DNA to the nitrocellulose membrane in the absence of the DNA-binding protein being tested.

Most proteins bind to nitrocellulose, but individual binding affinities are dependent on the surface characteristics of the particular protein. Therefore, the retention of a particular DNA–protein complex on the nitrocellulose filter will depend on the surface characteristics of the protein, the binding capacity of the nitrocellulose membrane, the time that the DNA–protein complex has to interact with the filter, and the regimen used to wash the filter. A rapid flow rate through the filter may not permit the binding of some DNA–protein complexes to the nitrocellulose membrane, and extensive washing of the filter may remove DNA–protein complexes with low affinities for nitrocellulose. The optimum conditions needed to bind a DNA–protein complex to the nitrocellulose membrane will be different for each protein and should be investigated for each filter binding assay.

Fingerprint, Protein

Two-dimensional peptide mapping, or protein fingerprinting, was introduced by Ingram in 1956 (1). In this approach, the protein is cleaved by **trypsin** or another proteinase to obtain complete digestion into peptides. Then, the peptides are separated on a solid support by electrophoresis in the first dimension and chromatography in the second, to produce a two-dimensional pattern or map. The position of each peptide is determined by its mobilities in the two dimensions and is sensitive to its covalent structure. The advantage of a two-dimensional separation is that many peptides are separated simultaneously, and two different mobilities of each can be examined.

Fingerprints are most useful in comparing closely related proteins because the one or a few peptides that differ are often easy to detect. They end up at altered positions, whereas the majority of the peptides are unaltered and remain at the same positions in each map. The latter serve as references in detecting spots corresponding to variant peptides. The deviating peptides are eluted from the support and characterized by amino acid analysis, by sequence determination, as with the Edman Degradation, or by mass spectrometry. This approach requires that a significant number of the peptides generated have identical sequences. Thus, two-dimensional peptide mapping is used to evaluate the extent of identity among closely homologous proteins.

A classical example of protein fingerprinting is the early work by Ingram on the **sickle cell** form of hemoglobin (1). Tryptic mapping revealed an altered position for only one pair of peptides detected after two-dimensional separation of the digests of normal and sickle cell hemoglobins. Glu6 of the normal b-chain is replaced by Val in the sickle form because of an A to T mutation in the corresponding **codon** of the b-chain gene (2).

The protein substrates for digestion are purified in solution by conventional chromatographic techniques or isolated via SDS-PAGE, followed by electroelution (3). The protein is **precipitated** with **trichloroacetic acid** (30% (w/v)) at 4°C for 4 h to desalt the preparation and to concentrate the protein in a small volume before digestion. After centrifugation, removal of the supernatant, and gently washing with acetone the "pellet" at –20°C (the pellet is not normally visible), the appropriate digestion buffer is added, followed by the proteolytic enzyme. This is efficient if the amount of protein is greater than about 1 nmol. The protein substrate may also be digested directly in the SDS/polyacrylamide gel without previous electroelution (see Cleveland Map). It is detected by brief staining with Coomassie Brilliant Blue or by visualization using 1 *M* KCl, followed by excision and treatment of the gel slice by a combination of drying and rehydration in digestion buffer that contains the proteinase (4, 5). Small, proteolytically cleaved peptides will diffuse out, while undigested or only partially digested proteins remain in the gel piece. The outer liquid that contains the peptides is concentrated by **lyophilization** to a small volume suitable for application to the first dimension of the mapping. Frequently, the amount of peptide material is insufficient for visualization of the map via standard staining (using ninhydrin). In this case **radiolabeling** of the protein or detection by **fluorescence** techniques is necessary.

Trypsin is often used for proteolysis because of its high specificity for cleavage at lysine and arginine residues, which can be taken to completion. An enzyme to substrate ratio of about 1:50 (w:w) is often used in a volatile buffer of ammonium bicarbonate, pH 8.1, at 37°C for 2 to 24 h. Even large polypeptides are completely degraded into small peptides that are separated by the combination of electrophoresis and chromatography. However, for proteins that generate a large number of peptides, radiolabeling and autoradiography are often necessary to obtain a distinct pattern without too many spots that overlap or cluster. For this purpose, one frequently employs labeling of cysteine residues by carboxymethylation with [^{14}C]-**iodoacetic acid**, of tyrosine residues by **iodination** with ^{125}I, or of proteins **phosphorylated** with ^{32}P.

Electrophoresis is the normal separation in the first dimension before ascending **thin-layer chromatography** in the second. The glass or plastic support is covered by a thin silica or cellulose layer. The electrophoresis buffers should contain volatile components. Many solvent systems have been suggested for the second dimension (6), but they have an organic solvent in common, often an alcohol, to promote the chromatographic mobility of **hydrophobic** peptides. A classical solvent is composed of butanol, acetic acid, water, and pyridine in volume ratios of 15:3:12:10 at pH 4 to 5. After drying, the fingerprint is visualized by ninhydrin, fluorescent techniques, stains for specific residues, or autoradiography.

Fingerprinting gives information on the subunits and the homogeneity of a protein. The number of total spots, or of those containing Cys, Tyr or other residues that are detected specifically, can be compared with the number of peptides expected from amino acid analysis and the molecular weight of the protein. If the sample is homogeneous and composed of a single polypeptide chain, the number of peptides generated should fit the frequency expected from the composition. If the number of spots detected is substantially lower, it probably indicates that the protein is composed of multiple, identical, polypeptide chains. If it is significantly higher, the sample has more than one individual polypeptide.

Two-dimensional peptide mapping is also efficient in analyzing structural variants of the same polypeptide, that is, protein **isozymes** (Fig. 1), or in identifying truncated forms and other types of posttranslational modification. Then, peptide maps reveal whether smaller or deviating polypeptides are related to other forms of the protein (identical peptide maps except for missing or deviating fragments) or are unrelated (no peptide similarities). Finally, two identical dimensions of peptide mapping, carried through with an intermediate step of chemical modification to alter a specific amino acid type, are used to detect all peptides containing that type of residue. This was the principle for the previously so popular "**diagonal**" methods (7) based no separations on paper or thin-layer plates. The peptides that contain the modified residue are differentiated by modifying them covalently after the first dimension. The second dimension is identical to the first, so that all of the unmodified peptides have the same mobilities in both dimensions. Only the modified peptides lie running off the diagonal formed by the unaltered peptides. Now, this approach like all original mappings, can be extended to modern situations by two identical runs of HPLC, capillary electrophoresis, or other microseparation. Again, the principle is always to detect any forms that deviate between the two separations.

Figure 1. Two-dimensional peptide map of acidic peptides of two similar isozymes (with E and S subunits, left and right, respectively) of an alcohol dehydrogenase. Resolution was by paper electrophoresis at pH 6.5 (horizontal) and at pH 3.5 (vertical). Strips of paper from the first dimension were stitched in opposite polarity so that the maps form mirror images through a vertical center line. The spots that differ in the E and S maps are marked (E1 and S3 are clear extra spots; S4 and S5 have only slightly shifted positions). From Ref. 8 with permission.

Fingerprinting DNA

“DNA fingerprinting” refers to methods of detecting, in **eukaryotes**, unique **DNA** patterns, which allow the identification of individuals with a probability of error similar to (or lower than) that obtained by comparing fingerprints in humans. These unique, individual patterns of DNA are the result of Mendelian inheritance of polymorphic, **hypervariable loci** of repetitive DNA. The most useful loci are those consisting of tandem repeats of short (15 to 60 bp) or very short (3 to 5 bp) specific base sequences. Different **alleles** are produced by variation in the number of repeats per locus, an event that arises by **unequal crossing over**, "slippage" during DNA replication, or other means (see text below). These phenomena are favored by tandem repetition, and they are responsible for a mutation frequency several times greater than that of "traditional" point or chromosomal mutations. They can give rise to arrays of up to several hundred such repeated units.

The terms "**minisatellites**" and "**microsatellites**" are commonly used to define these loci. The names are derived from the general definition of "satellite" for repetitive DNA, because its buoyant density frequently differs from that of the bulk DNA, due to a shift in its average base composition (G and C are usually present in increased amounts). This alters the buoyant density of such DNA and causes it to separate from the bulk of fragmented DNA as a separate satellite band in CsCl buoyant density gradient centrifugation .

Historically, DNA fingerprinting was introduced in 1985 in the article "Hypervariable minisatellite regions in human DNA" by A. Jeffreys et al. (1). These authors discovered a 33-bp region repeated four times in an **intron** of the human myoglobin **gene**. The same region was found scattered randomly in other parts of the human genome, as well as in the genomes of most vertebrates. The number of repeats of this unit varies widely at different loci, but the basic 33-bp element can always be recognized, mainly from the presence of a stable 16-bp "core."

Many other loci sharing the properties of Jeffreys' first minisatellite were found to be scattered in the genomes of most higher organisms (2-4). Arrays belonging to the same "family" of minisatellites can be identified by the specific, stable core sequence present in every one of its tandemly repeated units, the polycore . The very great variability in the length of minisatellites in different locations of a single genome, and among genomes, represents a highly reliable means of individual identification. Its best use is in comparing individuals of single families or very small populations (see text below).

Technically, individual DNA patterns are produced by digesting genomic DNA with one or more restriction enzymes whose recognition sites (preferably not exceeding four bases) are not present in the repeated unit. Minisatellites will thus survive digestion, and the restriction fragments containing them can be resolved by agar gel electrophoresis according to their length (ie, molecular weight). They can then be transferred to a nylon membrane by blotting and can be identified by **hybridization** with an appropriate labeled oligonucleotide probe (see **Southern blotting**). A sensitive probe is a tandem repeat of sequences complementary to the polycore of the minisatellite under study. The labeling is either by radioactivity or by one of several enzymatic reactions leading to a visible product (see **ELISA**). The result is a ladder of DNA restriction fragment bands containing the polycore sequence, representing DNA fragments of different molecular weights, which is referred to as a "DNA profile." Different individuals normally have different DNA profiles, unless they are related genetically.

Comparison of different profiles can only be made between closely similar electrophoretic lanes; it is thus essential that individual profiles to be compared are run on the same gel. The index of similarity commonly used in comparing profiles is the "band sharing coefficient ," which gives the probability that a band of a given molecular weight will be shared within a fingerprint (5). Shared bands are those that have migrated in the gel the same distance and are therefore aligned in adjacent lanes.

Although the stretch of DNA that can be amplified by the polymerase chain reaction (**PCR**) is much shorter than the longest minisatellite variants, fingerprints have recently been produced by PCR using arbitrary primers (6, 7). This technique has proved simpler and has provided more information on types and frequencies of mutations occurring within individual minisatellites.

1. Microsatellites

Microsatellites represent a category of short tandem repeats whose length does not exceed 2 to 5 bp; they share the variability in repeat number of minisatellites, although not quite so great, and always remain within the limits of length that can be comfortably amplified by PCR. Technically, this is a great advantage; it only requires that the flanking sequences be known, to provide the primers required for PCR. Microsatellites are abundant in higher vertebrates, scattered in the genome at individual loci. In contrast with Jeffreys' multilocus minisatellites, microsatellites tend to be species- or taxon-specific; their abundance, however, frequently allows one to find some that are present in most species of a rather high taxon group. They have been mentioned here because of their structural similarity with minisatellites, but their use is different and will not be described here.

2. Multilocus and Unilocus DNA Fingerprints

The above discussion has been of multilocus fingerprinting, where the minisatellite is present at multiple loci within the genome. Some minisatellites are, however, present at only a single locus. Variability in their repeat number is still very great, however, causing heterozygosity to be the rule and a very high polymorphism in repeat number among individuals. The distinction between the two types of multilocus and unilocus minisatellites is not clear cut, however. If a family of minisatellites is hybridized with a probe at high stringency (high temperature of annealing or high salt concentration), the number of hybridizing bands in the gel will be decreased, in some cases, to a single one. This occurs when the repeats are similar, but not identical; random point mutations may cause single repeats to diverge slightly and to hybridize with the probe only under conditions of low stringency.

Hypervariable single-locus minisatellites have a number of advantages over multilocus fingerprints. The main advantage is probably their straightforward identification in different individuals and their unambiguous recognition as alleles of the same locus of any variable band identified by a specific probe. This makes single-locus fingerprinting more suitable than multilocus for population analysis.

The isolation of single-locus minisatellites is achieved by separating on the basis of size DNA fragments from a genome expected to be rich in minisatellites (G–C rich), cloning them in **cosmid vectors** made to accept inserts within a given range of sizes (charomids), and propagating them in rec-minus bacteria, to overcome the instability typical of any tandem-repeated sequence (8). Specific polycore probes will identify individual minisatellite loci in the vectors plated at low density. Those that hybridize with the probe at high stringency are potential single-locus minisatellites, which can be isolated and sequenced to construct probes that will be very specific.

3. Applications

The best use of multilocus fingerprinting is in the identification of individuals. The probability that two unrelated individuals share the same electrophoretic pattern is exceedingly low. The proportion of electrophoretic bands shared by two unrelated members of a population, a and b, is $x = ((N_{ab}/N_a)+(N_{ab}/N_b))/2$, where N_{ab} is the number of bands common to the two individuals and N_a and N_b are the total number of bands observed in the two individuals (usually up to 30). The band sharing coefficient, x, is related to the allele frequency q by the equation $x = 2q–q^2$, assuming that shared bands are identical alleles from the same locus and that all bands have the same population frequencies. If the bands are indeed independent markers, the mean probability that all N bands in an individual's profile are present in a second unrelated individual is x^N. For an individual with 30 scorable bands in a population with an average $x = 0.2$, the probability of another unrelated individual sharing the same pattern is less than 10^{20}.

These characteristics prompted the forensic use of DNA fingerprinting in criminal and civil areas (9, 10). Identification of individuals from traces of biological material is possible, given the small amount (nanograms) of DNA required for a profile and the resistance to degradation of DNA, even under the most unfavorable environmental conditions.

Multilocus fingerprinting is also the method of choice for determining close genetic relatedness ($r = 0.5$ or, at most, 0.25). The Mendelian segregation of bands ensures that a progeny inherits, on average, a random 50% of its bands from each parent. Extra bands (ie, those not present in either parent) are found with a frequency ranging from 10^2 to 10^4, as a result of the high but variable mutation rate of minisatellites of different sizes. In practice, both in the forensic field and in fields dealing with animal behavior, the most common problem easily solved by multilocus fingerprinting is the assessment of paternity. When the profiles of all partners (mother, progeny, and presumed father) are available, paternity can be affirmed or rejected with probabilities that depend on the total number of bands, on the proportion of bands shared, on the presence of new bands (mutations), and on the assumption of independence among loci. In individual cases, neither the probability of mutation nor that of loci not being independent severely affect the diagnosis. For example, the probability of not detecting incorrect paternity (ie, that the putative father will possess by chance say six of the paternal specific bands) is of the order of 5×10^5 (so long as the putative father is not related to the true one).

In the animal field, this method of paternity testing has shown how widespread is the phenomenon of "extra-pair copulation" in species classified as monogamous (11).

In population studies, multilocus fingerprinting is not the best method of analysis. The average band sharing coefficient between pairs of random, unrelated members of even a large population depends upon both inbreeding and polymorphism. Specifically, high band sharing could indicate that the population is partly inbred (ie, is not a random-mating one) or that it was subjected to a recent population bottleneck that reduced drastically the number of individuals and the range of minisatellite's sizes still represented.

Population-level comparisons may be carried out only among populations effectively so small that individual variability is drastically reduced and population-specific genotypes may emerge. One of the main problems in population analysis is the impossibility of assigning bands to a specific locus: Bands shared (co-migrating) by different individuals are not necessarily identical alleles of a single locus. This problem is overcome by using single-locus probes: If more than one is available for the same study, the total amount of information (ie, number of usable bands) will approach that of multilocus fingerprinting. Presently, microsatellites have supplanted single-locus minisatellites in population genetic analysis: The type and amount of information obtained is similar, but the method of revealing microsatellite patterns is much simpler and faster.

Single-locus minisatellites found to segregate in close association with genetic traits have been very useful in the mapping of these traits (12) and, sometimes, in the isolation of the linked gene. In human medical genetics, single-locus minisatellites have been used as markers of potentially hereditary diseases, when linkage could be shown between the two in sufficiently extended pedigrees. Also, synthetic oligonucleotides, especially if rich in G and C, have been used as probes for detecting minisatellites to be used for mapping human genetic diseases (13, 14). Again, microsatellites have now entirely supplanted minisatellites for this purpose.

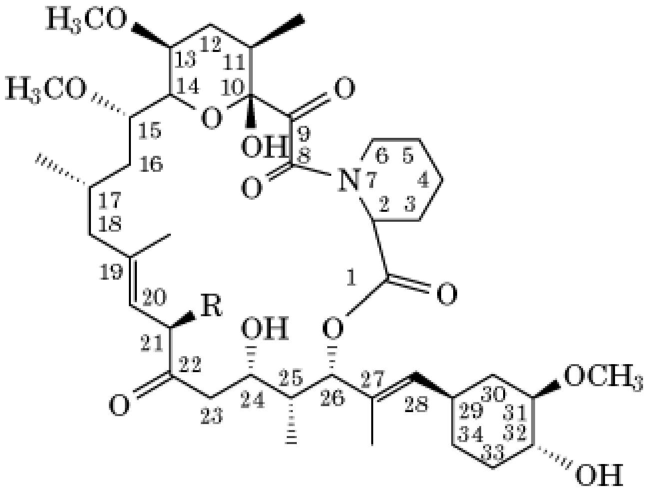
FK506

The immunosuppressive drug FK506 (also known as tacrolimus) is a 23-membered macrocyclic lactam (Fig. 1) that was first isolated from a strain of *Streptomyces tsukubaensis* in Japan in 1987 (1). In addition to blocking the T cell immune response, FK506 has neuroprotective properties (2, 3) and antiparasitic effects (4). It was first used clinically for immunosuppression in 1989. The target of FK506 for immunosuppression is thought to be the cytosolic FK506-binding protein, FKBP12, which is also a **peptidyl prolyl *cis*/ *trans*** isomerase (PPIase). Upon binding to FKBP12 within a deep **hydrophobic** pocket, the **imide** bond of FK506 adopts a *trans* conformation, concomitant with reorganizing the conformation of the pipecolinic ring and of the pyranose ring. Recently, a cell-permeable, covalently linked dimer of FK506 (FK1012) was constructed as a tool to achieve controlled cross-linking of intracellular receptor domains for gene activation (5). It utilizes the high binding affinity of FK506 for the receptor FKBP12, which is effective at less than nanomolar concentrations. A number of derivatives that bind to and inhibit FKBP have been reported, some immunosuppressive and others not (6).

Figure 1. The structure of immunosuppressant FK506.



FK506 R: $CH_2CH{=}CH_2$
ascomycin R: CH_2CH_3

Despite structural similarities to rapamycin in a major part of the macrocycle, many biological effects of FK506, including the arrest of clonal T cell expansion, are reminiscent of another class of immunosuppressants, cyclosporin A (CsA), rather than rapamycin. This finding was the first evidence of a common upstream target for the two different classes of immunosuppressants, FK506 and cyclosporin A. As monitored by affinity chromatography, the FKBP12/FK506 complex binds the same protein from a calf thymus extract, the protein **phosphatase** calcineurin, as has been obtained with the complex of CsA and its target cyclophilin Cyp18. In both cases noncompetitive inhibition by the complex is observed in the nanomolar concentration range. Considering that the structures of Cyp18/CsA and FKBP12/FK506 are unrelated in amino acid sequence and spatial organization, the similar inhibition of calcineurin is striking. FK506 acts as a pro-drug, in that only the complex of the drug and its receptor is active. Two segments of FKBP12 comprising the loops in the region of residues 40 and 80 plus an effector region of FK506, the carbon chain C17 to C32, may be involved in drug activation. In the **X-ray crystallographic** structure of the human FKBP12/FK506/calcineurin complex, the FKBP12/FK506 portion contacts two distinct areas on calcineurin that do not directly obstruct both the active site and the substrate-binding cleft of the protein phosphatase. On the contrary, blocking a rather distant subsite of the phosphatase/protein phosphate recognition region is responsible for phosphatase inhibition (8).

Both CsA and FK506 block the induction of clonal T cell expansion at the early G_0 to G_1 transition of the cell cycle. They exert down-regulation of transcription of a number of similar lymphokine genes.

Flagella—Prokaryotes

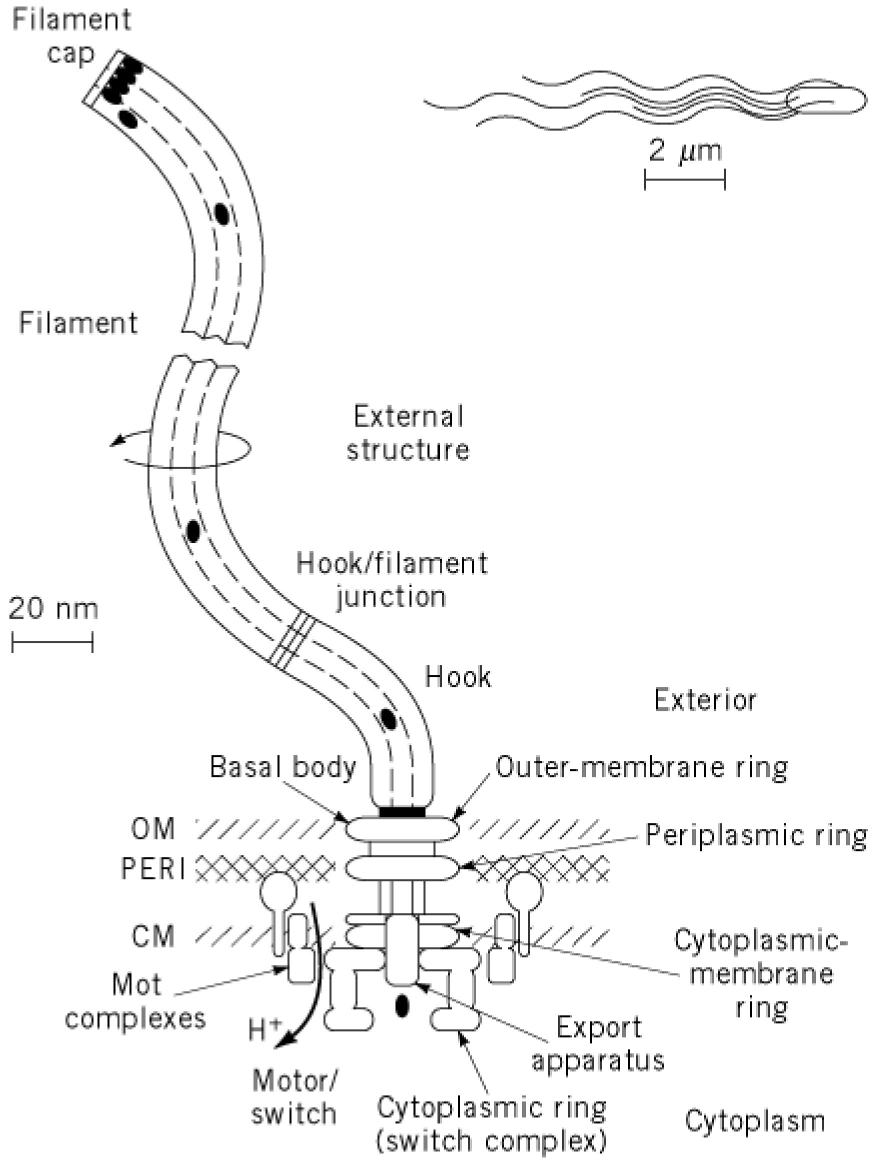
Flagella are the propulsive **organelles** of a wide variety of unicellular organisms, both **prokaryotes** and **eukaryotes**. However, prokaryotic flagella differ in almost every respect from their eukaryotic counterparts (see **Flagella—eukaryotes**).

1. Motility and Behavior

Prokaryotic flagella are largely external appendages that project far from the cell surface (Fig. 1, top right); for example, a typical rod-shaped **bacterium** is about 1 or 2 µm long, but its flagellar filaments can be 10 µm long. The motor resides at the cytoplasmic membrane and is a rotary device that transmits the rotation to the external flagellar filament. The motor is not driven by ATP hydrolysis like most mechanoenzymes (see **Energy transduction**), but by a proton-motive force (or in some marine and alkaliphilic bacteria, by a sodium-motive force); protons that have been actively pumped out of the cell by the electron transport chain are allowed to flow down their electrochemical potential gradient through the flagellar motor and surrender their potential energy in return for hydrodynamic work against the resistance of the aqueous medium (see also Chemiosmotic Coupling). The filament is very thin (about 20 nm in diameter) compared to its length, with a length/diameter ratio of about 500, and has a completely regular helical or corkscrew shape. When rotated by the motor, it therefore functions as a propeller or Archimedes screw. Depending on the handedness of the helix (left-handed or right-handed) and the direction of rotation of the motor (counterclockwise or clockwise), the cell will experience a pushing or a pulling force. The flagellar motors of most bacteria are reversible, that is, they possess a switch or gear that will alternate the direction of rotation between counterclockwise and clockwise rotation. In the simplest cases, such as *Pseudomonas* spp., which have a single flagellum at one pole of the cell, this results in a shuttling motion. In the case of species such as *Escherichia coli* or *Salmonella*, which have several flagella originating more or less randomly around the cell body, the rotation direction that corresponds to pushing results in the individual flagellar filaments coalescing into a propulsive bundle to produce the motion called *running* or *swimming*, while the opposite direction causes the bundle to fly apart and produce a chaotic motion called *tumbling*. This tumbling randomly orients the cell, so that the next episode of swimming is largely uncorrelated with the previous one. The resulting trajectory is a zigzag or random walk in three-dimensional space.

Figure 1. The bacterial flagellum, showing its four major structural elements: external structure (white), basal body

(light gray), motor/switch (medium gray), and export apparatus (dark gray), along with their various substructures. The outer membrane (OM), periplasmic space (PERI), and cytoplasmic membrane (CM) of the bacterium, in which the flagellum machinery is embedded, are also shown. To drive motor rotation, protons flow through the motor down their potential gradient (toward lower H^+ concentration). External proteins, such as flagellin (black ovals), are selectively passed through the export apparatus, travel down a central channel in the nascent structure, and assemble at its distal end. Most of the flagellum is tiny, so that only the filaments are evident at the scale of the bacterial cell (**top right**).

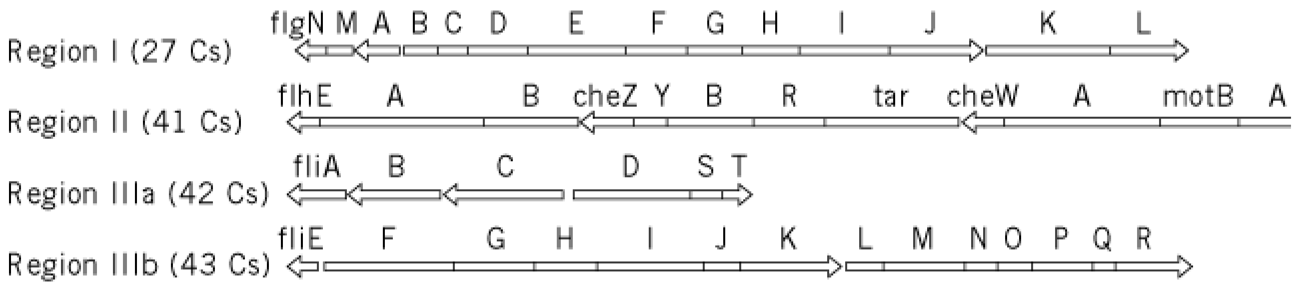


The above description applies when the cell is moving in an isotropic environment. However, if there are gradients of various chemicals (beneficial ones such as the amino acid aspartate or noxious ones such as phenol) and if the cell has **receptors** to detect these chemicals (or light, pH, temperature, etc.), it carries out an ongoing evaluation of whether its environment is improving or deteriorating. If the former is correct, it keeps going; if the latter is correct, it tumbles and then reevaluates whether its new direction is better than its old one. The net effect is a statistical drift to a better life; this behavior is called chemotaxis (or, more generally, *taxis*). The evaluation is in time, even though it is achieved by travel through space—a stationary bacterium could not make the measurement. Thus bacteria possess a rudimentary memory.

2. The Flagellar Gene System

Flagellar, motility, and chemotaxis **genes** (about 60 in all, depending on definition) are highly clustered into just four main regions of contiguous genes (Fig. 2). The organization of the genes shown in Figure 2 is for *Salmonella* (and is almost identical for *E. coli*); in other species, such as the developmental bacterium *Caulobacter crescentus* or the **Gram-positive** bacterium *Bacillus subtilis*, the genetic organization is somewhat different. The four gene clusters contain operons ranging in size from a single gene to more than 20 in some species. These operons fall into a hierarchy of expression by transcription, with gene products at one level playing a role in transcription of lower levels. In most cases, the controlling elements are of a more or less conventional sort, such as transcriptional activators and dedicated sigma factors for transcription initiation. However, there are at least two unconventional mechanisms. The first is a negative regulator, FlgM, which operationally seems like a **repressor** but is in fact an anti-sigma factor rather than a DNA-binding protein. The second is the highly unusual mechanism by which FlgM is inactivated in the last stage of the expression hierarchy; when flagellar assembly has proceeded to a fairly advanced degree, the flagellar structure itself becomes competent to export FlgM from the cell (thus inactivating it), using the same export pathway that is used for the process of flagellar export/assembly itself (see text below).

Figure 2. The four clusters of flagellar genes on the chromosome of *Salmonella*, along with their positions (Cs, centisom
the operons (open arrows) and the genes they contain. Different gene symbols (*flg*, *flh*, and *fli*) are used for the four regic
Region II, which contains flagellar genes, also contains motility (*mot*) genes (see text and Fig. 1) and chemotaxis (*che*) g



3. Flagellar Structure and Function

Flagellar structure can be divided into several categories (Fig. 1):

1. *External structure*. This is the structure that is most evident by light or electron microscopy and includes the helical filament and a hook-shaped structure that acts as a universal joint for the filament.
2. *Basal body*. This structure is embedded in the cell surface (outer membrane, **periplasmic** space, and cytoplasmic membrane) and consists of (a) a rod whose distal end is joined to the hook, (b) an outer-membrane ring and a periplasmic ring, which together act as a bushing for the rod, and (c) a cytoplasmic-membrane ring to which the proximal end of the rod is firmly attached. The external structure and the basal body are passive components; that is, they are not part of the energy transducing machinery.
3. *Motor/switch*. The motor/switch can be subdivided into two categories. The first is a set of so-called Mot complexes that surround the cytoplasmic-membrane ring; these complexes, which are stationary, are involved in the generation of torque but not in the switching of rotation direction. The second is a cylindrical switch complex or cytoplasmic ring, mounted onto the cytoplasmic-membrane ring and projecting into the cytoplasm. The switch complex is involved both in the generation of torque (together with the Mot complexes) and in the switching of rotation direction. It is the rotating element of the motor and causes the cytoplasmic-membrane ring, the rod, the hook, and the filament to rotate as a single unit.

4. *The export apparatus*. This is the least understood structure, but available evidence suggests that it is located at the center of the cytoplasmic-membrane ring and projects out into the cytoplasm. There may also be components that shuttle between the cytoplasm and the components associated with the membrane.

The protein composition and approximate subunit stoichiometry of most of the substructures of the flagellum are known:

1. filament cap (FliD), ~10 subunits;
2. filament (FliC or flagellin), ~20,000 subunits;
3. hook/filament junction (FlgK/FlgL), ~10 subunits each.
4. hook (FlgE), ~130 subunits;
5. rod (FlgB, FlgC, FlgF, FlgG, FliE), ~5 to 25 subunits each;
6. outer-membrane ring (FlgH), ~25 subunits;
7. periplasmic ring (FlgI), ~25 subunits;
8. cytoplasmic-membrane ring (FliF), ~25 subunits;
9. cytoplasmic ring or switch complex (FliG, FliM, FliN), ~30 to 40 subunits each;
10. Mot complexes (MotA, MotB), ~12 subunits each;
11. export apparatus (composition and stoichiometry not well-characterized).

Thus there is a wide range of stoichiometries, with flagellin being by far the most abundant.

4. Flagellar Morphogenesis and the Flagellar Protein Export Process

The assembly of the flagellum proceeds for the most part in a linear fashion—that is, subunit by subunit of the first substructure, then subunit by subunit of the second substructure onto the first, and so on. The first substructures to be assembled are those associated with the cytoplasmic membrane, and the last are the ones furthest away from the cell. Thus a description (oversimplified) of the order would be: cytoplasmic-membrane ring and export apparatus → switch complex and Mot complexes → basal–body rod → periplasmic and outer-membrane rings → hook → filament.

The subunits of the basal-body rod, the hook, the filament, and some other minor but essential substructures are added to the distal end of the growing structure and get there by first passing through the export apparatus (in a process that probably requires energy and certainly requires specificity of recognition) and then traveling down a central core that exists in the structure (Fig. 1).

4.1. The Flagellar Export Pathway is a Type III Secretory Pathway

It has recently become evident that the pathway for export of flagellar proteins is but one member, albeit a rather special one, of a large family of pathways that are used by pathogenic bacteria for the secretion of virulence factors directed against the host; these pathways are called type III secretory pathways (see Protein Secretion). The similarities within this family extend beyond operational ones, such as lack of signal peptide cleavage, to biochemical ones. There are at least six flagellar components (FlhA, FlhB, FliI, FliP, FliQ, FliR) that have homologues in the virulence factor secretory apparatus. FliI is an ATPase, which could be driving **active transport** of the protein substrates. Remarkably, it is homologous to a fundamentally important protein for bacteria (and for mitochondria and **chloroplasts**): the catalytic subunit of the proton-translocating F_0F_1-ATPase (see ATP Synthase).

Flow Cytometry

Flow cytometric analysis of **eukaryotic** cells, also known as fluorescence-activated cell sorting (FACS), was first developed in the late 1960s. FACS has been a tool primarily of immunologists because of its power in dissecting the complex subsets of cells derived from the blood. It has found clinical application in the classification of leukemias and lymphomas, as well as a tool for prognosis in HIV disease. Because of the relative expense of the equipment, it has been slow to progress into many other areas of biological research. However, the past decade has seen significant expansion in the techniques that are designed for FACS analysis. In particular, several developments came about that make FACS an extremely powerful tool for molecular biology analysis. These include (a) the development of FACS-based assays for reporter genes (initially, b-**galactosidase**; now including several other hydrolases) and (b) the introduction of the inherently fluorescent proteins, such as green fluorescent protein (GFP; see Luciferases And Luciferins). As the technology becomes cheaper and more widespread, these applications (and others) will become a common tool in the arsenal of molecular biology.

1. Molecular Biology by FACS: A Basic Overview

Flow cytometry is a technology that characterizes populations of cells, on a cell-by-cell basis, in terms of their fluorescence properties. Several different fluorescent signals can be monitored simultaneously and independently. On the basis of the amount of each fluorescence exhibited by each cell, the instrument can decide whether that cell should be sorted (separated from all others) or simply discarded. The sorted cells can be recovered in a viable state for further biochemical processing or culture. Most flow cytometric sorters can process as many as 5000 cells per second, with excellent purity and specific recovery of cells occurring as infrequently as one in a million.

Fluorescence is the fundamental parameter evaluated by a flow cytometer, so the most common molecular biology technique performed by FACS is quantification of reporter gene activity. Thus, either intrinsic or enzymatically generated fluorescence serves as the surrogate assay for the number of protein molecules synthesized from a particular gene construct introduced into the cell. The intensity of the fluorescence is, in general, linearly related to the expression from the gene construct, so the FACS can quantify directly, on a cell-by-cell basis, the **translation/transcription** activity of the reporter gene.

It is important to recognize that the measurement is made on each cell independently, so the analysis of a cell population can be displayed as a distribution of activities. Thus, heterogeneous gene expression within a population can be resolved; for example, the presence of a few highly expressing cells along with a majority of nonexpressing cells is easily detected. Furthermore, the sorting capabilities of the instrument can then be used to isolate either the positive or negative cell fraction.

Cells are passed through the interrogating laser beam one-by-one in a stream, so it is necessary that the sample be prepared as a suspension of individual cells. It is possible to monitor adherent cell populations after removing the cells from the substrate—for example, by treatment with a proteinase such as **trypsin** . It is not possible, however, to use the FACS on solid tissue samples without dispersing the cells. Virtually any cell type can be used; successful assays have been performed on **bacteria**, **yeast**, and **Drosophila** cells, as well as on a wide variety of mammalian cells.

2. Reporter Genes assays for FACS

The most common application of FACS in molecular biology is the quantitative measurement of reporter gene expression. A variety of reporter genes are amenable to FACS analysis, including cell surface markers, hydrolases, and GFP. Surface markers are genes coding for membrane-bound proteins that are not normally expressed by the cells of interest. These can be detected using fluorescently conjugated monoclonal antibodies and standard immunophenotyping methods. These assays are not necessarily quantitative; that is, the amount of surface expression may not always correlate with transcriptional activity. The introduction of foreign proteins on the surface of cells also prevents the introduction of such cells into a host, because of immunological rejection.

The other types of assays rely on intracellular expression of proteins that can be detected enzymatically or are inherently fluorescent, such as GFP. In 1988, Nolan et al. developed the first FACS-based assay for an enzymatic reporter gene (1-3). This assay uses the fluorogenic substrate fluorescein digalactoside (FDG). FDG is nonfluorescent until hydrolyzed; it can be easily introduced into the cytoplasm of cells. Cells that have high b-galactosidase activity (eg, that are transfected with the bacterial *lacZ* gene controlled by a promoter active in the host cells) will hydrolyze the FDG to yield fluorescent **fluorescein**. The amount of fluorescence generated is quantitatively related to the amount of cellular b-galactosidase. This assay has extreme sensitivity (it can detect cells with as few as 5 molecules of enzyme) and a large dynamic range (at least 5 orders of magnitude). More recently, assays for b-glucuronidase and b-glucosidase have also been introduced that are similar to the one for b-galactosidase (4).

The last few years has seen an explosion in the use and development of GFP as a reporter gene. A variety of mutations have been introduced into the gene to produce proteins that are more highly fluorescent and with altered fluorescence spectra. The primary advantage of the GFP assay is ease of use: the expressing cells become spontaneously fluorescent. In addition, the genes encoding the varieties of GFP are relatively small (~1.5 kb) compared to *lacZ* (~3.5 kb), giving greater flexibility in designing vectors.

3. Why Is FACS Such a Powerful Tool?

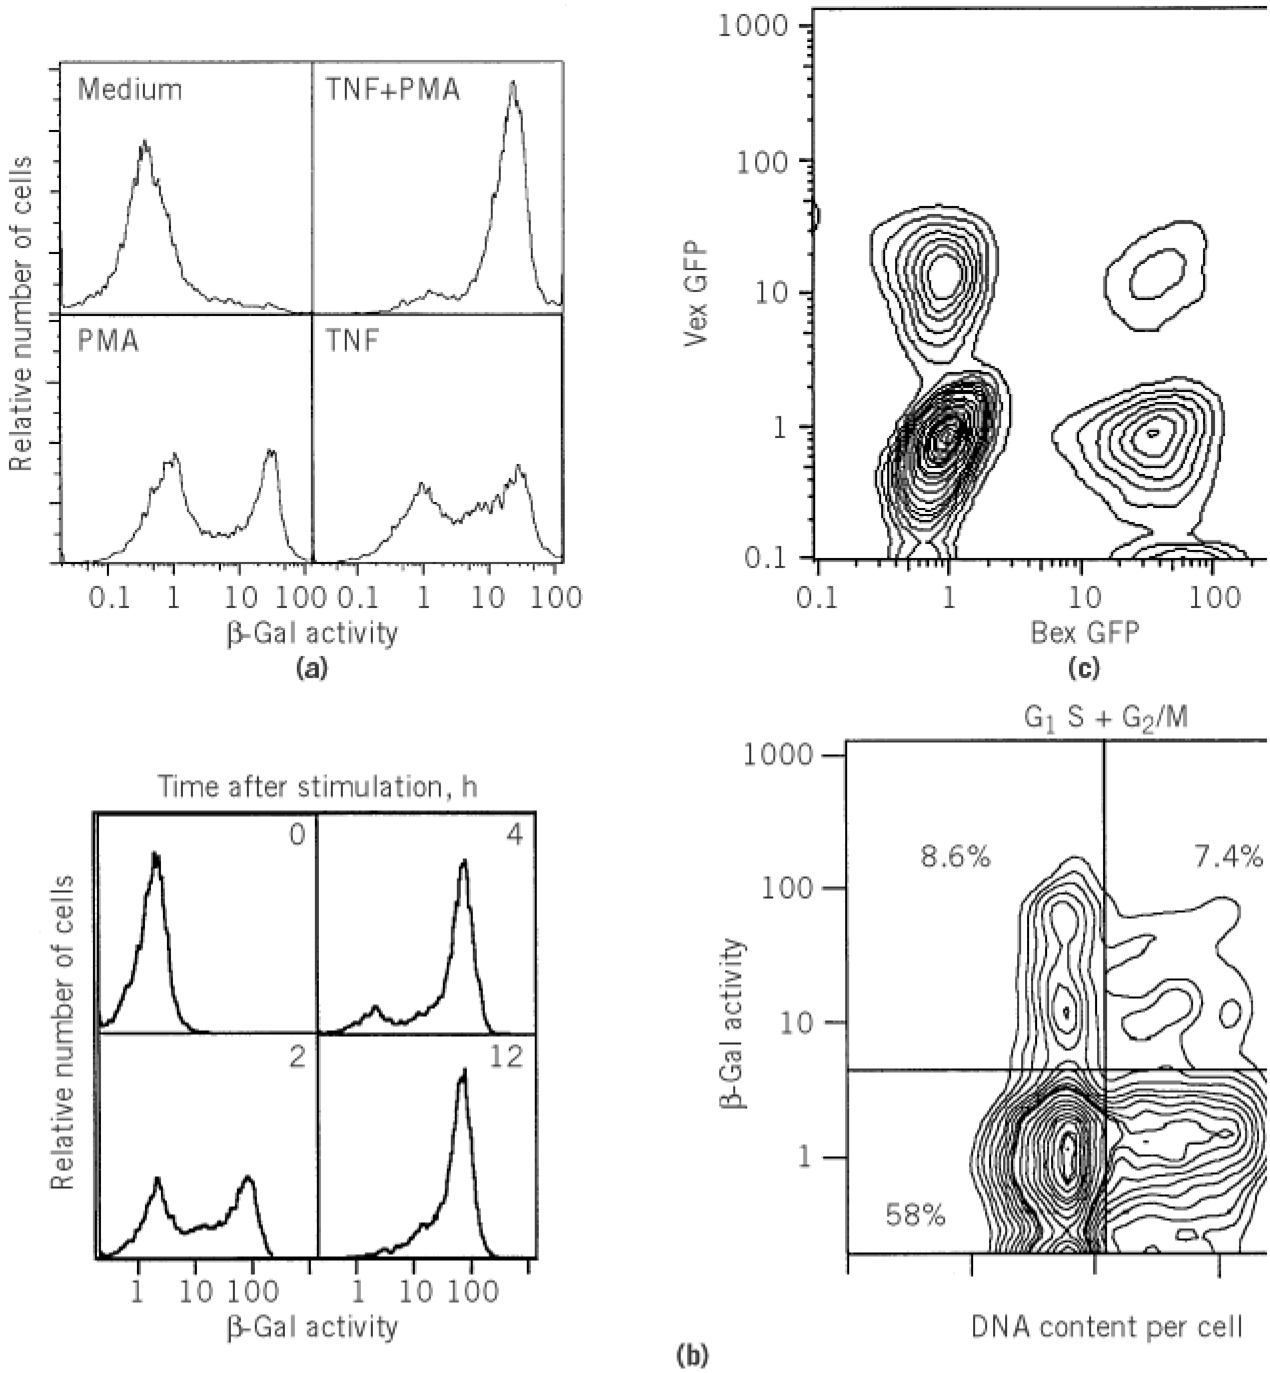
There are three principal reasons:

1. FACS analyses collect data on each individual cell, presenting the data as a distribution of activity.
2. FACS analysis is multiparametric (the ability to measure several parameters simultaneously on each cell).
3. The FACS can viably sort cells based on these measurements.

4. Analysis of a Distribution

Biological systems are rarely, if ever, homogeneous. Indeed, even the responsiveness of a **clone** is often complex. This has become even more evident since the advent of FACS analysis. Figure 1 shows two examples of such heterogeneity. These examples demonstrate how a cloned population of cells (which has a uniform, single integration of a reporter gene construct) responds in a heterogeneous way to stimulations. It is immediately apparent that such complexity is completely missed by using standard, bulk assays for reporter gene activity. Bulk assays measure the average amount of activity in a population, with no information about the distribution within that population. The figure demonstrates that the signal transduction mediated by effector molecules does not affect all cells identically; some respond rapidly, whereas others remain resting for at least a period of time.

Figure 1. Three examples of flow cytometric analysis of gene expression. (**a**) A reporter gene construct consisting of a transcriptional fusion of the *lacZ* gene to the HIV long-terminal repeat (LTR), the promoter/enhancer region for HIV typ stably transfected into 293 S cells. Basal expression is shown in the *top left* panel. After stimulation with tumor necrosis (TNF) or **phorbol ester** (phorbol myristate acetate, PMA) for 6 h, most cells have significantly elevated the expression c reporter gene. Thus, the response to these factors is not homogeneous, even within this cloned cell line. The synergistic s (TNF+PMA) results in activation of the construct in virtually all cells. (**b**) In this example, the *lacZ* gene was fused to a i promoter containing three adjacent binding sites for NF-AT, the nuclear factor of activated T cells, and transfected into t transformed Jurkat T cell line. The b-galactosidase activity corresponds to the degree of activation of the nuclear factor. After stimulation of the cells with PMA+ionomycin, there is a graded response over time. At the early time points, some responded and others haven't; note the dichotomy in the response. Those cells that have responded have fully turned on t promoter (ie, the position of the positive peak at 2 h is essentially the same as at 12 h). What increases over time is the *fr* responding cells. (*Right*) Cells stimulated with PMA+ionomycin for 2 h were stained for b-galactosidase activity and DN content. The multiparametric capability of the FACS allows the simultaneous measurement of these values. This analysi that cells progressing through the cell cycle are more likely to respond early after stimulation (nearly half of the respondi are in S+G_2M; less than one-third of nonresponding cells are in cycle). (**c**) The generation of spectral mutants of the inhe fluorescent GFP allows for simultaneous measurement of two different genetic elements in the same cell. “Vex” is viole GFP, and “Bex” is blue-excited GFP. In this example, cells were infected with retroviruses expressing one or the other C Uninfected cells, singly infected cells, and cells infected with both viruses can be easily distinguished by measuring the t fluorescence signals by FACS.



5. The Power of Multiparametric Analysis

A typical FACS experiment can measure at least three different fluorescent species, in addition to measurements related to cell size and shape. Thus, one can combine a typical reporter gene expression assay (using one fluorescent channel) together with two other assays. These might include assays to measure DNA or RNA content, cell surface **phenotype**, viability, and so on. In addition, one could choose a second, independent reporter gene assay using a second color, in order to measure simultaneously two independent genetic elements (ie, enhancers, promoters, repressors). Figure 1 c shows such an analysis, using two different versions of the inherently fluorescent protein GFP (5). Another analysis that can benefit from such simultaneous measurement is the dissection of enhancer elements. By transfecting the same cells with different reporter genes fused to different enhancer elements, one can now measure the relative activity of each enhancer element in the same cell in response to stimulations.

6. Sorting (Selection)

Perhaps one of the most underutilized capabilities of the FACS is the ability to sort cells viably based on any of the measurement parameters. Effectively, this means that any reporter gene used in the context of the FACS becomes (in addition) a selectable marker. Selection by FACS has several advantages over standard drug-based cytotoxic selectable markers. Generally, selectable marker systems rely on a combination of toxic compounds and genes that encode resistance or sensitivity to the toxic compound. These systems work by killing or halting the growth of all cells that do not (or do) produce some threshold amount of the protein encoded by the selectable marker gene.

Survival-dependent selection systems have several disadvantages. For example:

1. The selection system is inherently toxic, often even to cells expressing the resistance gene.
2. The selection generally takes many cell divisions, or a period of weeks for mammalian cells.
3. The cells below (or above) the threshold amount of the selecting protein are dead and unavailable for further study.
4. It is difficult or impossible to select for different expression levels of the marker.
5. The cells must generally be able to reproduce in culture.

On the other hand, FACS analysis of reporter genes allows the sorting capabilities of the FACS to isolate cells based on virtually any level of expression of the nontoxic reporter genes. The FACS can analyze and sort from as many as 5000 cells per second, so 1 cell in 10 million could be selected in an hour of sorting, making FACS as efficient as drug-based selectable markers.

The ability to select cells based on a particular level of expression is a big advantage over standard selection methods, for several reasons. First of all, cells expressing very low levels of the b-galactosidase enzyme (eg, 10 molecules) can be detected and sorted; such low levels might not be sufficient to confer drug resistance. Second, cells expressing virtually any level of enzyme can be selected (for instance, only those expressing more than 100,000 molecules per cell). Third, cells that rapidly change expression of the reporter gene in response to a stimulus can be selectively sorted. These capabilities give FACS assays the ability to select cells that would be impossible to select using standard drug selection methods.

Finally, the ability to sort cells based on gene expression levels allows the concomitant determination of other parameters that can only be determined by, for example, biochemical assays on lysates. For instance, by sorting cells with different expression levels and then doing messenger RNA quantification on the sorted cells, a comparison of message levels within defined subsets of a population can be done (eg, see Ref. 2).

7. Summary

Besides the analysis of reporter genes, other technologies are becoming available for FACS analysis. For instance, fluorescent *in situ* **hybridization** (FISH) for both RNA and DNA, even after *in situ* polymerase chain reaction (PCR), has been successfully performed by FACS. The FACS-based enzyme assays have also been extended to nonmammalian systems. Reporter gene analysis has been performed in **plant** cells (6), **Drosophila** cells (7), **yeast** (8), and **bacteria** (8, 9), complete with viable sorting of the cells for further analysis.

Flow cytometric analysis is an aspect of the majority of immunologically related research, as can be evidenced by perusing any immunology journal. Since the relatively recent introduction of this technology to molecular biology, it has been growing quickly as the applications become more advanced and as the technology becomes more accessible. Flow cytometry has already proven to be a unique and powerful adjunct for molecular analyses; in the years to come, it will undoubtedly become a common tool.

Fluctuation Test

The fluctuation test was invented by Luria and Delbrück in 1943 to determine whether bacterial **mutants** arise before any **selection** for their presence or only after the **bacteria** are subjected to selection (1). It was enormously influential because by showing that mutations arise randomly before selection, it provided strong evidence that bacteria and **viruses** are normal organisms possessing heritable genetic determinants. Thus it opened the way for the genetic analysis of bacteria and their viruses and led eventually to modern molecular biology. Luria and Delbrück measured the number of mutants resistant to **bacteriophage** T1 in a large number of replicate cultures of *Escherichia coli*. They reasoned as follows. If mutants occur after the culture is exposed to the phage (ie, in response to selection), then little variation should occur among cultures in the number of mutants. In fact, the distribution would be Poisson with the variance equal to the mean. However, if mutants arise at random during nonselective growth of cells, the probability of a mutation would be constant per generation per cell. But the consequence of that mutation would depend on when during the growth of the population the mutation occurred. In a binary dividing population, a cell that sustains a mutation gives rise to a **clone** of identical descendants, each of which is a mutant. Thus a mutation during early generations gives rise to a large clone of mutant cells, whereas a late mutation gives rise to few mutant cells. Among a large set of identical cultures of dividing cells, the few cultures in which the mutation happened in the early generations (the jackpots) have a large number of mutants, whereas the majority of the cultures have none or a few mutants. The predicted distribution, called the Luria–Delbrück distribution, has a variance much larger than the Poisson distribution. This is what Luria and Delbrück observed. Their test is known as “the fluctuation test” because it measures the degree of fluctuation in the number of mutants found in replicate cultures.

Interest in the fluctuation test has been revived recently by the controversy surrounding the phenomenon known as "directed" or "adaptive" mutation (2). By obtaining the highly variant distribution, Luria and Delbrück proved that mutations occur before selection. Because the selection they used was lethal, however, they did not prove the converse that mutations could not also arise after selection. Indeed, when the selection is not lethal, it has been found that mutations do arise in response to selection. Part, but not all, of the evidence for postselection mutation is that in a fluctuation test the distribution of the number of mutants per culture deviates from the Luria–Delbrück toward the Poisson distribution. This has inspired new models describing the distribution of mutant numbers when one or another of the underlying assumptions of the Luria–Delbrück analysis are not met (2, 3).

The fluctuation test is also useful in determining mutation rates during nonselective growth. First applied by Luria and Delbrück themselves, the computation of mutation rates has been refined since then. But all commonly applied techniques still involve assumptions and compromises. Nonetheless, the power of the fluctuation test is that a true mutation rate, ie, the number of mutational events per cell division, is obtained, not a mutant frequency that can be dramatically skewed by jackpots.

The fluctuation test consists of a large number of identical cultures inoculated with a number of cells few enough to ensure that no preexisting mutants are present. These cultures are allowed to grow, achieving at least a thousandfold increase in cell number. Then mutants are selected, usually by plating each entire culture onto a selective agar medium. After a suitable time to allow the mutant clones to grow, the resulting colonies are counted. The parameter used for calculating the mutation rate is m, the mean number of mutations (not mutants) per culture. This is, perhaps, a difficult concept to understand because it is a function of the mutation rate and also of the number of cells at risk for mutation (and thus one requirement for a proper fluctuation test is that every culture has the same number of cells). To date, however, the only solved methods to determine the mutation rate from fluctuation test results are based on the distribution of m. Then the value of m is usually divided by $2N$, twice the final number of cells in the culture, to obtain the mutation rate as mutations per cell per generation (because a culture of N cells contains a total of $2N$ cells during its entire history). Some researchers attempt to correct for asynchronous divisions by dividing m by $N/\ln 2$ instead. These calculations assume that the initial number of cells is trivial compared to the final number, that the proportion of mutants is always small, that mutants grow at the same rate as wild-type, and that reverse mutations are negligible.

The data obtained from a fluctuation test are the number of mutants x_i in each culture. From the number of mutants, there are several commonly used methods to obtain estimates of m (often called estimators), of which five are described here.

1. The P_0 method (1). If the probability of mutation is constant per cell per generation, then the number of mutations per culture has a Poisson distribution (although the number of mutants has a Luria–Delbrück distribution). The probability of no mutations (and thus no mutants) P_0, is e^{-m}, the first term of the Poisson distribution. Thus, the P_0 estimate of m is obtained from the proportion of cultures that have no mutants as $m = -\ln P_0$.
2. The method of the mean (1). Although the extreme variance of the Luria–Delbrück distribution is caused by mutations early in the growth of cultures, these are, in fact, rare events. After the critical point where the total population size (all of the cells in all of the cultures) is large enough so that the probability of a mutation approaches unity, every succeeding generation makes an equal contribution to the number of mutants (from new mutations plus the growth of preexisting mutants). Assuming that no mutations occur before the critical point, the value of m is derived as $x_{mean} = m\ln(mC)$ where x_{mean} is the mean number of mutants per culture and C is the number of cultures.
3. The graphical method (4, 5). Because each generation produces an equal number of mutants after the critical point, the accumulated distribution of the number of mutants per culture, Y_x, is

estimated as m/x, where Y_x is the number of cultures with x or more mutants. Thus a plot of log Y_x vs. log x gives a straight line with a slope of –1. The intercept at log $x = 0$ gives log m. The advantage of this method is that the straight line can be fit by eye to the intermediate values, which are not caused by jackpots.

4. The method of the median. Although the mean number of mutants fluctuates widely depending on the number of jackpots present, the median is not so influenced and is thus a more stable statistic. Lea and Coulson (6) found empirically that $(x_{median}/m) - \ln(m) = 1.24$. This equation is easily solved for m by iteration.
5. The maximum likelihood method. This method relies on solving, at least approximately, the Luria–Delbrück distribution and then generating the most likely value of m for the experimentally determined x_i values. Although this is the most accurate method of estimating m, it has been shunned in the past because of the difficulties in calculation. However, a reasonably adequate way of obtaining m is to solve Eq. (50) of Lea and Coulson (6) by iteration. In addition, Koch (7) provided exact values of m obtainable from the median and upper and lower quartiles of the distribution, which was extended to the upper quartiles by Cairns et al. (2). Simpler algorithms and sophisticated computer programs, however, make the maximum-likelihood method now computationally feasible (8).

Of these methods, the mean (2) is the least accurate because it is skewed by jackpots. The utility of the other methods depends on the value of m. If $m \leq 1$, the P_0 method (1) is reliable, so long as P_0 is determined with sufficient accuracy. When $m = 1 \text{to} 4$, the median method (4) is convenient and adequate. At values of m larger than 4, the median can still be used, but the maximum likelihood method (5) is preferable. Another advantage of the maximum likelihood method is that the standard deviation of m, and thus of the mutation rate, can be approximated (9). Further discussions and refinements can be found in Refs. 9-11.

The phenomenon of phenotypic lag, in which the expression of a new mutant phenotype is delayed, complicates determining mutation rates from fluctuation tests (3, 7, 12).

Fluid Mosaic Model

The liquid-like properties of lipid liquid crystals are assimilated into this model for the structure of cell membranes and for the organization of its protein and lipid components. The concepts that underlie this model assume that integral membrane proteins are “a heterogeneous set of globular molecules, each arranged in an amphipathic structure, i.e. with the ionic and highly polar groups protruding from the membrane into the aqueous phase, and the nonpolar groups largely buried in the **hydrophobic** interior of the membrane” (1). In this model the membrane is perceived as a mosaic of a continuous phospholipid bilayer that is periodically interrupted by proteins randomly distributed throughout the bilayer. The phospholipid bilayer is considered a viscous solvent that allows the dissolved proteins to diffuse laterally within the plane of the membrane. (See also Membranes, and Amphipathic.)

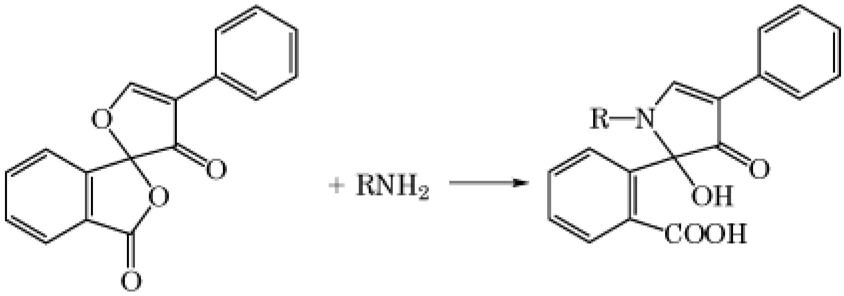
Fluorescamine

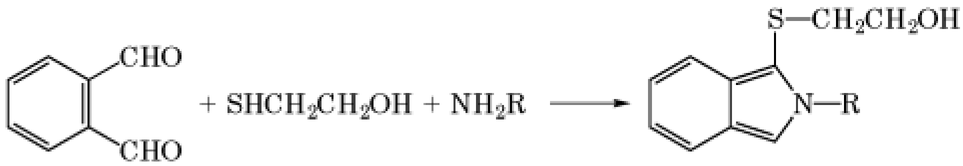
Fluorescamine [I] reacts readily with primary amino groups to form highly **fluorescent** compounds [II] Scheme 1, even though fluorescamine itself is nonfluorescent. The fluorescent products have an excitation maximum at 390 nm and an emission maximum at 475 nm. These properties make fluorescamine ideal for detecting amino groups, especially in proteins, **peptides**, and amino acids. It is 10 to 100 times more sensitive in detecting primary amino groups than the ninhydrin reaction. Fluorescamine is also employed as a reporter group in protein chemistry and immunology.



[I] Fluorescamine [II] Fluorescent compound

The formal nomenclature for fluorescamine is 4-phenylspiro[furan-2(3H),1″-(3′H)-isobenzo furan]-3,3′-dione or 4-phenylspiro[furan-2(3H),1′-phthalan]-3,3′-dione. It has a molecular weight of 278.27 and a melting point at 154 to 155°C.

Because fluorescamine has low solubility and stability in water, *o*-phthalaldehyde [III], which reacts similarly with primary amino groups and gives highly fluorescent products [IV] Scheme 2, is sometimes substituted for fluorescamine (1, 2):



[III] o-Phthalaldehyde

[IV] Fluorescent product

To quantify proteins with fluroescamin (3), a sample solution (10 to 250 mL, containing 500 ng to 50 µg of protein) is made up to 1.5 mL with 0.05 M phosphate buffer (pH 8). Then 0.5 mL of fluorescamine solution, made by dissolving 30 mg of fluorescamine in 100 mL of dioxane, is added to it with vigorous stirring. The emission at 475 nm, upon excitation at 390 nm, is quickly determined. This method is based on the reaction with primary amino groups, so the extent of emission varies depending on the amino acid composition of the proteins, any contaminating compounds having primary amines interfere with the assay.

Fluorescamine reacts with amino acids promptly at pH 9 and yields fluorescent products. The reaction product with ammonia has low fluorescent intensity (less than 1% of the normal products with primary amines). Thus, this reaction is employed for automatic amino acid analysis with a fluorescence detector.

Fluorescamine is used to detect **electroblotted** proteins (4) by visualizing transferred proteins on the transfer membrane with UV light. This method is very sensitive, it is also applied to detect peptides on filter paper or in the eluate from column chromatography. Fluorescamine is also used to test the completeness of other reactions of primary amines (5).

Fluorescence Energy Transfer

In principle, the fluorescent light emitted by a fluorophore (the energy donor) can be reabsorbed by another chromophore (the energy acceptor) in the same molecule or somewhere else in the solution, provided that the absorption spectrum of the acceptor overlaps with the fluorescence emission spectrum of the donor (see Absorption Spectroscopy and Fluorescence Spectroscopy). Such an energy transfer by emission and reabsorption of light is extremely inefficient. A much more efficient energy transfer between donor and acceptor can occur in a nonradiative process, which involves the coupling of their transition dipoles. This process is called resonance energy transfer. It depends on:

1. the extent of overlap between the fluorescence band of the donor and the absorption band of the acceptor,
2. the distance between the two chromophores, and
3. the relative orientation of their transition dipoles.

Resonance energy transfer is strongly sensitive to distance and varies with the inverse sixth power of the distance R between donor and acceptor. This is very useful to measure distances in macromolecules and changes in distances as a result of conformational changes in proteins and nucleic acids. An important number in energy transfer is the characteristic transfer distance R_0. R_0 is the distance between donor and acceptor at which fluorescence emission from the donor and energy transfer to the acceptor are equally probable. Förster developed a theory to correlate the efficiency of energy transfer with R and R_0. The characteristic distance R_0 can be calculated (primarily from the spectral overlap between donor and acceptor), and consequently the distance R between donor and acceptor can be determined from the measured efficiency of fluorescence energy transfer. Values for R_0 often lie in the range between 1 and 5 nm. Thus, distances up to about 8 nm can be measured by energy transfer.

In proteins, energy is transferred primarily from **tyrosine** to **tryptophan** residues. Tryptophan residues can also transfer their energy to natural acceptors, such as **NADH**, riboflavin, or heme. For measuring distances in proteins or nucleic acids, often both donor and acceptor are introduced by site-directed labeling (see Reporter Groups). A naphthyl group is often used as the donor and a dansyl group as the acceptor in such experiments. A detailed list of useful donor/acceptor pairs is found in (1).

Fluorescence Microscopy

Fluorescence microscopy uses the contrast created by fluorescent molecules, fluorophores, that emit light of a specific wavelength when excited by incident light of a different (shorter) wavelength. By using filters, one can select an appropriate wavelength for excitation of the fluorophore and a second filter can eliminate light of wavelengths other than that emitted by the fluorophore. The second filter is very important as it removes the much more intense excitation light, so that the emitted signal is detected in the absence of the excitation light and other stray light, giving fluorescence microscopy an excellent signal-to-noise ratio. Fluorescence microscopy universally uses epi-illumination in which light from above is reflected off the surface of the specimen by light emerging from the objective lens. Epi-illumination has the advantages that (1) unabsorbed light is directed away from the observer and (2) the alignment is simplified since the objective lens acts as its own condenser. It is important to understand the capabilities and limitations of the fluorophores. Because a specimen can be stained with a finite quantity of fluorescent dye, which decays or photobleaches when illuminated, the microscope must be configured to efficiently excite and detect the limited number of emitted photons before complete bleaching has occurred. Although a large number of fluorescent dyes have been discovered, relatively few are suitable for fluorescence microscopy (1).

Immunofluorescence light microscopy is the most common technique of fluorescence microscopy and involves the use of antibodies labeled with fluorophores to visualize distributions of proteins and nucleic acids within a specimen. This technique can be performed by either *direct* or *indirect* antibody labeling. Direct immunofluorescence requires the conjugation of a primary antibody with a fluorophore, commonly rhodamine and fluorescein. Indirect immunofluorescence, on the other hand, uses a fluorophore conjugated secondary antibody which was raised against the immunoglobulin type of the primary antibody. For example, if the primary antibody is raised in a rabbit, the secondary antibody might be a goat anti-rabbit antibody. Indirect immunofluorescence is the more common of the two techniques because making a fluorophore conjugate of each primary antibody is time-consuming and can decrease the affinity or specificity for the antigen. Furthermore, the indirect technique may be more sensitive because more than one molecule of the secondary antibody may bind to a molecule of the primary antibody (2), creating an amplification of the signal. Indirect immunofluorescence has motivated the development of a large number of commercially available secondary antibodies conjugated to various fluorophores, so in order to do immunofluorescence microscopy, one need only raise and characterize the primary antibody and then purchase the secondary antibody. A key consideration in immunofluorescence microscopy is confirmation of the specificity of both fluorophore and antibodies. In order for immunofluorescence results to be validly interpreted, one must demonstrate that (i) the secondary antibody recognizes only the primary antibody, and (ii) the primary antibody recognizes only the antigen. This means that the secondary antibodies must not cross-react with intrinsic proteins and do not recognize each other. It is also necessary to establish whether autofluorescence from compounds intrinsic to the tissue can mimic the appearance of fluorophores. This test is easily done by examining an unstained specimen using the same excitation and emission filters intended for use with the fluorophore.

Fluorescence microscopy can also be used to monitor intracellular compartments through the use of fluorescent indicator dyes, which report on their local environments. Some of the fluorescent dyes useful for microscopy are membrane potential indicators such as JC-1 (3). Using this probe, it was shown that heterogeneity in mitochondrial membrane potential exists between different mitochondria in the same cell (4). Other fluorescent dyes are ion indicators, which can report the pH or concentrations of calcium, chloride, magnesium, potassium, and sodium ions either qualitatively or quantitatively (5).

With the appropriate choice of fluorescent labels and proper equipment, one can do multilabeling [sometimes called multicolor (6)] to localize two or more molecular species using fluorophores with different excitation and/or emission wavelengths. By using multicolor immunofluorescence microscopy, the neurotransmitters, serotonin and substance P, were observed in separate populations of spinal cord fibers (6) and the motor neurons and the substance P fibers, which wrap around them, could be separately visualized. Another example is the use of DiOC6 to label mitochondria and ethidium bromide to label mitochondrial DNA in *Euglena gracilis* cells (7).

Fluorescence Quenching

After excitation by absorption of light (see **Absorbance spectroscopy**), a chromophore can lose the absorbed energy, and thus return from the excited state to the ground state, either by emitting a photon (observed as fluorescence) or alternatively by nonradiative processes, such as exchange of heat with the solvent. For a particular chromophore, the quantum yield of the observed fluorescence depends on the relative rates of fluorescence emission and the competing nonradiative processes. Under conditions where such nonradiative processes are very slow, one photon is emitted for every photon absorbed, and the quantum yield (the number of photons emitted per number of photons absorbed) approaches one. In practice, the observed quantum yields are often much smaller than one because nonradiative processes compete efficiently with the emission of light. Such a decrease in quantum yield is called fluorescence quenching . The collision of a chromophore with certain molecules in the solution is an effective means to quench fluorescence; such a process is called collisional quenching.

Radiationless transitions can occur by two major routes: internal conversion and intersystem crossing. In internal conversion, the first excited electronic singlet state is converted to the ground singlet state by exchange of vibrational energy (ie, heat) with the solvent. In intersystem crossing, the first excited singlet state is converted to the first excited triplet state. This triplet state is more stable than the corresponding singlet state and is very long-lived, because transitions between triplet and singlet states are nominally forbidden. They are accompanied either by heat exchange or phosphorescence (ie, emission of light with low energy).

Intersystem crossing is triggered by magnetic fluctuations in the system. It is thus greatly facilitated by collisions of the excited molecules with molecules or ions that contain unpaired electrons or loosely held electron clouds (such as acrylamide or iodide anions). The efficiency of collisional quenching depends on the frequency of the collisions, ie, on the concentration of the added quencher and exposure of the fluorophore to the solvent. The susceptibility to collisional quenching can be used to measure the degree of exposure to solvent of a fluorescing group (such as a tryptophan residue in a protein). Experimentally, the ratio of the fluorescence in the absence and in the presence of a quencher is measured as a function of the concentration of the quencher and plotted in a Stern–Volmer diagram. The Stern–Volmer quenching constant is derived from this plot. It is a measure of the exposure of the fluorophore to the quencher. Static quenchers do not obey the Stern–Volmer relationship. They form nonfluorescent complexes with the fluorophore, and the binding constant can be derived from the quenching experiments.

Fluorescence Spectroscopy

1. Fluorescence

Fluorescence emission of light is observed when, after excitation by the absorption of a photon (see Absorption Spectroscopy), an electron returns from the first excited state back to the ground state. Absorption and emission are both virtually instantaneous processes and occur in about 10^{-15}s. The average lifetime of the excited state is about 10^{-8}s, which is a short time, but seven orders of magnitude longer than the time required for light absorption and emission. In the excited state, some energy is always lost by nonradiative processes (such as transitions between vibrational states). Therefore, the energy of the emitted light is always less than that of the absorbed light, and the fluorescence of a chromophore thus occurs always at greater wavelengths than its absorption. Fluorescence emission is much more sensitive to changes in the environment of the chromophore than light absorption. As the lifetime of the excited state is long, a broad range of interactions or perturbations can influence this state and thereby the emission spectrum. Fluorescence is thus an excellent and extremely sensitive probe to investigate the structure and function of proteins.

2. Fluorescence of Proteins

The aromatic amino acid residues phenylalanine (Phe), tyrosine (Tyr), and tryptophan (Trp) exhibit fluorescence emission when excited in the wavelength range of their absorption spectra. In proteins that contain all three aromatic amino acids, the emitted fluorescence is usually dominated by the contribution of the Trp residues, because both their absorbance at the wavelength of excitation and their quantum yield of emission are considerably greater than the corresponding values for Tyr and Phe. This is expressed by the “sensitivity” parameter (Table 1), which is 730 for Trp and 200 for Tyr. Phenylalanine fluorescence is not observed in native proteins, because its sensitivity of 4 is very low. In addition, Phe and Tyr fluorescence is also decreased by energy transfer (see Fluorescence Energy Transfer) to Trp residues.

Table 1. Absorbance and Fluorescence Properties of the Aromatic Amino Acids[a]

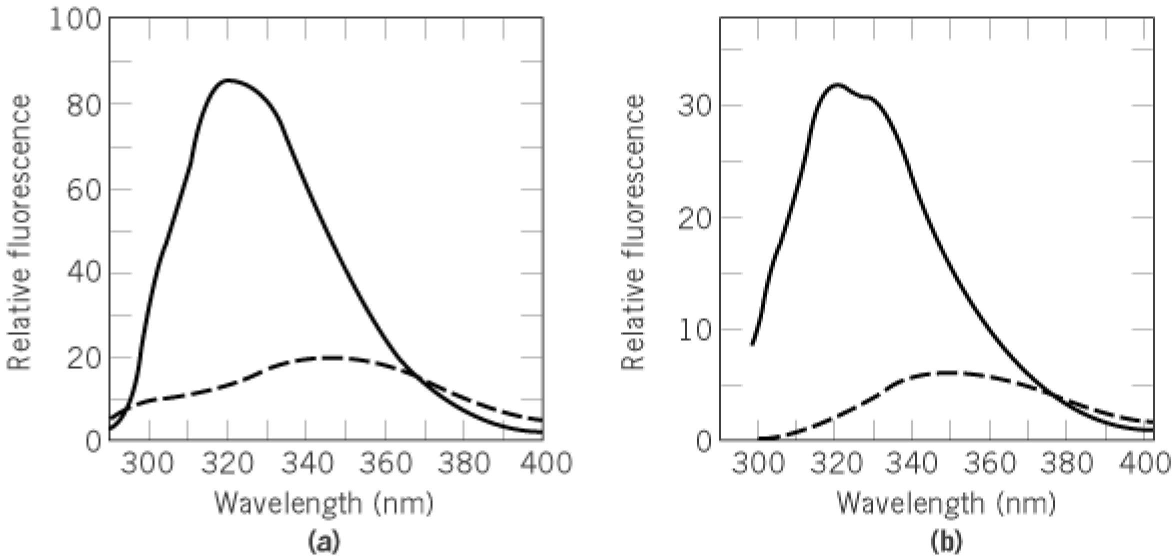
	Absorbance		Fluorescence		Sensitivity
Compound	**l_{max}(nm)**	**ε_{max}($M^{-1}cm^{-1}$)**	**l_{max}(nm)**	**f_F**[b]	**$\varepsilon_{max} \times f_F$**[b] **($M^{-1}cm^{-1}$)**
Tryptophan	280	5600	355	0.13	730
Tyrosine	275	1400	304	0.14	200
Phenylalanine	258	200	282	0.02	4

[a] In water at neutral pH; data are from (2).

[b] f_F, fluorescence quantum yield.

Changes in protein conformation, such as unfolding, very often lead to large changes in the wavelength and intensity of fluorescence emission. The fluorescence emission of Trp residues in native proteins can be either greater or smaller than the emission of tryptophan in aqueous solution. Consequently, the fluorescence intensity can either increase or decrease upon protein unfolding. The emission maximum is usually shifted from shorter wavelengths to about 350 nm, which corresponds to the fluorescence maximum of tryptophan in aqueous solution. The exact location of this maximum depends to some extent on the nature and concentration of the buffer. In a **hydrophobic** environment, such as in the interior of a folded protein, tryptophan emission occurs at shorter wavelengths (indole shows an emission maximum of 320 nm in hexane). As an example, the emission spectra of native and of unfolded **ribonuclease T $_1$** are shown in Figure 1. RNase T_1 contains 9 Tyr residues and only one Trp (Trp59), which is inaccessible to solvent in the native protein.

Figure 1. Fluorescence emission spectra of native (—) and of unfolded (– – –) RNase T_1. Native RNase T_1 (1.4 µM) was in 0.1 *M* sodium acetate pH 5.0; the sample of unfolded protein contained 6.0 *M* GdmCl in addition. Fluorescence was excited at (**a**) 278 nm and (**b**) 295 nm. The bandwidths were 3 nm for excitation and 5 nm for emission. Spectra were recorded at 25°C in 1 × 1 cm cells in a Hitachi F-4010 fluorimeter. From Ref. 1.

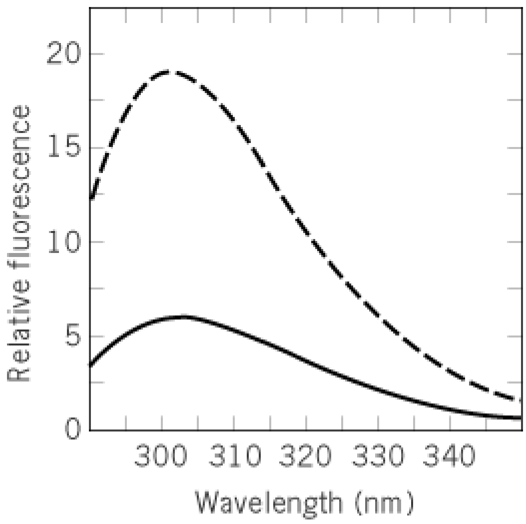


The fluorescence of the Trp residues of a protein can be investigated selectively by excitation at wavelengths greater than 295 nm. Because of the red shift and increased intensity of the absorbance spectrum of tryptophan when compared with tyrosine protein absorbance above 295 nm originates almost exclusively from Trp residues. A comparison of the emission observed after excitation at 280 and 295 nm gives information about the contribution of the Trp and Tyr residues to the observed fluorescence spectra. The data for RNase T_1 in Figure 1 show that the shapes of the fluorescence spectra observed after excitation at 278 and 295 nm are virtually identical. The measured emission originates almost completely from the single Trp59, which is inaccessible to solvent and hence displays a strongly blue-shifted emission maximum near 320 nm. Tyrosine emission is barely detectable in the spectrum of the native protein, because energy transfer to Trp residues occurs. Unfolding of RNase T_1 by **guanidinium chloride** results in a strong decrease in tryptophan fluorescence and a concomitant red shift of the maximum to about 350 nm. The distances between the Tyr residues and Trp59 increase upon unfolding, so energy transfer becomes less efficient. As a consequence, the Tyr fluorescence near 303 nm becomes visible in the spectrum of the unfolded protein when excited at 278 nm (Fig. 1*a*), but not when excited at 295 nm (Fig. 1*b*). The examples in Figure 1 indicate that, unlike absorbance, the changes in fluorescence upon folding can be very large, and the contribution of the Trp residues can be studied selectively by changing the excitation wavelength. Thus, fluorescence measurements are extremely useful to monitor conformational changes in proteins.

Multiple bands in an emission spectrum do not necessarily originate from different Trp residues of a folded protein. Figure 1 shows that even single Trp residues, such as Trp59 of RNase T_1, can give rise to several emission bands. It indicates that the protein can adopt different conformations that equilibrate more slowly than the lifetime of the excited state (about 10^{-8}s).

The fluorescence emission maximum of tyrosine remains around 303 nm, irrespective of its molecular environment. Therefore, the unfolding of proteins that contain no Trp residues is usually accompanied by changes in the intensity, but not in the wavelength of emission. As an example, the fluorescence emission spectra of the Trp59Tyr variant of RNase T_1 (which is devoid of Trp residues) in the native and unfolded states are shown in Figure 2. A decreased Tyr fluorescence in the native state (as in Fig. 2) is frequently observed. It is thought to originate in the folded state from **hydrogen bonding** of the tyrosyl hydroxyl group and/or the proximity of quenchers (see Fluorescence Quenching), such as disulfide bonds.

Figure 2. Fluorescence emission spectra of 1.5 µM of native (—) and of unfolded (– – –) Trp59Tyr-RNase T_1. This protein contains 10 Tyr residues, but no Trp residue. The native protein was in 0.1 *M* sodium acetate, pH 5.0; the unfolded sample contained 6.0 *M* GdmCl in addition. Fluorescence was excited at 278 nm, the spectra were recorded as in Figure 1. From Ref. 1.



2.1. Environmental Effects on Tyrosine and Tryptophan Emission

The fluorescence intensity generally decreases with increasing temperature. This decrease is substantial, and to a first approximation, Tyr and Trp emission decrease by more than 1% per degree increase in temperature. Denaturants such as urea and guanidinium chloride also influence the fluorescence of Tyr and Trp (1).

3. Practical considerations

3.1. Fluorescence Spectrophotometers

Fluorescence spectrophotometers ("fluorimeters") are single-beam instruments. The light from an intense source (usually a Xenon lamp) passes first the excitation monochromator to select the excitation wavelength, and is then focused into the center of the cuvette. The fluorescence emission is usually monitored at a right angle relative to the exciting beam; it passes through the emission monochromator and is detected by the sample photomultiplier. Most spectrofluorimeters operate in a split-beam mode, where a small portion of the incident light is directed to a reference photomultiplier to correct the fluorescence signal for inherent instabilities of the light source. To avoid baseline drift, some instruments interrupt the light beam periodically or employ pulsed lamps. The dark periods are used to adjust the baseline during the measurement. This increases the long-term constancy of the measured fluorescence.

3.2. Cuvettes for Fluorescence Measurements

Cuvettes for measuring fluorescence have polished surfaces on all four sides. Quartz cells are required for work in the UV region. For routine work, rectangular cuvettes (0.4 × 1 cm) are convenient. Since the exciting beam illuminates only the central part of the cell, the observed fluorescence intensity does not decrease necessarily when cuvettes with reduced cross sections are used. Cuvettes and glassware are easily contaminated with fluorescing substances that may leak out of plastic containers or are present in laboratory detergents. Before measurements, the cleanliness of the cell (and the distilled water) should be checked routinely by filling the cuvette with water and recording a blank in the wavelength range of interest. There should be no emission except the Raman peak of water.

3.3. Raman Peak of Water

In water, a Raman scattering peak is observed that is separated from the incident radiation by a fixed energy difference. After excitation at 280 nm (as in fluorescence experiments with proteins) the Raman peak of water is at 315 nm, ie, it overlaps with the emission spectrum of proteins. The Raman peak must therefore be subtracted from the measured fluorescence spectra. The performance of a fluorescence spectrometer can be checked easily by recording the signal-to-noise ratio at the Raman peak of water.

Fluorodeoxyuridine

Fluorodeoxyuridine (FUdR) is a mutagen and a potent inhibitor of thymidylate synthase (1), which leads to depletion of cellular pools of precursors to thymidine. The accuracy of both DNA replication and DNA repair is dependent upon a balanced supply of deoxyribonucleoside triphosphate (dNTP) precursors of DNA (2, 3), and perturbation of their relative levels has far-reaching effects. These include point mutation, **chromosomal** breakage, exchange or loss, as well as a stimulation of mitotic and meiotic recombination. Thus a large number of experimental systems and assays have responded positively to FUdR or its precursor 5-fluorouracil (summarized in Kunz et al. (3)), although they (unlike 5-bromo-, 5-iodo-, and 5-chlorodeoxyuridine) were not mutagenic for T4 bacteriophage in early studies (4). Unlike other nucleoside base analogues, such as 5-bromouracil or 2-aminopurine, FUdR does not directly affect base-pairing properties, but instead causes nucleotide pool imbalances through depleting dTTP and increasing dATP and dCTP pools (3).

Fluorography

Fluorography (or photofluorography) is the technique of photographing an image produced by light emitted from a fluorescent screen or material. Light is produced by the excitation of a fluorescent material by ionizing radiation, which is produced when charged particles (electrons or beta particles) emitted from radionuclides such as tritium (^{3}H), carbon-14 (^{14}C), phosphorus-32 (^{32}P), sulfur-35 (^{35}S), or iodine-125 (^{125}I) interact with the material. The emitted light exposes the film, and an image is recorded.

Fluorography is a common technique used in molecular biology blotting experiments to increase the sensitivity of medium-to-low energy beta-particle-emitting radioisotopes embedded in gel slices. A fluorescent screen is sometimes used to amplify the amount of light produced. A fluorescent screen is a sheet of material that is coated with fluorescent reagents (fluorophores, luminophores, or fluorochromes).

Fluorescence enhances the intensity of the image recorded in the film and makes it possible to obtain images in shorter time periods and with less radioactivity than conventional autoradiography. Fluorographic detection of blotted samples can reduce exposure times by factors of 5 to 10 and can increase sensitivity by factors of 3 to 5 over the use of dried gels (1). Fluorography works best with flashed film and exposures of film at –70°C. Film flashing helps to detect weak bands or spots. Flashing also helps to reduce the threshold of detection. Before fluorography, gels should be fixed with 30% isopropyl alcohol and 10% acetic acid to immobilize the separated proteins and to remove non-protein components that might interfere with subsequent staining.

Radiation-free fluorographic techniques for Southern blots have been developed using

chemical luminescence. Samples are placed on a chemiluminescent substrate sheet, and the blot is exposed to X-ray film for about 70 min at 37°C.

In other industrial and medical applications, fluorescent materials respond also to radiation from gamma-emitting radioisotopes, X-ray sources, electron beams, and charged particles. A fluorograph is the photograph produced by the light from fluorescent materials, and a fluoroscope is a device for viewing the light from fluorescing materials. A fluorescence digital imaging microscope is an instrument for viewing microscopic images of fluorescing substances, which are stimulated by ultraviolet light and filtered so that the observer sees only the fluorescence emission and not the stimulating light.

Fluorography is sometimes called abreuography in honor of Manuel de Abreau, a Brazilian physician who discovered the technique.

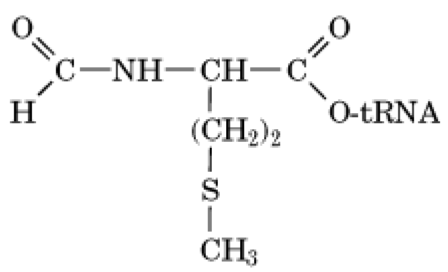
fMET (*N*-Formyl Methionine)

Protein biosynthesis usually starts with *N*-formyl methionine (Fig. 1), which is directed by the initiation codon AUG, or rarely in bacteria by GUG or UUG. The same triplet AUG is decoded as a normal methionine during elongation. These distinct types of recognition are carried out by distinct transfer RNAs, initiator $tRNA^{fMet}$ and elongator $tRNA^{Met}$. The initiator tRNA carries a methionine residue that has been formylated on its amino group (*N*-formyl-methionyl-$tRNA^{fMet}$, or fMet-$tRNA^{fMet}$). Synthesis of fMet-$tRNA^{fMet}$ proceeds in two steps: (i) aminoacylation of the initiator tRNA with methionine and (ii) formyl transfer from formyltetrahydrofolate to the methionine amino group. The latter reaction is catalyzed by a formyltransferase.

Figure 1. fMet (*N*-formyl methionine).

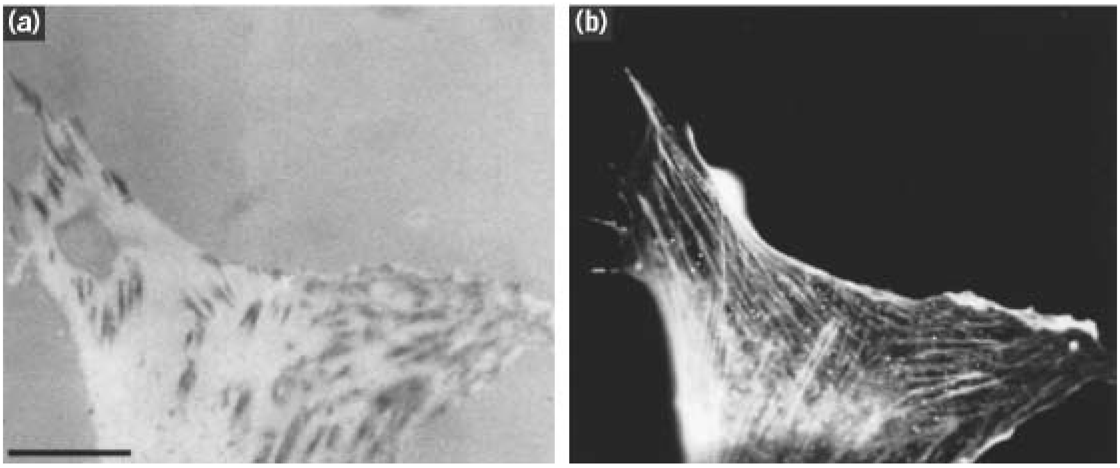


Only fMet-$tRNA^{fMet}$ is used for initiation of protein synthesis, because it enters part of the P site on the prokaryotic 30S or eukaryotic 40S ribosome subunit (see Initiation Complex and Initiation Factor (IF)). Often the *N*-terminal formyl residue is removed by a specific deformylase enzyme. Sometimes the methionine residue at the terminus is removed by an aminopeptidase. These reactions occur rather rapidly, probably when the nascent polypeptide chain reaches the length of 15 to 30 amino acids.

Focal Contact

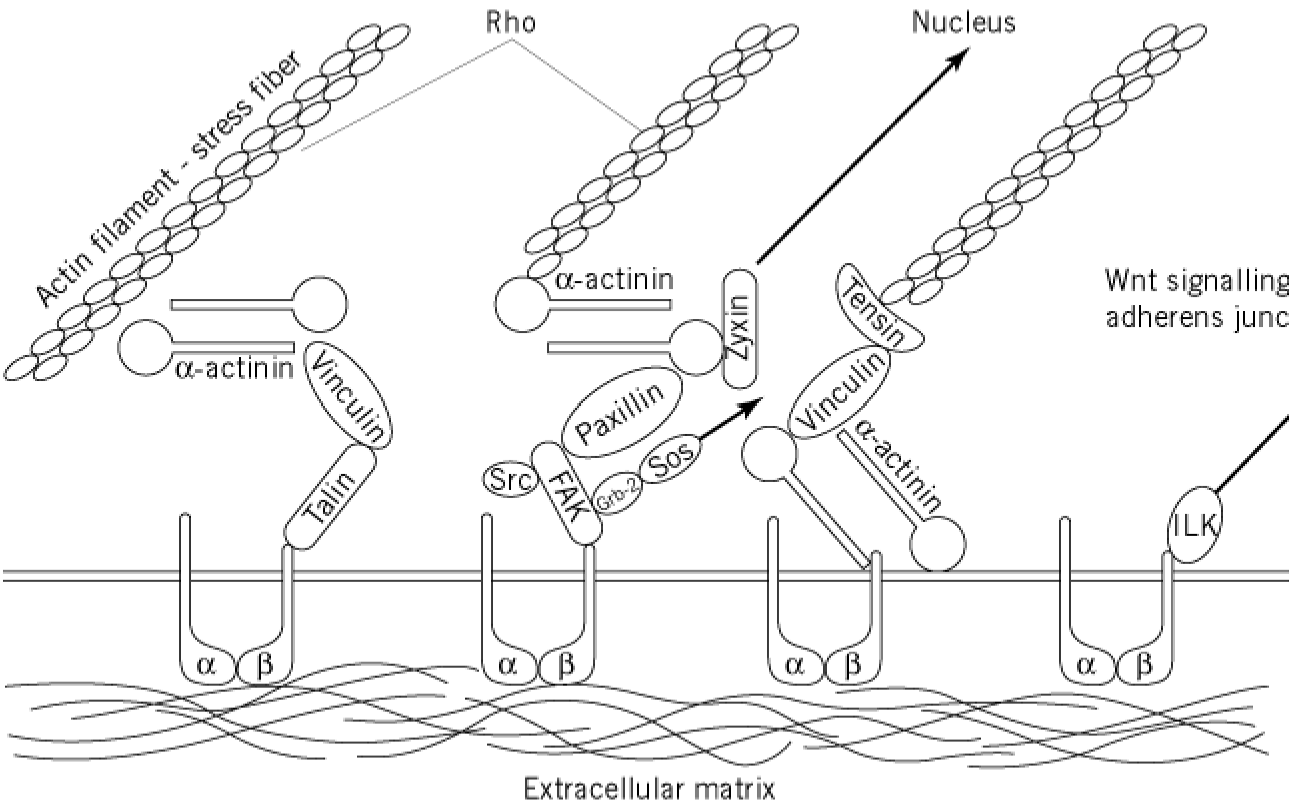
Focal contacts, focal adhesions, or adhesion plaques are cell "junctions" by which many cell types in culture adhere to their substratum, being regions of closest approach between the lower cell surface and the substratum, a separation of approximately 10 nm. Elongated structures that may be 3 to 4 mm in length, they may be recognized as black areas by interference reflection microscopy (Fig. 1), by electron microscopy, or by staining with antibodies against one of their numerous components (1, 2) (see text below). These contacts are points at which the actin cytoskeleton associates with the cell surface, and are located at the cell-surface termini of actin **microfilament bundles**, called stress fibers. Focal contacts and stress fibers do not have clear equivalents *in vivo*, although their molecular composition resembles that of the dense bodies of smooth muscle. Nevertheless, the molecules, molecular interactions, and cellular functions that have been discovered by studying focal contacts are likely to be of great importance in regulating cell behavior *in vivo*. In tumor cells, disruption of focal contacts is associated with the transformed phenotype (3). The components of focal contacts are involved both in extracellular matrix adhesion and signal transduction.

Figure 1. (**a**, **b**) Interference reflection image (**a**) and fluorescent image showing phalloidin staining for F-actin (**b**) of a cultured fibroblast, illustrating focal contacts and stress fibers. Focal contacts are the elongated black areas in **a**. Note how the actin stress fibres terminate at focal contacts at their peripheral ends. (Photographs provided by Dr. G. Ireland.) Bar=10 μ m.



The principal adhesive components of focal contacts are integrins (4) (Fig. 2) although they also contain membrane heparan sulfate proteoglycan. These adhesion receptors bind the cell to components of the extracellular matrix, such as fibronectin and vitronectin. Several actin-binding proteins associate with the cytoplasmic side of the plasma membrane at focal contacts. These include a-actinin (2), vinculin (5), talin (6), and tensin (7), the first two of which are also found in intermediate junctions . Talin and a-actinin have been shown to bind to the cytolasmic domains of integrins, particularly the b1 subunit (6, 8). Tensin has actin filament-capping activity. The location of these proteins to focal contacts and their binding interactions are based on a variety of types of evidence, including expression of mutant proteins and *in vitro* binding between purified, recombinant, or synthetic proteins or peptide fragments. The precise manner in which these proteins interact in focal contacts is not understood. Collectively, they provide a link between the integrin adhesion receptors and the actin cytoskeleton.

Figure 2. Diagram showing some of the major components of focal contacts and their possible molecular interactions. sı
Grb 2 = growth factor receptor bound protein 2, SOS = son-of-sevenless, ILK = integrin-linked kinase, a = integrin a suk
b = integrin b subunit. Arrows indicate signaling pathways, details of which are not shown. For further details, see text.



Cells must be able to break and reform focal contacts in order to move. They have been shown to contain the proteinase calpain, which is able to cleave talin and may be involved in modulating junctional adhesion (9). Alternatively, **phosphorylation** signals generated from within the cytoplasm may modulate the adhesiveness of focal adhesions through regulation of integrin function (10). The oncogenic **tyrosine kinase** pp60 ^{src} and protein kinase C, both present in focal contacts, appears to be able to modulate integrin-mediated adhesion, reducing cell-substratum adhesion (11). Such an adhesive change is likely to be important in tumorgenicity, increasing the invasive properties of cells.

An important function of focal contact components is the transduction of signals from outside the cell. Such signals may be involved in regulating a variety of cellular processes, including motility, cell division, gene expression, and apoptosis. An example of a focal adhesion signaling molecule is the focal adhesion kinase (FAK) (12). This is a tyrosine kinase that is activated by ligand binding to integrins (13). FAK has been shown to bind to the cytoplasmic domain of the b1 integrin subunit and also to the vinculin-binding protein paxillin (14). Phosphorylation of FAK in response to integrin-ligand binding increases its tyrosine kinase activity (15). It is also able to associate with a number of other signaling proteins via its various phosphotyrosine residues. Thus, it binds $pp60^{src}$ via the latter's src homology **(SH2)** domain (16) and similarly binds growth factor receptor-bound protein, or Grb2 (17). The latter interacts with the guanine nucleotide exchange factor mSOS1, which activates the **Ras** signaling pathway. FAK may also be involved in regulating focal contact turnover, because fibroblasts from FAK – /– mice show increased numbers of more persistent focal contacts (18).

Another focal contact-associated signaling molecule is the integrin-linked kinase (ILK), a **serine-threonine kinase** that can bind directly to the cytoplasmic domains of b1 and b3 integrins (19). Its kinase activity modulates cell–matrix interactions. Overexpression of ILK in epithelial cells results in reduction of tumorgenicity and loss of cell–cell adhesion and anchorage-independent growth. Furthermore, it causes down-regulation of expression of the zonula adherens adhesion molecule E-cadherin, translocation of b-catenin to the nucleus, and formation of a transcriptional regulating complex between b-catenin and the transcription factor LEF-1. Thus, ILK mediates cross-talk between cell–matrix and cell–cell adhesion, as well as regulation of the wnt signaling pathway (20).

Both paxillin and another focal-contact associated protein called zyxin possess so-called LIM domains, **zinc-finger** motifs that are also found in a number of proteins involved in the regulation of gene expression (21, 22). Paxillin becomes tyrosine-phosphorylated on matrix ligand binding, suggesting that it is involved in signal transduction (21). Zyxin binds to a-actinin, binds to other proteins that have potential signaling functions, such as the vasodilator-stimulated phosphoprotein (VASP), and has a nuclear export sequence. It has also been shown to shuttle between the focal contact and the nucleus, suggesting that it may provide a direct signaling link between matrix receptors at the cell periphery and gene regulation (23).

Regulation of focal contact formation is also regulated by the small Rho GTPase. Overexpression of Rho in quiescent cells causes focal contact formation and stress fiber assembly, whereas inhibition of Rho leads to focal contact disassembly (24). This aspect of Rho signaling is one of several integrated signaling pathways involving small Gtpases that participate in regulating cell adhesion, cell motility, and actin cytoskeleton.

Footprinting

Protein binding sites on DNA can be detected *in vivo* and *in vitro* by a technique termed “footprinting”. This depends on the principle that a bound protein molecule can protect DNA from cleavage or modification by a nuclease or a chemical reagent. The binding site is then defined by a region of reduced reactivity, which is determined by analyzing the products of the cleavage reaction on denaturing polyacrylamide gel. The footprint of the protein appears as a gap in the normal pattern of cleavage.

In vitro DNase I is commonly used for enzymatic footprinting and dimethylsulfate and hydroxyl radicals are employed for chemical footprinting. DNase I targets the minor groove of DNA and is also sensitive to the local conformation of the bound DNA such that cleavage is enhanced where the minor groove is on the outside of DNA wrapped around the protein. Dimethylsulfate under footprinting conditions methylates the N7 position of guanine in the major groove and the N2 position of adenine in the minor groove. This methylation sensitizes the sugar-phosphate backbone to mild alkaline hydrolysis, enabling the sites of reaction to be determined. For hydroxyl radical footprinting the radicals are generated by the reaction of hydrogen peroxide with an Fe^{2+} –EDTA complex (the Fenton reaction) and they react with a backbone sugar resulting in the cleavage of the backbone. This reagent targets the minor groove and lacks sequence specificity, although it is sensitive to groove width, cleaving preferentially where the minor groove is widened. A similar type of reagent, Mn-porphyrin, has the opposite conformational selectivity, cleaving DNA where the minor groove is narrow.

Footprinting Proteins

Protein footprinting is a methodology to gain information about protein conformation and interactions by probing the structure of polypeptide chain that is labeled at one end. The protein of interest is end-labeled and reacted with a probe in such a way that susceptibility of a site on the protein to the probe leads to breakage of the polypeptide backbone nearby. The sites of backbone scission are deduced from the lengths of peptides containing the end label, which can be estimated readily by SDS-PAGE. Alteration of the backbone cleavage pattern indicates that the end-labeled protein has undergone a conformational change and/or interaction with other macromolecules. The principle is the same as that for **footprinting nucleic acids**, which has been used widely. Protein footprinting has only recently become feasible with the advent of techniques to end-label proteins.

Information on scission sites or modification sites can be obtained by peptide mapping as well, but footprinting has three advantages:

1. *Facility* Peptide mapping requires purification of individual cleavage products and amino acid analysis and/or the *N*-terminal sequence of each (see Protein Sequencing). Footprinting determines the lengths of many peptides, and hence many cleavage sites, in a single operation without isolating individual fragments.
2. *Sensitivity* Determination of the *N*-terminal amino acid sequence of a peptide typically requires 10 pmol of peptide. Footprinting is generally more sensitive; for instance, **radiolabeling** has virtually no detection limit.
3. *Selectivity* In large multisubunit complexes, peptide mapping will be complicated by the plethora of peptides to be purified and analyzed. In footprinting, information is obtained only on the polypeptide chain that was end-labeled.

1. Methods to End-Label Proteins

Currently there are three ways to end-label proteins:

1. Chemical modification of the N-terminus (1, 2). The protein is first subjected to one round of Edman Degradation. All amino groups become phenylthiocarbamylated, except for the one at the very *N*-terminus, which was originally the imino group of the second amino acid residue before the Edman reaction. This unique amino group can be reacted with either a radioactive or a **fluorescent** reagent, resulting in labeling of the *N*-terminus. This method inevitably destroys the folded structure of the labeled protein prior to probing, and information can be obtained only at the level of the primary structure.
2. Specific antibody binding to either terminus (3, 4). In this method, an antibody raised against a peptide comprising the amino acid sequence of either terminus is used to detect peptides containing the terminus. A more convenient alternative is to place an epitope, against which an antibody is already available, at one end of a protein and to express the epitope-tagged protein through recombinant DNA techniques (see Protein Engineering).
3. Phosphorylation at either terminus (5, 6). This is based on the sequence specificity of protein **kinases**, such as heart muscle kinase, which is less stringent than antigen-antibody recognition. An amino acid sequence that can be phosphorylated by a kinase is attached to a protein at the gene level. The site is labeled using the kinase with [g-^{32}P] or [g-^{35}S] ATP.

2. Methods to Probe Protein Structure

As is apparent from the principle of nucleic acid footprinting, structure probing has to result in scission of the polypeptide backbone, either directly or indirectly. There are common advantages and disadvantages for each type of method. In direct probing methods, probing immediately leads to backbone scission. An advantage of direct methods is their simplicity in comparison with indirect ones, which involve additional reactions. One major drawback is that scission of the peptide backbone often renders the fragments generated more susceptible to ensuing scissions, particularly when the scission has occurred within a folded structural unit. This causes a problem, especially in quantitative analyses, when the first cleavage sites have to be identified. In indirect methods, chemical modification of a side chain is followed by scission of an adjacent peptide bond (or prevention thereof) after one or more subsequent steps. Because modification of a solvent-accessible side chain in one entire protein molecule is unlikely to perturb the folded structure extensively, or to enhance the reactivity of other residues of the same molecule, indirect methods should not suffer from the problems that direct methods do.

Hitherto, five probing methods, two direct and the other three indirect, have been devised and employed:

1. One direct method is **proteolysis** (4-6). Endoproteinases have been extensively used to delineate the **domain** structures of proteins, because well-folded structural units are more resistant to proteolysis than regions linking them. Interaction with other macromolecules may block some cleavage sites. In addition, conformational changes are often reflected in changes in susceptibility of sites cleavable by proteinases. Although proteolysis has been useful, the biophysical basis of the interaction between the probing proteinase and the probed protein molecule is not entirely understood.
2. The other direct method uses oxygen radical, typically generated by the Fenton reaction, to cleave the backbone (7). It is likely that the reactivity of the oxygen radical with the peptide backbone is more directly related to solvent accessibility than is that of proteinases. The extent of side-chain damage by the oxygen radical per backbone breakage is not known.
3. One indirect method utilizes a combination of reversible and irreversible modifications of lysine residues (8). The protein is first subjected to limited citraconylation (see Anhydrides). Removal of the citraconyl groups after irreversible **acetylation** of the remaining lysines recovers unmodified lysyl residues only at the sites where the first modification was introduced. Complete digestion of these polypeptide chains by a lysine-specific endoproteinase generates fragments that end at a first modification site.
4. A second indirect method utilizes oxidation of methionine residues, which blocks cleavage at such residues by **cyanogen bromide** (9). Oxidation of individual methionines is observed as a decrease in the amount of peptide fragments generated by cyanogen bromide. In such cases where modification prevents cleavage, the extent of cleavage must be carefully controlled to ensure that all observable peptides will not be reduced to the shortest peptide containing the end label.
5. The last method utilizes cyanylation of cysteine residues by 2-nitro-5-thiocyanobenzoic acid (10). Raising the pH induces slow cleavage of the peptide bond at the S-cyanocysteine, thus turning the modified side chain into a cleaver. Because the cyano group can transfer to a free sulfhydral, ie, an unmodified cysteine within the same peptide, during the slow cleavage, unreacted cysteine residues have to be blocked beforehand, eg, with N-ethylmaleimide.

The latter three methods were devised on the basis of side-chain modification schemes developed in the 1960s and 1970s (see Chemical Modification). More of them may be revived to create new footprinting methods.

3. Variations and Future Prospects

Various tagging technologies have been used widely in molecular and cellular biology. This indicates that use of a label is not limited to detection of peptides. For instance, some end labels can also serve to isolate terminal fragments. DNA-binding sites of a protein were delimited by immunoprecipitating peptide fragments with a terminal epitope tag, following transfer of radioactivity from DNA and partial proteolysis of the radiolabeled protein (11). Although SDS-PAGE has a fairly good resolution, other methods of determining molecular weights of proteins, such as mass spectrometry, can also be employed after peptides are separated with the use of a tag. In another example of use of a tag other than labeling, a protein kinase site was used to identify protein–protein interactions that blocked phosphorylation of the site (12).

A complex of iron and EDTA, Fe-EDTA, that generates oxygen radical can be crosslinked to specific sites on macromolecules (13). This attachment of a cleavage center onto a macromolecule rather than remaining free in solution allows mapping in the vicinity of the cleavage center (13), when combined with end labeling of its interaction partner, be it a protein molecule or a DNA molecule.

Because the principle of footprinting is the same for proteins and for nucleic acids, much parallel can be drawn from the longer experience of nucleic acids footprinting. The interference experiment scheme (14), in which macromolecules are first subjected to modification and later separated according to their remaining functionality, has yet to be applied to proteins.

Founder Cell

Founder cell is a term that has been used to describe an aspect in the initiation of aggregation in slime molds, especially Dictyostelium. These organisms are normally single cells, but when environmental conditions become unfavorable, they aggregate to form a composite. One cell in a population, the founder cell, will begin signaling to the others by secreting pulses of a chemoattractant. *Dictyostelium discoideum* uses the normally intracellular second-messenger molecule cyclic AMP (cAMP) as its chemoattractant. Other species use a variety of chemoattractants, such as pterin derivatives and small peptides. Cells in the immediate area of the founding cell respond in two ways. They first migrate toward the chemoattractant source, and then they secrete additional cAMP signal. An extracellular **phosphodiesterase** degrades the cAMP between the waves. The resulting temporal and spatial waves of the chemoattractant flow through the environment. As the cells respond, they move together, then pause and move again, until almost all the cells in an area are in a central aggregate. The timing of the pulses and the rate of motility, combined with the enzymatic rates of signal degradation and secretion, determine the size and shape of the aggregate (1).

Exactly what causes a single cell in a population of apparent equals to become a founder cell is unknown, but it must be tightly regulated for the aggregates to end up with an optimum number of cells. Allowing cells to divide to increase the size of the aggregate is not an option, because cell-cycle arrest occurs very early in the developmental program. Once a cell adjacent to a founder responds, that cell cannot itself become a founder. There are some data that suggest that the differentiation events that occur in the founder cell do so before neighboring cells become competent for chemotaxis. Perhaps a diffusible factor secreted from the founder is involved in that process (2).

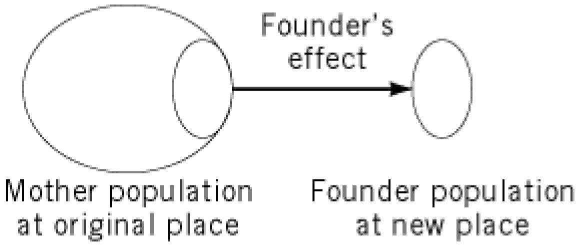
Founder Effect

When a small number of individuals from an original population immigrate to a certain place, the new population founded by those people might have much less genetic diversity compared with those of the original population (Fig. 1). This is generally the case, because a few founder people cannot have sufficient genetic variation to reflect that of the mother population. Such a drastic decrease of genetic diversity within a population is known as the founder effect. This effect most often occurs when a segment of a larger population becomes isolated as the result of colonization of a geographically isolated area, a catastrophic event, artificial isolation, and so on. These founding populations contain only a fraction of the genetic diversity of the population from which they originated.

Figure 1. Founder effect.



When founders are individuals sampled randomly from the mother population, the founder effect has the same influence as genetic drift, which is the stochastic change of gene frequencies due to random mating. The effect of genetic drift becomes stronger when the population size is smaller (1);

therefore, the founder effect is similar to the effect of genetic drift when the size of the initial population in a given geographical area suddenly becomes extremely small. In particular, the drastic reduction in size of a population has the same effect, which is now called the "bottleneck effect" (Figs. 2 and 3). Strictly speaking, the founder effect can be considered to be a particular form of the bottleneck effect. The difference between the founder effect and the bottleneck effect is that the former occurs in a different place, whereas the latter takes place in the same location.

Figure 2. Bottleneck effect due to a transient decrease in the population size.

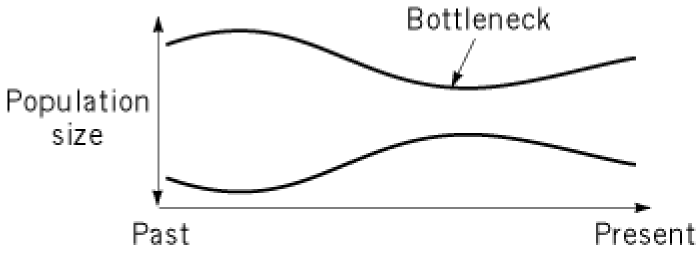


Figure 3. Decrease in the heterozygosity of individuals of a population resulting from the bottleneck effect. The bottleneck size is given by N_0. The intrinsic growth rate is given by *r*. Following the bottleneck, it is assumed that the population grows uniformly (2).

Four-Helix Bundle Motif

The four-helix bundle is a common protein motif that is observed in protein structures, in which four **a-helices** pack together lengthwise, in an antiparallel manner (Fig. 1). The four a-helices that form the bundle can derive from four independent polypeptide chains or from a single polypeptide chain. This structural motif has been observed both as an isolated three-dimensional fold and as a **domain** within much larger and more complex protein structures. The helices of four-helix bundles are longer than average (~20 residues, as opposed to the usual 10) and are amphipathic, with **hydrophobic** residues buried in the core. The antiparallel packing of the helices in the bundle may be favored by interaction between the helix dipoles.

Figure 1. Schematic representation of the backbone of a four-helix bundle protein, taken from the structure of bullfrog ferritin (1). This structure has the up–down–down–up topology; the two "up" helices are shown as purple coils and the two "down" helices are shown as green coils. Note the long connecting loop between the second and third helix. Connecting loops and an additional *C*-terminal helix are shown in yellow. The *N*- and *C*-termini are labeled. This figure was generated using Molscript (2) and Raster3D (3, 4). See color insert.

The four-helix bundle is one of the simplest protein folds and is used by a wide range of proteins with diverse functions. Proteins with a four-helix bundle structure include growth hormones, **cytokines**, and ferritins. The four helices may splay apart to generate a binding pocket for **cofactors** and metal ions, or they may coil around each other to form a supercoil. In the latter case, the twist of the helices in the coiled coils alters the usual helical structure so that there are 3.5 residues per turn, rather than 3.6. This means that every seventh residue in the helix is identically placed with respect to the axis of the helix. The seven positions of this heptad repeat are denoted *a* to *g*, and residues *a* and *d* point into the core of the bundle and are usually hydrophobic.

Several classes of four-helix bundle motif have been defined. These include (a) the simple up–down–up–down topology, where consecutive helices have short connections and alternating directions, (b) the up-down-down-up topology, where there is a long loop or crossover connection between helices 2 and 3, and (c) the up–up–down–down topology that is typical of the cytokine four-helix bundles, with two long crossover connections between helices 1 and 2 and helices 3 and 4. In most cases, the helices are aligned so that each pairwise interaction is antiparallel. There are also sub-classes within each of these classifications. The simplicity of the four-helix bundle motif has made it a common target for protein design.

Frameshift Mutation

A frameshift mutation is a type of mutation that results from the addition or deletion of ($3n \pm 1$) **nucleotides** (where n is an integer). The addition or deletion of nucleotides that are not multiples of three disrupts the triplet reading frame of the gene (see Genetic Code). Technically defined, a frameshift mutation is within the coding portion of the gene, but the term is commonly used for any insertion or deletion of a few bases. Frameshift mutations were first described by Crick *et al.* (1) who used them to decipher the triplet nature of the genetic code. Although point mutations only alter one (or no) amino acids (see Missense Mutation), frameshifts alter nearly all of the amino acids downstream of the mutation until a **nonsense codon** is encountered during translation and the polypeptide chain is terminated. Frameshift mutations are induced by a wide variety of intercalating agents, such as ethidium bromide.

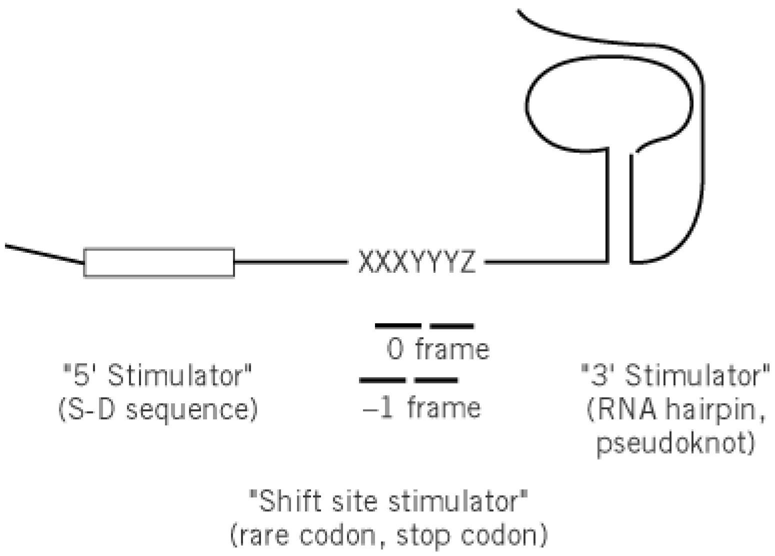
Frameshifting

Frameshifting is a change in reading frame during **gene** expression. Transcription errors, or a posttranscriptional process such as RNA Editing, can cause frameshifting. For example, a fraction of the b- amyloid precursor protein and ubiquitin B messenger RNAs in the lesions of Alzheimer's disease are subject to transcriptional frameshifting (1). Most of the frameshifting cases, however, occur during translation (2).

The reading frame is accurately maintained during translation. The average occurrence of frameshift errors is estimated to be 5×10^{-5} per codon or lower. Aminoacyl tRNA imbalance, due to amino acid starvation or mutations in translation factors or aminoacyl-tRNA synthetases, elevates the error rate. A class of suppressor tRNAs increases frameshifting at particular codons (3). In these cases, the effects are nonspecific. On the other hand, a minority of mRNAs have specific sites for frameshifting that is essential to synthesize the correct gene product. Such natural frameshifting is genetically programmed by specific signals on the mRNAs and, in some cases, is highly efficient (up to 50%). Almost all the known programmed frameshifting is either +1 (reading frame shifts to the 5′ direction by one nucleotide) or –1 frameshifting (to the 3′ direction by one nucleotide). An extreme exception is bypassing of 50 nucleotides within the coding region of **T4 phage** gene 60. The most crucial signal is the sequence of the frameshift site itself. Frameshift sites are often accompanied by a cis-acting sequence element (or stimulator) located either 3′ or 5′ to the frameshift site. Stem-loop or pseudoknot structures of RNA and the **Shine–Dalgarno** sequence are known to function as 3′ and 5′ stimulators, respectively (Fig. 1). In some cases, a frameshift site itself contains a rare codon or a stop codon as a shift-site stimulator. The basic function of these stimulators is to pause the elongating ribosome to trigger frameshifting. Natural frameshifting stands as a class of reprogrammed genetic decoding (or recoding).

Figure 1. –1 frameshift site motif and stimulators.



Most frameshifting has been found in *virus* genomes and mobile genetic elements. The former includes several retroviruses such as human immunodeficiency virus 1 (**HIV**-1) and plant RNA viruses, as well as bacteriophages such as MS2, **T7**, and **l**, while the latter includes yeast retrotransposons Ty1 and Ty3, and bacterial **insertion sequences** (Table 1). In many cases, frameshifting is required for the expression of polymerases (including **reverse transcriptase** and RNA-dependent RNA polymerase). Some retroviruses, such as human T-cell leukemia virus 1 (HTLV-1) or mouse mammary tumor virus (MMTV), require two frameshifting events to access the reverse transcriptase reading frame. Retroviral frameshifting appears to be a mechanism to keep the synthesis rate of the functional proteins small relative to that of the structural proteins. Although the efficiencies of these frameshifting events are different from one case to another, proper efficiencies are important for optimal viral propagation or transposition in the cases investigated. In viruses and mobile elements, –1 frameshifting is predominant, whereas some viruses and the yeast retrotransposons have +1 frameshift sites.

Table 1. Natural Frameshifting in Wild-Type Genes (2)

Designation	Sign	Double Shift	Stimulator and Features
Mammalian antizyme	+1	No	3′ pseudoknot; regulated by pathway product, polyamines (autoregulation)
Retrovirus *gag-pol*			
RSV	–1	Yes	3′ pseudoknot
HTLV-1	–1	Yes	3′ stem loop
HIV-1	–1	Yes	3′ stem loop
Coronavirus IBV	–1	Yes	3′ pseudoknot
Yeast retrotransposon Ty1	+1	No	Shift site rare arginine codon
Yeast virus L-A	–1	Yes	3′ pseudoknot
Bacterial genes			
RF-2	+1	No	5′ Shine–Dalgarno sequence; autoregulation
dnaX	–1	Yes	5′ Shine–Dalgarno sequence; 2 DNA polymerase subunits
IS insertion elements	–1	Yes	3′ stem loop or pseudoknot
Phage T7 gene *60*	+50	No	Matched take off and landing sites; 5′ polypeptide, 3′ stem loop, and stop codon

There are only a few instances of frameshifting in bona fide cellular genes. In bacteria, two chromosomal genes, *prfB* encoding release factor 2 (RF-2; see Release Factor) and *Escherichia coli dnaX* encoding the g subunit of **DNA polymerase** III, are expressed by frameshifting. The reading frame of RF-2 switches to the +1 frame, while DnaX shifts to the –1 frame. In higher eukaryotes, there is only one cellular gene known thus far to have frameshifting, the gene for antizyme that is a regulatory protein of the cellular polyamines. Both isoforms of antizyme (AZ1 and AZ2) are expressed by +1 frameshifting that is stimulated by polyamines. RF-2 and antizyme frameshifting is involved in the specific autoregulation (4, 5).

A majority of –1 frameshift sites are characteristic heptamers with a **consensus sequence** of X XXW WWY (presented as a preshift reading frame; X and Y are one of any nucleotides and W is either A or U). In addition, most of these –1 shift sites are accompanied by either pseudoknot or stem-loop structures 3′ to the frameshift site. A simultaneous shift model has been proposed for the shift mechanism, in which the ribosome and the two tRNAs in the P and A sites slip back on the mRNA by one nucleotide, forming new base paring between the tRNAs and the mRNA. Downstream RNA structures stimulate the process by, at least in part, causing ribosomal pausing at the frameshift site (Fig. 1).

Analyses of +1 frameshifting have revealed that their mechanisms are not as uniform as –1 frameshifting. The codon 3′ adjacent to the frameshift site is either a termination codon or a "hungry" codon [a codon decoded by low-abundant tRNA and thus having low efficiency (6)]. In at least two cases, tRNA slipping and pairing at the new position are not necessary.

Frameshifting can be hinted from open reading frame analysis of complementary DNA sequences or by a disagreement between the sequences of cDNA and its protein product. It is, however, sometimes difficult to prove before knowing the amino acid sequence of the protein. Frameshifting can be induced by expression of exotopic genes or artificial sequences. It is noteworthy that translational frameshifting, even with a low efficiency, can partially rescue frameshift mutations and modifies the phenotype in both experimental and naturally occurring systems, demonstrating the biological importance of frameshifting.

Free Energy Calculations

1. Statistical Mechanical Averaging

With a given set of potential functions, one can evaluate various average properties of the system by **computer simulation**. In particular, it is useful to simulate experimentally observed macroscopic properties using microscopic models. This can be done using the theory of statistical mechanic, which tells us that the average of a given property, *A* (which is independent of the momentum of the system), is given by

(1)

$$\langle \mathbf{A} \rangle = \int \mathbf{A}(r)P(\mathbf{r})d\mathbf{r} = \int \mathbf{A}(\mathbf{r}) \exp\{-U(\mathbf{r})\beta\} d\mathbf{r}/z(U)$$

$$= \int \exp\{-U(\mathbf{r})\beta\} d\mathbf{r}$$

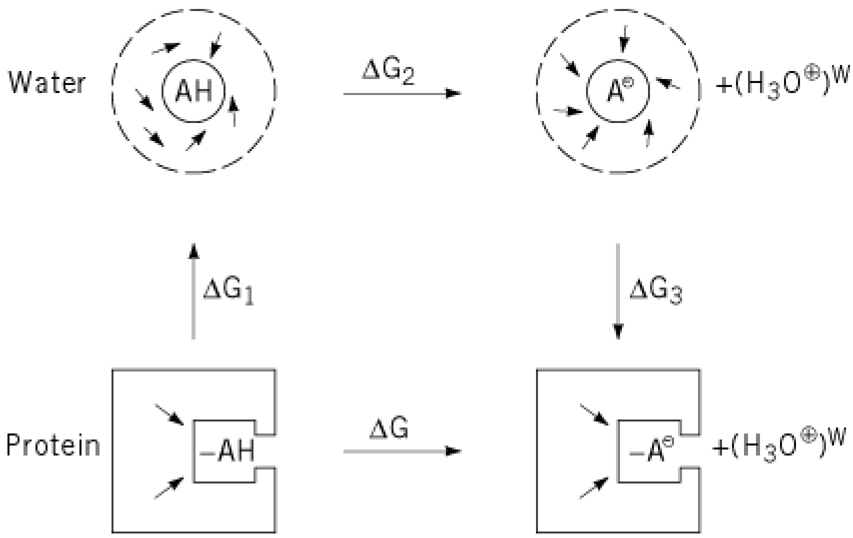
where b = $(1/k_B T)$ (k_B is the Boltzmann constant and T is the absolute temperature), and $d\mathbf{r}$ designates the volume element of the complete space spanned by the $3n$ vector **r** associated with the n atoms of the system (1). The evaluation of equation (1) requires us to explore all points in the entire conformation space of the given system. Such a study of a solvated macromolecule is clearly impossible with any of the available computers. However, one can hope that the average over a limited number of configurations will give similar results to those obtained from an average over the entire space. With this working hypothesis, we can try to look for an efficient way of spanning phase space. Present-day computers can be used to span a significant number of conformations by **Monte Carlo** (MC) **calculations** or by molecular dynamics (MD) methods.

Calculations of average properties may converge extremely slowly. This is the case, for example, for thermodynamic properties such as **enthalpy** and **entropy**. Fortunately, **free energies** converge faster than enthalpies or entropies, due to entropy-enthalpy compensation. This is quite useful because most biological processes depend on the relevant free energies and not on their individual components. We describe below the general methods for using simulations to obtain free energies.

2. Thermodynamic Cycles

Many biochemical processes can be described by *thermodynamic cycles* of the same type as used in chemistry (eg, the Born–Haber cycle (2, 3)). For example, the energetics associated with the deprotonation of an ionizable group in a protein can be described by the cycle as shown in Figure 1 (4). Using such a cycle allows one to replace calculation of the physical process of moving the proton from the protein to water by the much simpler comparative calculation of "mutating" the given acid from its unionized form in the protein and in water. The use of thermodynamic cycles in microscopic calculations of free energies of biological processes has been introduced in the early 1980s (4, 5), and it is now a major part of many approaches of free energy calculations of biological processes.

Figure 1. The thermodynamic cycle used to estimate the energetics of dissociation of an acidic group of a protein. The DG_i are given by $\Delta G_1 = G^w_{sol}(\mathrm{AH}) - G^p_{sol}(\mathrm{AH}), \Delta G_2 = 2.3RT(\mathrm{p}K^w_a - \mathrm{pH})$, and $\Delta G_3 = G^p_{sol}(A^-) - G^w_{sol}(A^-)$, where p and w designate protein and water, respectively.



3. Free Energy Perturbation and Related Approaches

Evaluation of free energies by statistical mechanical approaches is extremely time-consuming, due to the need to sample all the relevant configurational space. Fortunately, it is possible in some cases to obtain meaningful results using perturbation approaches. Such approaches exploit the fact that many important properties depend on local changes in the macromolecules so that the effect of the overall macromolecular potential cancels out. Such calculations are usually done by the so-called **free-energy perturbation** (FEP) **method** (6, 7) [also related to the umbrella sampling method (7)]. This method evaluates the free energy associated with the change of the potential surface from U_1 to U_2 by gradually changing the potential surface using the relationship

$$U_m(\lambda_m) = U_1(1 - \lambda_m) + U_2\lambda_m \qquad (2)$$

The free-energy increment $\delta G(1 - \lambda_m \rightarrow \lambda'_m)$associated with the change of U_m to $U_{m'}$ can be obtained (7) by

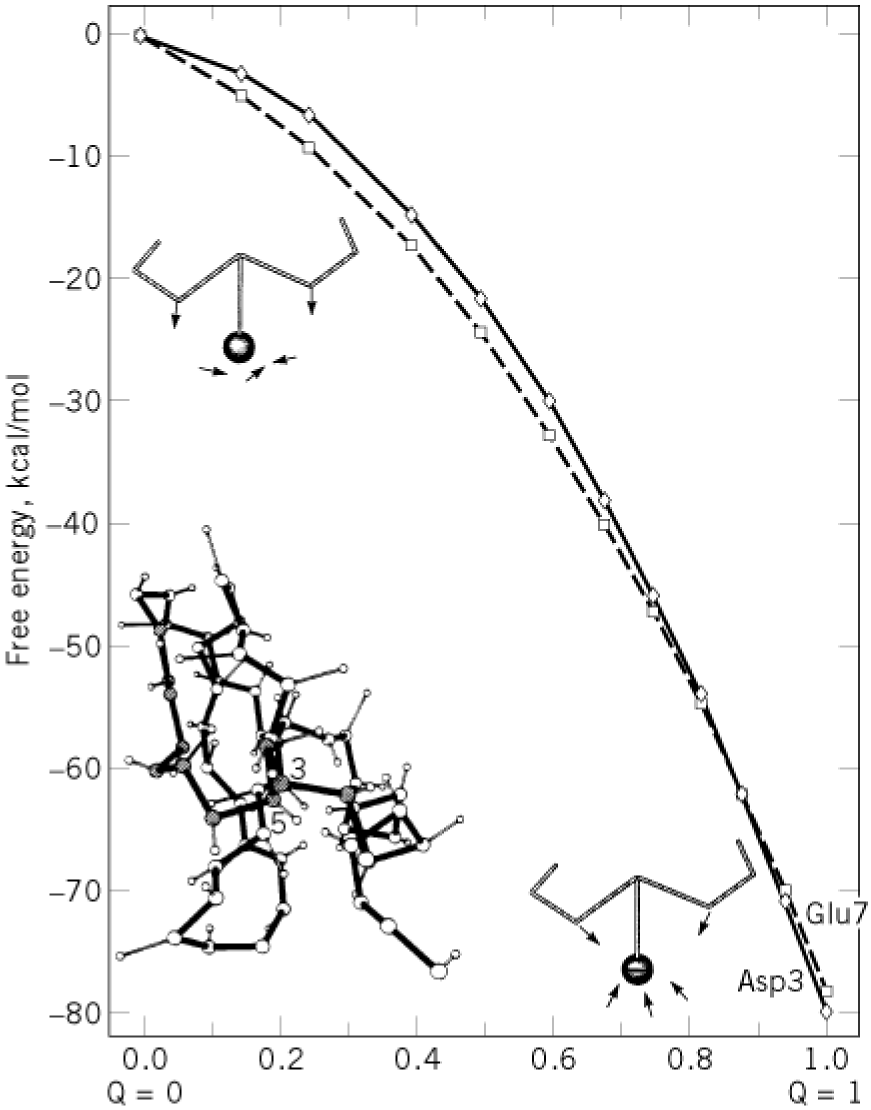
$$\exp\{-\delta G(\lambda_m \rightarrow \lambda_{m'})\beta\} = \langle \exp\{-(U_{m'} - U_m)\}\beta\rangle_m \qquad (3)$$

where $\langle\ \rangle_m$ indicates that the given average is evaluated by propagating trajectories over U_m. The overall free energy change is now obtained by changing the 1_m in n equal increments and evaluating the sum of the corresponding dG:

$$\Delta G(U_1 \rightarrow U_2) = \sum_{m=0}^{n-1} \delta G(\lambda_m \rightarrow \lambda_{m-1}) \qquad (4)$$

An example of the use of Eq. (4) in calculating free energy of a biological system is given in Figure 2, which considers the solvation free energy of ionizable residues in BPTI.

Figure 2. Calculations of the free energy of charging Asp 3 and Glu 7 in BPTI. The figure describes the calculated "solvation" free energy obtained with the use of equation (4) as a function of the charge of the corresponding acid.



The FEP approach has been used extensively in studies of free energies of biological systems (eg, Refs. 8 and 9) and more details are given in **Computer simulation**. It must be emphasized here that the convergence of FEP approaches is quite slow and that obtaining meaningful results requires proper treatment of long-range effects.

Many times it is very useful to estimate the free energy of biological processes by the so-called *linear response approximation* (LRA) (10). This approximation assumes that the protein and solvent environment respond linearly to the forces associated with the given process. This leads (11) to the equation

$$\Delta G_{a\to b} = \frac{1}{2}(\langle U_b - U_a\rangle_a + \langle U_b - U_a\rangle_b) \tag{5}$$

Such an approximation is, for example, the basis of macroscopic electrostatic theory, where the free energy of charging a positive ion, with a charge $Q = 1$, is given by the well-known result $\Delta G = \frac{1}{2}U(Q=1)$. Although it is hard to accept that the LRA provides a reliable way of describing the energetics of macromolecules or of realistic molecular systems, it was found by simulation studies that this is a reasonable approximation in particular for processes that depend on electrostatic effects (12-14).

Free Energy Relationships

Understanding any chemical reaction requires knowledge about the transition state for the reaction, because the free energy of the transition state determines the rate at which the reaction occurs (see Kinetics). The transition state cannot be observed directly, but its properties can be inferred from the effects of changes in various parameters on its free energy, the rate of the reaction. One method of doing so is to study the chemical reaction in a series of closely related reactants and to correlate the variation in the rates of reaction with the physical parameters of the reactants. Such observations are referred to as free energy relationships.

In hydrolytic reactions, the reacting groups are generally classified as nucleophiles or electrophiles. Nucleophiles donate an electron pair, and are generally bases, whereas electrophiles have opposite properties and generally are acids. Protonation converts a nucleophile to an electrophile. For example, an $–NH^2$ group is a nucleophile, whereas its protonated $NH^+{}_3$ form is an electrophile. The strengths of their nucleophilicity and electrophilicity can be indicated by their respective tendencies to acquire or donate protons and can be measured by the pK_a value (see Buffers). The reaction of a nucleophile with a proton is similar to the reaction of the nucleophile with any other group, so that a relationship would be expected between the pK_a of a nucleophile and its reactivity in a chemical reaction. The pK_a is a measure of the relative free energy of the nucleophile, whereas the logarithm of the rate constant for a reaction is a measure of the free energy of the transition state for the reaction. Such relationships are generally evident from plots of the logarithm of the rate constant k, for a chemical reaction, versus the pK_a values of a series of related nucleophiles, known as Brønsted plots. Such plots can be made for a series of nucleophiles attacking a particular ester or amide bond, for example, or for one nucleophile attacking a series of molecules that have leaving groups with different pK_a values. Linear correlations are found frequently for a given chemical reaction and a series of related reactants, so long as the reactants are sufficiently related and no special factors, such as steric hindrance, affect their rate of reaction. The general form of the linear relationship is expressed as

$$\log k = \beta \mathrm{p}K_a + \text{constant} \quad (1)$$

When the reactant is an electrophile, the equation is the same, except that the parameter b is changed to a. The values of a are generally negative, whereas those of b are generally positive.

The slope of a linear Brønsted plot, the value of a or b, provides important information about the transition state of the reaction. Their sign and magnitude are generally interpreted as an indication of the amount of charge developed in the transition state and whether the transition state is closer to the reactants or the products in its physical properties. The values of a and b should be between 0 and 1, because complete transfer of a proton in the transition state gives a value of 1.0 and no transfer gives a value of 0. For ester hydrolysis, the values are usually 0.3 to 0.6. For example, the attack of tertiary amines on esters with poor leaving groups (e.g., alkoxides) gives values of +1.5 for the series of attacking nucleophiles and –1.5 for variation in the alcohol leaving group (1). These very large values indicate that the transition state for this reaction is close to the products. In contrast, the reaction of very basic nucleophiles with activated esters (e.g., phenolates) has relatively small values, +0.1 to 0.2 for variation of the nucleophile and –0.1 to –0.2 for variation of the leaving groups; this indicates that the transition state in this case is closer to the ester substrate.

Although free energy relationships were developed with reactions between small molecules, they are also useful in molecular biology in phenomena as diverse as **protein folding** (2).

Freeze Fracture

Freeze fracture is a preparative procedure for visualizing the distribution of proteins within the lipid bilayer of membranes by transmission electron microscopy. The membrane samples are rapidly frozen to a very low temperature and then fractured with a knife blade. Fracturing occurs along planes where the intramolecular forces are weakest. In membranes, these planes occur along the center of the phospholipid bilayer, where the apposing fatty acid chains of the monolayer leaflets interact. Freeze fracturing thus exposes the nonpolar interior of the membrane. Integral membrane proteins that cross the bilayer interrupt the fracturing process and are carried along with either monolayer leaflet, leaving pits in the apposed monolayer. The fracture faces are shadowed with metal, and the proteins appear as small particles. The technique may be combined with **immunolabeling** to visualize the location of specific proteins (1).

Freeze etching utilizes freeze-drying of the fractured frozen samples to remove water, thereby exposing the components of the surfaces of the fractured samples; the surfaces are then shadowed for viewing in the electron microscope.

Frictional Coefficient, Ratio

The translational frictional coefficient, *f*, is a measure of the resistance to movement of a molecule; this resistance is a function of both the size and the shape of the molecule. It can be measured experimentally either by its rate of diffusion or its rate of sedimentation.

As would be expected, the translational frictional coefficient is inversely proportional to the diffusion coefficient, $D°_{20,w}$, under standard conditions of water at 20.0°C and extrapolated to zero concentration:

$$f = \frac{RT}{N_A D^\circ_{20,w}} = \frac{k_B T}{D^\circ_{20,w}} \tag{1}$$

where R is the gas constant (8.314×10^7 erg mol^{-1}K^{-1}) and N_A is Avogadro's number (6.022×10^{23} mol^{-1}).

Likewise, the frictional coefficient is inversely proportional to the sedimentation coefficient, $s°_{20,\,w}$ under the same standard conditions:

$$f = \frac{M_r(1 - \bar{v}\rho_{20w})}{N_A s^\circ_{20,w}} \tag{2}$$

where v is the partial specific volume of the macromolecule and $r_{20,w}$ is the density of the standard solvent, water at 20°C.

It is usually more informative to use the **frictional ratio**, f/f_0, which is the dimensionless ratio of the observed translational frictional coefficient to that of an equivalent spherical molecule of the same anhydrous mass and density. This corrects for the size of the molecule and gives an indication of its shape. The greater the frictional ratio, the more asymmetric it is likely to be. The frictional ratio can be calculated from the diffusion coefficient by the following equation:

$$\frac{f}{f_0} = \frac{k_B T}{6\pi\eta_{20,w}} \cdot \left(\frac{4\pi N_A}{3\bar{v}M}\right)^{1/3} \frac{1}{D^{\circ}_{20,w}} \tag{3}$$

The frictional ratio depends intrinsically on the conformation, flexibility, and degree of solvation (by water, salt ions, and any other solvent molecules) of the macromolecule. This degree of water association is termed the hydration of the macromolecule, d, and is defined as the mass in grams of associated solvent per gram of anhydrous biomolecule. This associated solvent includes both chemically bound solvent and also solvent physically entrained in the interstices in the molecule. The value of d is typically between 0.2 and 0.5 g/g for proteins, although it is a notoriously difficult parameter to pin down with any accuracy.

The function defining the shape and flexibility of the biomolecule is the *Perrin translational frictional function*, *P*:

$$P = \frac{f}{f_0} \cdot \left(\frac{\bar{v}}{\bar{v} + \delta/\rho_0}\right)^{1/3} \tag{4}$$

where r_0 is the density (in grams per milliliter) of the bound solvent. For a molecule that is fairly rigid on a time-averaged basis, the gross conformation can be specified using *P* in terms of the axial ratio of the equivalent hydrodynamic ellipsoid or in terms of sophisticated arrangements of spheres called *hydrodynamic bead models* (see Diffusion).

Fungi, Filamentous

The fungi represent one of the most diverse groups of organisms encountered in the natural world; approximately 70,000 different species have been described although estimates as high as 1.5 million fungal species are likely to exist. Even though a large fraction of fungi are believed to be unculturable, their importance to the natural environment of the planet cannot be underestimated. Thus, a clear understanding of their physiology at a molecular level seems prudent if not essential. The past 10 years have seen an explosion of information in this field, due primarily to the ability to transform a wide variety of these previously intractable organisms. Yet, even with the exponential advances in recombinant techniques (especially sequencing technologies) gained over the past several years, filamentous fungi appear to be the forgotten model system; perhaps it is because the completion of the first eukaryotic genome, *Saccharomyces cerevisiae*, was a fungus, albeit a yeast, or perhaps it is because of the success of the human genome project that the perception is that we need not look at additional fungi as model organisms. However, while *Saccharomyces* provides an excellent framework for studying eukaryotic systems, it clearly lacks some critical parameters that filamentous fungi can elucidate, in particular, multicellular differentiation and pathogenicity. In addition, it should be kept in mind that a large percentage of the expressed sequence tags (ESTs) identified from filamentous fungi do not have detectable homology to sequences already present in any of the available databases, including the *Saccharomcyes* genome). Therefore, the filamentous fungi as a group provide a complex and somewhat unique perspective of the microbial world that should not be overlooked.

Two of the most well known filamentous fungi, *Aspergillus nidulans* and *Neurospora crassa*, are exceptional model organisms. They have a long genetic history and are continuing to be pursued as excellent subjects in which to study development, gene regulation, circadian rhythms, and genome structure. As the functions and interactions of proteins and intracellular molecules is elucidated from a variety of organisms, including the fungi, humans appear to have more in common with their distant eukaryotic ancestors than previously thought. It is important to keep in mind that the filamentous fungi are part of the group of organisms that include the yeasts, *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*, two of the best understood eukaryotic organisms from a genetic and molecular standpoint. In general, the molecular biology of the entire kingdom may be viewed as more similar than dissimilar; not only are there are two-component signal transduction systems, transcriptional inducers and repressors, but the conservation of protein sequence is remarkable in many areas. Wherever commonalities have been searched for they have been found, with a few exceptions that may yet prove to be due to insufficient data.

1. Why Study Fungi?

Fungi are a biochemically diverse set of organisms, producing a wide variety of acids and degradative enzymes that support their absorptive lifestyle and play an essential role in the degradative processes of our entire ecosystem. They decompose numerous substrates by secreting a wide variety of very efficient degradative enzymes, thus providing an efficient means to recycle much of the earth's biomass. In addition, their fermentative capabilities provide a means to bake bread and ferment a wide variety of fruits and vegetables. The fungi have also been exploited commercially as efficient producers of enzymes such as glucoamylase, lipase, cellulase, and pectinase. In addition, fungal secondary products have been used in the synthesis of numerous pharmaceuticals, including penicillin, cyclosporin, and mevalonin.

On the other hand, some fungi can have a devastating effect: their uncontrolled growth can irrevocably damage entire forests, crops, or agricultural feed products. Some of the most intensely studied fungi are phytopathogenic; *Magnaporthe grisea* (pathogen of rice), *Ustilago maydis* (corn), *Cryphonectria parasitica* (chestnut blight), etc. Aflatoxin, a single secondary metabolite produced by *Aspergillus flavus*, causes millions of dollar of damage to the corn industry annually. In terms of human disease, medically important species of fungi are increasing in prevalence due to a dramatic rise in the incidence of immunocompromised patients. The most significant human pathogen is *C. albicans*, a dimorphic organism that switches between a yeast-like growth phase not unlike that of its distant cousin, *S. cerevisiae*, to a hyphal growth phase that has been associated with its virulence *in vivo*. Other well-known fungal pathogens include *Aspergillus fumigatus*, *Blastomyces dermatitidis*, *Coccidioides immitis*, *Cryptococcus neoformans*, *Histoplasma capsulatum*, and *Pneumocystis carinii*. Many are associated with high mortality rates. All of these fungi are either filamentous or dimorphic in nature. A wide variety of classical genetic and modern molecular techniques are presently available to analyze these organisms, as well as the lesser well-known, but certainly not less virulent pathogens. What is important to keep in mind is the similarities between the fungi, the “big picture.” Each of the individual organisms’ details can be gleaned from further readings.

2. Physiology and Taxonomy

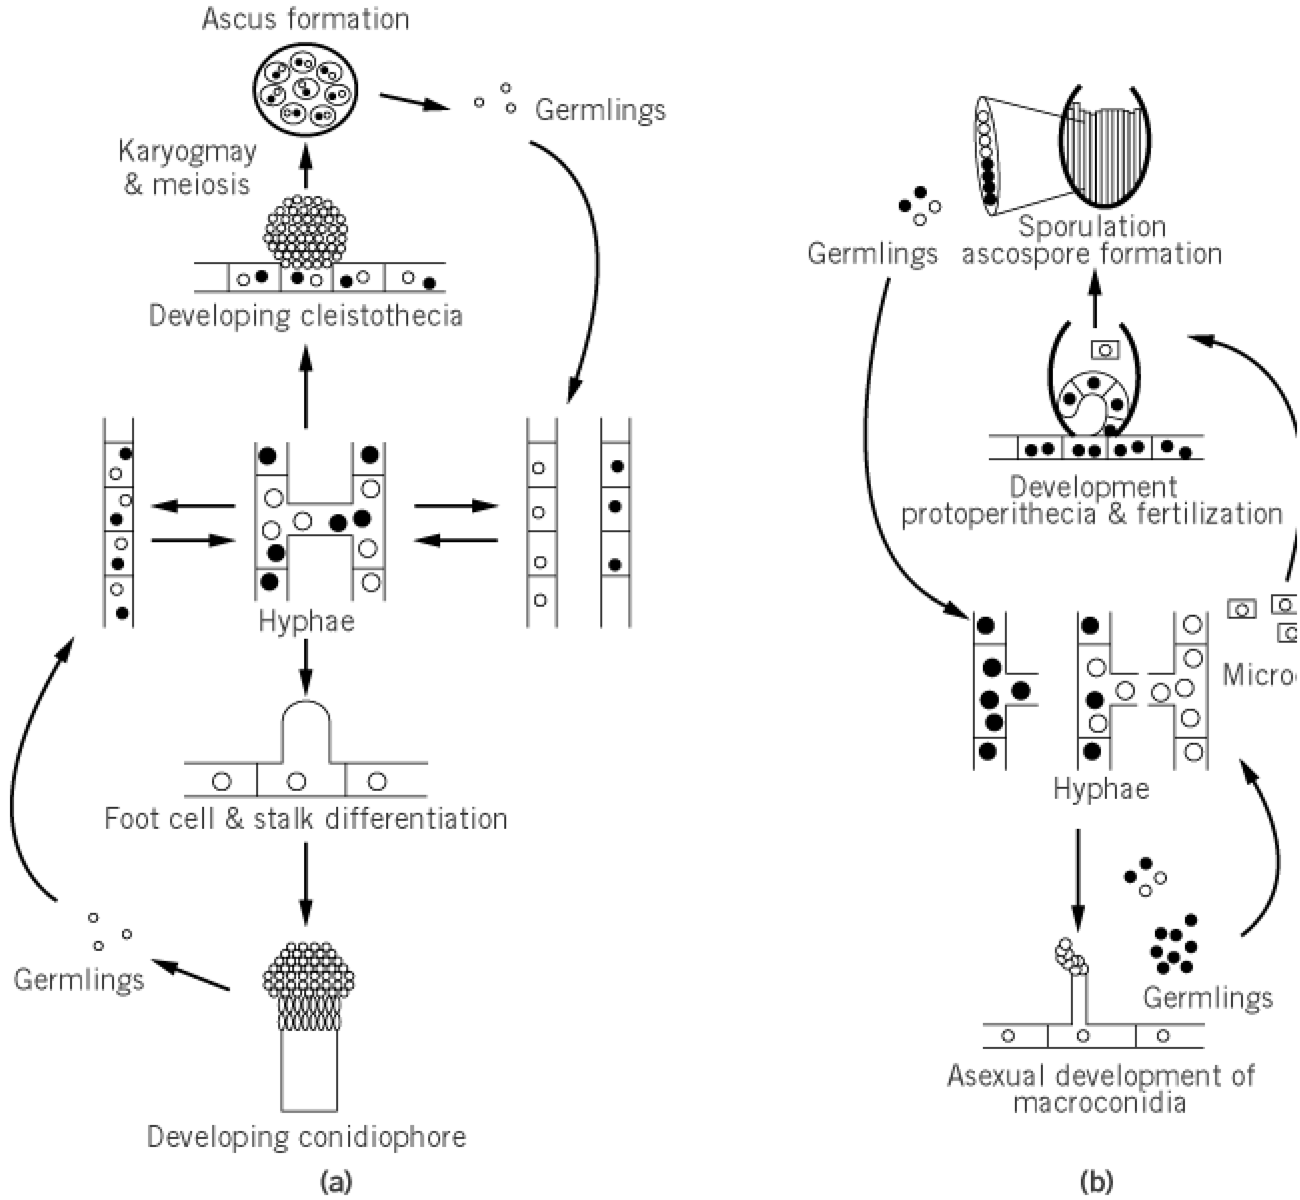
The taxonomy of the fungi is complex, and students interested in further classification or taxonomy of fungi are referred to Ref. 1. Over the past several decades, their special place in the taxonomy of biological organisms has been reclassified from a subdivision within the plant kingdom to part of the eukaryotic world. Within the new scheme [bacteria, archea and eukarya (2)], note that the division between plants and fungi has disappeared. Even with this new assignment, there have been many proposals for their classification based upon nutritional requirements, cytology, or morphogenesis (1, 79). Perhaps the most enlightening description of the taxonomical state of the field is described by Ainsworth, “the question of the number of kinds of fungi can be more usefully approached by first considering some of the main factors which determine their recognition. ¼ Their [fungi] recorded number and distribution is closely correlated with the number and distribution of mycologists. ¼ Some taxonomists are perhaps unduly impressed by small differences ¼ others, are lumpers ¼ recognize far fewer kinds”. By and large the fungi are regarded as having five phyla: oomycetes (water molds), zygomycetes (common molds), ascomycetes (sac fungi), basidiomycetes (club fungi) and deuteromycetes (imperfect fungi having no sexual stage). With the advent of recombinant DNA technology and new DNA sequencing paradigms, it will be possible to re-evaluate the relationships between certain fungi by their sequence **homologies**, rather than by their morphology or nutritional biochemistry. Most of the research has been centered upon a few species of the ascomycetes and basidiomyecetes although *C. albicans*, a member of the fungi imperfecti, has been the source of a great deal of research due to its critical role in medical mycology.

Like most of their taxonomy, fungal life cycles may vary from simple (as in the yeasts) to complex (as in the basidiomycetes). Fungi are typically non-photosynthetic heterotrophic organisms that absorb nutrients from their surrounding environment. As multicellular organisms, they display a wide range of morphological types from the microscopic yeasts and water molds to the multicellular mushrooms. They may exist as a multinucleate undifferentiated mass of cells during all or part of their life cycle, or form complex highly developed reproduction structures. In their vegetative state, fungal cells may be unicellular (yeast-like) or filamentous (mycelial or hyphal-like) in shape. Many are capable of switching between the two forms, which has been the source of a great deal of interest, especially with regard to the regulatory circuits involved and the effect on pathogenicity. All fungi are eukaryotic, but the cell may be uninucleate or multinucleate, haploid, diploid or dikaryotic during part of their life cycle. They typically contain a cell wall, which may explain their original classification within the kingdom of plants; however, the cell wall contains polymers of chitin and glucans rather than the more usual cellulose of plants.

3. Fungal Life Cycles and Reproduction

Fungi display a variety of reproductive choices. They may reproduce either asexually or sexually, or both. The fungal spore is specialized for reproduction, survival and, in some cases, dispersal. Not only are there heterothallic species such as *Neurospora crassa* that require different mating types in order to undergo sexual reproduction, but homothallic species (self-maters) such as *Aspergillus nidulans* and pseudohomothallic species that switch mating types (such as *Saccharomyces cerevisiae*) as well. Further, there is an assortment of fungi that do not appear to undergo sexual reproduction at all (e.g.-fungi imperfecti, including *Candida albicans*). The life cycles of *Aspergillus nidulans* and *Neurospora crassa* (Fig. 1) serve to illustrate many of the salient features found in this highly divergent group of organisms.

Figure 1. Schematic representation of the life cycles of *Aspergillus nidulans* and *Neurospora crassa*. (**a**) *Aspergillus nid* Asexual reproduction involves formation and maturation of conidiophores (described in the text) and uninucleate spores conidia. Vegetative haploids grow as monokaryotic or dikaryotic hyphae. These cells may then undergo sexual reproduc (upper portion of the cycle), initiated with the formation of specialized fruiting body called the cleistothecia. Eight binuc ascospores are formed within an unordered ascus. (**b**) *Neurospora crassa*. Asexual reproduction involves the formation c hyphae and the development of conidiophores, producing millions of multinucleate spores called macroconidia. Vegetati haploids grow as monokaryotic or dikaryotic hyphae. Cells of the opposite mating type are required for sexual reproduct Sporulation is initiated by the formation of the protoperitheicia, which is fertilized by microconidia of the opposite matir (see text). Cellular fusion is followed by a complex developmental pathway that involves synchronous nuclear division, karyogamy, and meiosis to yield hundreds of asci within the perithecium (see text for details).



3.1. Life Cycle of *Neurospora crassa* (3, 4)
N. crassa is a haploid ascomycete found in two non-switching mating types, *A* and *a* (referred to as "big A" and "little a"). Strains of either type grow as branching, thread-like cells called hyphae. These hyphal cells are typically interconnected and multinucleated. The mycelium is homokaryotic if all the nuclei present have the same genotype, and it is heterokaryotic if they have a different genetic composition. The fusion of haploids to produce diploid nuclei is rare; thus **heterokaryons** are naturally stable.

Certain stresses (a dry environment or carbon starvation) activates the asexual developmental pathway, which is also called conidiation. Aerial hyphae grow away from the mycelial substrate and develop a spore-producing structure that contains conidiophores. Conidiophores are chains of cells that grow by budding and develop into multinucleates spores called macroconidia. These bright orange spores are an ideal means of dispersal, as they are small (5–10 mm) and abundant.

In contrast, sexual sporulation has rather exacting nutritional requirements. It begins with the formation of protoperithecia—the female reproductive apparatus of the organism. Poorly characterized metabolic and environmental signals induce protoperithecial development in the absence of strains of the opposite mating type. In fact, more is known about the conditions that inhibit development than those that activate it. For example, protoperithecia are sparsely formed on nutritionally complex media, on submerged liquid cultures, and at temperatures above 27°C. The absence of ammonium ions seems to be critical to induce their formation, as does a marginal degree of nitrogen starvation or intense carbon deprivation. In addition, blue light is known to stimulate their formation.

Development of microconidia occurs in the absence of strains of the opposite mating type. These asexual spores are small and uninucleate, grayish-brown in color. They are formed within the vegetative hyphae and rupture through the cell wall as they mature. Microconidia are thought to function primarily as male fertilizing agents for the developing protoperithecia.

Being heterothallic, *Neurospora* must mate with strains of the opposite mating type to form sexual spores or ascospores. For this, trychogynes, specialized hyphal elements that emanate from protoperithecia, are fertilized by male elements (macroconidia, microconidia, or vegetative cells) of the opposite mating type. Fusion, or plasmogamy, initiates the development of the perithecium, the multicellular sexual apparatus. After plasmogamy, the male- and the female-derived nuclei coexist in a heterokaryotic tissue and divide mitotically until they are sorted into dikaryotic tissue, in which each cell compartment contains only one nucleus of each mating type. The nuclei then pair and undergo a series of synchronous mitoses until the tip of the hyphal cell in which they reside bends to form a hook-shaped cell called a *crozier*. There, the two nuclei undergo a coordinate mitosis yielding, after septum formation, a uninucleate basal cell, a uninucleated lateral cell, and a penultimate ascus mother cell that contains one nucleus of each mating type. It is in this cell that karyogamy, meiosis, and postmeiotic mitoses take place resulting in an ascus containing eight haploid spores in an order that reflects their lineage. About 200 such asci are generated within a typical perithecium. Once mature, the ascospores are ejected from the ascus through the ostiole in the perighecial beak. Meiotic segregation and recombination can be studied in *Neurospora* by analyzing individual asci or random ejected spores.

3.2. Life Cycle of *Aspergillus nidulans* (5-7)

A. nidulans is a homothallic ascomycete that does not require different mating types for sexual reproduction. As a vegetative mycelium *A. nidulans* grows via apical extension in which genetically distinct nuclei can coexist in a single thallus as heterokaryons or separately, maintaining the homokaryotic state. Although the hyphae have what appear to be individual segments, the cross walls contain pores so that the mycelium is in fact a multinucleate structure. Within the growing mycelia mat, nuclei are also capable of fusion, producing diploid thalli. This is also a relatively rare event in naturally occurring populations, but may be accomplished in the laboratory with the use of complementing auxotrophies present in each of the donor hyphae (8).

Sexual reproduction involves the formation of specialized fruiting bodies called cleistothecia containing fertile hyphae. Since *A. nidulans* is homothallic, mating occurs within a colony of uninucleate cells, much like wild type strains of *S. cerevisiae*. Nuclear fusion (karyogamy) and meiosis occur within the cleistothecia followed by the formation of ascospores within individual asci. Further differentiation of the postmeiotic nuclei involves two mitotic divisions producing binucleate ascospore progeny.

Asexual reproduction in *A. nidulans* involves the formation of multicellular conidiophores and uninucleate conidia. In response to signals that are as yet poorly understood, a single hyphal segment from the vegetative mycelium develops into a foot cell, which differentiates a specialized stalk and metulae. Repeated divisions of the metulae give rise to uninucleate phialides cells which undergo additional rounds of division to produce conidia. Thus, conidia are uninucleate and haploid, whereas ascospores are binucleate. A great deal of research has been applied to understanding the genetic and biochemical mechanisms that govern conidial development in *A. nidulans*. See Ref. 9 for review.

Although both *Aspergillus nidulans* and *N. crassa* have long genetic systems that make them ideal for study of a wide variety of eukaryotic problems, the use of recombinant DNA techniques and transformation systems in all of the fungi has enlarged the wealth of information that can be gleaned from pursuing some of the more genetically intractable organisms.

4. Genome Structure

The **genomes** of fungi range in size from around 7-8 Mb for *Pneumocystis carinii* and *Ashbya gossypii* to near 40 Mbp for some of the basidiomycetes (see Table 1). The presence of introns may be rare, as for *C. albicans* and *A. gossypii*, or they may be widely distributed, as for *A. nidulans*. It is estimated that the filamentous fungi will contain anywhere from 4500 genes in the smallest fungi to 9,000–12,000 genes in the largest genomes (Phillipsen, personal communication) (10). Because most fungal chromosomes do not condense during mitosis, their karyotypes cannot be determined by cytological methods. A size estimate may be determined utilizing pulsed-field gel electrophoresis techniques in which whole chromosomes are resolved using alternating electrical fields. Some examples are given in Table 1.

Table 1. Genome Size and Karyotype

Organism	Size (Mb)	Number of chromosomes	References
Ashbya gossypii	8.85	7	22, 54
Aspergillus nidulans	31	8	55, 56
Candida albicans	16–17	8–9	57, 58
Coprinus cinereus	37.5	13	59
Cochliobolus heterostrophus	35	15–16	13
Histoplasma capsulatum	~31	7	60

The genomes of fungi are known to be somewhat plastic, as evidenced by the chromosome length polymorphisms (CLPs) observed for many different species using pulsed-field electrophoretic techniques to separate whole chromosomes by size. This polymorphism can be accounted for by both mitotic and meiotic events and is observed in both sexual and asexual fungi [reviewed in (11)].

The mechanisms by which these changes are initiated are largely unknown, but the presence of repetitive elements within the genome has been suggested to play a critical role. Reciprocal translocations have been demonstrated in two isolates of *C. albicans* (12) and in *C. heterostrophus* (13), and the expansion/contraction of tandem ribosomal DNA repeats has been documented as the cause of some CLPs in *C. albicans* (14), *Coprinus cinereus* (15) and *Cladosporium fulvum* (16). Subtelomeric regions of fungi are known to contain repetitive DNA sequences that have proven useful in fingerprinting individual isolates. Until recently, fungi were thought to lack transposon elements, which have been shown to influence genome fluidity in other systems. They have been identified in a number of species; a representative few are presented in Table 2. It is interesting to note that, while transposon-mediated inactivation of essential genes would, *a priori*, have severe consequences on single-celled systems such as *S. cerevisiae*, it would be of little consequence to the coenocytic lifestyles of the small and filamentous. In fact, transposons may have had significant effects upon fungal genome evolution.

Table 2. Insertional Elements in Filamentous Fungi

Organism	Element	Size	Length of ITR (bp)	Copy no.	Reference
Nectria haematococca	Nht1	2.2 bp	–	0–100 copies	70
Fusarium oxysporum	Fot1	1.9 kbp	44	4–100	71
Botrytis cinerea	Flipper	1.8 kbp	48	0–20	72
Magnaporthe grisea	Pot2	1.9 kbp	43	~100	73
	MGR586	1.8 kbp	42	0–50	74
	MAGGY	5.6 kbp	–	0–100	75
Aspergillus niger	Tan1	2.3 kbp	44	1	76
	Vader	0.44 kbp	44	~15	76
Cochliobolus carbonum	Fcc1	1.8 kbp	64	>10	77
Neurospora crassa	Tad1-1	6.9 kbp	–	~40	78

Another source of CLPs may be dispensable or “B” chromosomes. These chromosomes are not present in all members of a species, and their absence is generally thought to offer no advantage or disadvantage to the organism. Fungi, as well as other plants and animals, have small dispensable chromosomes or portions of chromosomes that may be dispensable. Their existence has been conclusively demonstrated in *C. heterostrophus* (13), and *N. haematococca* (17).

There are a number of sequencing efforts in the fungi that will shortly answer many of the questions concerning comparative genome structure (18): *Aspergillus nidulans* (19), *Candida albicans* (20), *Neurospora crassa* (21), and *Ashbya gossypii* (22) are well on their way to completion.

5. Conclusion

The past decade has been a particularly exciting time for those working on the filamentous fungi.

With the ability to transform these organisms with homologous and heterologous fragments of DNA, it has been possible to make great strides in a number of areas. Not only has there been a much greater understanding of developmental pathways, molecular clocks, and mating type in these organisms, but topics such as incompatibility, pathogenesis and evolution have been addressed at a molecular level. Furthermore, as more genomes are squenced, bioinformatics and functional genomics will play an even greater role as scientists begin to uncover the function of each of the proteins expressed in a given organism. What was once the gold of biochemists and geneticists can now be mined by molecular biologists studying human disease since fungi allow us to peek into the world of mammalian biology. Like all reviews of this nature, this one is far from complete, space limitations prevented the inclusion of many interesting topics, however excellent reviews in the field are available (a partial list is given below): transformation systems (23, 24); mating (25-28); control of gene expression (29); protein production and secretion (30-32); development and sporulation (4, 7, 8, 25, 27, 33); DNA modification strategies (34-36); fungal chromosomes and plasmids (11, 37-41); incompatibility (42); signaling (43); virulence and pathogenesis (44-50); circadian rhythms (51, 52); evolution (53).

Precise sequence information on these genomes can be accessed at the following sites:

Fusion Gene, Fusion Protein

Fusion genes consist of unrelated genes, or gene fragments, that have been joined in-frame to produce a coding sequence that is **transcribed** and **translated** as a single unit. The resulting gene product is called a *fusion protein* (as well as a chimeric or hybrid protein). The fused gene elements most often encode functionally and structurally distinct protein **domains**.

In nature, several examples of fusion genes exist. Circumstantial evidence supports the hypothesis that the assembly of relatively small domains into functional proteins is an important factor in evolution (1). These natural gene fusion events result from processes such as gene duplication and exon shuffling. The possibility of deleting and adding such domains during evolution suggests that proteins are often tolerant to changes involving whole domains.

Ubiquitin, a small, highly conserved **eukaryotic** protein, is another example of a naturally occurring gene fusion, as it is expressed from gene fusions to either itself (generating polyubiquitin) or to one of two **ribosomal** proteins (2). A third example is the **genomes** of many **viruses** that consist of several genes fused together. On expression, a polyprotein is produced, which is further processed by a virus-encoded proteinase to generate single proteins (3).

Gene fusions generated by use of recombinant DNA technology have been used experimentally for a number of purposes, such as protein expression and purification, construction of reporter systems, and medical applications, as well as in systems for directed evolution of proteins. The first-mentioned application is by far the most common and, therefore, this aspect of gene fusion technology will be treated in greatest detail (see Expression Systems).

1. Gene expression and protein purification

There can be several reasons for applying the fusion gene approach in a gene expression strategy. Fusion to the desired product of an affinity chromatography or purification "handle" or "tag," with unique **ligand-binding** characteristics, allows the use of the properties of the fused handle for purification. In many cases, the handle is useful for detection purposes as well. The handle can be removed later, if necessary, to obtain the native product. The most commonly used handles seem to be protein A, which binds to immunoglobulin G; glutathione **S-transferase**, which binds to its substrate glutathione; maltose-binding protein, which binds to maltose, and poly**histidine**, which binds to metal ions (4). A combined affinity handle with more tags integrated can allow a simplified screening of various purification and detection methods (5). These general fusion systems for expression and purification ensure a reasonable expression level (when the fusion partner gene is positioned upstream of the gene of interest) and allow rapid recovery of the gene product without the need for time-consuming optimization. Other advantages of gene fusion technology with relation to protein expression and purification are summarized in Table 1.

Table 1. Alternative Purposes of Using a Fusion Strategy in Protein Expression and Purification

Problem	Solution
Low solubility, caused by misfolding	Fusion to a protein with solubilizing or chaperonelikeproperties, eg, protein A, thioredoxin, or ubiquitin (7, 8)
Proteolytic degradation	A dual-affinity approach in which the protein of interest is fused between two different affinity chromatography handles (9)
Proteolytic degradation; recovery problems	Fusion to trpE, cII, or an amphiphilic extension often results in the formation of inclusion bodies, offering protection and simplified purification; **denaturation** followed by refolding is required (10, 11)
N-terminal heterogeneity (in bacteria)	Addition of fusion partner, whose removal generates a homogeneous N-terminus
Detection	Fusion to a partner that can be readily detected by, eg, immunological methods or its enzymatic activity

Toxicity; formation of disulfide bonds (in bacteria); recovery; proteolytic degradation	The protein of interest has to be removed from the cytoplasm; fusion with a signal peptide directs the protein of interest to a specific compartment (eg, periplasm, cell wall, culture medium) [see Secretion Vector)

The removal of the affinity handle is most often the bottleneck of the purification procedure. The usefulness of chemical cleavage is limited, as these agents recognize only one amino acid and harsh conditions are often applied during the cleavage. Enzymatic methods can represent a problem if the proteinase used is not sufficiently specific. Furthermore, the cleavage efficiency can be low because of the inaccessibility of the recognition sequence by the proteinase. Finally, one or more purification steps are required to remove the proteinase again after cleavage. Now, the use of recombinant fusion proteinases equipped with a purification handle may be able to solve some of these problems. If the handle is of the same kind as that of the fusion protein to be processed, the cleavage can, in principle, be carried out directly on the column (6). Another solution to the problem of removing the fusion partner is presented in the IMPACT system (New England Biolabs), where the protein of interest is C-terminally fused to an affinity tag that binds chitin. These two fusion partners are separated by a modified protein splicing element, the intein domain. The splicing element undergoes self-cleavage at its N-terminus under reducing conditions when the fusion protein is bound on a chitin affinity column. The cleavage causes the release of the target protein while leaving the affinity tag bound to the column.

2. Potential medical applications

Many pharmaceutical protein drugs are rapidly cleared from the circulation after administration, making frequent supply of large doses of the therapeutic drug necessary. It has been demonstrated that the *in vivo* half-life of a drug can be increased by fusion to a carrier that is more stable *in vivo* (12).

Drug targeting is another interesting application of gene fusions. One portion of the fusion protein targets the drug to a specific cell type, for example, by interacting with a **receptor** molecule, whereas the other part, the drug itself, has the specific activity of interest.

Immunogenic peptides or proteins for the production of vaccines are often small and difficult to produce because high purity is necessary. A means of overcoming these difficulties is to produce the protein as a fusion protein. Normally, the native protein does not have to be released by cleavage. A particularly effective fusion partner is the serum albumin -binding region of streptococcal protein G, which seems to have inherent immunopotentiating properties, probably by providing T-cell help for antibody production (13).

The gene fusion technology has also proved valuable in gene therapy. Transcriptionally inducible systems have several critical shortcomings, such as the delay between induction and the appearance of optimal protein activity, plus the problem of activating specific genes without affecting others. **Hormone**-binding domains (HBD) of **steroid receptors** can be used to regulate heterologous proteins post-translationally. The protein to be regulated is fused to an HBD, so that it becomes inactive in the absence of hormone. The inactive state can be rapidly reversed by the addition of the cognate steroid hormone (14). Chimeric versions of the steroid hormone receptors have also been applied for the regulation of **gene expression** at the transcriptional level. The chimeric receptor is composed of an HBD, a specific DNA-binding domain, and a transcriptional activation domain, each with unique specificity. The chimeric receptor is kept in the inactive state, until an activating ligand is bound. The active chimeric receptor is now capable of binding to specific response elements associated with the target gene, thereby inducing its expression (15).

3. Research Applications

Gene fusion technology has also been used to generate powerful research tools of general interest (16). The **phage display** system is based on the fusion of the gene encoding a product of interest to one of the genes encoding a **bacteriophage** coat protein. The fusion protein will thereby be displayed on the surface of the phage, and the corresponding gene will be packaged into the phage particle, allowing its later identification by DNA sequencing. The system is used for the selection of a mutational variant of the protein of interest with specific characteristics from a pool of randomized versions of the protein.

The yeast two-hybrid system is a method developed for the detection of protein–protein interactions. The system takes advantage of the fact that many eukaryotic transcriptional activators, including the yeast GAL4, contain two discrete domains, the DNA-binding domain and the transcriptional activation domain. If the two domains are physically separated, GAL4 becomes inactive. Two different cloning vectors are used to generate separate fusions of these GAL4 domains to genes encoding proteins that potentially might interact with each other. The recombinant hybrid proteins are coexpressed in yeast. If the non-GAL4 parts of the two hybrid proteins interact with each other, the DNA-binding domain will be tethered to the transcriptional activation domain. As a result of a two-hybrid interaction, the GAL4 transcriptional activator will be functionally reconstituted and will activate transcription of reporter genes having upstream GAL4 sites. In this way, the protein–protein interaction is made **phenotypically** detectable.

Scientists have found inspiration to develop gene fusion technology by studying nature's way of evolving proteins with new functions by fusing genes encoding distinct protein domains. Gene fusion technology has now found widespread use in biotechnology and medicine and promises to be a key technology for the future.

G Banding

G-banding is a simple technique that is usually the method of choice for identifying and studing chromosomes. The first step is to fix the chromosomes with methanol and acetic acid (Carnoy's reagent), which removes the vast majority of the histone proteins. Non-histone proteins remain behind and obviously contribute most to banding patterns. The structural basis of banding is unknown, although the G-bands are presumably where DNA is accessible to thiazine dyes. The second step in G-banding is usually to pretreat the chromosomes by enzymatic digestion using a proteinase, such as **trypsin** or a mixture of proteinases, such as pronase. Alternatively, any other treatment that damages the protein content of chromosomes, such as high pH, can be used. As enzyme digestion proceeds, the removal of structural proteins relaxes the chromosomal compaction, leading to the selective local expansion of chromosomal volume (1). The last step is to stain the chromosomal preparations with Giemsa–Leishman's stain or Wright stain. The dark G-bands alternate with light bands in **prophase** and **metaphase** chromosomes.

General features of G-bands in terms of chromatin structure include the presence of AT-rich DNA sequences, the absence of potentially active **promoter** elements (CpG Islands), and indications that chromatin is late replicating, condenses early in mitotic and meiotic prophase, and is not **DNase I sensitive**.

G-banding is most useful in the analyzing vertebrate chromosomes, where the large number of bands and hence information content has allowed accurate **phylogenetic** comparisons between species. In medical cytogenetics, banding patterns of human chromosomes achieve a resolution of up to 2000 G-bands. Chromosomes can be divided into segments dependent on the most prominent bands, which can then be further subdivided by finer analysis of visible bands. G-banding allows defining chromosomal rearrangements and breakages. For example, a chromosome break at the point Xq 27.3 (long arm, band 2, primary subband 7, subdivision 3) is associated with the form of mental retardation known as Fragile X syndrome (see Acentric Fragment).

G-Protein-Coupled Receptors

Almost two thousand **genes** have been identified, on the basis of their predicted protein structure, that encode for proteins characterized as G-protein-coupled receptors (GPCRs). It is likely that there are actually several thousand. GPCRs are currently classified into 100 or so subfamilies, based on their structure, ligand specificity, and biological effects. These molecules have a characteristic sequence that predicts seven **transmembrane**-spanning segments, with a cytoplasmic tail of varying lengths. GPCRs are known to interact with a variety of hormones, neuropeptides, chemokines, biogenic amines, nucleosides, eicosanoids, phospholipids, growth factors, and aromatic compounds that act as olfactants or odorants. Some examples include thyrotropin, interleukin 8, epinephrine, and bombesin. Moreover, scores of "orphan" receptors have been identified by cDNA cloning and are still in search of ligands.

1. Receptor Structure

The wide variety of ligands for GPCRs dictate that several structural variations might allow for the variety of their regulatory features. One common feature of all of these receptors is seven stretches of 20 to 25 **hydrophobic** amino acid residues, which are thought to form a-helices that span the membrane (see a-Helix). Thus, the overall structures of these receptors resemble that of bacteriorhodopsin (1). The amino-terminal sequences lie outside the cell, and they vary in size among the family from 7 to 600 amino acid residues. In the case of some receptors, especially those for larger peptide hormones, such as thyrotropin or thrombin, the amino-terminal sequences are critically involved in ligand binding. In most cases, however, ligand binding is thought to occur primarily within key residues in the membrane-spanning regions. A series of mutational studies with the b-adrenergic receptor and other GPCRs (2) have suggested that the ligand may associate with the a-helix near the outer surface, binding in a plane parallel with the membrane. Another conserved structural feature is the loop between the fifth and sixth a-helices, the domain most critical for interactions with G proteins (see GTP-Binding Proteins). It is likely that agonist binding induces a conformational change in the receptor that permits interactions of this domain with G proteins (3). The carboxyl tail of the receptor is cytoplasmically oriented and varies in length among receptors. Mounting evidence suggests that this domain may play a crucial role in receptor cross-talk and desensitization.

Identification of the regions in GPCRs involved in ligand binding has emerged mainly from studies employing point mutations and receptor chimeras. Advances in this area have been led by studies on b-adrenergic receptors (4). Mutant forms of the receptor have been constructed and expressed in cells, to evaluate the binding of both agonists and antagonists. Studies such as these have led to models in which the ligand is thought to bind at the outer surface of the receptor, among several of the transmembrane domains. In the case of the catecholamine agonist isoproterenol, two serine residues in the fifth transmembrane helix are thought to form hydrogen bonds with the hydroxyl groups on the catechol ring (2). In addition, a phenylalanine residue in a-helix 6 participates in binding via hydrophobic interactions with the catechol ring itself. Similar types of interactions have been elucidated for nucleoside and nucleotide receptors.

Agonist binding to GPCRs is thought to induce movements among the transmembrane domains, a conformational change that is translated into G-protein interactions. Although the molecular dynamics of this process remain poorly understood, a number of models have been proposed to explain signal generation within the receptor (3). One aspect of receptor activation that may play an important role is receptor dimerization, a process that is well characterized in activation of other receptor subtypes. Recently, it has been proposed that the protonation of key transmembrane residues are required for activation. Additionally, it has been reported that intramolecular interactions within certain intracellular loops maintain the receptor in the inactive state prior to ligand binding, which is subsequently disrupted by the interaction with activating ligand.

The specificities of receptors, both for ligands and for G proteins, have been explored by construction of chimeras. Although the overall structural features of these receptors are generally conserved, there is little sequence similarity among the superfamily. Indeed, even among the three known subtypes of the b-receptor, there is only 50% identity. Thus, chimeric receptors have revealed domains of the proteins that are necessary for binding specificity and that dictate which G proteins might be coupled to each receptor (4).

2. G Proteins

The proteins that serve as tranducers for the GPCRs are known as GTP-binding proteins, or G proteins. These molecular linkers exhibit a heterotrimeric structure, consisting of a, b,and g subunits. The heterotrimeric G proteins belong to a superfamily of Gtpases, which share a common structural core. In general, the functions of G proteins are dictated by the receptors with which they interact, an interaction mediated by the asubunit. Thus far, over 30 different a subunits have been identified, along with six b and g subunits. The a subunits fall into five different classes, each with a characteristic impact on its effector.

The asubunit of G proteins interacts with guanyl nucleotides and in general controls the activity of the complex (5, 6). When no ligand is bound to the receptor, a is maintained in the GDP-bound state. In this form, a is complexed to the b and g subunits, which prevents it from interacting with effectors. b and g subunits together form a tight complex. Upon ligand binding, the receptor interacts with the asubunit, leading to the displacement of GDP and the subsequent binding of GTP. In its GTP-bound state, Ga then dissociates from the bgcomplex and is activated, interacting with effectors such as adenylate cyclase. This activation is temporal and is terminated by the intrinsic GTPase activity of Ga, which hydrolyzes the GTP, leaving GDP bound to the protein.

The GTPase activity of Gafamily members is subject to different types of regulation. The proteins can be frozen in their activated state by adding nonhydrolyzable analogues of GTP, such as GTPgS, effectively blocking the GTPase activity of the protein. Additionally, certain bacterial toxins irreversibly modify G-protein a subunits, catalyzing the covalent addition of ADP-ribose from intracellular NAD. ADP-ribosylated Ga cannot hydrolyze GTP, thus leaving the protein in a persistently active state. In the case of **cholera toxin**, this activation results in a modification of Gas, causing the persistent activation of adenylyl cyclase, and leading to massive diarrhea (5, 6). Ga proteins are also regulated by endogenous proteins called for regulators of G proteins (RGs), (7). This family of regulatory proteins now comprises over 20 members, and they seem to function as long-term regulators of G protein signaling.

Although they were originally thought to function only as inhibitors of a, bg subunits in some cases can interact directly with effectors upon their release from Ga subunits, causing either stimulation or inhibition of activity. For example, in certain neuronal systems, cells may contain different forms of adenylyl cyclase that are differentially regulated by G proteins. bg subunits can stimulate the activity of the type III form of cyclase, but have no effect, or can even inhibit, the type II form of the enzyme. Additionally, bg subunits can directly stimulate phospholipase C-b in some cells (8).

3. Effectors

In most cases, G-protein a subunits interact directly with one or more effector proteins in the plasma membrane, to induce the release of soluble second messengers that in turn amplify the hormonal signal into the cell. While the number of effectors continues to grow, four distinct types have been studied in detail: adenylate cyclases, phospholipases, **ion channels**, and **phosphodiesterases**.

gal Operon

The *gal* operon of **bacteria** encodes enzymes of galactose metabolism that constitute an amphibolic pathway and is transcribed by two **promoters**. Several cis-acting DNA sequences (**control elements**) and a variety of regulatory proteins, including a **histone**-like protein, modulate the two promoters in a multitude of ways usually found in animals and not in bacteria (Table 1). The *gal* operon has revealed several new features of gene-specific transcriptional regulation that were previously unrecognized. Perhaps such multivalent control mechanisms are required to regulate the synthesis of amphibolic enzymes.

Table 1. Repression and Activation of Transcription of the *gal* Operon

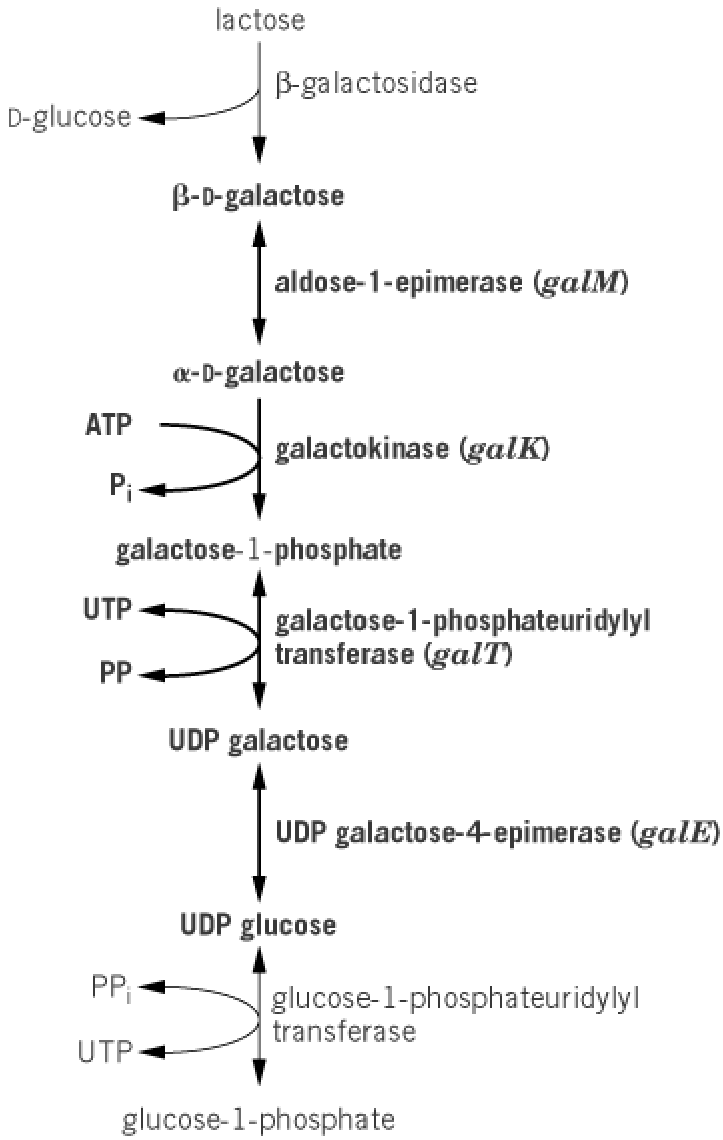
Promoters	Regulatory protein and DNA elements[a]		
	GalR, HU	GalR or GalS	cAMP•CRP
	O_E, O_I	O_E	*AS*
*P*1	Repression	Repression	Activation
*P*2	Repression	Activation	Repression

[a] The regulatory effects of GalR and GalS are epistatic to the effects of cAMP•CRP.

1. Enzymes of the *gal* Operon

The galactose metabolizing enzymes (Fig. 1) are involved in (i) the catabolism of D-galactose that was either imported into the cell by **permeases** or generated intracellularly by hydrolysis of disaccharides and (ii) the synthesis of precursors (UDP galactose and UDP glucose) of complex carbohydrates (1, 2). For catabolism, only a-D-Galactose is converted to galactose-1-phosphate by galactokinase (3). b-D-galactose, generated, for example, by hydrolysis of lactose by **beta-galactosidase**, must change to the a-anomer before it can be phosphorylated. Although b-D-galactose can mutarotate spontaneously to the a-anomer at a slow rate, the enzyme aldose-1-epimerase is largely responsible for the mutarotation *in vivo* (2). Thus, aldose-1-epimerase links the enzymes of lactose and galactose metabolism into a common pathway (Fig. 1).

Figure 1. The Leloir pathway of D-galactose metabolism. As shown, D-galactose is generated intracellularly by hydrolysis of the disaccharide lactose. The parts of the pathway catalyzed by enzymes of the *gal* operon are shown in bold. They are encoded by the genes shown within the parenthesis in italics.

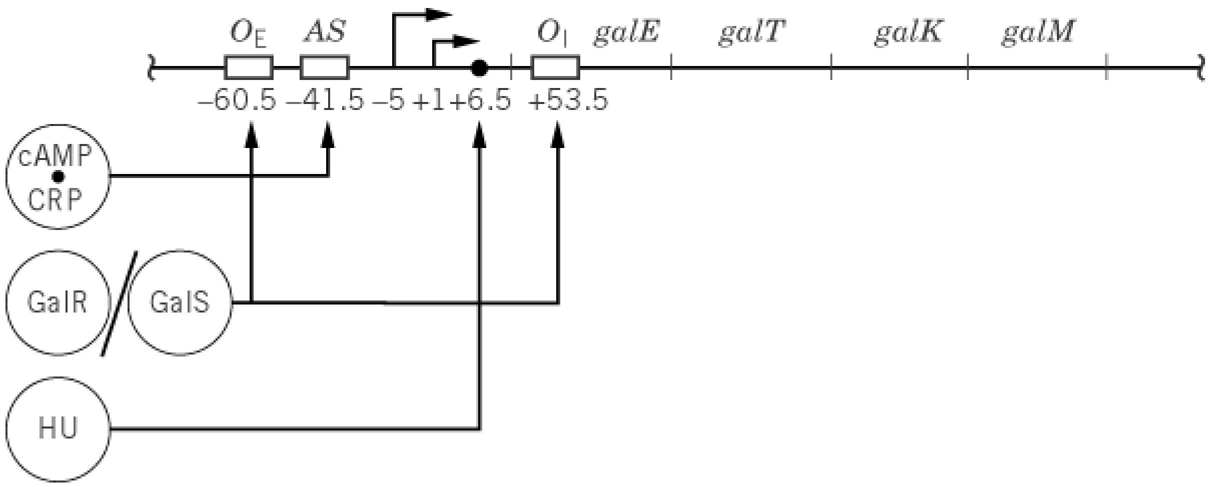


2. Regulation of Transcription

The structural genes and the associated regulatory elements of the *gal* operon are shown in Figure 2. The *gal* operon is transcribed from two promoters, *P*1 and *P*2, which are separated by 5 base pairs (bp) (4, 5). The dominant regulator of the *gal* operon is the Gal repressor (GalR) (6). GalR, together with the histone-like protein, HU, acting as a corepressor, keeps the expression from the *gal* promoters low (7, 8). The operon is induced 15-fold in the presence of D-galactose or some of its nonmetabolizable analogs, such as D-fucose (9). The inducer lifts the repression by an **allosteric** effect on GalR. It is not known whether the true inducer is the a- or the b-anomer of the sugar, or both. Besides the major negative control by GalR and HU, the two promoters are also regulated by

GalR alone (10), by a Gal isorepressor, GalS (11-13), and by a complex of cyclic AMP (cAMP) bound to cyclic AMP receptor protein (CRP), cAMP•CRP (4, 5, 14-16). As described below, *P*1 and *P*2 are regulated by these regulators in opposite directions. The *gal* promoters are also modulated by *cis*-acting DNA sequences without the participation of any regulatory proteins.

Figure 2. The structure of the *gal* operon. The regulators are shown as circles and their cognate DNA control elements as open bars. Their mode of actions are explained in the text. The adenine tracks present upstream of the promoter are not shown.



3. Regulation without Regulatory Proteins

3.1. Control of *P*1 by Adenine Tracks

The intrinsic strengths of the two promoters are comparable, and they are moderately active in the absence of any regulatory proteins, both *in vivo* and *in vitro*. *In vitro*, the intrinsic strength of *P*1 is twofold enhanced because of the periodic presence of four to six adenine residues centered at positions –84.5,–74and–63 on the DNA (17). The adenine tracks bend the DNA toward the face of *P*1 to which **RNA polymerase** binds. The DNA curvature induced by the adenine tracks may help formation of a RNA polymerase-promoter complex (caging) that is more optimal for transcription initiation at *P*1 (18).

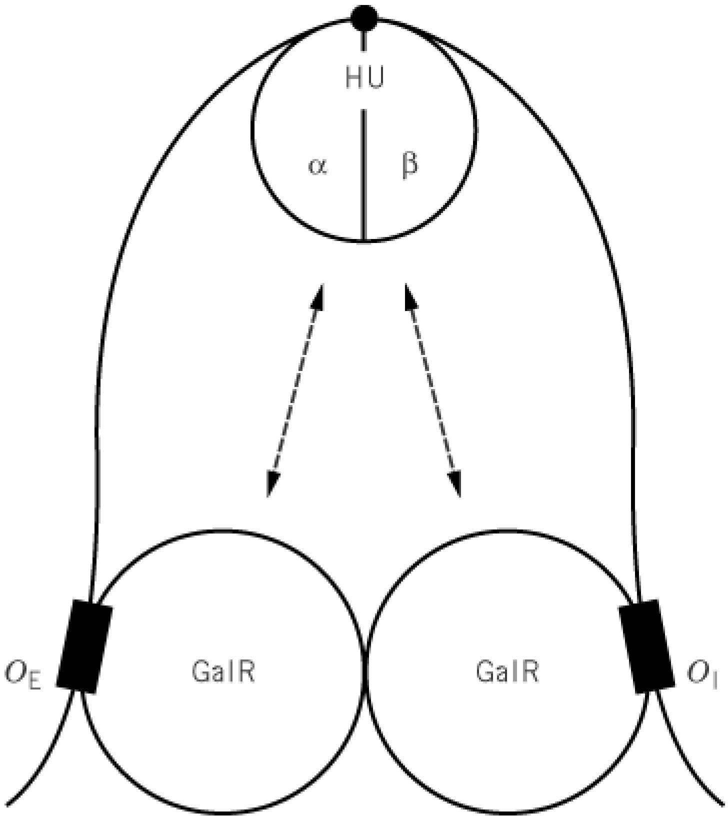
3.2. Control of *P*2 by UTP

Transcription of the *gal* operon from the *P*2 promoter is very low when the concentration of UTP is high and *vice versa*, both *in vivo* and *in vitro* (19). UTP regulates the step of promoter clearance by RNA polymerase at the *P*2 promoter in an intriguing way. *In vitro*, RNA polymerase clears at *P*2 poorly and makes a large amount of aborted RNA oligomers, unlike at *P*1. At high concentrations of UTP, it also synthesizes pseudo-templated RNA oligomers of the composition pppAU $_n$ (n = 2to≥20) because the enzyme "stutters" while adding uridine residues present at positions 3–5 of the *P*2 RNA and not the *P*1 RNA. RNA polymerase clears the promoter more efficiently and makes template-encoded normal *gal* RNA at low UTP concentrations. The involvement of UTP in the synthesis of UDP sugars by the galactose pathway may be the reason for the control by UTP (Fig. 1) analogous to the way UTP controls its own synthesis in the pyrimidine operons (20). At high UTP concentrations, the levels of UDP galactose and UDP glucose are high and inhibit the synthesis of enzymes, specifically, galactose-1-phosphate uridyltransferase and uridine diphosphogalactose epimerase, that make them.

4. Repression by GalR and HU: DNA Looping

Transcription from the two *gal* promoters is coordinately repressed (negative control) by GalR and HU acting together (7, 8). The repression requires binding of GalR to two operators, O_E and O_I, which are similar 16-bp sequences with a dyad symmetry (Fig. 2) (21-23). O_E is located upstream of the promoters at position –60.5, whereas O_I is located within the structural gene *galE* at position +53.5. The two operator-bound GalR molecules associate with each other in the presence of the cofactor, HU (a heterodimer of two subunits, HUa and HUb), resulting in the formation of a DNA loop encompassing the promoters (8, 24) (Fig. 3). The DNA looping presumably changes the structure of the promoters, making them refractory to RNA polymerase caging (18, 25). The nucleoprotein complex that represses the *gal* promoters is called the Gal repressosome, because its formation is by binding of a histone-like component of the bacterial nucleoid as well as a repressor (26). Although GalR binds to O_E and O_I in both the absence and presence of HU, GalR binding alone does not bring about DNA looping and the associated simultaneous repression of the promoters (27). HU is absolutely necessary for the effect; it cannot be replaced by other histone-like proteins. Although HU is not a sequence-specific DNA binding protein, one molecule of HU heterodimer binds to and bends the *gal* DNA centered at an architecturally critical position (8). Genetic analysis and modeling defined the GalR surfaces interacting to form a stacked, V-shaped tetrameric structure (28, 29). Evaluation of the DNA elastic energies gave unambiguous preference to a DNA loop in which O_E and O_I adopt an antiparallel orientation causing undertwisting of DNA (29). Since HU binding depends on GalR binding to both O_E and O_I and the binding of GalR to the operators is enhanced by HU, GalR and HU bind **cooperatively** (8). GalR piggybacks HU to the critical position on the DNA through a specific GalR-HU interaction (31). The entire process facilitates the GalR-GalR interaction resulting in cooperativity. The GalR-HU contact may be transient and was not in the final repressosome structure. The dependence of HU binding on GalR renders the HU-containing nucleoprotein complex that brings about repression of *P*1 and *P*2 sensitive to inducer D-galactose for transcription derepression. Such a mechanism is an example of how DNA that is "condensed" by binding proteins and made refractory to RNA polymerase action can become available for transcription in response to specific signals.

Figure 3. The DNA looping of the *gal* promoter by binding of the GalR regulator and HU corepressor. The details of binding of the two proteins are discussed in the text.



5. Regulation in the Absence of DNA Looping: Interaction between GalR and RNA Polymerase

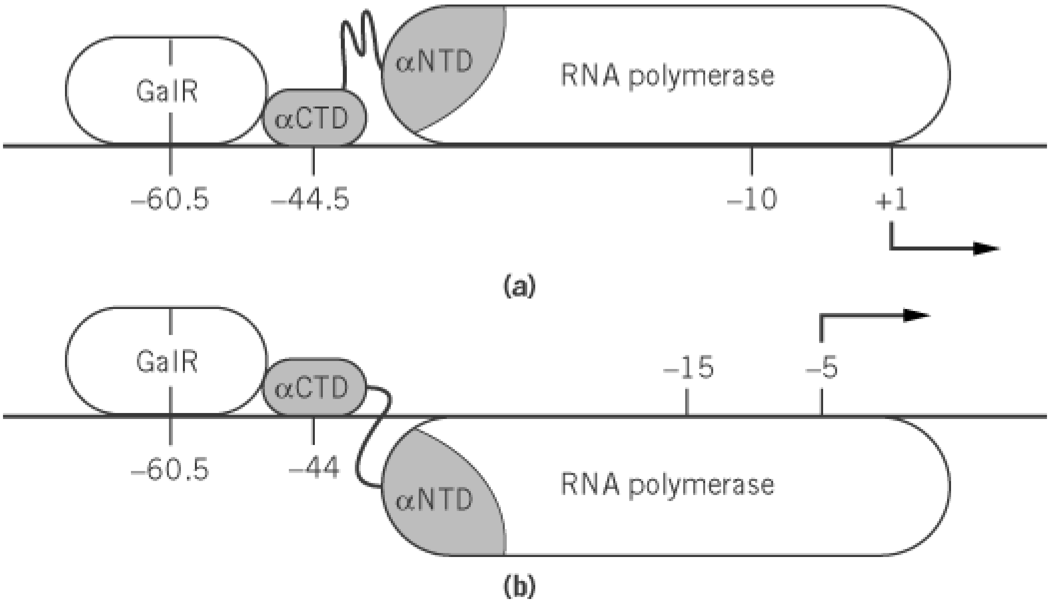
Without DNA looping (ie, in the absence of HU), occupation of O_E alone by GalR represses *P*1 (by about four- to fivefold) and activates *P*2 (twofold) (10, 27). Binding to O_I does not affect this dual control. The activation of *P*2 and repression of *P*1 are independent of each other. GalR exerts its specific regulatory effect on one promoter even when the other is mutated. The activation of *P*2 or repression of *P*1 is not an intrinsic property of the promoter; the regulation can be reversed by switching the angular orientation of the promoters relative to O_E by inserting a 5-bp segment, that is, half of a DNA helix, between O_E and the promoters. Both activation of *P*2 and repression of *P*1 require the formation of a specific GalR-RNA polymerase-DNA complex at each promoter. RNA polymerases containing a subunits that carry specific amino acid alterations in their carboxy terminal domain (aCTD), or that are missing the aCTD, abolish the regulatory effect of GalR without affecting intrinsic transcription, suggesting that GalR activates and represses by a direct contact with the promoter-bound RNA polymerases.

5.1. Activation of *P*2

Activation of *P*2 by GalR bound to DNA at position –60.5 (–55.5 with respect to *P*2) parallels the activation of transcription of several promoters by activators that also bind around position –60 on the DNA and act by enhancing open complex formation (32). An exposed segment (not necessarily the same segment) of aCTD is contacted by the DNA-bound activator to activate transcription (33, 34). aCTD is connected to the rest of the RNA polymerase molecule by a flexible hinge (35, 36). In *P*2, as in these systems, aCTD binds at the region 40 bp upstream of *P*2 (37) (Fig. 4).

Figure 4. Repression of *P*1 promoter and activation of *P*2 promoter by a contact between DNA-bound GalR and the aCTD of RNA polymerase. The two domains aNTD and aCTD of the RNA polymerase a subunit are shown shaded.

The aCTD is connected to the rest of RNA polymerase by a flexible hinge. Note the differences in the topography of the two cases.



5.2. Repression of *P*1

GalR occupying DNA at position –60.5 represses *P*1, not by hindering RNA polymerase binding, but by contacting aCTD, which binds to *P*1 at position 45 bp upstream of *P*1 (10, 27, 37) (Fig. 4). GalR inhibits isomerization of RNA polymerase complex at *P*1. How contacts between the same two proteins bring about opposite effects at the two promoters remains to be determined. It is not known why and under what conditions the dual behavior of GalR toward *P*1 and *P*2 in the absence of DNA looping is triggered in cells.

6. Gal Isorepressor

The *gal* operon is also regulated by an isorepressor (GalS). Although GalS does not seem to repress the *gal* promoters by DNA looping, the isorepressor does stimulate *P*2 and repress *P*1, the same way that GalR does by binding to O_E, except that the effects are weaker. GalR and GalS modulate a few other operons, including those encoding both high- and low-affinity galactose **active transport** systems (12, 13, 38). The degree of regulation by GalR and GalS varies from operon to operon, perhaps to coordinate galactose metabolism and to transport efficiently under a wide range of galactose availability.

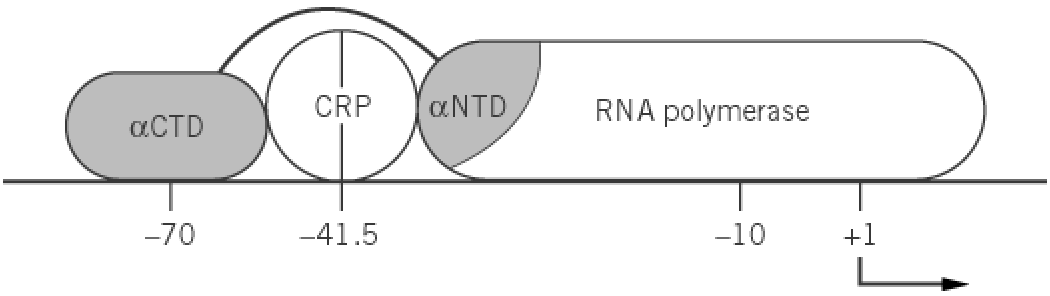
7. Properties of GalR and GalS

GalR and GalS are 85% similar in their amino acid sequences (12). By their homology with proteins (GalR-LacI family) whose structures are known, GalR and GalS are expected to have two-domains connected by a flexible hinge (39). A helix–turn–helix motif in the amino domain of each subunit of GalR and GalS dimers recognizes half of a dyad symmetry in O_E and O_I. The carboxy domains contain the inducer binding sites, which have been defined by isolation and characterization of inducer nonbinding (noninducible) repressor mutants, such as *galR*^{S} and by modeling (40, 41). The mechanism by which the inducer derepresses the *P*1 promoter under conditions of nonlooping by binding to the O_E-bound GalR has been studied in detail. Despite the demonstration that inducer binding can dissociate GalR from the operator, *P*1 can be derepressed under conditions when O_E is occupied by a GalR-inducer complex (42). These results show that dissociation of a repressor from an operator is not obligatory for transcription. Since the O_E-bound GalR interacts with RNA polymerase to inhibit open complex formation at *P*1 at a postbinding step, the inducer acts by allosterically neutralizing the inhibitory contact between the proteins without dissociating the repressor from DNA (10, 17).

8. Regulation by cAMP•CRP

Like GalR and GalS, the global regulator cAMP•CRP complex also has differential effects on the *gal* promoters; but unlike GalR and GalS, the complex activates transcription from *P*1 (three- to fourfold) and represses the same from *P*2 (10-fold) (14, 16). Unlike a large group of promoters, such as the *lac* promoter, in which cAMP•CRP dimer activates transcription by binding at position –61.5 on DNA and contacting RNA polymerase through the aCTD (see Lac Operon and Cyclic Amp Receptor Protein (CRP)/Catabolite Gene Activator Protein (CAP)), the regulatory complex brings about dual control in the *gal* operon by binding to DNA at position –41.5 (37, 43, 44) (Fig. 5). Whereas it is believed that cAMP•CRP represses *P*2 by sterically hindering RNA polymerase binding to the overlapping –35 element of the promoter, the molecular mechanism of activation of *P*1 is different from that in the *lac* promoter. cAMP•CRP stimulates transcription initiation at *P*1 by stimulating both RNA polymerase binding (closed-complex formation) and isomerization (45). A patch of amino acid residues (called *region 1*) of the promoter distal subunit of the cAMP•CRP dimer interacts with an a-helix (helix 1) of the aCTD and helps the latter to stretch away from the *N*-terminal domain (aNTD) to bind to the region upstream of cAMP•CRP. A different amino acid residue patch (called region 2) in the promoter proximal subunit of cAMP•CRP interacts with a different segment of the aNTD. The contact with the aCTD is responsible for increasing the RNA polymerase binding, whereas the interaction with the aNTD stimulates the isomerization step. This shows how the same regulatory protein can activate transcription initiation at two different biochemical steps by making entirely different contacts with RNA polymerase. Nevertheless, the dual roles of cAMP•CRP enable the *gal* operon to be expressed primarily from *P*1 in cAMP-proficient cells and from *P*2 in cAMP-deficient (eg, glucose grown) cells.

Figure 5. Activation of *P*1 by cAMP•CRP by two different contacts with RNA polymerase. The two domains aNTD and aCTD of the RNA polymerase a subunit are shown shaded. Details are discussed in the text.



9. Summary

The study of the *gal* operon in *E. coli* has shown new ways and means of gene regulation at the level of transcription initiation: (i) how proteins bound to spatially separated sites on DNA communicate by DNA looping; (ii) how specific and nonspecific DNA binding proteins cooperate to “condense” DNA, making the latter unavailable for transcription, while remaining sensitive to an inducing signal; (iii) how the same regulator brings about opposite effects on promoters — activation and repression—by making direct contact with RNA polymerase; and (iv) how an inducer allosterically changes a repressor to neutralize the inhibitory effect of repressor still bound to DNA. Besides studying the detailed biochemical mechanisms of such controls, the two interesting questions remain: What are the physiological reasons for the multitude of controls, and how are these diverse controls coordinated in the cell?

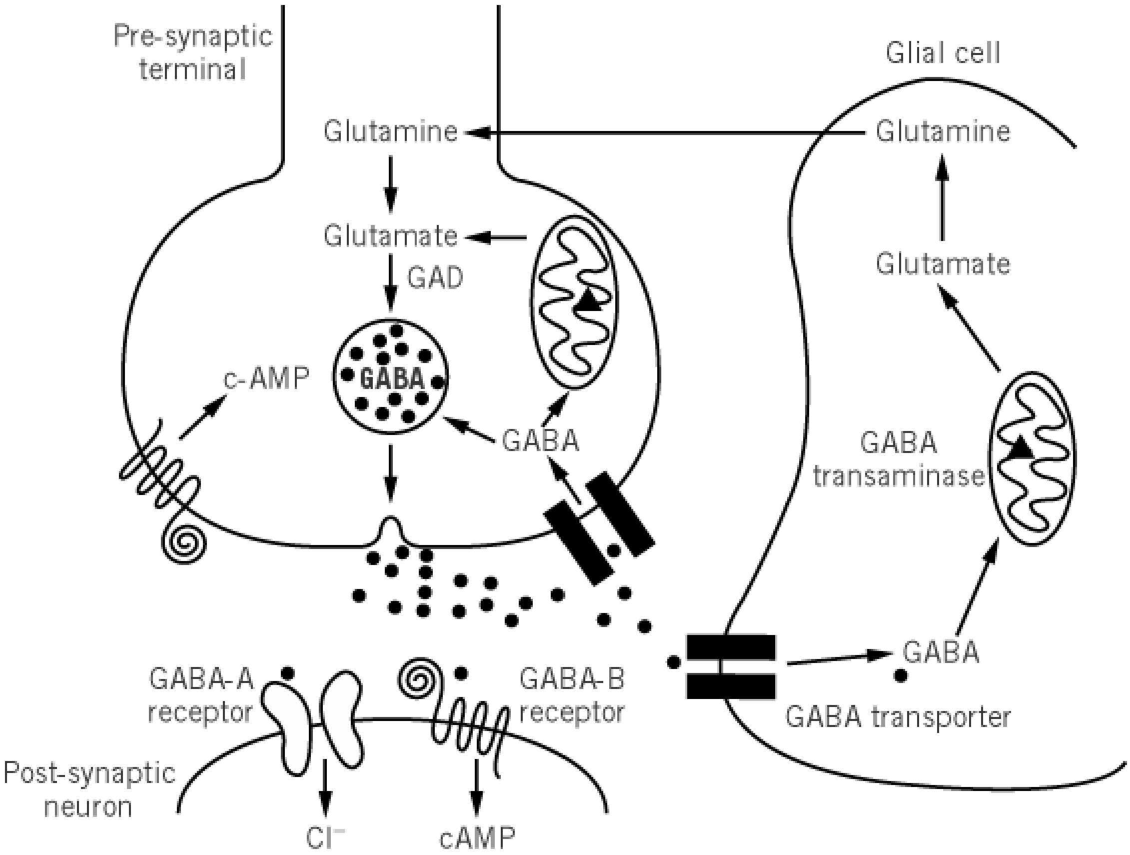
Gamma-Aminobutyric Acid (GABA)

g-Aminobutyric acid (GABA) is widely found in both vertebrates and invertebrates and in both neuronal and non-neuronal tissues. By far, its most understood and arguably most important role is as a neurotransmitter (Fig. 1). GABA is synthesised from glutamate by the enzyme glutamic acid decarboxylase (GAD). It is stored in vesicles within the synaptic terminal of neurons. When an action potential comes down the axon and reaches the synaptic terminal, calcium channels are activated, resulting in calcium influx. This leads to fusion of the neurotransmitter-containing vesicles with the cell membrane and release of the neurotransmitter, in this case GABA, into the synaptic cleft. The GABA diffuses across the synaptic gap and binds to its receptor. GABA receptors are of two types, ionotropic ($GABA_A$) or metabotropic ($GABA_B$), and their activation leads to hyperpolarization of the postsynaptic membrane and a decrease in the excitability of the cell. The response is terminated by desensitization of the receptors and by removal of the GABA from the synapse into the presynaptic terminal or surrounding glial cells. The latter is achieved through specific transporter proteins referred to as GABA transporters. Once taken up into a cell, two potential fates await it. The GABA can be taken up into mitochondria and metabolized to succinic semialdehyde (by GABA transaminase), and then to succinic acid, and enter the tricarboxylic acid pathway. This is referred to as the *GABA shunt*. Alternatively, in the presynaptic terminal, it can be recycled into synaptic vesicles and, thereby, made available for subsequent release.

Figure 1. A schematic of the vertebrate GABAergic synapse. GABA (filled circles) is generated from glutamate by glutamic acid decarboxylase (GAD). When released from presynaptic vesicles into the synaptic cleft, it diffuses across and binds to postsynaptic $GABA_A$ and $GABA_B$ receptors. It may also bind to presynaptic $GABA_B$ receptors. GABA is removed from the synaptic cleft into surrounding glial cells or the presynaptic terminal by GABA transporters. It is directly recycled into synaptic vesicles or taken up by mitochondria, converted by GABA transaminase (filled triangle) to succinic semialdehyde, and enters the tricarboxylic acid pathway.



1. Glutamic Acid Decarboxylase

GAD converts glutamic acid into GABA. In mammals there are two forms, GAD65 and GAD67 (named according to their apparent molecular weights), which are the products of two different genes (1). These two forms of GAD are expressed throughout the nervous system and also in several non-neuronal tissues including the pancreas, oviduct, and the testis. Most GABAergic neurons in the brain express both forms of GAD, but their relative abundance varies (2). GAD67 is distributed widely throughout the neuron, while GAD65 tends to be concentrated at the axon terminals (3). The role of GAD in non-neuronal tissues is, in general, poorly understood. Relatively high levels of GABA and GAD are found in the islets of Langerhans beta cells of the pancreas (4). These cells are destroyed in the autoimune disease insulin-dependent diabetes mellitus, and one of the major antigens is GAD. GAD has some amino acid sequence identity with a coxackievirus polypeptide, and it has been proposed that IDDM may result from molecular mimicry between the virus and GAD (5).

2. GABA Receptors

2.1. GABA$_A$ Receptors

GABA$_A$ receptors are ligand-gated ion channels. When GABA binds to specific recognition sites on the receptor, this triggers a conformational change leading to opening of the intrinsic anion channel allowing chloride ions to flow through into the cell. This opening of the ion channel is transient (10s of milliseconds). Two molecules of GABA must bind to open the ion channel. GABA$_A$ receptors are members of a larger ligand gated ion channel family, which contains nicotinic acetylcholine receptors, strychnine-sensitive glycine receptors, and 5-HT3 receptors. To date, the mammalian GABA$_A$ receptor gene family consists of 15 subunits (a1–a6, b1–b6, g1–g3, d, e, q)(6, 7). b4 and g4 have been identified in avain brain (8). Three other subunits, r1–r3, have also been identified. They are expressed primarily in the retina and have a pharmacology that differs from $GABA_A$ receptors. As such, there are suggestions that they be classified as $GABA_C$ receptors (9). $GABA_A$ receptor subunits are 450 to 550 amino acids in length and have the structural features of the ligand-gated ion channel gene family: a putative signal peptide, a putative large extracellular domain, four putative transmembrane domains, the second of which is thought to line the pore of the channel. The subunits are classified by their relative deduced amino acid sequence homologies; within a group (eg, the a subunits), the subunits are approximately 70% homologous, whereas between groups (eg, a versus b) they are approximately 40% homologous. All the subunits have unique distributions of expression in the brain, and this expression is developmentally controlled (10). The native receptor is formed from the coassembly of the subunits in various combinations, resulting in a family of receptor subtypes. The precise subunit composition of receptor subtypes is not yet known. However, it is likely that most receptors are formed from the coassembly of a and b subunits with either a g, d, or e (or both g and q) subunit (6, 7). The receptor is a pentamer, the subunit stoichiometry of which is probably $(a)_2(b)_2(g)$ or $(a)_2(b)(g)_2$(11, 12)).

$GABA_A$ receptors are the site of action of a number of clinically important drugs including benzodiazepines (prescribed as anxiolytics, anticonvulsants, and sedatives), barbiturates, and general anaesthetics, all of which act through unique allosteric modulatory sites on the receptor, potentiating the action of GABA in opening the channel. The use of transgenic, so called “knock-in” mice has been used to delineate which $GABA_A$ receptor subtypes are responsible for the anxyiolytic properties or the sedative properties of benzodiazepines (13, 14).

$GABA_A$ receptors are also found in insects, at the neuromuscular junction and the nervous system. The subunits that have been identified (eg, *Rdl*) are homologous to vertebrate $GABA_A$ receptor subunits (15). They are the sites of action of a number of insecticides, including dieldrin. Sequencing of the *C. elegans* genome has indicated that the family of putative $GABA_A$ receptor subunits may be quite large (16).

2.2. $GABA_B$ Receptors

These are metabotropic receptors, interacting with a guanine nucleotide binding protein (G-protein) to produce its effect, which are slower than those of the ionotropic $GABA_A$ receptor (17). Activation of the $GABA_B$ receptor can lead to inhibition (or activation) of adenyl cyclase, inhibition of voltage-gated calcium channels or activation of potassium channels (18). There is evidence that $GABA_B$ receptors can be both postsynaptic and presynaptic. The postsynaptic $GABA_B$ receptors, as compared with $GABA_A$ receptors, produce a slow and long lasting inhibition. Presynaptic receptors may act as autoreceptors, acting through a feedback mechanism to reduce the release of neurotransmitter (19). The first cDNA encoding the $GABA_B$ receptor was reported in 1997 (20) and is referred to as $GABA_B1$. Subsequently, a homologous cDNA was identified ($GABA_B2$), which heterodimerizes with $GABA_B1$, and, indeed, the current consensus of opinion is that native $GABA_B$ receptors exist as such heterodimers (21). The receptor polypeptides have seven putative transmembrane domains and have significant amino acid sequence homology with metabotropic glutamate receptor gene family. There is no significant sequence homology with $GABA_A$ receptors or with other G-protein coupled receptors.

Baclofen, a $GABA_B$ receptor agonist, is used in the clinic to treat the spasticity that can result from spinal injury and also multiple sclerosis (22).

3. GABA Transporters

GABA transporters are located primarily on presynaptic terminals and surrounding glia, where they have three main functions: to regulate the concentration and duration of GABA in the synaptic cleft; to prevent the diffusion of the GABA to surrounding synapses; and to take up the GABA, thereby allowing for recycling or metabolizing. They are transmembrane proteins that use sodium and chloride ion cotransport to allow uptake of the GABA against the electrochemical gradient (23). To date, four subtypes of GABA transporter have been identified, GAT-1 (24), GAT-2 (25), GAT-3 (25), and BGT-1 (26). They are members of a larger gene family of neurotransmitter transporters including those for 5-HT, epinephrine, glycine, taurine, proline, and dopamine. The GABA transporters are approximately 600 amino acids long with 12 putative transmembrane domains and exhibit 50% to 70% amino acid sequence identity with each other. They have unique distributions in the brain, with GAT-1 being the most abundant and widespread and GAT-3 being the least abundant, with expression apparently restricted to the leptomeninges (27).

A number of compounds are known that inhibit GABA uptake by acting on GABA transporters. These include Tiagabin, which is an anti-epileptic (28).

Gamma-Carboxyglutamic Acid

g-Carboxyglutamic acid residues are found within the highly homologous *N*-terminal domains of various vitamin K–dependent proteins (see Calcium-Binding Proteins). Such residues are generally abbreviated as “Gla”; their structure is depicted in Figure 1. Gla residues are the result of a post-translational modification of glutamic acid residues by a vitamin K-dependent carboxylase, also known as g-glutamyl carboxylase, which introduces a second carboxyl group into the side chain. The two carboxyl groups give this amino acid considerable affinity for cations, especially Ca^{2+}, as in the chelators EDTA and EGTA. This modification is required for the calcium-mediated interaction of the Gla proteins with the negatively charged phospholipid membrane and is also essential for the formation of the native protein conformation.

Figure 1. Molecular structure of a g-carboxyglutamic acid residue.

of Glu residues to Gla in vitamin K–dependent proteins).

Gamma-Turns

A gamma-turn is a type of nonregular **secondary structure** in protein structures that causes a change in direction of the polypeptide chain. In the g-turn, a hydrogen bond is formed between the backbone carbonyl oxygen of one residue (*i*) and the backbone amide NH of the residue two positions further along the chain (*i* + 2) (Fig. 1). This (*i*) to (*i* + 2) interaction distinguishes g-turns from b-turns, which have an (*i*) to (*i* + 3) hydrogen bond. There are two types of g-turns, the classic and the inverse, which have different backbone dihedral angles for the (*i* + 1) intervening residue. The two g-turn types are, however, related by an inversion of the signs of the f and y angles (classic: 70° to 85° and –60° to –70°, respectively; inverse: –70° to –85° and 60° to 70°, respectively) (see Ramachandran Plot), so their backbone conformations are mirror images of one another. This is analogous to the difference between the type I and I′ and type II and II′ b-turns. The classic g-turn is less common than the inverse type, because of the unfavorable f and y angles, and is found almost exclusively at the ends of **hairpins** (that is, the classic g-turn usually connects two adjacent antiparallel b-strands).

Figure 1. Schematic representation of a g-turn in a protein structure. (**Left**) The g-turn is shown connecting two b-strands in a hairpin motif. (**Right**) The detailed atomic structure of the g-turn is shown. Residues are numbered 1 to 3 for (*i*) to (*i* + 2). The hydrogen bond between the backbone carbonyl oxygen of residue 1 and the backbone amide nitrogen of residue 3 is shown as a dotted line. This example is a classic g-turn, because the backbone angles for the (*i* + 1) residue are f+67° and y–48°. Oxygen atoms and nitrogen atoms are shown as dark spheres. This figure was generated by Molscript (1) and Raster3D (2, 3).

Gap Junction

Gap junctions are specialized cell junctions, membrane plaques that provide hydrophilic channels for direct intercellular communication. They permit the passive diffusion of molecules of 1000 daltons or less between the cytoplasm of adjacent cells. They do not facilitate the transfer of large polymers, such as polypeptides, RNA, and DNA. Molecules that may pass through gap junctions are such as cyclic AMP, **inositol phosphates**, and **calcium** ions. They thus permit the intercellular transfer of cytoplasmic signals. Gap junctions are widespread in body tissues in both excitable and nonexcitable cells, and they are important in embryonic development.

Ultrastructurally, gap junctions appear as a pair of parallel unit plasma membranes separated by a uniform gap of 2 to 3 nm. Lanthanum infiltration reveals the presence of regularly arranged cross bridges connecting the plasma membranes (1). The junctions are composed of a regular hexagonal array of subunits, the connexons (see text below). In rat hepatocyte gap junctions, the lattice has a unit-cell dimension of 8.5 nm. The intercellular cross bridges are created by pairing of connexons between the plasma membranes of adjacent cells (2).

The connexon is the functional unit of gap junctions. This is a hexameric assembly of proteins called connexins (3) (Fig. 1). Thirteen different connexins are known from rodent tissues. The connexins range in molecular weight from 26,500 to 49,600 daltons (4). They are referred to either by a Greek nomenclature or on the basis of their molecular mass. Thus, connexin a1 is also known as Cx43, having a molecular weight of 43,000. Different connexins show greater or more specific expression in certain tissues and one, Cx38, is predominantly or exclusively expressed in the embryo. Each connexin has four helical transmembrane domains, both the amino and carboxy termini being located in the cytoplasm, and two cytoplasmic and one extracellular loops (5, 6). The third transmembrane domain is amphipathic in character, and it is believed that six of these domains from the subunits of the hexamer form the hydrophilic channel in an assembled connexon (6, 7). Two connexons in the plasma membranes of adjacent cells bind to each other by means of their extracellular loops, thus creating a hydrophilic channel between the cytoplasms of the two cells and allowing the passage of molecules of 1.5 nm or less in diameter. Formation of the gap junction intercellular channel requires a 30° rotation to interdigitate the two apposing connexons (8). Channels formed by a different connexins have differing permeability properties (9), and single-channel conductances vary from 20 to several hundred picosiemens (10). The permeability properties of gap junction channels may be modulated by **phosphorylation** and cytoplasmic calcium concentration and are voltage-dependent (10, 11). Change in the configuration of the subunits is believed to regulate the channel opening, either by blockage or by rotation, so that the channels may be either open or closed (12).

Figure 1. Gap junctions, connexons, and connexin. (**a**) The gap junction provides hydrophilic channels for intercellular communication. Connexons pair between adjacent cells, giving an intercellular gap of 2 nm with a ladder-like appearance to the intercellular space. (**b**) In cross section, each connexon appears as a hollow cylinder, the walls of which are made up of six connexin subunits. (**c**) Connexin is a molecule with four transmembrane domains: its NH_2

and COOH termini inside are the cell, and there are two extracellular and one intracellular loop. (**d**) In the junction plaque, the connexons are arranged in a hexagonal array.

The expression of several connexons in the same individual cells enables the formation of different types of channels, either homotypic channels with identical connexins paired between cells, or heterotypic channels with connexons composed of different connexins paired between cells. Alternatively, individual connexons could be heteromeric; that is, they could be composed of mixtures of connexin subunits. There is evidence that this occurs in some situations, for example, with connexins Cx32 and Cx26 (13). On the other hand, some connexins appear to be incompatible, being unable to link via their extracellular domains to form a channel—for example, connexins Cx43 and Cx40, which are expressed in the heart Purkinje fibers and the ventricular myocardium, respectively (14). This expression pattern is believed to be important in regulating the electrical conducting properties within cardiac muscle. The full functional significance of the different connexin subunits is an important area for future investigation. Connexin mutations are involved in some human diseases. Cx32 mutations are involved in the X-linked form of Charcot–Marie–Tooth syndrome (15), Cx43 in visceroatrial heterotaxia syndrome (16) and Cx26 in hereditary nonsyndromic sensorineural deafness (16). Visceroatral heterotaxia affects left- or right-sided development of the heart. The point mutations involved are believed to involve sites for connexin phosphorylation, implying that these are important for the regulation of connexin function. Null mutations of the connexin Cx43 in mice results in death shortly after birth due to swelling in and blockage of the right ventricular outflow of the heart (17). Other connexin null mutations cause equally specific defects. Thus, mice lacking Cx40 have cardiac conduction abnormalities resembling atrioventricular and bundle branch block (18), absence of Cx37 causes female infertility because failure of oocyte development (19), and mice lacking Cx46 develop cataracts because of proteolysis of lens crystallins (20). Signals transmitted through gap junctions have been implicated in cellular growth control and vice versa in tumorgenic cell lines, consistent with a tumor suppressor function for gap junctions (21). The importance of gap junctional communication in developmental signaling is demonstrated by the severe defects that result from blocking it (22).

Gap Penalty

Aligned **homologous** protein and **nucleotide sequences** may include gaps inserted in one or more sequences to maximize the sequence similarity. These gaps are called indels and correspond to positions where insertion or deletion mutations have occurred. Superposition of homologous protein structures may reveal quite accurately the sites of indels. However, algorithms that **align sequences** must place the gaps at positions that maximize the score of the sequence alignment (1). Gap penalties are used to limit the number and length of gaps that can be opened in the sequences. The usual cost for inserting a gap is defined as Cost = GOP + Gaplength * GEP. Gaps scored in this way are called "affine gaps." The two parameters in the equation are GOP, the gap-opening penalty, and GEP, the gap-extension penalty. The actual values of the penalties used must be in balance with the scores for aligned sequence segments. The values depend on the sequence nature and length, the number and length of genuine gaps, and the residue exchange values in the mutation matrices that are used to score substitutions. The penalties are usually calibrated by trial and error, although it should be possible to infer a likely value from the residue exchange values (while a formal hidden Markov model (HMM) should use actual gap insertion probabilities). In certain situations, more is known about where gaps are likely to occur—for example, if a tertiary structure is known (2), or if an existing alignment is being used that already has gaps in it. In this case, gap penalties can be varied in a position-specific manner, ie, lowered at sites where gap insertion is more likely. Position-specific gap penalties are applied in alignment-based profile or HMM database searches (3, 4) and in multiple alignments—for example, by the program Clustal W (5).

A variant form of gap penalty, called a "frame penalty," is applied in some algorithms that compare a protein sequence to the three translation reading frames of a nucleic acid strand (6). As well as gap penalties for in-frame gaps, shifts in the reading frame are given an analogous cost composed of a frame-opening penalty (FOP) and a frame-extension penalty (FEP). Customization of the frame penalties can optimize alignment where errors in sequence determination result in frameshifting, or where frameshifts affecting coding sequences arise naturally due to **introns**, RNA Editing, or translational frameshifting. Introns can be crossed if the FEP is set very low. The expressed sequence tag (EST) database entries (7) have high error, and searches at the highest sensitivity require a relatively low FOP.

Optimization of gap penalties is essential for the good performance of sequence alignment algorithms, and users should take the time to conduct their own trials. Default settings cannot be optimal for all situations.

Gas-Liquid Chromatography

Following the suggestion by Martin and Synge (1) that the mobile phase for partition chromatography could just as easily be a gas, James and Martin (2) introduced gas-liquid chromatography in 1952. In gas-liquid chromatography, the main mechanism of retention is the partition of an analyte, which is introduced into the mobile gas phase between the gas phase and a stationary liquid phase. The latter is deposited upon the surface of small solid particles or on the walls of a capillary column (capillary gas-liquid chromatography). The theory and application of capillary columns were first expounded by Golay (3). It was found that these columns had the advantages of low resistance to gas flow and high efficiencies equivalent to thousands of plates. Analysis of lipids is the best application of (capillary) gas-liquid chromatography in molecular biology. A detailed practical description is beyond the scope of this article, so interested readers are directed to the monograph *Gas Chromatography and Lipids: A Practical Guide* by Christie (4).

Gastrula, Gastrulation

The gastrula is a stage in early embryogenesis during which the process of gastrulation occurs. After fertilization and the cleavage divisions, a single layer of cells called the **blastula** forms. The blastula may be hollow or filled with yolk. It can also consist of a large disc of cells on top of the embryo derived from large, yolky eggs [see Meroblastic Cleavage]. Regardless of the structure of the blastula, the process whereby the single cell layer gives rise to the three germ layers (endoderm, mesoderm, and ectoderm) is called gastrulation. Gastrulation usually involves changes in cell shape and cell migration. This cell migration can occur as single cells, as in sea urchin gastrulation, or the movement of sheets of cells, as in the involution of cells in fish embryos (a process called epiboly).

Gauche Conformation

The mathematical term gauche means not lying in a plane. In stereochemistry, specific conformations that are related by rotation about a single covalent bond between two tetrahedral atoms have been called gauche when none of the substituent atoms lie in the same plane (see Torsion Angle). Conformers where the substituents are staggered, and the torsion angle between the largest substituents on two neighboring carbons is about 60°, are termed gauche (1). These conformers are typically *syn* or *anti* clinal in the more rigorous designation of torsional conformers (see Conformation) (2). The alternative conformations are *anti* and eclipsed. The two gauche conformers and one *anti* conformer about the C4′—C5′ ribose bond of AMP are shown in Figure 1.

Figure 1. The conformations of the three rotameric conformers of 5′—AMP. The first two are gauche because the torsion angle defined by O5′—C5′—C4′—C3′ is between 0 and ±90°. The third conformer is *anti* because this torsion angle is 180°.

GC Box

A GC box is a *cis*-acting transcriptional regulatory element (see Transcription Factors, Eukaryotic promoters) that contains the sequence 5′-GGGCGG-3′ at its core and is bound by the transcription factor Sp1. GC boxes are found upstream of a number of genes transcribed by RNA polymerase II and increase the transcriptional rate of the gene above the level that could be achieved by the transcriptional core machinery in the absence of a GC box. Because Sp1 is a ubiquitous factor in eukaryotic cells, the presence of a GC box in a transcriptional regulatory region increases the level of expression of the gene. GC boxes may exist in one or multiple copies, depending on the promoter, and may be found in either orientation relative to the direction of transcription from the downstream initiation site. They are generally found upstream of the transcription initiation site and of the **TATA box**, if a TATA box is present. In some cases GC boxes, acting through the binding of Sp1, have an important role in assembling transcription complexes on promoters without an apparent TATA box.

Gel Electrophoresis

The capacity of electrophoresis to resolve macromolecules differing in size, shape, or conformation ("size separation," **molecular sieving**) is dramatically augmented when it is carried out in gels rather than simply in a buffer. This improvement in resolution arises from two causes: (1) The rate of change of electrophoretic mobility with gel concentration (the "retardation coefficient") is directly related to the size and shape of the molecule (see Ferguson Plot); and (2) the convection and dispersion of a band of macromolecules are much reduced in gels relative to solutions. Since macromolecules (proteins, nucleic acids, and carbohydrates) are the building materials of biology, gel electrophoresis has become a ubiquitous separation method in the molecular biology laboratory. Two types of polymers capable of gelation are universally used: (1) polyacrylamide and (2) agarose. The concentrations of each are selected to achieve effective molecular sieving by tailoring the pore architecture to the dimensions of the charged species to be separated.

One of the key advantages of gel electrophoresis over chromatography is the possibility of varying the gel concentration continuously so as to achieve any effective pore size within a continuum. The average pore size in a gel can range from a fraction of a nanometer (corresponding to the diameter of organic acids) to 50 to 100 nm (corresponding to the diameter of plant **viruses**) and up to nearly a micron. Another benefit of gel electrophoresis is its adaptability to gradients of pore sizes (see Pore Gradient Electrophoresis) and to the simultaneous analysis of samples containing large numbers of components: up to 30 to 50 in gels of a single dimension and up to several thousand in two-dimensional gel electrophoresis.

Gel electrophoresis of multiple samples can be carried out simultaneously on multiple channels of vertically or horizontally oriented gel slabs, using either a single gel concentration or a concentration gradient. This application of gel electrophoresis allows one to compare the mobilities of bands in the various channels of the gel. Such a comparison can give information concerning the identity or nonidentity of two macromolecules, so long as the migration distances are unaffected by differences between the channels in conductance (sample ionic strength, Joule heat dissipation, or wall adherence). When the charge densities of species are equalized, as in the case of nucleic acids or with proteins coated with an ionic detergent (see SDS-PAGE), the rate of migration may depend on primarily the particle size, due to sieving by the gel. Additional and more reliable information concerning the properties of each species in a sample can be derived from gel electrophoresis at multiple gel concentrations (see Ferguson Plot).

To be effective, gel electrophoresis needs to be conducted at an optimized gel concentration and under optimized buffer conditions (see Disc Electrophoresis). The optimal resolving gel concentration is mathematically defined for any particular pair of charged species and can be derived from the Ferguson plots of those species. For large numbers of electrophoretic separations, their automation becomes important. Two kinds of apparatus automatically record and quantify the band pattern: (1) a gel electrophoresis apparatus with an **absorbance spectroscopy** detector at the end of the migration path that records the bands as they pass sequentially, and (2) a horizontal gel slab apparatus equipped with a mobile fluorescence detector that scans the migration path at desired intervals. The latter apparatus type has preparative capacity, which allows for sequential electroelution steps, with simultaneous computation of the recovery, to ensure that it is complete. It is applicable to polymer solutions (see Particle Electrophoresis), as well as gels.

Typically, gel electrophoresis zones are detected by fixation of the band in the gel and staining with a specific dye or an enzyme activity (see Electrophoresis and Overlay Assay: Enzyme Zymography of Plasminogen Activators and Inhibitors). Fixation can be replaced by blotting, which permits additional methods of identification such as hybridization of DNA bands or the immunodetection of proteins bands by **Western blots** .

Gel Retardation Assay

The gel retardation assay, also known as the bandshift assay or electrophoretic mobility shift assay (EMSA), is used to detect DNA-binding proteins in crude cell extracts and to study the binding activity of purified DNA-binding proteins. It is also applicable to the study of RNA-protein interactions. The basis of the assay is that protein–DNA complexes remain intact when gently fractionated by gel electrophoresis and migrate as distinct bands more slowly than the free DNA fragment. The assay is simple and quick, and the use of radioactive binding-site DNA makes it highly sensitive. It can be used for both highly sequence-specific and nonspecific proteins, and nonspecific proteins, such as histones. Gel retardation assays can be used quantitatively to estimate dissociation constants for protein-DNA complexes. Additionally gel retardation experiments can be used to visualize protein–protein interactions between a DNA-binding protein and other non-DNA-binding proteins. The binding of a second protein to a protein-DNA complex to form a triple complex is visualized by a further retardation of mobility that is called a supershift. Supershift experiments can also be used to assay the binding of a second DNA-binding protein to the DNA or the binding of a second molecule of DNA to the protein. The assay is useful for proteins with a DNA association constant $>10^7 M^{-1}$.

A further use of the gel retardation assay is to detect DNA bending induced by a DNA binding protein. This depends on the principle that when a protein binds to a DNA fragment of moderate length (in the range of 100–250 bp) the average distance between the ends of the DNA fragment is decreased and there is a greater resistance to the passage of the complex through the pores of the gel. The extent of the resulting retardation depends on the position of the protein binding to the ends of the fragment. The greatest retardation is observed when the binding site is positioned centrally. By comparison with proteins that induce a bend of known magnitude this method can be used to obtain an estimate of the DNA bend induced by a protein.

Gelsolin

Gelsolin is an abundant and ubiquitously expressed actin-binding protein, which confers calcium sensitivity to the regulation of the dynamics of the microfilament system (1). There are also high concentrations of a gelsolin isoform in plasma. The latter is a 755-residue protein with an N-terminal extension of 25 amino acid residues. In the presence of micromolar concentrations of Ca^{2+}, gelsolin binds alongside an actin filament, severs it at that site, and then remains bound to the (+)-end on one of the resulting fragments. Gelsolin has two actin-binding sites, and in the presence of Ca^{2+} ions it nucleates filament formation from a solution of G-actin with subsequent (–)-end growth of the polymer. From the minimal 2:1 complex of actin and gelsolin, one of the actin monomers can be released, if Ca^{2+} is removed by EGTA. The second, more tenaciously bound actin monomer can only be released by the binding of PtdIns 4,5-bisphosphate to the gelsolin. Therefore, both polyphosphoinositides and Ca^{2+} ions might be involved in the control of the effects of gelsolin on the turnover in the microfilament system. As shown by gene knockout experiments, gelsolin is not essential for survival. Only limited defects in motility processes have been detected, but overexpression of gelsolin in fibroblasts results in increased motile activity. Gelsolin has recently been shown to be a downstream effector of rac for fibroblast motility (2).

The structure of gelsolin has been studied extensively. It belongs to a family of actin-binding proteins that contain 1–6 repeats of 120–130 amino acid residues. Gelsolin has 6 such structurally related repeats (S1-S6), which may have arisen through gene triplication of a prototype gene, which subsequently went through gene duplication. First, the three-dimensional structure of a complex between actin and subfragment 1 of the cytoplasmic form of gelsolin was solved by crystallography (3), and later the 3D-structure of the entire plasma gelsolin molecule (4). Recently, electron cryomicroscopy and helical reconstruction has been used to identify gelsolin binding sites on filamentous actin (5).

The different parts of the gelsolin molecule appear to have descrete functions. Subfragment 1 binds an actin monomer in the absence of Ca^{2+} and can cap actin filaments. Subfragment S1-S6 also binds actin monomers and competes for the same binding site on actin as fragment S1, but now the binding is Ca^{2+}-sensitive. The S2 domain by itself binds to the side of actin filaments in a Ca^{2+}-independent way. Subfragment S1-S3, can sever actin filaments. Nucleation of actin polymerization can be achieved *in vitro* with S2-S6. Thus, although gelsolin can bind to the side of the actin filament in the absence of Ca^{2+}, further action to sever the actin filament requires the involvement of the Ca^{2+}-

dependent actin binding site. Polyphosphoinositides bind to the S2 domain and dissociate the actin:gelsolin complexes. Despite efforts to determine the gelsolin binding site on F-actin by cryoelectron microscopy and helical reconstructions a convincing mechanism for the severing action of gelsolin has not yet been obtained.

Gene Amplification

A fundamental property of living cells is their orderly transmission of genetic information from generation to generation. One aspect of this property involves a mechanism that controls **genomic** replication and ensures one complete doubling of each replicon during each cell generation. Another aspect of this property is the placement of genes so that they are expressed properly and so that each daughter cell receives the genes in the appropriate configuration. Now it is appreciated that deviations from this principle occur commonly and that amplification of DNA sequences and rearrangement of sequences occur often.

Amplification of DNA sequences, the differential increase in a specific portion of the genome compared with the remainder, occurs during development and during the vegetative growth of cells. The processes of **polyploidization** and endoreduplication, where the entire chromosome complement is multiplied in one nucleus, is not discussed here. Additionally, aneuploidy (or trisomy) can also result in a differential increase in a portion of the genome, but this is distinct from DNA amplification and is not discussed further.

Developmental amplification has been documented extensively in both germ-line cells and somatic cells of many organisms. Clearly these changes in the DNA content of the nucleus of cells are carefully regulated and lead to the appearance of the extra DNA at a predetermined time and, in many cases, the dissipation of this DNA on cue.

Another type of DNA amplification (sporadic) is detected when cells are overcoming adverse environmental conditions. Amplification of this type, usually observed by selection for a desired phenotype, has been found in bacteria, yeast, insects, and vertebrates. Salient features of this amplification process are being studied in several laboratories, and several general characteristics have emerged. These include (*1*) multistep process leading to the generation of highly amplified sequences; (*2*) a karyotype characterized by chromosomal abnormalities; (*3*) a genetic instability of the resistant (amplified) phenotype which may extend into a marked clonal variation among cells; (*4*) a spontaneous rate of detection which varies but (*5*) may be increased by manipulations of the cellular growth conditions (among these, treatment with carcinogens).

Carcinogenesis has been studied since Potts' initial observation that chimney sweeps are prone to scrotal cancer. Several general characteristics of the carcinogenic process have emerged and must be accounted for in any hypothesis addressing the molecular events involved. These include (*1*) the seemingly multistep nature of the process; (*2*) the chromosomal abnormalities (in many cases non-random) that accompany most oncogenic states; (*3*) the clonal variation encountered in tumor cell populations; and (*4*) the ability of the rare (in some cases) process to be markedly increased by physical and chemical agents (known as carcinogens).

These two processes, DNA amplification and carcinogenesis, share several characteristics. Understanding of both are fundamental to our ability to understand how living organisms, single cells or complex organisms, respond to adverse environmental conditions. Several excellent reviews of both processes have appeared in the literature (1-8). This article begins by briefly reviewing programmed and sporadic amplification. The remainder addresses the measurement of sporadic DNA amplification in cells that have begun the carcinogenic process and demonstrate differing tumorigenic potential.

1. Gene Amplification and Development

1.1. In Germ-Line Cells

The earliest suggestion of developmental DNA amplification was made by King in 1908 when she described the extra “chromatin” (associated with forming nucleoli) that arose in the oocytes of the toad Bufo during pachytene (9). Later studies showed that these “masses” contain DNA, and **hybridization** studies demonstrated a great excess of sequences that code for ribosomal RNA (10). This differential synthesis of rRNA genes is correlated with the appearance of hundreds of nucleolar organizers during the pachytene stage of meiosis. Similar examples of this phenomenon are seen in other amphibians, Xenopus, *Rana*, *Eleutherodaclylus*, *Triturus* (10), and in an echuiroid worm, the surf clam (11) and many insects (12). Documentation of rDNA amplification is particularly amenable because the rDNA forms nucleoli, which are distinctive in appearance, and because most rDNA sequences have a relatively high guanosine–cytosine content, which allows separating them from bulk DNA by CsCI density gradient centrifugation. These two aspects of rDNA have been important in recognizing this and other phenomena (magnification and compensation) in which the rDNA copy number changes under various genetic conditions.

The most complete study of oogenic rRNA gene amplification has been made in *Xenopus laevis*. In this animal, the early primordial **germ cells** do not contain amplified rDNA. Amplification is initiated in both oogonia and spermatogonia of the tadpole during sexual differentiation and germ cell mitosis and results in a 10 to 40-fold increase in rDNA genes. The premeiotic amplification is lost at the onset of the meiotic prophase. This loss is permanent in male germ cells but is temporary in female germ cells. Early during the meiotic prophase, the oocyte nucleus undergoes a second burst of rDNA amplification that results in a 1000-fold increase in ribosomal genes (13). The mechanism by which the first extrachromosomal rDNA copies are produced in the premeiotic stage is unknown, although circular structures have been observed (14). Because the number and placement of ribosomal **cistrons** do not change, a mechanism involving disproportionate replication is favored. The second burst of rDNA amplification probably involves a **rolling circle** intermediate. Such structures have been observed by Hourcade et al. (15) and could account for the increase of rDNA in the oocyte during the given period (16). When the oocyte nucleoli are hypotonically disrupted, DNA rings in the shape of beaded circles are visible. Although the rDNA content is constant, the sizes and number of the rings are variable, suggesting fission and fusion of nucleoli during oogenesis (17). The sizes of the circular molecules are integral multiples of a basic unit. Using molecular techniques, it was found that this basic unit is the DNA segment that codes for one precursor rRNA molecule, plus the accompanying nontranscribed spacer region. It is interesting to note that extrachromosomal, circular molecules that contain rDNA are also found at a low frequency (0.05 to 0.15% of the total number of molecules) in *Xenopus* tissue culture cells and in *Xenopus* blood cells (18). The circles are oligomeric lengths corresponding to between one and four rDNA repeat units. The presence of interlocking circles of equal size indicates that the circles are not *in vitro* cyclization artifacts but probably represent free rRNA genes. One question this raises is whether or not free DNA circles carry other genomic sequences or if they are limited to rDNA sequences. It has been suggested that the difference in the state of rDNA between a somatic cell and an amplified germ cell may only be one of degree (14).

The cytological literature contains many other references to extrachromosomal DNA in oocytes. One of the most striking examples is found in dytiscid water beetles, such as *Rhyncosciara*. The nucleus of each oocyte contains a large chromatin mass, termed Giardina's body, in addition to the chromosomal complement. In older oocytes, this DNA is associated with multitudes of nucleoli and contains an increase in rDNA sequences (12). Hence, amplification of rDNA occurs during maturation of the oocyte. However, hybridization studies indicate that only a fraction of the extrachromosomal DNA is rDNA sequences, indicating that other DNA sequences (of unknown function) are also amplified (12).

Although the phenomenon of gene amplification in Tetrahymena, also results in a considerable increase in rDNA sequences, it is somewhat different from that in oocytes described previously. Tetrahymena contain two types of nuclei in each cell, a transcriptionally quiescent **micronucleus** that is responsible for genetic continuity and a macronucleus that is derived from the micronucleus in a developmentally regulated process whereby micronuclear sequences are eliminated, rearranged, and amplified (19-21). Considerable amplification of many micronuclear sequences occurs that results in the macronucleus containing 45 times the haploid amount of DNA. Some of this increase is accounted for by amplification of rDNA sequences, which are present as a single integrated copy in the micronucleus but in 200 copies in the macronucleus (20-22). These amplified rDNA sequences are present as linear, extrachromosomal, **palindromic** molecules (21, 23). The present data favor a model whereby excision of the single rDNA copy is followed by amplification (21).

The amplification, rearrangement, and elimination of sequences is also developmentally regulated to varying extents in the slime molds, Physarum and **Dictostelium** (Zellweger et al., 1972) and in another ciliated protozoan, *Stylonychia* (Prescott and Murti, 1973). Studies of the molecular structures of these amplified DNA sequences have been undertaken and have revealed interesting structures at the termini.

1.2. In Somatic Cells

Gene amplification during differentiation of somatic cells also occurs and again was first detected by morphological criteria. Several regions of the polytene chromosomes in the larval salivary glands of the fly *Rhynchosciara americana* showed a **puffing** response to hormone treatment that was carefully defined both temporally and spatially. These puffs contain greater amounts of DNA than surrounding regions (24). Two of these puffs, characterized at the molecular level, contain a 16-fold increase of DNA sequences that code for peptides used in the synthesis of the cocoon. Amplification and puff formation depend on the developmental stage of the cell and on the cell's position within the gland (25). Puff formation is not peculiar to the salivary gland chromosomes of *Rhynchosciara*, because it has also been observed in the cells of Malpighian tubules and intestinal cells of the same insect. In addition, puff formation has also been observed in different tissues of *Chironmidae*, *Drosophila*, *Sciara*, *Hybosciara* and other diptera (24). In some cases it is thought that it is under hormonal control (26, 27). In *Rhynchosciara* and *Sciara*, the extra DNA remains associated with the original chromosomal site until lysis at pupation (27, 28). In *Hybosciara* and *Sarcophaga*, in contrast, the extra DNA is released as micronuclei from several sites, similar to that released in the oocytes of amphibians (29). It is interesting that several of the bands that puff during the larval stage in *Rhynchosciara* are identical to those bands that are overrepresented in the differentiated chromosomes of *Sciara ocellaris*. This suggests that certain germ-line events observed in *Rhynchosciara* occur in somatic cells of other species (27).

In many cases of differentiation, somatic cells acquire adequate amounts of messenger RNA to produce abundant proteins by accumulating stable mRNA molecules over a period of days. Examples of such are the silk fibroin genes, the ovalbumin genes, and the beta-**globin** genes. It is thought that this is controlled at the transcriptional or posttranscriptional level. In other cases, however, such as during the synthesis of the insect eggshell by the ovarian follicle cells of *Drosophila*, little time is allotted to produce the specific mRNAs that are needed in large quantities. In these latter cases the rates of transcription and translation are not high enough to produce adequate amounts of protein. Spradling and Mahowald (30) found that this need is met by differential amplification of the chorion gene sequences in the ovarian follicle cells. To study the regulation of expression of the chorion gene proteins, they produced complementary DNA clones complementary to egg chamber RNA. In this way they isolated sequences that code for the major endochorion and exochorion proteins, s15, s18, s36, and s38. Using the s36 clone as a probe, they found that these sequences are more abundant in follicle cells during the terminal stages of egg chamber development than in nonovarian tissue. The sequences that code for s15, s18, and s38 were also being specifically amplified during oogenesis. Spradling (31) found that the chorion genes are located on the X-chromosome are in two clusters, s36 and s38, and are amplified 15-fold. The s15 and s18 loci are on the third chromosome and are amplified 60-fold. The genes in both clusters are amplified at the same time and both homologues are amplified equally. Sequences that flank these genes are also disproportionately replicated, but not to as great an extent. This results in a gradient of amplification that spans 90 kbp of DNA, is maximal in the center, and does not display any discrete termination sites. Amplification of the two linked chorion genes s36 and s38 (but not s15 and s18) is reduced in ocellar mutants. The ocelliless phenotype is a pleiotropic mutation characterized by homozygous females and males that totally lack ocelli (simple eyes or photosensitive organs). They also exhibit an abnormal pattern of bristles in the ocellar region of the head. Ocelliless females lack parovaria, an accessory gland of the reproducing tract, and produce abnormal chorions (which surround the egg), which leads to sterility. The ocelliless mutation has been identified as a small chromosomal inversion and has one of its break points lying near the s36 gene (32). In this inversion, the site for initiating DNA replication responsible for amplifying the chorion genes was moved near the other break point. Using cloned probes for the nonchorion genes now present near the end of the inversion, it was found that the gene copy numbers of these sequences were increased. This result suggests that clustering of the chorion genes has biological significance. Developmentally controlled activation of a single **origin of replication** can result in the amplification of several genes.

Changes in the DNA content of the nucleus of germ-line cells and somatic cells during development is common. Amplification of rRNA sequences and others that code for proteins that needed in large amounts during that particular phase of development have been extensively documented. In still other cases, the nature of the amplified DNA cannot be totally accounted for by known sequences, and it probably contains amplified sequences of unknown function. Such sequences have been implicated in the differentiation of the orchid Cynidium (33), the differentiation of peas (34), and in the flowering of the tobacco plant, Nicotiana (35). Further studies are needed to relate these instances of DNA amplification to the overall development of higher organisms.

2. Gene Amplification and Acquisition of a Selected Phenotype

Duplication and amplification of genetic material in cells has long been documented as a means for overcoming deleterious growth conditions. Unlike amplification that is specifically regulated during development, amplification as a means of survival is a more sporadic event whose frequency is often detected at levels much lower than those in developmental amplification.

2.1. Bacteria

The first well-documented example of gene duplications in bacteria that provides an adaptive advantage was seen by Novick and co-workers (36-38). Bacterial strains were grown for long periods of time in limiting concentrations of lactose in the chemostat. The bacterial strains that emerged synthesized four times the maximal normal amount of **beta-galactosidase** . The ability to produce large amounts of enzyme was unstable and could be transferred by conjugation at a time when the lac operon genes were expected to be transferred. It was concluded that the ability to overproduce beta-galactosidase was due to extra copies of the *lac* genes in these strains. The spontaneous rate of duplication was estimated at 10^{-3} and 10^{-4} in a similar system (39). Overproducers that have similar characteristics were subsequently reported for other enzymes, such as ribitol dehydrogenase, b-lactamase (40), and several others (for an excellent review, see Ref. 41). Roth and co-workers demonstrated that duplications up to a quarter of the Salmonella chromosome occur at large homologous segments, such as the rRNA genes (41, 42). Such large duplications depend on the *recA* system. On the other hand, duplications in the range of 10 to 30 kbp are independent of *recA* and do not involve very large homologous segments of DNA (42-44). Edlund and Normark (45) detected tandem duplications of 10 to 20 kbp at the *E. coli* chromosomal *ampC* locus that codes for b-lactamase and confers resistance to ampicillin . After a stepwise selection in increasing concentrations of ampicillin, 30 to 50 copies of the duplications analyzed at the restriction fragment level had different end points. The junction points of the amplified unit in one case was sequenced, and the original duplication occurred at a sequence of 12 bp that was repeated on each side of the *ampC* locus, 10 kbp apart.

Tlsty et al. (46) detected amplification as revertants of certain leaky Lac- mutants. The DNA sequences, which were amplified, contained the *lac* operon and anywhere from 7 to 32 kbp of flanking sequences. These regions were amplified 100-fold. More than 160 independent events were analyzed at the restriction fragment level, and the majority had different end points. These amplifications and as those studied by Normark are not mediated by large homologous sequences (47). Virtually all of the duplications detected and subsequently studied in bacteria have been tandem. Genetic techniques have permitted localizing the end points of these tandem duplications to two different classes of sequences, those composed of large homologous sequences of DNA (such as ribosomal genes or transfer RNA genes in *E. coli*) and those not. The former type may be visualized as occurring by a recombination system for which we have already identified the enzymes. The latter class of duplications raises the question of the lower limits of homology that may be used by such a system, or it raises the possibility that it is a different system entirely that mediates duplications whose end points lack long homologous stretches.

Several bacteriophages also amplify genetic markers. Lambda phage (45), **T4 phage** (48), and **P1 phage** (49) may use mechanisms that parallel those used by viral sequences in mammalian cells. The mechanism is yet unknown.

2.2. Yeast

Resistance to the toxic effects of copper in *Saccharomyces cerevisiae* is mediated by tandem gene amplification of the CUP1 locus (50) but differs from sporadic amplification events characterized in other organisms. The CUP1 locus of yeast codes for a small copper-binding protein. Copper-sensitive strains contain one copy of this locus and, when grown in elevated concentrations of copper, fail to produce resistant derivatives that have a higher gene copy number of CUP1 genes on one chromosome. Infrequently, copper-resistant strains isolated in the laboratory and to carry up to 10 tandem duplications of the CUP1 region, which has 2kbp. Further amplification could be achieved by growing the copper-resistant strains in elevated copper concentrations. The authors postulate that the mechanism of amplification in this instance proceeds by forming a disome for chromosome VIII (which carries the CUP1 locus). Copper-resistant mutants of the sensitive strain are disomic for chromosome VIII. Then, the amplification or tandem iteration could result primarily from subsequent unequal chromosome or sister chromatid exchanges. The formation of a disome may constitute an initial event in the process. Now the system is being used to estimate the frequency of sister chromatid exchanges, unequal crossovers, and gene conversions in this region. The break points occur in the nontranscribed spacer region (51).

A second example of gene amplification in yeast has molecular structures more similar to those described in other organisms. A yeast strain resistant to antimycin A, an alcohol dehydrogenase inhibitor, contains multiple copies of a nuclear gene, ADH4, an isoenzyme of alcohol dehydrogenase. The amplified copies are 42 kbp long, display a linear, extrachromosomal, palindromic structure, and contain **telomeric** sequences. Their structure resembles that of the amplified rDNA genes in the macronucleus of Tetrahymena and related cilliated protozoa, except that the nuclear copy remains within the chromosome. In contrast to that often observed in mammalian amplification (see later), the extrachromosomal copies of this gene are stable during mitotic growth. Amplification of the ADH4 gene is relatively rare (~10^{-10}mutations/cell/generation), and alternative mutations of antimycin A-resistance are in the majority.

2.3. Protozoans

Drug resistance in protozoan parasites is common and presents a serious problem for the chemotherapy of diseases caused by such pathogens as Trypanosoma, Leishmania, and Plasmodium (52-54). Recently, Leishmania strains resistant to the well-known chemotherapeutic agent methotrexate have been isolated and analyzed for their mechanism of resistance. Organisms that are resistant to high concentrations of methotrexate (1mM) have a 40-fold increase in dihydrofolate reductase (DHFR) which in this organism is associated with **thymidylate synthetase** (**TS**). The resistant organisms contain amplified regions of DNA that can be observed directly on **ethidium bromide**-stained gels of restriction enzyme digests. The amplified region is 56 kbp long, has a copy number about 80-fold higher than that of wild-type organisms, and codes for the DHFR-TS genes and other sequences of unknown function (56). Direct visualization of the amplified DNA fragments in this system and the amplified sequences described in the *lac* region of *E. coli* (see previous), provide a valuable advantage in identifying sequences involved in generating a desired phenotype. These sequences may be observed because of the low complexity of the genomic DNA in these organisms. The targets of most drugs used for treating pathogenic protozoans and the targets of many selection protocols in bacteria are unknown. The direct visualization of amplified DNA in these organisms provides a means for obtaining these target sequences and gaining insight into their mechanisms of action.

Recent studies have shown that *Plasmodium falciparum* contains genes analogous to the **multidrug-resistance** (mdr) genes in mammalian cells. Parasites that resist chloroquine are also resistant to other antimalarial drugs, similar to the phenomenon of multidrug resistance seen in human tumors. Wilson et al. engineered a probe using sequences that are conserved in the mammalian P-glycoprotein to identify mdr-like sequences in *P. falciparum* . Their studies showed that drug-resistant parasites contain amplified copies of these specific DNA sequences when compared to their drug-sensitive siblings.

2.4. Invertebrates

Amplification of rRNA genes in *Drosophila* during oogenesis does not occur as has been described in *Xenopus* (see previous section). However, sporadic amplification of the rRNA genes during one generation has been observed under specific genetic conditions. Amplification of the rDNA genes in this situation results in reversion to a wild-type phenotype. Each sex chromosome carries approximately 130 to 150 rRNA genes (56). The phenotype is wild type if the diploid cell carries at least one normal locus (~130genes), whereas the phenotype is altered (bobbed) if the genome carries less than 130 genes (56, 57). The intensity of the bobbed phenotype (slow development, thin chitinous cuticle, reduced body traits, and short bristles) is inversely proportional to the number of genes for rRNA. An increase in rDNA copy number is observed in the progeny of phenotypically bobbed males. It involved rapid accumulation of rDNA at either nucleolus organizer by unknown mechanisms. The rDNA that accumulates during the first generation does not have a noticeable effect on the phenotype of the fly. The phenotypic effects of the magnified rDNA become evident in the F2 progeny if the rDNA is transmitted by males and if the genotype of the F2 generation is characterized again by rDNA deficiencies. In other words, the extra copies of rDNA are eliminated if the amplified fly is crossed with a normal (bb+) female. The phenotypic inheritance of amplified rDNA requires integration and inheritance through the male germ line. Two hypotheses have been proposed to explain rDNA magnification, disproportionate replication of rDNA (58, 59) or unequal sister chromatid exchange (60). Recent experiments demonstrating the decrease of magnification frequency in organisms that carry the rDNA on a ring chromosome strongly suggest unequal crossing over as the mechanism.

Another type of amplification in *Drosophila melanogaster* differs from rDNA magnification in several characteristics. This amplification, called compensation, occurs when one nucleolus organizer of the two homologues is completely deleted (X/O or X/X-no females). In such mutants, the remaining organizer "compensates" for the deletion of the rDNA sequences by a disproportionate replication of the remaining sequences on the intact homologue. Compensation may occur only on the X chromosomal nucleolus organizer, and the extra r-DNA is not inherited in subsequent generations. DNA magnification and compensation differ in several aspects (61): (1) In contrast to rDNA magnification, which restores only wild-type levels of rDNA sequences, compensation reaches values that exceed the rDNA copy number of the nucleolus organizer in the wild-type fly. (2) Gene compensation occurs only on the X chromosomal nucleolus organizer. The Y nucleolus organizer is refractory to compensation. As discussed earlier, amplification may occur on either. (3) rDNA accumulated during compensation is not inherited in subsequent generations as is the rDNA resulting from amplification. Compensation occurs in somatic cells and is not passed along. (4) When a genotype carries only one nucleolus organizer in the diploid chromosome set and the same genotype is partially deleted for rDNA in the remaining nucleolus organizer, the conditions for both compensation and amplification are in place. Genetic studies that compare Xbb^{+}/O flies with Xbb/O flies show a much greater increase in rDNA in the Xbb/O flies, which suggests that magnification and compensation can occur simultaneously. An interaction between homologous chromosomes is a prerequisite for initiating compensation. If two complete nucleolus organizers are on one X chromosome, compensation still occurs.

Using various deficiencies for the X chromosomal heterochromatin, evidence has been presented for the existence of a genetic locus that regulates rDNA compensation (62). This locus, called the compensatory response (cr), is located outside the ribosomal cluster and in the X chromosomal heterochromatic region. The locus acts in *trans* to sense the presence or absence of its partner locus on the opposite homologue. If only one cr locus is present, it acts in *cis* by driving compensation (disproportionate replication) of adjacent rRNA genes. Not all embryos that have the proper genotype undergo compensatory amplification to emerge with an increased number of rRNA genes. Only a small fraction undergoes the putative compensatory amplification. In this respect, the amplification behaves like a mutagenic reversion to restore the functional phenotype.

Resistance to environmental agents, such as pesticides and toxic chemical waste, has been documented in laboratory stocks and natural populations of invertebrates. Selection of *Drosophila* larvae in increasing concentrations of cadmium yields strains that contain duplications of the metallothionein gene (63). The duplication is stably inherited in the absence of selection pressure and produces a corresponding increase in metallothionein messenger RNA. A survey of natural populations found that this is common (64) and may signal the early stages of the evolution of a gene family. The mosquito, *Culex quinquefasciatus*, develops resistance to various organophosphorus insecticides by overproducing the enzyme esterase B1. Molecular studies have demonstrated that the overproduction of the enzyme is the result of amplification of the esterase B1 gene some 250-fold (65). The resistant mosquito was normally developed and could reproduce. This observation raises questions of evolutionary significance for the duplication and amplification at least in invertebrates.

2.5. Plants

DNA changes in plants during response to environmental stress have been reported for flax (see Refs. 66-68). The suggestion that these changes in DNA content are induced by the environment awaits verification by further studies.

2.6. Vertebrates

DNA amplification in mammalian cells was first detected when murine tumor cell populations became resistant to chemotherapeutic drugs. Methotrexate, an often-used chemotherapeutic drug, inhibits the action of dihydrofolate reductase (DHFR), which is required for biosynthesizing thymidylate, glycine, and purines. Stepwise selection of cells in increasing concentrations of methotrexate generates highly resistant cells. Studies based on acquisition of resistance to methotrexate showed several alternative mechanisms of resistance. Cells resistant to the action of the drug had (1) altered the structure of the DHFR enzyme so that the folate analog was not efficiently bound (69-71); (2) altered their transport process so that the drug could no longer enter the cell (72); or (3) overproduced the DHFR enzyme (73, 74). Beidler and Spengler (75) detected chromosomal abnormalities in the cells that overproduce DHFR and suggested that they reflect an increase in gene dosage. Schimke and co-workers obtained a cDNA for the DHFR sequence and showed that the overproduction of DHFR results from amplification of the DHFR DNA sequence (76). Now, it is known that amplification of the DNA sequence coding for the target enzyme of a metabolic inhibitor is a common mechanism for overcoming the growth restriction (2, 77-80).

Among other examples of this phenomenon subsequently found, the best studied was amplification of the CAD gene. The CAD gene codes for a multifunctional protein that catalyzes the first three steps in the synthesis of pyrimidines. The aspartate transcarbamoylase activity is inhibited by the **bisubstrate analog**, *N* -phosphoacetyl-L-aspartate (PALA). PALA-resistant cells overproduce the aspartate transcarbamoylase and also the other two enzymes, carbamoyl synthetase and dihydroorotase (81). Wahl et al. (82) showed that overproduction of these enzymes results directly from amplification of DNA coding for these proteins.

Two other enzyme activities, orotate phosphoribosyl transferase and orotidine-5′-phosphate decarboxylase, are responsible for the final steps of pyrimidine biosynthesis and are encoded in a single polypeptide chain called UMP synthetase. Cells resistant to 6-azauridine or pyrazofurin (toxic pyrimidine analogues that inhibit the decarboxylase) demonstrate a coordinate increase in both of these enzyme activities (83). Overproduction of the two activities is due to amplification of the DNA sequences that code for the UMP synthetase (84, 85). Numerous other instances of DNA amplification have been described when the growth of cells is inhibited by metabolic inhibitors, toxic agents, or altered enzymes that have reduced efficiency. Thus a leaky mutant of hypoxanthine phosphoribosyl transferase amplifies its gene, and growth in cadmium results in amplifying metallothionein (86). Mutant mouse lymphoma cells that overproduce ornithine decarboxylase (up to 15% of total cellular protein) have been generated by selection for resistance to difluoromethylornithine (DFO), an inhibitor of the enzyme. The pseudodiploid wild-type cells become **tetraploid** when resistant to high levels of DFO (87) and amplify the ornithine decarboxylase genes. Compactin-resistant Chinese hamster ovary cells contain a 100 to 1000-fold increase in the amount of 3-hydroxy-3-methylglutaryl coenzyme A reductase, a pivotal enzyme in synthesizing cholesterol (88). Molecular analysis demonstrated that the sequences that code for this reductase are amplified 15-fold in these cells. Similarly, methionine sulfoxine-resistant cells that overproduce glutamine synthetase amplify these sequences. The discovery that multi-drug resistance in cancer chemotherapy is, in some cases, mediated by amplifying the mdr locus has been clinically important (89, 90).

As seen previously, the overproduction of an enzyme activity often indicates amplification of specific sequences. Such overproduction has been described in the resistance of cells to such diverse agents as hydroxyurea, aphidicolin, beta aspartyl hydroxymate, mycophenolic acid, tunicamycin, 5-flourodeoxyuridine (93), and several other drugs (for a comprehensive list and references, see Ref. 2). The demonstration that amplification is the basis of resistance in these cells waits cloning of the target genes in question. Although overproduction of specific enzyme activities often indicates gene amplification, exceptions exist, and each instance of overproduction must be properly analyzed before gene amplification is concluded. An example of this is seen in the studies of arginosuccinate synthetase (AS) overproduction. Canavanine is a toxic analog of arginine but is not an inhibitor of arginosuccinate synthetase. Canavanine-resistant cells overproduce arginosuccinate synthetase enzyme that is no longer subject to metabolic control by exogenous arginine (92, 93). Molecular studies show that this instance of overproduction is not due to amplification of the AS gene (92, 93) but is a regulatory mutation. A compactin-resistant regulatory mutant that overproduces HMG Co A reductase has also been found.

Selection pressure also leads to the amplifying sequences that have initially unknown functions. Baskin and co-workers (94) isolated cell mutants that are reciprocally cross-resistant to four diverse drugs; maytansine, adriamycin, Baker's antifol, and vincristine. The resistance is genetically unstable and is accompanied by the presence of double minute chromosomes (DMs) in the karyotype. These are small chromosomes that lack a centromeric sequence and therefore segregate randomly during mitosis. Genetic instability and the presence of DMs are two manifestations of gene amplification (94). Other cells that are cross-resistant to other structurally diverse and structurally unrelated drugs amplify the cell surface glycoprotein called P-glycoprotein. Resistance to agents, such as colchicine, actinomycin D, puromycin, and in some cases vinblastine, generate overproduction of a 170 kDa glycoprotein that reduces membrane permeability (89, 90).

The acquisition of a specific phenotype does not necessarily have to occur by the classic selection protocols that involve growth in cytotoxic substances. The fluorescence-activated cell sorter (FACS) allows detecting single cells that overproduce products, providing one can monitor the product (see Flow Cytometry). This instrument monitors the fluorescence of individual cells as they pass through a fluorescence detector and sorts out the rare deviant with ease. Johnston et al. (95) used this technique to detect amplification of the DHFR gene without growth in methotrexate inhibitor. Chinese hamster ovary cells were stained under nonselective conditions with fluorsceinated methotrexate, which binds quantitatively to DHFR. The cells exhibit heterogeneity in DHFR content. The cells that contain the highest DHFR content were sorted, grown in nonselective conditions, and reanalyzed. After ten successive rounds of growth and sorting, the population showed a 50-fold increase in fluorescent intensity and amplified the DHFR gene 40-fold. The population was highly resistant to methotrexate.

Using the same concept, Kavathus and Herzenberg (96) isolated mouse L-cells that amplified the human T-cell differentiation antigen, Leu-2. Mouse cells were **transfected** with the herpes simplex thymidine kinase (TK) gene and total human DNA. Transfectants that expressed Leu-2 on their surface (as detected with a fluorescent antibody) were sorted on the FACS. Although most Leu-2 transfectants had a narrow range of antigen density per cell, one showed considerable variability. The brightest cells were sorted again. Six rounds of FACS “selection” for the brightest cells produced cells with a mean fluorescence 40-fold greater than the original transfectant. The karyotype of these cells contained a multitude of DM's. A cDNA library was constructed using mRNA from the amplified Leu-2 transfectant, and the Leu-2 cDNA was identified by differential screening. The mouse line that overproduced Leu-2 antigen was confirmed as having amplified the human Leu-2 DNA sequence (96).

Thus, the FACS instrument dramatically facilitates detecting cells that contain amplified sequences, which might otherwise be overlooked in classical cytotoxic selection experiments. These cells may be detected soon after they are generated, without requiring growth into a visible colony. The FACS detects as little as a twofold increase in fluorescence. This allows identifying and isolating cells that have low or increased transient or unstable levels which be. Any fluorescent probe that quantitatively correlates with a specific molecule or metabolic process allows detecting and sorting cell populations that have successive increases (or decreases) of that tag. Using this concept, one can obtain cell variants that amplify (or delete) genes for which there is no available selective agent. The FACS provides a powerful tool for studying heterogeneity in cellular populations and specific amplification of DNA sequences.

The acquisition of a selected phenotype may often result from selection pressures that are unknown at that time. In these cases a certain phenotype may be accompanied by the manifestations of gene amplification for unknown sequences. Such an instance has been described in studying the sequences that are carried on the DMs and found in the homogeneously staining regions (HSRs) of neuroblastoma cells where these structures were first described. The sequences that are amplified in these lines are cellular “onc” genes, the N-myc oncogene (97). Now, amplification of **oncogenes** has been found in several tumor types containing DMs and HSRs (97) and is discussed later.

As a class of rearrangements, tandem duplications or amplifications cause very little loss of genetic information and are therefore probably not significantly deleterious to the cell. On the other hand, the extra copies are easily dispensed with when they are no longer necessary. This would circumvent any growth disadvantages that may be encountered under normal nutritional or environmental conditions. The only limiting factor in obtaining an amplified DNA sequence is the design of a selection system that allows detecting the sequence in question. This principle can be manipulated as a tool, that is, amplification of unknown gene sequences can be obtained to overcome defined selection conditions. For example, selection of cells that may grow in the continued presence of **DNA damaging** agents may result in some cases in amplification of DNA coding for DNA repair enzymes.

3. General Properties of Mammalian Gene Amplification

There are several characteristics of amplification that many of the systems discussed share in common. To illustrate these characteristics, I describe the general properties of methotrexate-resistant cells that result from amplifying the DHFR gene.

3.1. Multistep Selection to Obtain Highly Amplified Sequences

Classically, mammalian cells that contain amplified DHFR genes were obtained by a stepwise selection for cells that are highly resistant to methotrexate (MTX). Before the advent of cloning, the amplified phenotype was distinguished by overproduction of DHFR enzyme and the karyotypic abnormalities that accompany the overproduction. High methotrexate resistance (by virtue of amplification of the DHFR gene) cannot be obtained by a single-step selection protocol. It is a multistep process. The initial step is rate-limiting because cells that have an increased, but low copy number, are rapidly stepped up to a high level of resistance and a high copy number. When the initial increase in gene copy was examined more closely, Brown et al. (98) and Tlsty et al. (99) found that the stringency of selection is critical in obtaining cells that have amplified DHFR. Cells that amplify DHFR genes as a mechanism of resistance to methotrexate are most readily detected within a defined window of methotrexate concentration for the first step of selection. Growth of the cells above or below this range of methotrexate concentration reduces the frequency with which amplified clones were detected. Not only do incremental increases in drug concentration promote the rapid emergence of resistance, but they also specifically promote the rapid amplification of the DHFR gene (100). A shallow increment of stepwise selection allows for emergence of methotrexate-resistant amplified cells more rapidly than in a relatively large single-step selection protocol.

3.2. Karyotype Abnormalities

The second property of methotrexate resistant cells that have amplified their DHFR gene is the frequent karyotypic abnormalities in the cells. As indicated previously, abnormal chromosomal structures were associated with overproduction of the DHFR in the early studies of Biedler and Spengler (75). They described a marker chromosome in overproducing cells that have an elongated chromosomal arm. The term homogeneously staining region (HSR) was coined to describe a region of this chromosome that bands abnormally when stained with giemsa and, as was subsequently shown, is the site of the amplified DHFR sequences (76). This structure was associated with stable resistance to methotrexate. The resistant phenotype is retained even after subsequent growth in the absence of selection pressure. This is in contrast to the karyotype of cells that are unstably resistant to methotrexate. After extended growth in a nonselective medium, the resistant phenotype (amplification) diminishes rapidly and disappears. HSR structures were not found in unstably resistant cells. Close examination of the karyotype of unstably resistant cells, however, brought to light the presence of double minute chromosomes (DMs). These structures (and HSRs) were described by Balaban-Malenbaum and Gilbert (101) in cell lines obtained from human neuroblastoma. Subsequent work demonstrated that unstably resistant cells contain the amplified copies of DHFR on the double-minute chromosomes (DMs). The lack of centromeric structure in these fragments leads to their random (unequal) segregation at mitosis and a diminished number if selection pressure is no longer exerted on the cells (102).

HSRs are often found at the site corresponding to that of the amplified gene but may also be found at many other chromosomal site or sites. In several instances, multiple HSRs, each of which contain some copies of the amplified DNA sequences, are in one cell. The amplified copies of the target gene may be at the site of the resident gene or in another place or various places in the karyotype. Translocation of the amplified sequences has been observed often (103), and may provide clues about the mechanism of amplification. These translocations may be nonrandom in (see Refs. 104 and 105 for extensive review).

The mechanism leading to the generation of multiple HSRs is not known now. Typically a cell must contain a reasonable increase in gene copy number before an HSR is observed. The degree of amplification and the length of the amplified unit both play an important part in the ability to visualize an HSR. This principle is nicely illustrated by a study where only one of two cell lines, both of which have approximately 50 copies of an amplified sequence, contained a visible HSR. It is postulated that the amplified unit in the other cell line is so short that even a 50-fold reiteration does not make it visible. Similar consideration may be applied to the visualization of DMs. The chromosomal fragments are heterogeneous in size but routinely small and difficult to see. If a cell population has been selected for resistance to a high concentration of an inhibitor, amplification is extensive and DMs are more readily detected. During the initial steps of amplification, when resistance to relatively low concentrations of inhibitors is obtained, only a few DMs may be in any one cell, and visualizing them may be difficult.

The terms stable and unstable resistance are relative designations. Although cells that contain HSR's can lose the amplified gene copies when removed from selective pressure, this occurs at a much slower rate (months) than when amplified sequences reside on DMs (weeks).

What are HSRs and DMs? What is their molecular structure? Are the amplified sequences arranged in tandem configuration, in direct or inverted orientation? The first obstacle in characterizing the amplified unit derives from its large size. The DHFR gene, which is amplified to confer methotrexate resistance, is large: 31 kbp, including introns. The size of the amplified region is greater still. Gross estimates vary from 120 to 1000 kbp as the unit of DNA that is amplified. If one could analyze the end point or end points of the amplified units, information on the structure would emerge. Although the sequence of DNA that needs to be characterized is long, cloning of neighboring fragments (chromosomal walking) has been accomplished by several laboratories in both mouse and hamster models (106-108). The information derived from these endeavors has not provided the desired portrait of the amplified unit because of another obstacle. The amplified structure is continually changing at the molecular level in the chromosomal walking studies described previously. On each amplified cell studied, the amplified sequences correlate with the cloned map only up to a certain point and then diverge. Rearrangements of DNA accompany the amplification of genes, and the basic molecular DNA amplification is obscured by the dynamic aspect of the process. Karyotypic abnormalities are detected only in cells that are highly resistant to a given metabolic inhibitor (i.e., cells that have already progressed through much of the multistep process), although Hamlin and Montoya-Zavala found that the amplified DHFR gene in Chinese hamster ovary cells is uniform in size and exists in head-to-head and head-to-tail tandem repeats.

Recent studies in several laboratories have begun addressing the karyotypic abnormalities that are evident during the initial periods of selection for resistance. In contrast to classical studies on methotrexate drug resistance, where cells were grown for long periods of time in increasing concentrations of drug (stepwise selections), the recent studies are aimed at elucidating the initial molecular events of DNA amplification and have use a single-step selection with the drug. Cells resistant to these relatively low amounts of drug amplify the target sequence to a low extent, 5- to 10-fold (98, 99). DMs and HSRs that have this low copy number are difficult or impossible to detect. Small pieces of extrachromosomal DNA that are not visible with the light microscope have been reported (108-112). Several agents increase the incidence of DNA amplification. As the cells undergo the initial steps of DNA amplification within this period, other manifestations of chromosomal instability are observed, such as increases in the frequency of sister chromatid exchange, endoreduplication, and polyploidization. The production of extrachromosomal DNA has also been detected, but it is transient if selection pressure is not exerted on the cells. Pretreatment with hydroxyurea, ultraviolet light, or methotrexate itself increases the incidence of the initial amplification of the DHFR sequences (98-100). Similar observations were made using an **SV40**-transformed cell system to detect amplification of SV40 sequences (113) (see next section).

3.3. Genetic Instability

A third characteristic of methotrexate-resistant cells that have amplified the DHFR gene is the initial genetic instability of the resistant (amplified) phenotype, which is accompanied by a marked heterogeneity in the population. For example, Chinese hamster ovary cells were grown in 0.02 uM MTX and then analyzed for DHFR content by the FACS (114). The population of cells that emerged after the initial single-step selection showed a heterogeneous spectrum of DHFR content. Cloned cells from various portions of the spectrum were obtained and analyzed for homogeneity of DHFR content and stability of the elevated DHFR levels. CHO cells newly selected for methotrexate resistance are unstable with respect to DHFR levels, and the loss of the elevated DHFR levels was variable in the progeny of different cloned cells. This property of initial instability and heterogeneity is not to be confused with that described previously, in which stable and unstable resistance was associated with HSRs and DMs, respectively. The initial instability is observed in the newly selected population. When these cells are selected for a prolonged period in methotrexate, they have stable, elevated DHFR levels. During subsequent increases in the methotrexate concentration in the medium, the population becomes progressively more heterogeneous with respect to gene copy number. Once the initial increase in gene copy number has occurred, highly methotrexate-resistant populations are subsequently generated more rapidly. When the cells are grown for longer periods under fixed selection pressure (ie, at a constant methotrexate concentration) the population that emerges may contain either stable amplified genes or unstably amplified genes. The initial instability of the amplified DHFR genes in emerging, resistant CHO cells is consistent with the hypothesis that they are present as extrachromosomal pieces of DNA. Stabilization of the resistant phenotype could result from integration of these sequences into the chromosome at the site of amplification or elsewhere in the genome or could result from processes unknown now.

4. Frequency of Sporadic Amplification in Mammalian Cells

In the last few years it has become obvious that the frequency of gene amplification in different cells varies dramatically. Initially, gene amplification was measured in the models that were used to study the phenomenon, established rodent cell lines, such as S180, BHK cells, CHO cells, and 3T6 cells. The earliest type of measurement was colony formation in the presence of a given amount of cytotoxic drug, the clonogenic assay. Resistant colonies that emerged were analyzed for gene copy number. Although a critique of the various methods to measure gene amplification is beyond the scope of this review, it is important to note that the degree of stringency (concentration of the drug) is directly related to the extent of gene amplification. Therefore, incidence calculations that result from selections performed at different stringencies cannot be compared. Reported values for the rodent model systems were 10^{-6} to 10^{-4}. In 1983, Johnston et al. (95), used the flow cytometer and fluoresceinated methotrexate to analyze the emergence of cells that contain elevated DHFR enzyme content from a population that was not under selective pressure. They termed this the “spontaneous” rate of DHFR gene amplification. The emergence of individual cells that have elevated DHFR content was surprisingly high and varied considerably between clones (95). This frequency (10^{-3}) is high, especially when compared with the incidence at which methotrexate resistant colonies emerge (10^{-5}) when measured by the clonogenic assay. In a third method, (119) the entire population of cells was exposed to a stepwise selection and the populations were monitored for the appearance of subpopulations resistant to given concentrations of drug within a given time. All of these methods used rodent cell lines and concluded that amplification could occur at incidences of 10^{-6} or 10^{-4}, or rates that approached 10^{-3} events/cell/generation.

In the 1980s, studies of the frequency of gene amplification took three major directions. One approach was to study the effect of genomic position on amplification, the second was to measure amplification in different cell types and physiological states, and the third sought to identify agents that could increase the frequency of amplification.

4.1. Positional Effects

In an elegant set of experiments, Wahl et al. (116) developed a system to measure the increase in gene copy number of a specified marker placed in different locations in the genome. A CAD minigene was constructed and transfected into a Urd- hamster cell line. They found that the incidence of CAD minigene amplification varied from 10^{-3} to 10^{-3} and that the frequency was heritable. A parallel system (117) produced similar results by transfecting a DHFR minigene into a $DHFR^{-}$ cell line. Both studies concluded that the incidence of gene amplification is influenced by sequences or structures within the genome. Subsequent studies in the Wahl laboratory centered on identifying the *cis*-acting sequences that influence the frequency of gene amplification.

4.2. Nontransformed Versus Transformed Cells

In a second approach, several laboratories have begun examining the incidence of gene amplification in different cell populations. Early results, using the stepwise selection of nonturmorigenic and tumorigenic populations of CHEF cells, suggested that tumorigenic cells could amplify more rapidly than nonturmorigenic cells (115). More recently, using the clonogenic assay at defined stringencies of selection, Otto et al. (118) found a difference in the incidence of amplification between nontumorigenic and tumorigenic cell lines. In both studies, sample size was small (three and six cell lines, respectively), but extending these studies, using the clonogenic assay, to greater than 60 cell lines confirmed that generally highly tumorigenic cells amplify at a greater frequency than nontumorigenic cells. The correlation between assayed tumorigenicity and gene amplification is not strict however, and identification of the variables that help define these frequencies awaits further experimentation.

To date, most studies of gene amplification have used immortalized cell lines and biopsied tumor samples. In two studies, however, the amplification potentials of primary diploid cells, both human and rodent, were examined and compared quantitatively to the amplification potentials of their transformed counterparts. Strikingly, the difference in amplification incidence between "normal" cells and their transformed counterparts (in some cases tumorigenic) is immense (119, 120). The amplification potential was measured at two loci, the CAD gene and the DHFR gene. Quantitative data for both normal ($<2\times10^{-8}$) and transformed cell lines (10^{-4}) indicated a difference in frequency greater than four orders of magnitude (120). In one study, the generation of oubain resistance in both diploid and tumorigenic human cell lines was also measured to control for the ability to detect mutants. Although the rates of generating point mutations were identical, the generation of gene amplification at the CAD locus differed by at least four orders of magnitude. These studies suggest that there is some fundamental difference between normal cells and transformed cells that affects their ability to amplify.

In summary, these studies indicate that diploid cells lack a detectable frequency of gene amplification, whereas tumorigenic cells readily amplify DNA sequences. Present studies are designed to determine when the ability to amplify is acquired in converting a normal cell to a **neoplastic** cell and to isolate those molecular factors that regulate the process.

4.3. Enhancement of Amplification

When studies were initiated to identify agents that could increase the frequency of gene amplification, it was estimated that amplification in the rodent model systems occurs in one out of every 10^{5} cells. This is a very infrequent event if one wants to use biochemical or molecular techniques. The literature suggested that treatment of mammalian cells with carcinogenesis leads, among other things, to the production of HSRs and DMs (121). Because these two chromosomal abnormalities are linked to amplified genes, it was logical to test the possibility that treating mammalian cells with carcinogens could cause gene amplification. Studies with prototypical carcinogenic agents, such as UV light and chemical carcinogens, demonstrated that the incidence of gene amplification is increased by pretreatment with these agents (99, 122, 123). Other treatments, metabolic inhibitors, transient inhibitors of DNA synthesis, and hypoxia, could also increase the frequency of gene amplification (see Ref. 4 for a review). Most of these studies used the endogenous DHFR gene as a marker, but some also used other gene loci. In one study, MTX resistance, PALA resistance, and 5-fluorouridine resistance were cell be enhanced by treatment with ara-C, indicating that enhancement of gene amplification is not confined to the DHFR locus (124). Viral sequences also undergo amplification that is enhanced by pretreatment with carcinogenic agents. Lavi and co-workers (113, 125) observed dramatic increases in viral sequences after the cells were treated with agents, such as benzopyrene, aflatoxin, methlymethane sulfonate or a host of other carcinogens. The extent of enhanced of amplification ranged from a few fold to thousandfold. The basis for the enhanced gene amplification by carcinogen pretreatment is not yet known.

5. Considerations for Carcinogenesis

Carcinogenesis is believed to be a disruption of the homeostatic processes that control cell growth. The oncogenes identified to date contribute to this interpretation. Abnormalities in quantity or quality of growth factors, growth factor receptors, signal transducers, and proteins that control entry into the cell cycle have each been implicated in the genesis of neoplastic transformation. In addition, inactivation of those gene products that limit growth are also involved. These **tumor suppressor** activities contribute to the delicate balance that allows cells to grow when needed (tissue replacement, wound healing, etc.) and prevent cell growth when it is unneeded (terminal differentiation, senescence) (8). Mutations in each (or a combination) of these genes accumulates and results in progressive tumorigenicity. Continued accumulation of mutations allow the cells to acquire metastatic properties, such as invasiveness, angiogenesis, and drug resistance. Independent occurrences of these mutations allow tumor formation through alternate pathways (126). The process is believed to be multistep.

Gene amplification can be implicated in carcinogenesis in several different ways. Perhaps the most straightforward connection is the resulting drug resistance that occurs when detoxifying enzymes are overproduced, which is how gene amplification was discovered. The development of drug resistance remains one of the primary problems in fighting neoplasia. Obviously, elimination of drug resistance would do a great deal toward managing the disease. Experiments with tissue culture cells have shown us that a wide variety of loci may be amplified in mammalian cells. The amplification is usually manifested as an overproduction of the protein product that is targeted by the chemotherapeutic agent. Luria–Delbruck fluctuation analysis has demonstrated that amplification occurs spontaneously at a constant rate. It is the selective environment that allows them to be visualized. A study has compared the amplification rate in nontumorigenic and tumorigenic cells and found that the tumorigenic cells amplified the endogenous locus 100 times more than the nontumorigenic cell line (127). Restrictions on the loci that spontaneously amplify have not been encountered. Studies have also shown that more than one locus can be amplified at the same time (108).

The second connection between gene amplification and carcinogenesis involves the HSRs and DMs that have been observed in tumor cells for decades (121). Manifestations of gene amplification, HSRs and DMs have been widely reported in human tumor biopsy samples. Molecular studies have show that in many instances the genes amplified are oncogenes (97). It is assumed that the amplified oncogenes confer a growth advantage on the tumor cells that contain them. In some cases, amplification of specific genes correlates with the progression of some neoplasias. Seeger and Brodeur reported an increased extent and frequency of N-myc amplification in late stage neuroblastomas compared to early stage neuroblastomas. In this disease, the amplification of N-myc is used as a prognostic indicator for the severity of the disease. A similar story is emerging for the neu oncogene and its amplification in breast and ovarian cancer. A major unanswered question in the field of gene amplification is whether a nontransformed cell can ever undergo gene amplification or whether this type of genetic alteration is reserved for transformed cells alone.

The third implication of gene amplification in carcinogenesis relates to its nature. Gene amplification is a type of genetic rearrangement that (in mammals) is found only in tumor cells. Nowell (128) proposed a cellular scenario that accounts for the majority of observations made concerning neoplasia. He hypothesized that (at least in some cases) an early step in this process could be the acquisition of “genetic instability” (128). As the population of cells expands and generates a plethora of heterogeneous cells, subpopulations would emerge from the selective environment in the host and become the substrate for further change. This process could lead to the evolution of a cell population that is well suited to growth in the host tissue and can acquire the molecular characteristics that would lead to malignancy.

Nowell based his hypothesis on several pointed observations: (1) Oftimes, the karyotype of tumorigenic cells is abnormal. Rearrangements, such as deletions, aneuploidy, translocations, and homogeneously staining regions (HSRs) and double minute (DMs) chromosomes (known manifestations of gene amplification) are common. It is often easy to detect changes from the original karyotype. (2) Once a tumorigenic subpopulation emerges, further karyotypic changes are common. If Nowell's hypothesis is correct, elucidation of the molecular mechanism that underlies the continual change could provide a pivotal piece of information in our studies to understand the neoplastic process. To approach this question one could measure one or several of the types of genomic rearrangements that are detected in tumor cells. The hypothesis predicts that normal or nontransformed cells should display this abnormality at a lower frequency (or rate) than tumorigenic cells. This hypothesis has been addressed using gene amplification as the molecular marker for “genetic instability” (115, 118, 120) and, as indicated before, a vast difference in amplification ability exists. These results are consistent with the Nowell hypothesis. In two cases, deletion formation and recombination with an exogenous piece of DNA (Finn et al., 1989), the genetic rearrangement is more common in tumor cells.

6. Summary

The literature suggests that when gene amplification occurs in “normal” tissues, it is developmentally regulated. This evidence is compiled mostly from studies on *Xenopus* and *Drosophila* (see previous section). In higher organisms, the documentation of gene amplification as a developmental event is lacking. At present, we do not know if gene amplification can be developmentally programmed in mammalian cells.

Sporadic amplification occurs in unicellular organisms, such as bacteria and yeast, but it is lacking in the normal somatic tissues of higher eukaryotes. Several reports of sporadic amplification in the germ line cells of several organisms have been reported and shown to be heritable. In all of these cases, the phenotype demonstrated increased resistance to an environmental toxin (64, 65, 129). The extensive documentation of sporadic amplification in neoplastic tissues raises questions about when the neoplastic cell acquires the ability to amplify. Are the changes that initiate neoplasia the same that initiate the ability to amplify? In this regard, the stimulation of gene amplification by agents that cause cancer becomes an important observation. An insult, such as UV light, can initiate cells into the process that leads to tumor formation. Likewise, the same event can initiate and increase amplification frequency in transformed cells. Can these same agents cause gene amplification in “normal” diploid cells? These and similar questions must be answered before we can determine the extent of contributions that gene amplification holds for carcinogenesis.

Gene Cluster

In many cases, functionally related **genes**, each of which codes for a separate protein, are clustered physically on a chromosome in a *gene cluster*. In **bacteria**, the **gene expression** of all members of the cluster can be under the control of a single **promoter**, and a single **operator** controls their expression. This operator and the accompanying cluster of structural genes constitute an integrated topological and functional unit, known as an operon.

In **eukaryotes**, related genes produced by gene duplication are often found clustered on a chromosome. The clusters can be rather complex, ranging from two or a few adjacent related genes, as in the case of the **apolipoprotein** A-1-III and A-IV genes on human chromosome 11, to a tandem array of several hundred identical genes. Well-studied cases of clustering include the genes for globins, the major histocompatibility complex, and **homeotic** proteins. The members of the cluster may acquire slightly different functions or are used in different stages of development, such as fetal and adult hemoglobins.

Gene Dosage

Gene dosage refers to the number of copies of a given **gene** in a cell or in a nucleus. An increase in the gene dosage may result in the production of a higher level of the product of that gene, unless the gene is subject to autonomous regulation. Where sexes differ in the number of sex chromosomes, a dosage compensation effect may keep the levels of expression similar.

Gene Duplication

Gene duplication is the creation of a copy of a **gene** within the (Fig. 1). Genes can be duplicated through several types of mechanisms. Among these are random **breakage and reunion**, **unequal crossing over** (Fig. 2), **retrotransposition** and over**replication**. Gene duplication is a major source of functional genetic diversity. This diversity is achieved through the divergence and the acquisition of new functions of the copies over time (Fig. 1).

Figure 1. Gene duplication. A duplicated copy can acquire a new function or become a pseudogene.

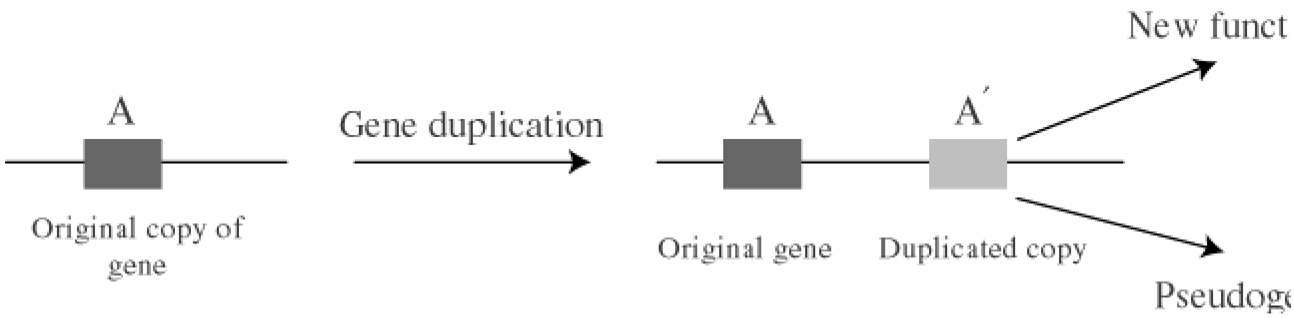

Figure 2. Creation of a gene family through gene duplication by unequal crossing-over.

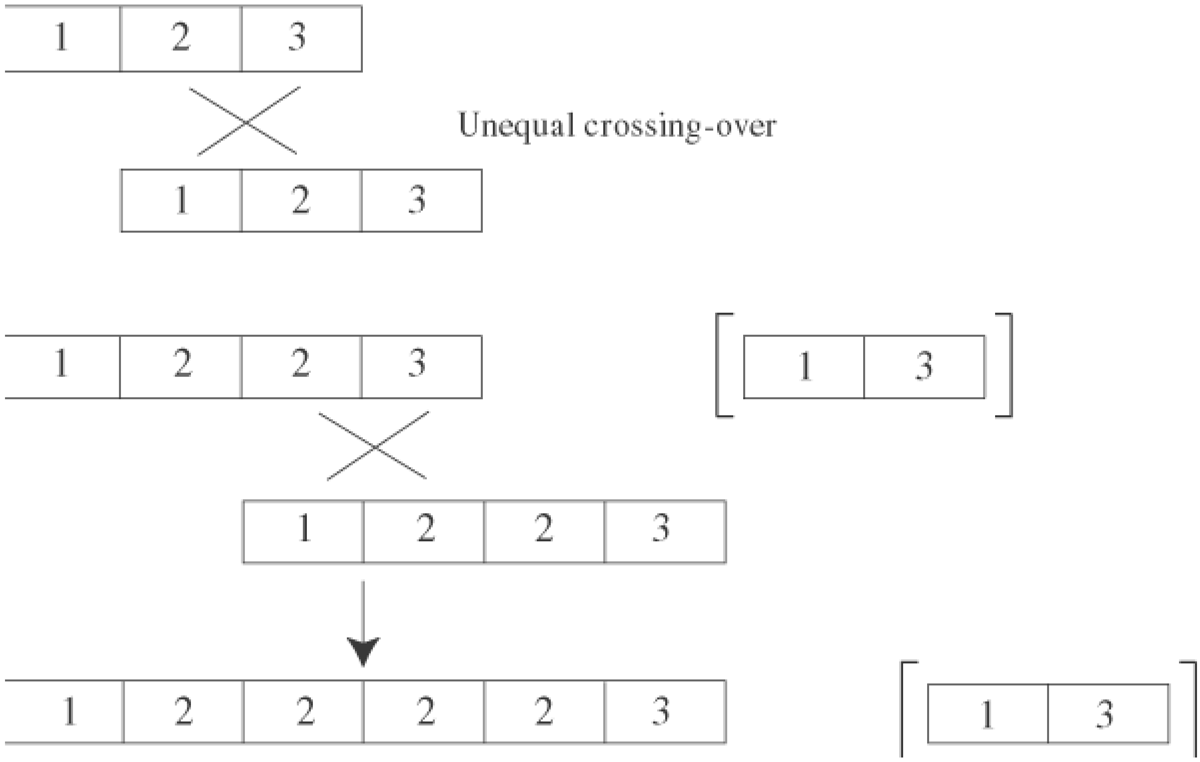
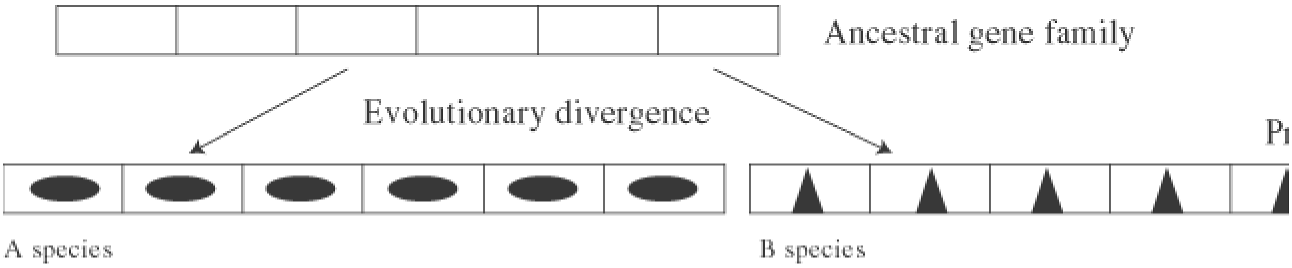


Duplication can involve either genes or , as well as entire , and be either complete or partial. Both genome duplication and gene duplication have been important in evolution. Such duplication generates a related set of genes, or , enabling an increase of genomic diversity by creating new gene functions. It is well known that the genome contains a variety of gene families in a repeated or scattered fashion. These gene families are considered to have emerged evolutionarily from their ancestral form through gene duplication (Fig. 3). Once gene duplication has taken place by unequal crossing over of one chromosome, the other chromosome may lack certain sets of genes. Therefore, it follows that the number of gene members within a particular gene family may have changed during evolution, both increasing and decreasing.

Figure 3. Concerted evolution in gene families of species A and B.



Once a particular nucleotide sustitution takes place in a given gene member, the gene member can pr within the gene family through gene duplication during evolution. When gene duplication takes plac unequal crossing over, propagation of a particular gene member within the gene family in a species i than the evolutionary divergence of the gene families between different species. In this case, the sim different gene members within a given gene family in the same species becomes greater than that be corresponding gene families in different species (Fig. 3). This type of evolution is called "concerted'

Pseudgenes are often created after gene duplication (2). Pseudogenes are dead genes in which a cop gene becomes non-functional due to a mutation-causing malfunction in the DNA sequence (Fig. 1). gene family contains a number of pseudogenes. This is also the case for the **major histocompatibili** gene family. Ohno (3) proposed that one copy of a gene duplication can enjoy the freedom to acquir that differs from the original gene. The original gene can keep its function, even if the counterpart be pseudogene. This theory implies that gene duplication can be an important source of providing new genome.

As the projects for sequencing entire genomes advance, the evolution of genome structure is starting particular attention. It is known that genome size has frequently increased as organisms have evolve increase in genome size, two major alternative hypotheses have been proposed: the genome gradual which asserts that the genome size increased due to the addition of new genes created by gene duplic "genome duplication theory," which contends that the entire genome has been duplicated, resulting i almost doubling in size. Although deletions occur in a part of the genome, the change of gene numbe taken place over an extended period of time.

Gene Families

Gene families are groups of **genes** with similar sequences that have been derived from a common evolutionary ancestor. Many of the structural genes in eukaryotes are members of gene families. The number of members in a gene family can range from two to hundreds of thousands per . For example, the family has more than 500,000 copies, displaying only minor variation in their nucleotide sequences. A genome can contain hundreds of gene families, and members of a family can be either scattered over several chromosomes or clustered together on a single chromosome.

The multiple genes of a family would be expected to evolve independently. In this case, copies within a species should have the same amount of divergence as those among different species. Those within a species are usually more homogeneous, however, implying that gene family members within a species are not evolving independently and that the family members within a particular species have descended from a common ancestor after species divergence. This would suggest that there are mechanisms for maintaining homogeneity among gene family members. These mechanisms appear to be , **unequal crossing over**, and **gene conversion**. The evolution of gene families through these mechanisms is called concerted evolution. (See).

Research in the area of gene families focuses on questions such as how the copy number of members changes during evolution and how these copies move to different locations. Further research interest in this area includes investigating the effect of copy number changes on gene diversity and identifying what mechanisms preserve similarity among family members (1).

The evolutionary importance of gene families depends heavily on their specific function. In the case of **ribosomal** RNA (rRNA) gene families, for example, it is known that the gene members are highly homogeneous (Fig. 1) (2). This can be explained by the fact that of genes requires a functional ribosome. Thus, all the many gene members in this family are preserved to be highly homogeneous during evolution (3). On the other hand, the form a gene family but are known not to be homogeneous, but relatively heterogeneous. The homeotic genes are directly involved in the control of genes related to the development of organisms. In the case of mammalian homeotic gene families, a single Hox gene cluster generally contains 13 genes, and this gene cluster is repeated four times (3). The nucleotide sequences of all gene members are not homogeneous except a small portion (about 60 codons) of the gene called a **homeobox** (Fig. 2) (5). The heterogeneity among the gene members in this family is due to each gene having a specialized role in their cascade to control the development of organisms.

Gene Fusion

Gene fusion is a phenomenon in which two different **genes**, or parts of the genes, are fused to each other during evolution, resulting in the creation of a new gene. When two particular genes are compared between two species, they can be fused in one species and separate in the other. To say with certainty that a gene is a fused gene, the separate genes should be identified as being the ancestral form by careful examination.

Unequal crossing over may be one of the molecular mechanisms for causing gene fusion by eliminating chromosomal material between two formerly separate genes. For example, the union in fungi between A and B components of the tryptophan synthetase enzyme (see Operons), which are normally separate in bacteria, is believed to have occurred through such gene fusion events (Fig. 1) (1).

Figure 1. The gene fusion event of A and B components on tryptophan synthetase gene (1).

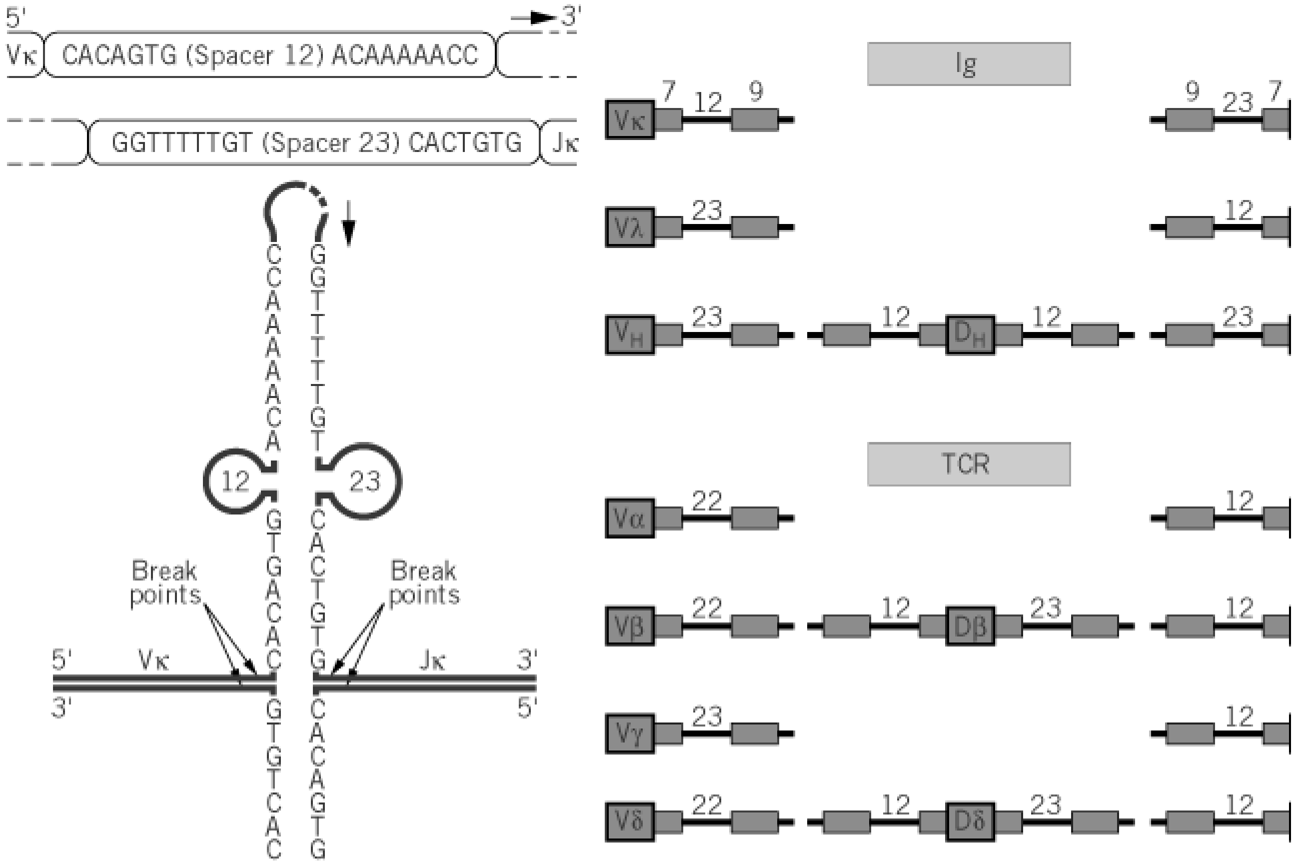
Gene Rearrangement

The unique feature of immunoglobulin gene organization is that these genes need to be rearranged before becoming functional. These rearrangements allow the immune system to generate a very large repertoire by recombination and random association of a limited number of gene segments (ie, between 200 and 300 in humans), leading to at least 10 million discrete immunoglobulins having different specificities. In the light chains, the **variable region** results from the random association of VL (Vk or Vl) and JL (Jk or Jl) genes. The heavy chains are more complex, because their diversity results from the random association of VH, D, and JH genes. Immunoglobulin genes are rearranged exclusively in the **B-cell** lineage, and these events constitute the hallmark of the B-cell differentiation in the bone marrow. Similarly, genes for the T-cell receptor (TCR) rearrange exclusively in T cells by a very similar process. Ig gene rearrangements require precise signals on the DNA, known as *recombination signal sequences* or (RSSs), that flank each of the V, D, and J gene segments and are recognized by highly specific recombinases encoded by two genes, termed RAG1 and RAG2 (for recombinase activating genes). RSSs consist of two **palindromic** sequences that are highly conserved, although not identical, between the different loci; one is a heptamer and one is a nonamer, separated by a spacer region 12 or 23 nucleotides long (Fig. 1). The two RSSs that participate to a given joint have always spacers of different lengths.

Figure 1. Recombination signal sequences of Ig and TCR genes. (**a**) The 3′ end of a Vk gene is followed by an RSS tha complementary to RSS 5′ of the Jk gene onto which Vk will be connected by the recombinase. (**b**) Schematic organizatic of the RSS in Ig and TCR genes.



The first recombination event, DH to JH, takes place in the early proB cells and is rapidly followed by the rearrangement of one of the VH segments to D-J. Another enzyme, terminal deoxynucleotidyl-transferase, is also active in proB cells and adds nucleotides in a random fashion during the joining of D to J and of V to D-J rearrangements. Addition of these non-germline-encoded nucleotides is known as N-diversity and considerably amplifies the repertoire, because both the sequence and length of VH and VL complementarity-determining region 3 (CDR3) are modified by this mechanism. Rearrangements are strictly regulated by their end product—that is, the chain they encode once they become functional. Thus, once a m chain is synthesized, it will block the rearrangement of the second IGVH allele. This requires that the m chain be expressed as a membrane protein (mm). In a mouse rendered transgenic for a membrane VDJ-Cm chain gene, endogenous rearrangements at the IGVH locus are blocked, so that B cells will make only the transgenic m. When the same experiment is performed with a VDJ-Cm gene without the M exons (thereby encoding only the soluble form of the m chain), endogenous rearrangements are no longer blocked. The fact that m regulates rearrangement only when expressed as mm strongly suggests that it operates at the cell surface. In fact, mm is coexpressed with the so-called surrogate light chain, composed of the product of two genes, l5 and VpreB, and expressed specifically in proB and preB cells (see B Cell). l5 is highly **homologous** to l and is **disulfide-bonded** to the m chain by its penultimate cysteine residue, whereas VpreB resembles a V Ig domain. The surrogate light chain (YL) has been shown to contribute efficiently to the regulation of allelic exclusion. The negative feedback that prevents the second allele from rearranging is probably a consequence of the turning off of the terminal deoxynucleotidyl-transferase and RAG genes. The RAG genes, but not the transferase, are reactivated as the preB cells cycle and induce light-chain gene rearrangement, with the same hierarchy of control on the second allele whenever the first has rearranged. The IgK locus is activated first. If both k alleles fail to produce a functional rearrangement, the IGL enters the game, with the same type of control. Finally it should be observed that the overall process of rearrangement is not very efficient, with only about 10% final success. This is obviously the price to pay for the complexity and partial randomness of the system.

Once both H and L genes have successfully rearranged, the resulting immunoglobulin is expressed at the B-cell surface. When stimulated by an antigen, specific clones proliferate and colonize the secondary lymphoid organs (lymph nodes, tonsils, spleen, etc.), where they become organized in germinal centers, in close contact with other partners of the immune response (ie, dendritic cells and T cells). Contact with T helper (Th) cells will promote the last step of gene rearrangement, called *isotype switching*, by which the VDJ gene region will be associated with a new constant heavy-chain gene. The classical most frequent switch that occurs in immune responses is IgM → IgG. A schematic example of all the rearrangements that lead to the production of an IgG molecule is given in Figure 2.

Figure 2. Rearrangement events that lead from Ig germline genes to synthesis of IgM and IgG molecules in the mouse model. Recombination first occurs at the IGVH locus, to generate a V(D)J combination (here chosen as VHn–D3–JH4) that is transcribed with Cm and processed as a m mRNA, resulting in the expression of a m chain that will associate with k chain (here Vk1–Jk2–Ck) that results from the second wave of rearrangement targeted at the IGVK locus. IgM is first expressed as a monomer at the cell surface of immature B cell (not shown). After antigenic stimulation, the pentameric form of IgM antibody is secreted by plasma cells and is rapidly replaced by an IgG (here IgG2a), which occurs by class switching (second line from bottom). Note that the switch will not change the VDJ region, so the antibody specificity is maintained.

Gene Recruitment

Gene recruitment is a phenomenon in which a particular **gene** becomes used during evolution as a gene with a totally different function. The term “gene recruitment” was coined because a gene has evolved as if it had been recruited to exhibit a different or another function. The most remarkable example of gene recruitment occurs with the crystallin genes (Table 1). Most of the crystallin genes that are expressed in the eye were found to be expressed in other tissues as enzymes. The exact same gene is expressed and used as a structural protein in one tissue, whereas it is expressed as an enzyme in other tissues. It is now thought that the enzymatic form of this protein should be considered to be the ancestral form and that it became a crystallin by gene recruitment. It seems that change of tissue specificity of gene expression is a prerequisite for gene recruitment.

Table 1. Eye crystallins and Their Relationships to Enzymes and Stress Proteins (1)

Crystallin	Distribution	[Related] or Identical
	Ubiquitous Stress Crystallins	
		Small heat shock proteins (aB)
a	All vertebrates

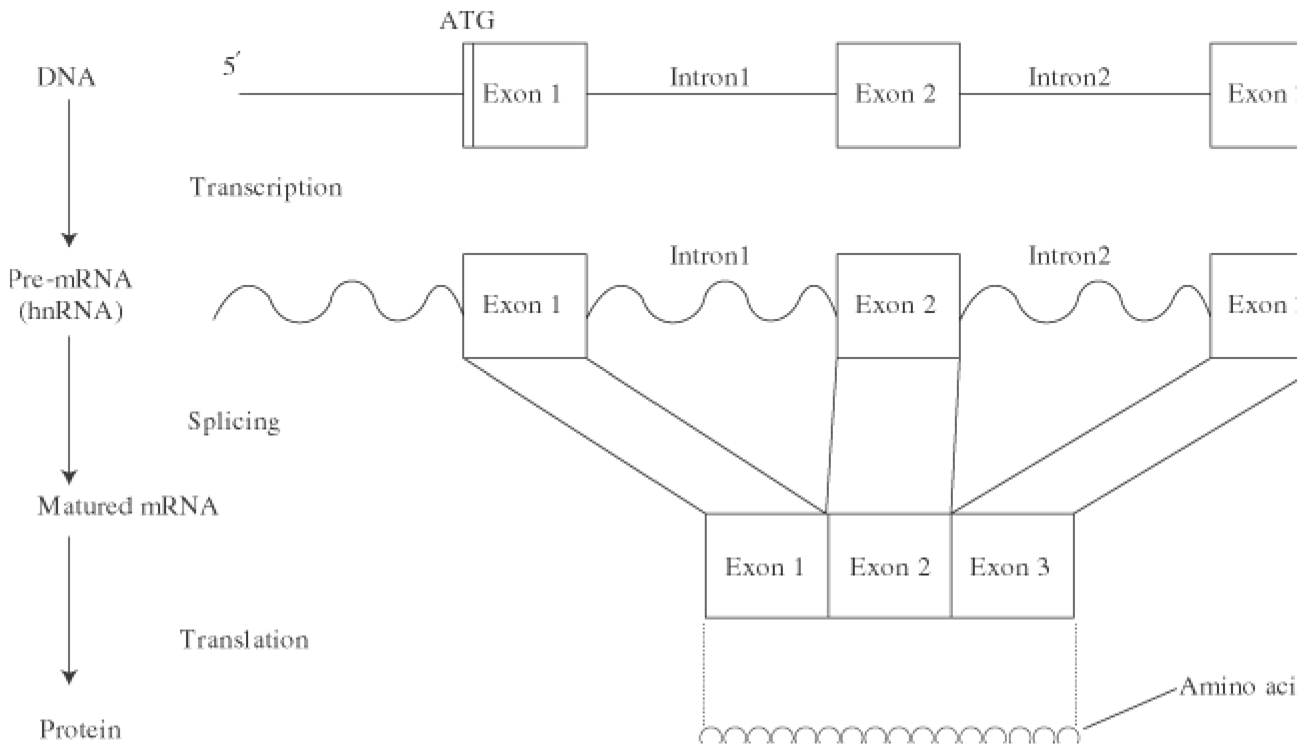
Gene Splicing

Many eukaryotic **genes** are split into a number of exons by the existence of **introns**. Gilbert coined the terms "exons" and "introns" in 1978 (1). As shown in Figure 1, (see top of next page) the human a globin gene is split into three exons by two introns. To produce the appropriate messenger RNA, introns must be removed to generate a proper collection of linked exons through gene splicing; as it occurs in the mRNA, it is commonly called RNA splicing. Therefore, in the case of eukaryotic genes, the essential information flow will be as follows; from DNA to mRNA precursor by transcription, from precursor mRNA to mature mRNA by RNA splicing, and from mature mRNA to protein by translation

Figure 1. Gene splicing steps in the production of mature eukaryotic mRNA as illustrated for the human a-hemoglobin g
Gene Splicing).



As for the evolutionary significance of the exon–intron structures of genes, the "exon shuffling" theory was proposed by Gilbert (1). He claimed that a variety of genes on the genome have been created by the shuffling and exchange of exons among different genes (1) (see Exon Shuffling). As introns do not possess any apparent function, it is considered that they are used as locations for genetic recombination. Thus, frequent shuffling of exons may have been major forces of gene evolution in eukaryotic organisms. There has, however, been some opposition to the "exon shuffling" theory. For example, the "domain shuffling" theory contends that the unit of shuffling is not an exon but a functional **domain** of a protein that may not correspond exactly to an exon (2). In fact, it is known that the Kringle domain, which is a characteristic supersecondary structure in some serine proteinases, was shuffled many times, and always as a unit, even though the Kringle domain consists of three exons (3).

With only a few exceptions, on the other hand, it is well known that prokaryotic genomes do not contain introns. If an intron is considered to have existed before the **divergence** between eukaryotes and prokaryotes, the splicing mechanism should also have existed for a long time since the early stages of evolution. This is the "early-intron" theory. On the contrary, the "late-intron" theory claims that introns have been inserted as **transposon**-like elements into various genes after the divergence of eukaryotes and prokaryotes. The evolutionary significance of gene splicing depends on which theory is correct.

Gene Structure

A *gene* is widely understood as the fundamental unit of genetic information, but a detailed description of a gene is not straightforward.

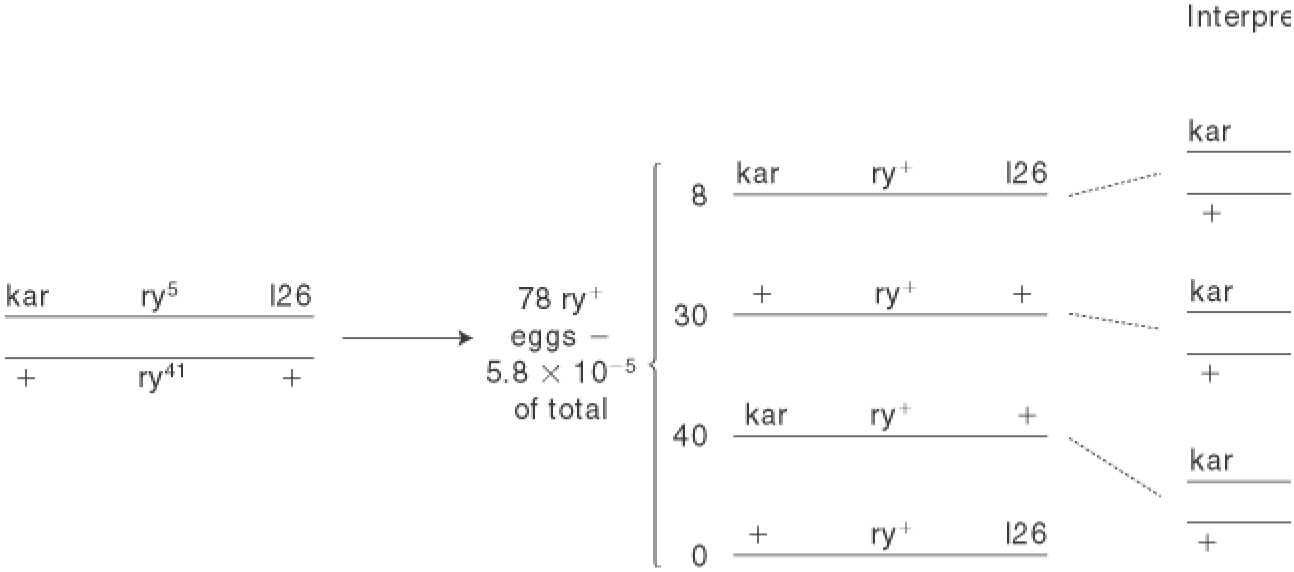
1. Intragenic Recombination and Colinearity with Polypeptide Chain

The first step in elucidating the structure of the *gene* was recognizing that it is subdivisible into linearly arranged, individually mutable sites. Until the 1950s it was assumed that genes are both units of function and indivisible units of genetic transmission. The functional criterion for different mutants affected in the same gene, that is **allelic**, was that, when brought together in a **heterozygote** or heterokaryon, they could not make good each other's deficiencies to produce a nonmutant **phenotype**. This criterion is still a good general guide, although, as detailed under Interallelic Complementation, there are circumstances in which it fails. The indivisibility criterion meant that two different mutant alleles of the same gene should not be able to **recombine** to yield a **wild-type** allele. This was sustainable only as long as only moderate numbers of meiotic segregants from heteroallelic **diploids** were screened.

In the fruit fly *Drosophila melanogaster*, M. M Green, working with the *lozenge* gene, and E. B. Lewis, with different genes, including *white*, demonstrated rare crossing over between mutants previously thought to be allelic and dubbed these recombining mutants *pseudoallelic* (1). Then Pontecorvo and his colleagues found that the sexually reproducing fungus *Aspergillus nidulans* produces wild-type recombinants from crosses between several pairs of alleles, with a frequency on the order of 1 in 10,000, and challenged the idea of pseudoallelism, thinking it likely that mutual recombinability is a typical feature of mutants that are allelic in the functional sense. This view was strengthened by Benzer's analysis of hundreds of mutations within the *rII* gene of **bacteriophage** T4, in which he showed that very nearly all pairwise combinations of noncomplementing mutants would yield wild-type virus at some frequency from mixed infection of bacterial cells (2). It was rare for different mutations within the same functional gene to fall at exactly the same site and, when at different sites, they would recombine with one another. It was shown that the same principle holds for the bacteria, *Escherichia coli* and *Salmonella typhimurium*, where the method of analysis was mainly **transduction**, and in fungi and *Drosophila*, where recombination within genes occurred during **meiosis**. In the **yeast** *Saccharomyces cerevisiae* the frequency of intragenic meiotic recombination is unusually high, up to several per cent of meiotic products.

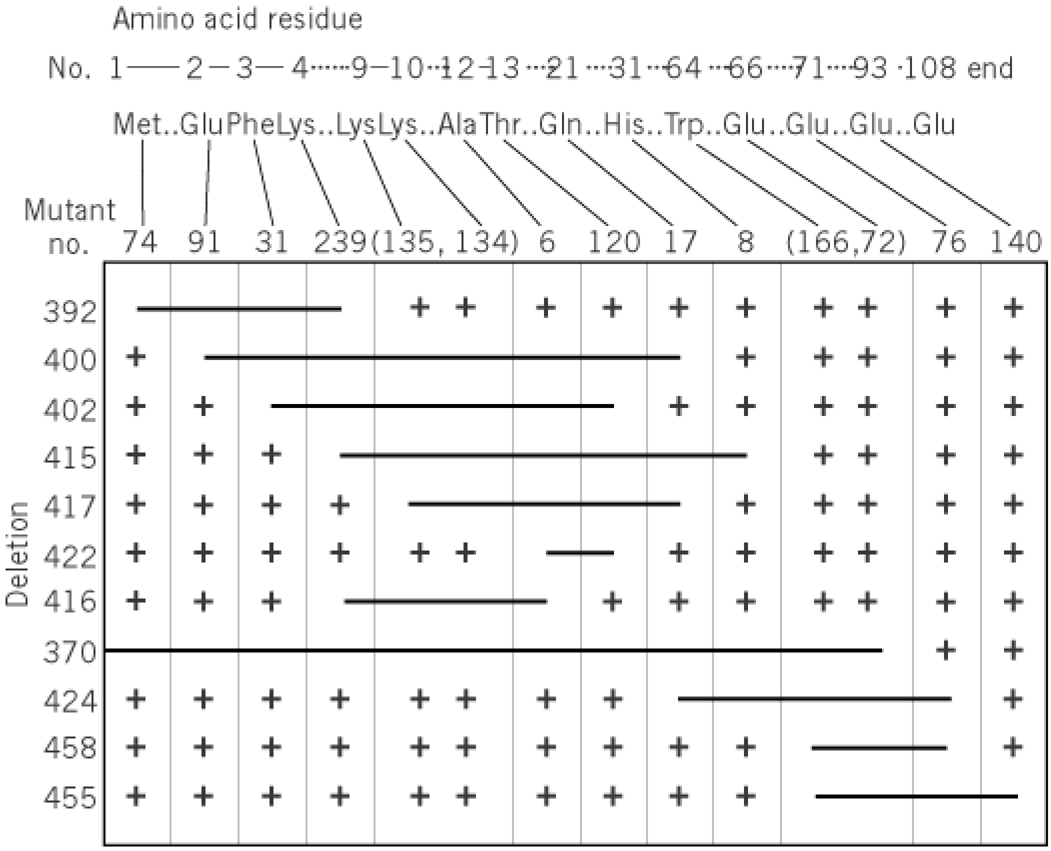
When recombination between allelic mutants was discovered, it became possible to map sites of mutation within a gene in a linear sequence. There are two general ways of doing this. The first uses flanking markers, gene differences that have visible effects (markers) closely placed on each side of the gene under analysis. If intragene recombination is due to classical **crossing over**, the flanking markers occur mainly in one or other of the two "crossed-over" combinations among wild-type interallelic recombination products, depending on which way the mutational sites are placed with respect to the flanking markers. Figure 1 shows an example from the analysis of the *Drosophila rosy* gene by Chovnick *et al.* (3).

Figure 1. Recombination within the *rosy* (*ry*) gene of *Drosophila*, which encodes xanthine dehydrogenase (XDH). Larva recombinant eggs from *ry5*/*ry41* (XDH–) females were automatically selected on purine-containing food, which kills XI parents contributed only mutant *ry*. The constitutions of the eggs with respect to mutations in closely placed flanking ger further test-crosses. The *ry*+ eggs not recombined for the flanking makers are presumed to be due to conversion of one o without crossing over. The high degree of association of 5–41 recombination with one flanking marker crossover class ir *l26*. Data from Ref. 3, whose analysis includes numerous *ry* mutant sites not shown here.



The second method, which gives clear results even when the recombination within the gene is due mainly to **gene conversion** without crossing over, relies on the principle of overlapping deletions. In any very extensive collection of allelic mutations, it is likely that some are due to deletion of segments of the gene, each of which overlaps several mutational sites and partly overlaps other deletions. No point mutation can recombine to form recombinants with a deletion that removes the corresponding nonmutant site, and neither do different deletions yield wild-type recombinants if they overlap. By crossing a suitable set of deletion mutants with each other and scoring the progeny for the presence versus absence of wild-type recombinants, one establishes the overlaps between the deletions, and then, by crossing the whole set to point mutations, localizes the mutational sites to one or other of the segments defined by the deletion overlaps. The method was first used by Benzer in his analysis of the T4 *rII* genes. An example from yeast, the *cyc-1* gene which encodes the protein of the respiratory pigment cytochrome ***c***, is explained in Fig. 2 (4).

Figure 2. Establishment of the sequence of mutant sites within the *Saccharomyces cerevisiae CYC1* gene that encodes cytochrome c. A set of overlapping deletion mutants were each tested for recombination with point mutants: + or – indicates whether or not wild-type recombinants were formed. The absence of recombinants means that the site of the point mutation falls within the segment deleted in the other parent. The deletion overlaps define the sequence of the mutant sites. The amino acid codon affected by each point mutation was determined biochemically. The sequence of codons corresponds to the sequence of mutant sites. From Ref. 4 by permission.

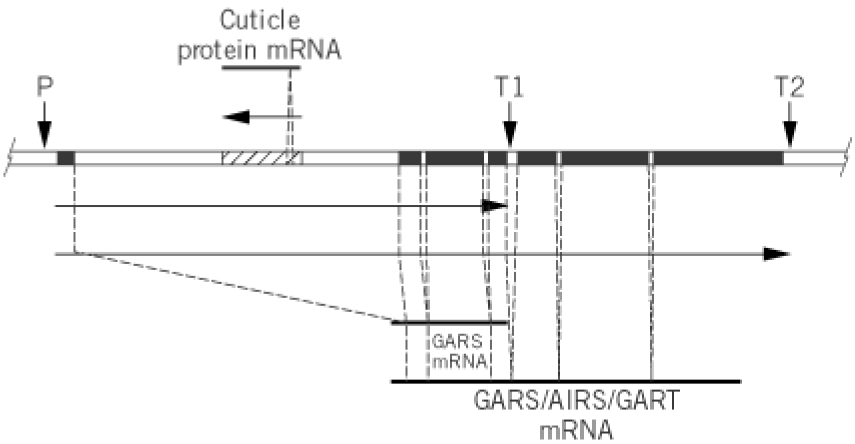


From this and many other examples, the gene emerged as a very finely subdivisible unit. Recognizing that the gene material is **DNA**, the concept, which still holds, is that every base pair of the DNA sequence is a potential site for mutation, separable from its neighboring nucleotides at some low frequency by recombination. Taken together with the idea that each gene is responsible for a single enzymic protein, which had emerged from the early *Neurospora* work, it was an obvious guess that the linear sequence of mutable and recombinable sites within the gene corresponds to the linear amino acid sequence of the polypeptide chain of the protein product.

Drosophia rosy (*ry*) and *Saccharomyces cyc-1* are particularly appropriate examples because their mutations affect well-characterized proteins, namely, the enzyme xanthine dehydrogenase in the first case and the protein of the respiratory pigment cytochrome *c* in the second. In both cases point mutations cause mostly single amino acid replacements in the polypeptide chain, and the sequence of the replacements along the polypeptide chain corresponds to the sequence of mutational sites along the gene map. The comparison is particularly extensive for yeast *cyc1* (Fig. 2). Numerous other examples could be given, and the principle, called *colinearity*, is so well established now in molecular biology that further substantiation through genetic mapping is hardly necessary. Genes, or at least those genes responsible for protein structure, are linear codes for the amino acid sequences of polypeptide chains with exceptions that are mentioned later. Parallel with examples of colinearity came the molecular identification of the gene as DNA, the demonstration of transcription of genic DNA into RNA, and the working out of the genetic **code** through which messenger RNA (mRNA) is **translated** into polypeptide sequence.

The original “one gene - one enzyme” concept was incomplete in several ways. The immediate products of genes are RNA molecules, not all of which are messengers for protein synthesis (e.g., **ribosomal, small nuclear** RNA, and transfer RNA), and not all proteins are enzymes. Among the enzymes, many are multifunctional, and one function can often be lost by mutation without eliminating other functions of the same polypeptide chain. As a result, analysis by mutation, complementation, and recombination may subdivide a gene into several functionally distinct domains, which may at first be confused with separate genes. A multifunctional, multidomain gene is sometimes called a *cluster gene*, to distinguish it from a gene cluster. Most of the known examples are in fungi, but they occur in *Drosophila* (eg, Fig. 3) and also in mammals. This sort of gene complexity is more extensively discussed under Interallelic Complementation.

Figure 3. The *Gart* gene of *Drosophila*, which exhibits several kinds of gene complexity: (1) an intron-exon structure (common to most *Drosophila* genes; introns are shown as open and exons as black segments); (2) the full-length mRNA encodes a trifunctional polypeptide that has three different enzymatic activities, abbreviated to GARS, AIRS, and GART, that catalyze successive steps in purine biosynthesis; (3) it has two polyadenylation/transcript termination sites, T1 and T2, one within the fourth intron resulting in a truncated mRNA that encodes only the functionally independent GARS domain; (4) it has a "nested" gene within its longest intron that encodes a cuticle protein and itself with an intron. From Ref. 11 by permission of the publisher, after Ref. 5.



2. Transcribed and Nontranscribed DNA Strands and the Minimal Gene

In writing about gene structure, it is useful to use the terms "*upstream*" and "*downstream* " to indicate orientation with respect to the direction of transcription of DNA into RNA. Only one strand of the DNA duplex is usually transcribed, and it is important to remember that the transcribed strand of a protein-encoding gene is not the *coding strand*, in the sense that the codon sequence is as seen in the messenger RNA, but rather the opposite-polarity complement of that sequence. The transcribed strand runs upstream-to-downstream in the chemical direction 3′ to 5′, whereas the mRNA and its amino acid codons run 5′ to 3′. To deduce the amino acid sequence from the transcribed strand using the standard codon tables (see Genetic Code), one must mentally convert it into its complement: A to U, T to A, G to C, and C to G. The amino acid sequence can be read directly from the nontranscribed strand, which is therefore often called the coding strand. It is best to distinguish the strands as transcribed or nontranscribed, bearing in mind that the sequence of the latter bears the immediately recognizable codons.

Once defined as a unit of transcription into RNA, the gene may be a relatively compact structure, at least when measured against more than 10^9 DNA base pairs in a typical mammalian genome or the even greater DNA contents (C-values) of some amphibia and higher plants. We can enumerate the essential components of a protein-encoding gene as follows. There must be a **promoter** segment to which **RNA polymerase** binds to initiate transcription a little way upstream of the transcription startpoint (with the exception that RNA polymerase III works with downstream promoters), and a transcription termination and polyadenylation signal. Within the transcribed region there are sequences corresponding to the different sections of the messenger transcript: an untranslated **leader sequence** (of various lengths in different genes and sometimes important for controlling translation), a ribosome binding site and initiation codon, an **open reading frame**, and a **termination codon**. The yeast *cyc1* gene (Fig. 2) is a good example of a simple gene.

3. Expansion of the Gene Beyond the Coding Sequence

To be transcribed into mRNA for polypeptide chains or other kinds of RNA molecule, genes need be no more than a few thousand base pairs (kilobase pairs or kbp) long. How, then is one to account for the apparently huge surplus of DNA in the genomes of many higher organisms? Humans, for example, have about 30 kb of DNA per gene if the current estimate of about 100,000 genes is correct. Part of the answer lies in the host of repetitive and arguably functionless sequences that have become established. But probably equally important quantitatively are the intervening sequences (**introns**) that subdivide the coding sequences into fragments (exons) that are **spliced** together, and the introns spliced out, after the gene has been transcribed. The sizes and numbers of introns vary widely among different organisms. They are hardly present at all in bacteria in only a few genes and then seldom more than a hundred bases long in yeast, more numerous but still short in filamentous fungi, sometimes much longer in *Drosophila*, and often both very numerous and extremely long in mammals. The typical mammalian gene consists of rather short exons, each on the order of only hundreds or even tens of base pairs, separated by introns extending up to tens of kilobases long. Thus a gene, whose function is to encode a polypeptide chain of just a few hundred amino acid residues, may be spread over a tract of some 100,000 base pairs.

In addition to introns, other sequences, which may fall some distance outside the units of transcription, have some claim to be considered parts of the gene and to expand its domain. Although enhancers may occur within introns, they are probably more often outside the transcribed gene sequence, often upstream but sometimes downstream. The same applies to **silencers**. Insofar as enhancer sequences are cis-acting, which they usually are, they may be considered as falling within the gene boundaries. If so, this may somewhat complicate the idea of the gene as a discrete functional unit if the same enhancer services two or more different transcriptional units. Thus, a single **locus control region**, an approximately 20-kbp sequence, not usually called an enhancer but at least some elements of which function as such, acts on all of the genes of the human b-globin gene cluster. Genes are also functionally linked through chromatin structure, changes in which repress or release the transcription of blocks of genes (see also Epigenetics, Position Effect).

4. Programmed Gene Restructuring

Although most genes in most organisms have constant DNA sequences, the same in the cells where they are transcribed as in the germ cells through which they are transmitted, there are examples of genes in a wide range of organisms that are restructured in the process of cellular differentiation. In unicellular organisms, bacteria, yeasts, and protozoa, where any cell can found a new population, gene restructuring is always reversible within the cell. Thus the switching of **flagellar** antigen in the bacterium *Salmonella typhimurium* is brought about by the inversion of a DNA segment with the effect of “switching off” one **antigen**-encoding gene by separating it from its promoter and thereby switching on another antigen gene of which the first antigen is a repressor (7). The inversion is reversible. In *Saccharomyces* yeast, the well-known **mating type** switch is due to replacing a segment of DNA at a transcriptionally activating site with a segment copied from another locus, where it had been transcriptionally silent. The potential for both mating types is held at silent “cassette” loci at all times, but only one mating type is expressed from the segment present at the activating (or, more correctly, nonsilencing) locus. Similar mating-type switching occurs in the fission yeast, *Schizosaccharomyces pombe*. A system not dissimilar in principle but with more options that again involves the transfer of gene sequences from silent to expressed loci, operates to switch the major surface antigen of the pathogenic protozoan ***Trypanosoma*** *brucei* (8).

In all the cases just mentioned, the potential for switching back to the status quo ante is retained within the cell nucleus. The situation is very different in ciliated protozoa, such as *Paramecium*, *Tetrahymena*, and *Oxytricha*, in which two kinds of nuclei are in the binucleate cells: a virtually "silent" ***micronucleus***, which contains the basic genetic material and has the potential for differentiation in different directions (e.g., to different mating types or different surface antigens) and an active **macronucleus**, in which a selection of genes is amplified and restructured to support a particular cell type. At meiosis, which generates haploid nuclei for sexual cross-fertilization or for a kind of self-fertilization called autogamy , the macronuclei degenerate and disappear and are replaced by division and restructuring of the micronuclei, with the opportunity for switching cell type. Some of the gene rearrangement seems quite bizarre. For example, in *Oxytricha trifallax*, a gene that encodes an actin protein whose exons are labeled 1 to 10, upstream-to-downstream in the macronucleus, was reshuffled from the order 3, 4, 6, 5, 7, 9, 10, 2, 1, 8 in the micronucleus (9).

Gene restructuring in mammals is the exception rather than the rule, but is centrally important in the immune system. The functional genes for the virtually infinitely large number of different immunoglobulins and T-cell receptor proteins are pieced together in a large number of possible permutations from DNA segments that are separated by hundreds of kilobases in undifferentiated stem cells. Note that the nucleic acid splicing involved here occurs at the level of DNA, not RNA as in splicing-out of introns. This topic is dealt with in more detail under Complex Loci, Immunoglobulins, and T-cell receptor.

A different category of incomplete genes are those made functional not by rearrangement at the DNA level but by splicing their RNA transcripts to leader sequences provided by what might be called supplementary genes elsewhere in the genome. Many or most messenger RNAs in the **Trypanosomes** acquire leader sequences and cap sites in this way (10). Something similar occurs in nematodes, and such systems may be widespread in the less well explored "lower" eukaryotes.

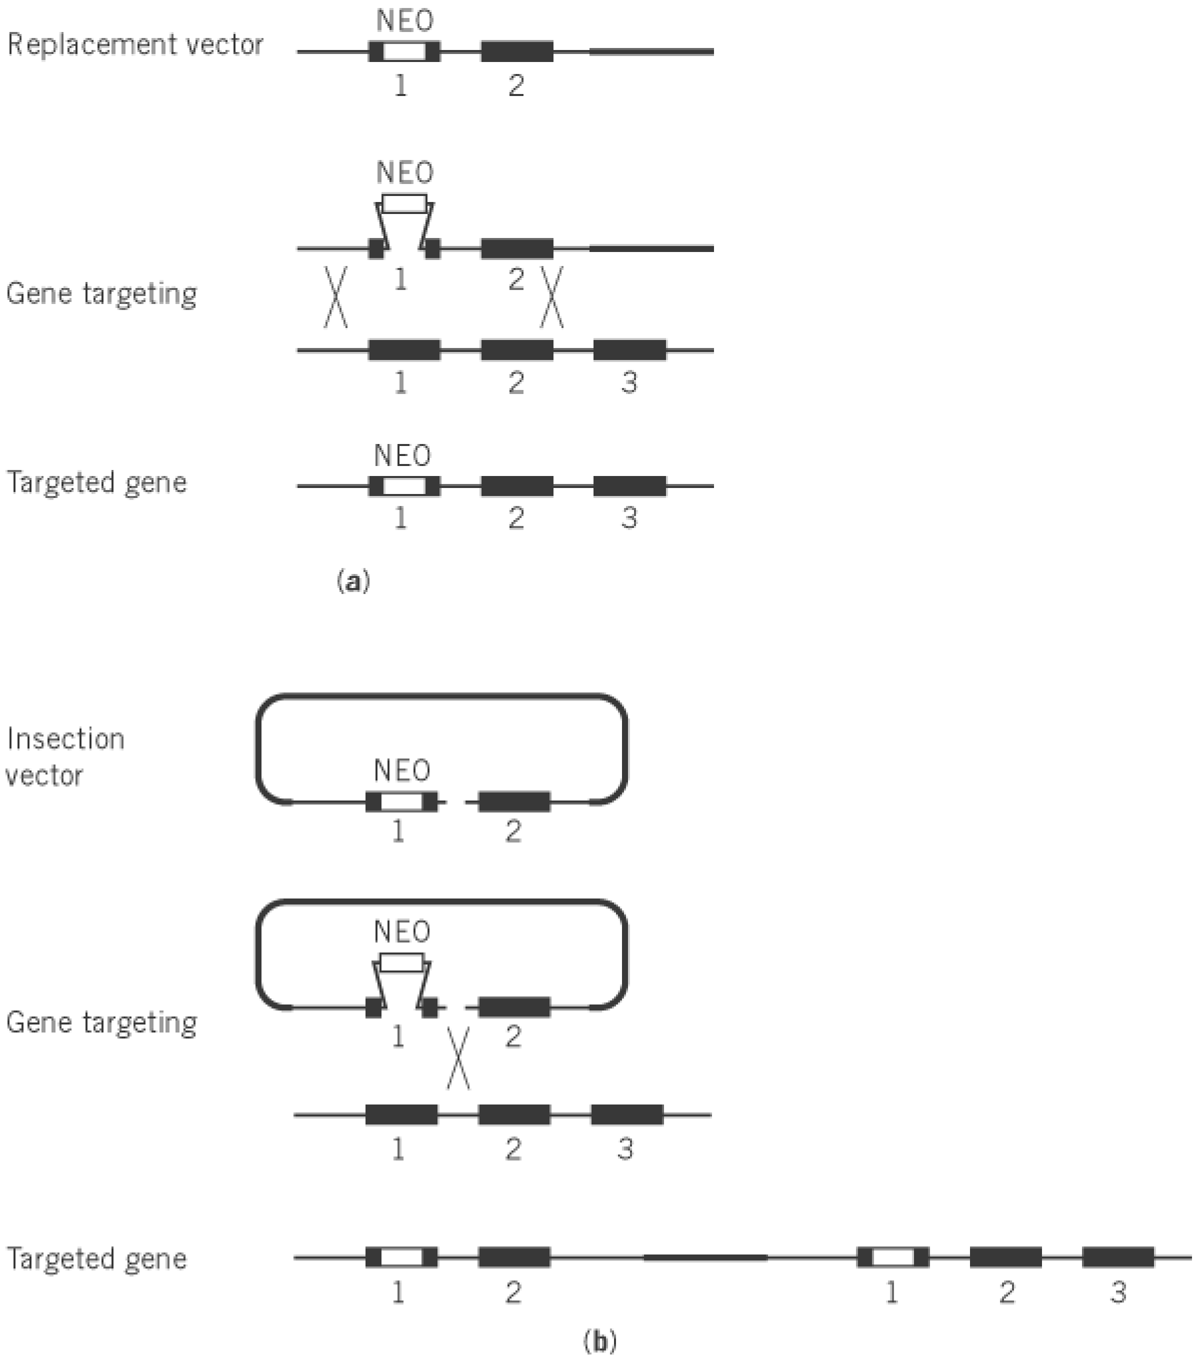
Gene Targeting

Gene targeting refers to the introduction of genetic alterations into predetermined sites within the genome via homologous recombination. A DNA vector containing genomic sequences surrounding the required genetic alteration is constructed by recombinant DNA techniques and introduced into the cell. Homologous recombination between the vector and genome results in insertion of the genetic alteration at the homologous endogenous location and production of a genetically modified cell (Fig. 1).

Figure 1. Diagrammatic representation of the generation of genetically altered mice by gene targeting. ES cell lines derived from the mouse blastocyst are cultured *in vitro* and transfected with a gene-targeting vector. Transfected cells are selected in the appropriate growth medium and homologous recombinants are identified by molecular screening methods. Correctly targeted clones are expanded and returned to recipient mouse embryos which develop to term in pseudopregnant recipient females. Chimaeric offspring which transmit the ES cell genotype through the germline are mated to generate mice heterozygous for the targeted gene. Male and female heterozygous mice are mated to generate mice homozygous for the targeted gene.

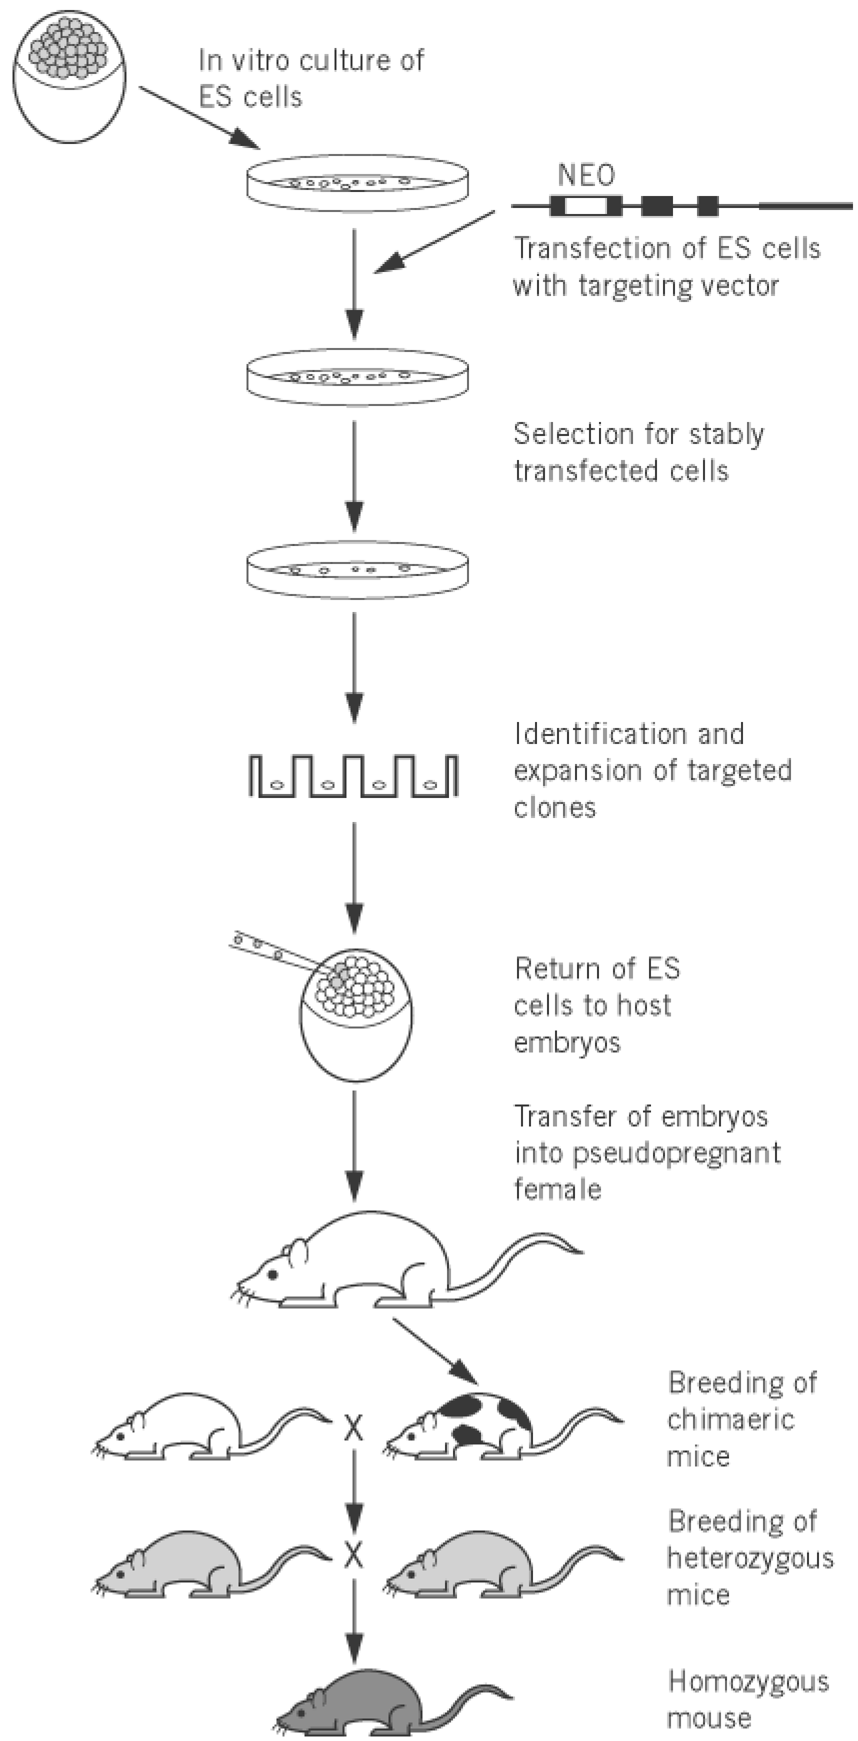


Gene targeting has been demonstrated with variable efficiencies in organisms as diverse as bacteria, yeast, and mammals, as well as in both haploid and multiploid cells. Strategies have been developed for the introduction of diverse mutations ranging from alteration of single nucleotides to incorporation of large DNA segments. Most recent interest reflects the realization that, by coupling gene targeting and reproductive technologies, genetically altered cells can be used as vectors for the creation of genetically modified multicellular organisms. This technology has been developed furthest in the mouse, and the term *gene targeting* is now most commonly applied to the generation of mutant mice. Application of gene targeting to other species has great potential for the analysis of gene function, treatment of human disease, and generation of novel agricultural products.

1. Generation of Null Mutant Mice via Gene Targeting in Embryonic Stem Cells

The early mouse embryo contains a pool of pluripotent cells that will give rise to all cell types of the embryo and adult. These cells can be isolated from preimplantation embryos and maintained in the undifferentiated state *in vitro* as embryonic stem (ES) cells. ES cells retain pluripotent differentiation capability even after long-term culture and can contribute differentiated progeny to all tissues, including the germline, following reintroduction into the mouse embryo (Fig. 2). Genetically altered ES cells can be used to transmit mutations constructed *in vitro* into the mouse germline, thereby enabling the creation of mice with predetermined mutations.

Figure 2. Diagrammatic representation of the generation of null mutations with replacement and insertion targeting vectors. (**a**) Replacement gene-targeting vector. (**b**) Insertion gene-targeting vector. Thin line, genomic DNA; thick line, plasmid DNA; numbered black boxes, exons; NEO, neomycin resistance selection cassette; X, region of homologous recombination.



The steps involved in making a mouse that carries an inactivated gene (null mutation) are shown diagrammatically in Figure 2. Standard recombinant DNA techniques are used to isolate a genomic clone corresponding to the region to be altered and to construct a gene-targeting vector. A positive selection cassette, such as the bacterial **neomycin**-resistance gene, which provides resistance to the aminoglycoside G418, is usually positioned within the genomic clone so that it is flanked by genomic DNA sequences. The targeting vector DNA is introduced into undifferentiated ES cells grown in the presence of leukemia inhibitory factor (LIF) or a feeder cell layer. A range of standard transfection techniques allow introduction of the vector DNA into ES cells, although electroporation is most commonly used (see Transfection). In most cases the introduced DNA integrates into the genome at random sites by nonhomologous recombination, but in a few cases (in the order of 0.5% to 10%) the introduced DNA is integrated into the genome at the homologous site. Stably transfected cells are selected for expression of the selection cassette. Individual clones are expanded and screened for homologous recombination by Southern blot or polymerase chain reaction (PCR). Correctly targeted clones are expanded *in vitro* and reintroduced into host embryos by injection into the blastocoelic cavity of 3.5 days post coitum (d.p.c.) embryos, or by co-culture with 2.5 d.p.c. morulae. Embryos are returned to pseudopregnant recipient female mice and develop into **chimaeric** mice. Usually the coat colors of the host embryo and the mice from which the ES cells were obtained differ, so that chimaeric mice can be identified by their chimaeric coat coloration. Chimaeric mice in which targeted ES cells have contributed to the germline give rise to progeny that are heterozygous for the targeted gene in all cells of the body. To produce mice that are homozygous for the targeted gene, heterozygous male and female mice are mated.

The most common application of gene targeting technology in mice has been the creation of null mutants, usually by positioning the selectable marker so that it disrupts or replaces the gene of interest. Two types of vectors are used for the creation of null mutations: replacement and insertion vectors (1). Replacement vectors are linearized at the extremities or outside the homologous sequence, and the vectors remain co-linear with the target sequence (Fig. 2a). To produce null mutations, a critical section of the coding region is replaced or disrupted with the selection cassette. Insertion vectors are linearised within the region of homology, and homologous recombination of these vectors leads to duplication of the genomic sequence (Fig. 2b). To produce null mutations with insertion vectors, the coding sequence is disrupted with vector DNA that also carries a selection cassette disrupting or replacing an essential region of the coding sequence. Mice carrying specific mutations have proved extremely valuable for basic biological investigations (2-4).

2. Improvements to Gene Targeting Efficiency

2.1. Parameters

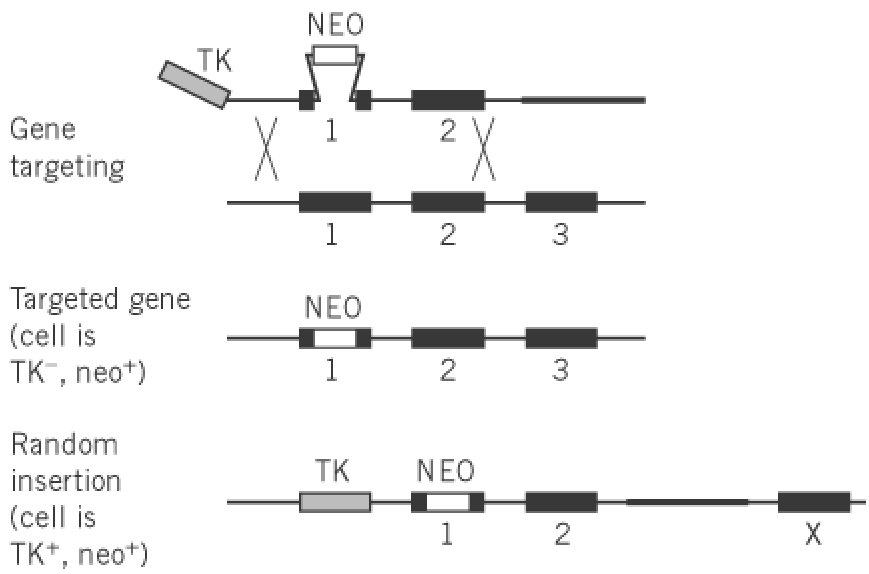
The mechanisms by which homologous recombination of replacement and insertion vectors occurs in mammalian cells are poorly understood. Genes can be targeted efficiently in ES cells regardless of whether they are expressed (5). The efficiency of homologous recombination can be increased by increasing the total amount of homology contained in a targeting vector (1, 6, 7). The relationship between the length of homology and the gene targeting efficiency is exponential between 2 and 10 kb, whereas increases in homology beyond 14 kb have little effect. The efficiency of homologous recombination can also be increased significantly by using genomic DNA for vector construction that is isogenic with the strain of mice from which the ES cells were derived (8, 9). The frequency of homologous recombination appears to be unaffected by the length of nonhomologous DNA introduced into the homologous site, at least up to 12 kb (10), and separate regions of extensive nonhomology can be introduced efficiently into the genome on a single replacement vector (11).

2.2. Vector Design

For loci that are targeted at low frequencies, identification of occasional homologous recombinants among a high background of stably transfected cells can be labor-intensive. Vector design can be modified to enrich for homologous recombinants. The positive-negative selection system (12) is based on the finding that nonhomologous regions at the extremities of replacement vectors are integrated during nonhomologous, but not homologous, recombination. A negative selection cassette, such as herpes simplex virus thymidine kinase (HSV-*tk*), which confers sensitivity to gangcyclovir or FIAU, is positioned outside the homologous sequence on a replacement vector.

Selection for vector integration, but against HSV-*tk* expression, enriches for homologous integrants (Fig. 3). When isogenic DNA vectors are used, enrichments in the range of 5- to 10-fold can be achieved. However, the findings that DNA ends can stimulate homologous recombination (13, 14), and that vector ends might initiate homologous recombination of replacement targeting vectors (11), suggest that the use of vectors containing homologous sequences at the extremities could also be advantageous. Selection cassettes that lack a **promoter** or a polyadenylation sequence (15) have also been used to improve the efficiency of gene targeting, since nonhomologous recombination of such vectors generally results in poor expression of the selection cassette. When recombined at the homologous site, the selection cassette is expressed efficiently due to appropriate positioning within the endogenous gene.

Figure 3. Diagrammatic representation of positive–negative selection gene targeting. Thin line, genomic DNA; thick line, plasmid DNA; black boxes, exons; NEO, neomycin resistance selection cassette; TK, thymidine kinase selection cassette; X, region of homologous recombination.



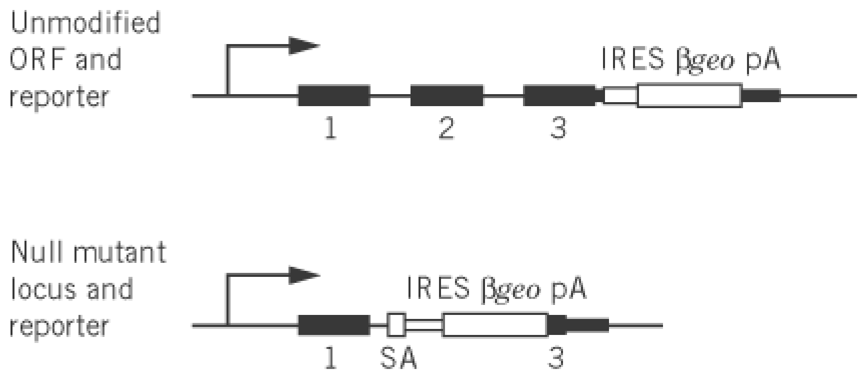
3. Applications of Gene Targeting

3.1. Mapping Gene Expression

Integration of reporter genes into the genome so that they are expressed under the transcriptional control of the endogenous gene provides a means to visualise the normal cellular sites of gene transcription *in vivo*. Expression of reporter genes such as **b-galactosidase** (*lacZ*) can be resolved at the cellular level by histochemical techniques. Chimaeric reporter/selection cassettes, such as the b-galactosidase-neomycin fusion b*geo* (16) that has the enzymatic activity of b-galactosidase and provides resistance to G418, can be used simultaneously as a reporter for gene expression and as a selection cassette for the identification of stably transfected ES cells. This eliminates potential transcriptional interference from promoters directing expression of the selection cassette in the targeting vector. Viral internal ribosome-entry site (IRES) sequences, which enable multiple coding regions to be translated from a single transcript in mammalian cells, can be used to couple expression of a reporter gene integrated into the 3′ untranslated region to expression of an unmutated open reading frame ((17), Fig. 4).

Figure 4. Diagrammatic representation of gene targeting with IRES reporter vectors to map the cellular sites of gene

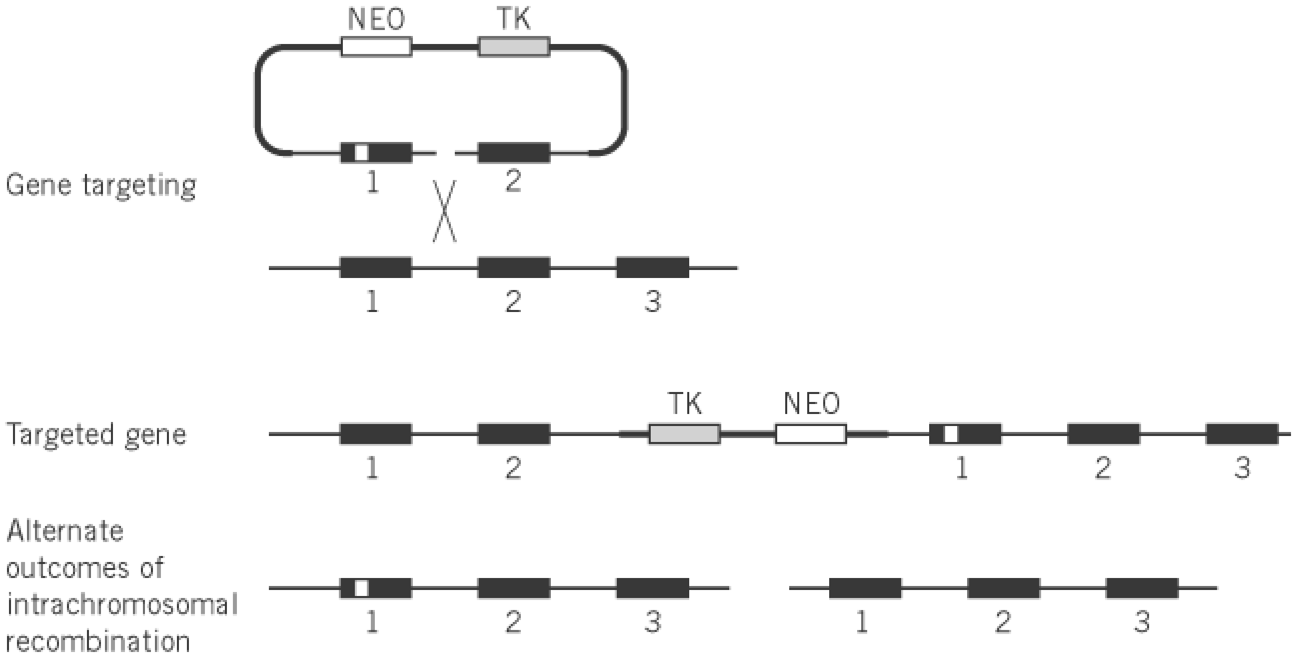
expression. Thin line, genomic DNA; thick line, untranslated region, numbered black boxes, exons; IRES, internal ribosome entry site; b*geop* pA, b-galactosidase/neomycin resistance cassette with polyadenylation sequence; SA, splice acceptor; arrow, endogenous expression signals. Entry of ribosomes at the IRES in dicistronic mRNA results in translation of bgeo protein controlled by expression signals in the endogenous gene; X, region of homologous recombination.



3.2. Sophisticated Genetic Alterations

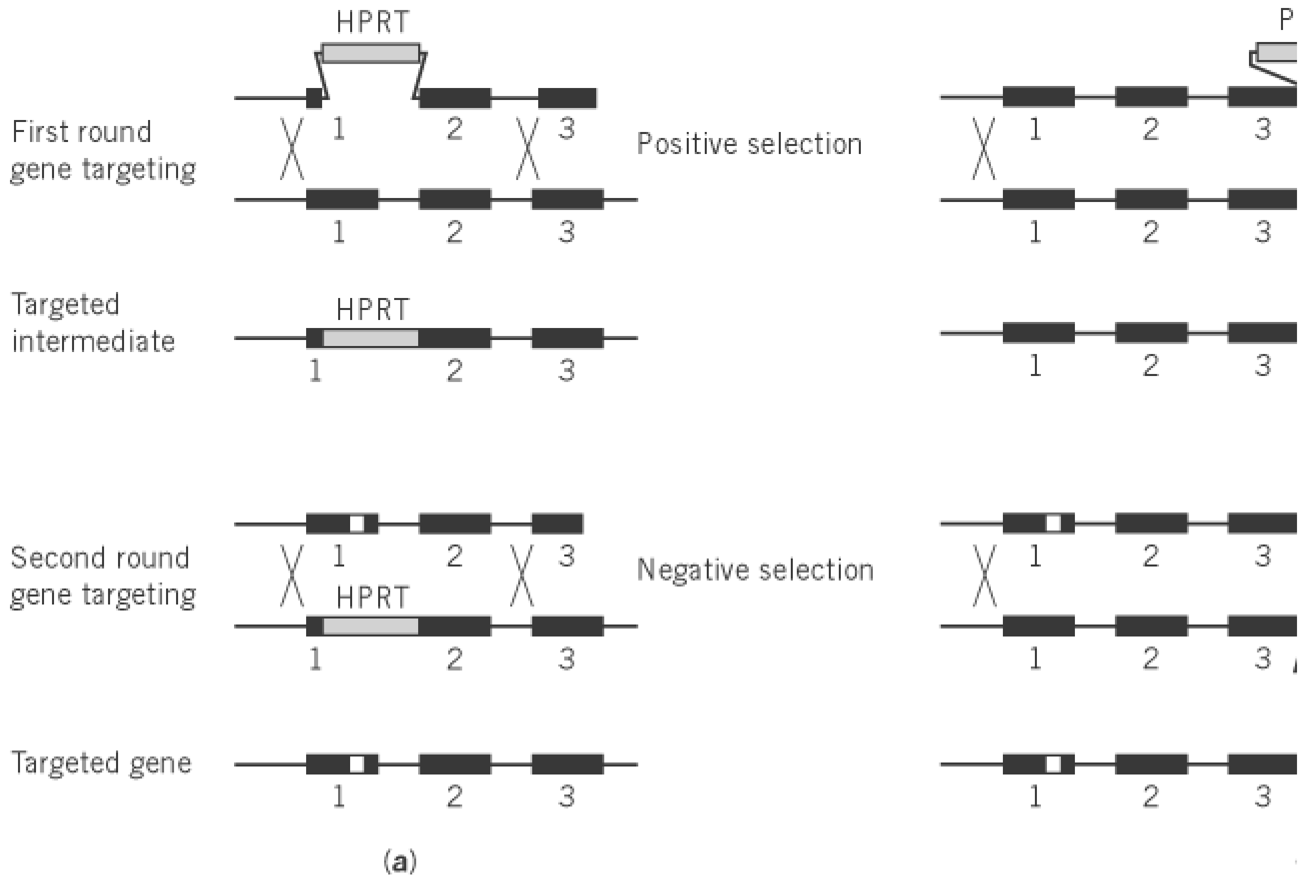
Refined gene targeting systems can be used for the introduction of subtle alterations, including single nucleotide changes, into the mammalian genome. Many of these are based on positive–negative selection cassettes such as HPRT which can be selected in hypoxanthine phosphoribosyltransferase-deficient ES cells positively in HAT medium and negatively in 6-thioguanine. In the hit-and-run system, also known as the in–out system ((18, 19); Fig. 5), the endogenous locus is modified by homologous recombination with an insertion vector that carries the desired alteration and a positive–negative selection cassette. This leads to duplication of the homologous site and is positively selected. Intrachromosomal recombination results in cells that lose the duplication and selection cassettes and therefore survive negative selection. A proportion of these cells maintain the desired alteration.

Figure 5. Diagrammatic representation of the hit-and-run gene targeting approach used to generate subtle genetic modifications. Two alternate outcomes of intrachromosomal recombination are illustrated. Thin line, genomic DNA; thic line, plasmid DNA; numbered black boxes, exons; NEO, neomycin resistance selection cassette; TK, thymidine kinase selection cassette; open box, subtle mutation.



In the targeting system first suggested by Reid et al. (20), and known as double replacement (21, 22) or tag-and-exchange (23), two successive gene targeting steps are used to introduce subtle alterations into the genome (Fig. 6a). A positive–negative selection (tag) cassette is introduced into the genomic locus by gene targeting. The tag gene is replaced by the alteration of interest in a second round of gene targeting, in which direct selection for loss of the tag gene prevents survival of nonhomologous recombinants. The efficiency of second-round targeting can be compromised by a high background of resistant lines that result from physical loss of the tag cassette in the absence of homologous recombination. This most commonly results from **gene conversion** in which the tagged gene is restored to wild type by nonreciprocal transfer of genetic information from the wild-type sequence (11, 21, 22). In a modified version of tag-and-exchange targeting, termed stable tag-exchange (11), an additional positive selection cassette positioned outside the coding region is introduced on the first-round targeting vector. This cassette is not replaced during the second round of targeting and is used to select against reversion of the tagged gene to wild type. This provides a significant improvement in the efficiency of two-round gene targeting approaches. Stable tag-exchange gene targeting is therefore advantageous when investigations require the introduction of multiple, independent subtle alterations into a single locus. In cases where the presence of an exogenous selection cassette within the altered sequence may be deleterious, it can be removed by site-specific recombination using systems developed for conditional gene targeting (see text below).

Figure 6. Diagrammatic representation of two-step gene targeting approaches used to generate subtle genetic modificati
(**b**) Plug-and-socket gene targeting. Thin line, genomic DNA; numbered black boxes, HPRT, HPRT selection cassette; o
selection cassette; DSocket or SocketD, alternative nonfunctional selection cassettes; Socket, functional socket selection
recombination between DSocket and SocketD; X, region of homologous recombination.

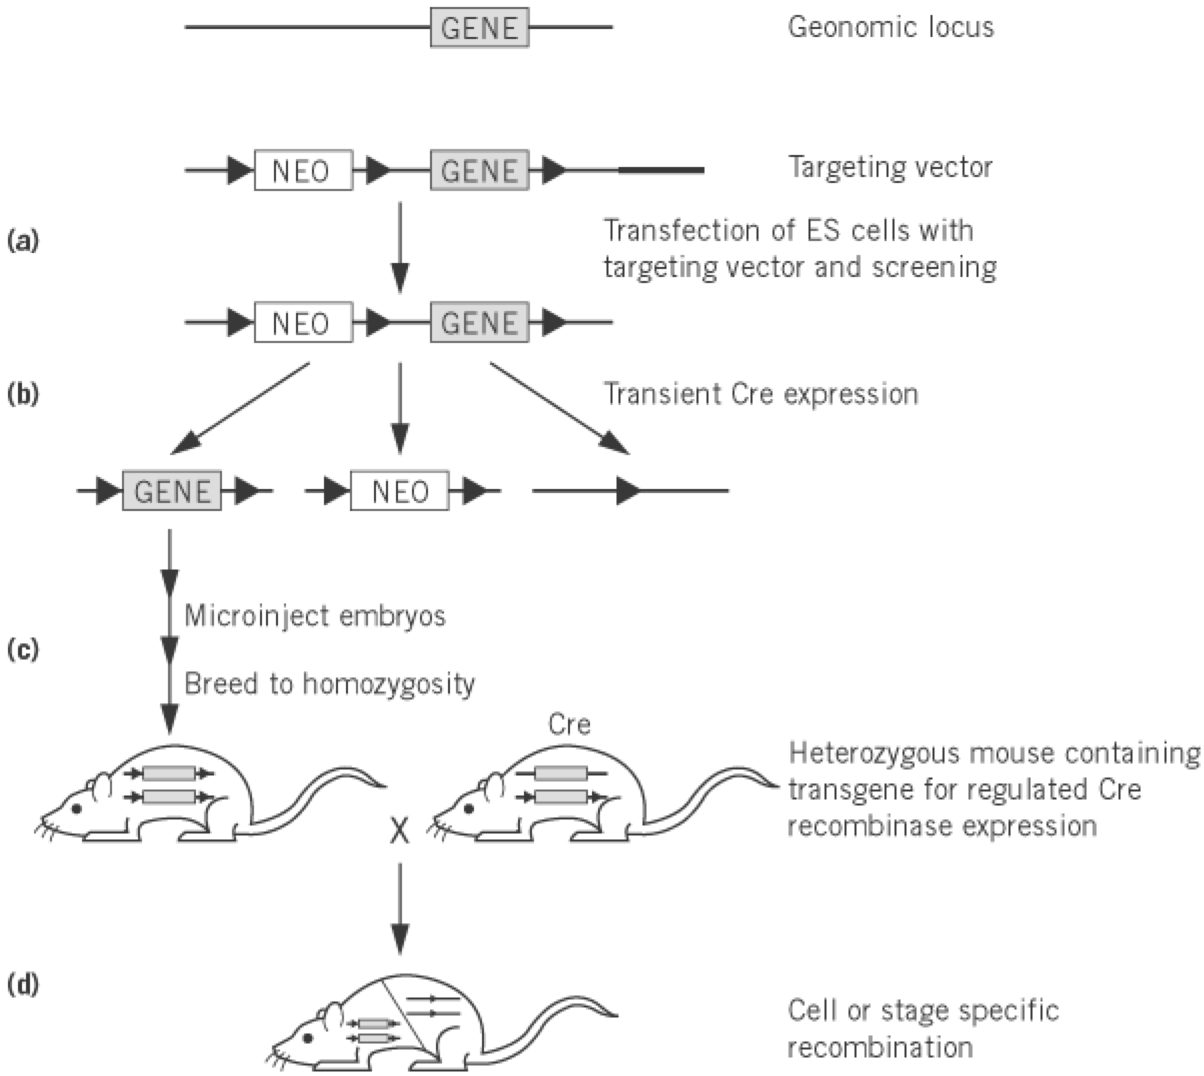


The two-step “plug and socket” system ((24); Fig. 6b) allows use of positive selection in both rounds of gene targeting. This potentially overcomes the background of cells surviving negative second-round selection due to loss of the negative-selection cassette in the absence of homologous recombination. The locus is initially targeted with a vector that contains a functional positive “plug” selection cassette and a second nonfunctional positive “socket” selection cassette positioned outside, but close to, the locus. The vector used for second-round targeting contains the desired alteration, along with an alternative nonfunctional version of the socket selection cassette. Homologous recombination creates a functional “socket” selection cassette that is selected, and it results in replacement of the plug selection cassette with the desired alteration.

3.3. Conditional Gene Targeting

Null mutations produced by conventional homologous recombination have provided valuable information about the biological significance of a large number of molecules. In cases where null mutations are lethal to the embryo, however, the role of the gene product cannot be studied at subsequent stages of development. Methods for the creation of **conditional mutations**, which allow control over the site and/or time of mutation *in vivo*, are based on site-specific recombination catalyzed by a yeast or bacteriophage DNA recombinase (Fig. 7). The bacterial Cre recombinase catalyses recombination between two specific 34-bp sequences called *loxP* sites. The locus of interest is modified by gene targeting such that *loxP* sites in the same orientation are placed on either side of the selection cassette and at the end of the gene to be mutated. The ES cells are then transfected transiently with a Cre expression cassette, resulting in recombination between *loxP* sites and deletion of the intervening sequences (see Introns, Exons). Cells in which the selection cassette alone has been deleted are identified and used to generate mice that carry a functional gene flanked by *loxP* sites. Homozygous offspring of these mice are crossed with mice that are heterozygous for the mutated gene and that also carry the Cre recombinase gene driven by a tissue-, cell-, or stage-specific promoter. Recombination and deletion/mutation of the *loxP* flanked gene is restricted to the tissues or stages of development where/when the Cre recombinase is expressed and allows direct investigation of the function of the gene at these positions or stages.

Figure 7. Diagrammatic representation of conditional gene targeting by Cre-*lox* recombination. (**a**) A targeting construct containing the gene of interest and a neomycin resistance (NEO) gene flanked by 3 *loxP* sites (black triangles) is introduced into the ES cell genome by homologous recombination. (**b**) Transient expression of Cre recombinase in the ES cells results in loss of the gene of interest, the NEO gene or both. (**c**) Cells containing the gene of interest flanked by *loxP* sites are used to generate chimaeric mice which are bred to homozygosity. (**d**) Homozygous offspring are crossed with a heterozygous mutant which carries a Cre gene driven by a cell- or stage-specific promoter, resulting in offspring in which the *loxP* flanked gene is deleted in the cells or at the stage where the Cre gene is expressed.



.

In addition to conditional mutations, Cre-*lox* technology can be applied to a wide variety of targeted mutation strategies, including replacement of a gene from one species with the same gene from another species (25) and insertion of a different gene into a particular genomic location (gene "knock-in"; (26)). Cre-*lox* recombination has also been used for the creation of subtle mutations (27), to enable controlled activation of gene expression by insertion of a *loxP*-flanked stop sequence between a gene and its expression signals (28), to generate complex genomic models for chromosomal rearrangements, translocations, and deletions (29), and to model diseases caused by mutations in somatic cells, such as cancers and aging.

3.4. Null Mutations *in Vitro*

Cell lines in which both **alleles** of a gene are mutated provide unique opportunities for biochemical analysis of gene function. ES cells with homozygous mutations can be isolated from homozygous mutant embryos, or constructed by genetic manipulation of heterozygous ES cell lines generated by gene targeting. This can be achieved by sequential targeting using different selection markers, or by increasing selection for expression of the neomycin-resistance gene by elevating the concentration of G418 (30), thereby selecting for rare cells in which gene conversion has replaced the wild-type allele with a second copy of the targeted allele. The developmental potential of mutated ES cells can be assessed by differentiation of the cells *in vitro*, or by examining the contribution of the cells to tissues in chimaeric mice following return to the blastocyst. This can permit analysis of cell decisions that are otherwise obscured by embryonic lethality, and in some cases it can be coupled with detailed analysis of cell differentiation by measurement of marker gene expression.

Differentiated cell lines with homozygous mutations can be isolated from mutant embryos or via *in vitro* differentiation of ES cells containing two mutated alleles. These provide a valuable resource, because the effects of mutation can be examined in established *in vitro* assays specific for differentiated cell types. The availability of a homogeneous cell population allows application of biochemical techniques, such as direct measurement of downstream effector molecules.

3.5. Disease Models

Human diseases can have as their origin a wide variety of genetic alterations, including point mutations, deletions/truncations, large chromosomal deletions, and chromosomal translocations. Animals with genomes modified to mimic these alterations can be generated by gene targeting and used to study the cellular and biochemical basis of the disease and to test potential therapies. For example, familial hypercholesterolemia caused by loss of the low-density lipoprotein receptor has been modeled by gene knockout (31), cystic fibrosis has been modeled by the creation of point mutations within the cystic fibrosis transmembrane conductance regulator gene (32), and a familial form of Alzheimer's disease has been partially modeled by replacing the mouse Ab domain in the b-amyloid precursor protein with a mutated human sequence (33). A limitation of this approach can be the failure of mice to display the mutant phenotype seen in humans. In some cases, this can be overcome by refinement of the gene targeting approach. For example, familial adenomatous polyposis coli (FAP) results in the formation of colorectal adenomas in humans due to mutation of the APC gene. Mice homozygous for an APC deletion die *in utero*, but conditional gene targeting of the mutation in the colorectal epithelium using Cre-*lox* recombination resulted in mice that develop colorectal adenomas (34).

3.6. Gene Targeting in Non-mouse Species

Theoretically, gene targeting could be used in any cell that supports homologous recombination and can undergo clonal proliferation *in vitro* following selection for recombinants. However, creation of organisms carrying the modified allele can be achieved only if an intact organism can be regenerated from the genetically modified cell. The creation of gene-targeted organisms other than mice has been restricted by the failure to isolate pluripotent ES cells from these species. A potential alternative to the use of ES cell technology is foreshadowed by the demonstration that nuclei of differentiated cells can be reprogrammed or reverted to pluripotency by insertion into enucleated oocytes. The application of this nuclear transfer technology to produce offspring that are genetically identical to the donor cells has been validated for sheep, mice, and cattle, for donor nuclei from several cell types, and for genetically modified cells (35-38). Using this technique, gene targeting would be carried out in the differentiated cells, and genetically altered organisms would be created by nuclear transfer.

Gene targeting in nonmammalian metazoans is not yet well advanced. While homologous recombination has been demonstrated in moss (39), there are not yet convincing reports of gene targeting in lower vertebrates, invertebrates, or higher plants. The latter are of particular interest, given the potential for agricultural application.

3.7. Therapeutic Gene Targeting in Humans

An important potential application of gene targeting is the precise genetic alteration of **somatic cells** for correction of disease-causing mutations by gene therapy, delivery of therapeutic compounds to the individual, or tissue reconstitution *in vitro*. Direct genetic manipulation of, for example, somatic stem cells is limited by the failure of existing technologies to support isolation, transfection, and proliferation of these cell types *in vitro*. Widespread use of genetically altered cell types for human therapy may emerge from the combination of nuclear transfer technologies, which enable reprogramming of somatic cell nuclei, and gene targeting. Somatic cell nuclei isolated from an individual could be reprogrammed to a pluripotent state by nuclear transfer, modified genetically, and differentiated *in vitro* into the cell type required for transplantation. The use of gene targeting approaches could broaden the use of genetically modified cells for human therapy. This is currently restricted by difficulties associated with controlling the location, timing, and levels of gene expression, the copy number and integration site of **transgenes**, and the host immune response to virally based vectors.

Genetic Code

1. The Universal Progenitor and Standard Code

Transfer RNA, tRNA, is the essential adapter in decoding the genetic information. The aminoacylation of specific tRNAs with particular amino acids, and productive pairing of the anticodons of these tRNAs with **cognate** codons of the messenger RNA (mRNA) are the central processes in decoding (see Aminoacyl tRNA Synthetases and Translation). Within the past 10 years, great strides have been made in discovering the intricate relationships between tRNAs and aminoacyl-tRNA synthetases that are essential for correct aminoacylation. In contrast, the identification of mRNA codons has long been established (1), and the resulting table of specifications of amino acids by codons is what is commonly called the *genetic code* (Table 1). However, the code has meaning only in terms of its readout and, since this is a dynamic process, it is necessary to consider the code and its readout together.

Table 1. The Genetic Code

	Second Position				
First Position	**U**	**C**	**A**	**G**	**Third Position**

	Phe	Ser	Tyr	Cys	**U**
U	Phe	Ser	Tyr	Cys	**C**
	Leu	Ser	Stop	Stop/Sec	**A**
	Leu	Ser	Stop	Trp	**G**
	Leu	Pro	His	Arg	**U**
C	Leu	Pro	His	Arg	**C**
	Leu	Pro	Gln	Arg	**A**
	Leu	Pro	Gln	Arg	**G**
	Ile	Thr	Asn	Ser	**U**
A	Ile	Thr	Asn	Ser	**C**
	Ile	Thr	Lys	Arg	**A**
	Met	Thr	Lys	Arg	**G**
	Val	Ala	Asp	Gly	**U**
G	Val	Ala	Asp	Gly	**C**
	Val	Ala	Glu	Gly	**A**
	Val	Ala	Glu	Gly	**G**

All organisms living on earth are derived from a common ancestor, and divergent evolution from this ancestor is the central unifying theme of biology. One of the most striking facets of derivation from a common ancestor is the presence of the universal progenitor, or standard code, in nearly all organisms. Slight deviations from this standard code have appeared in certain organisms and coding niches, such as mitochondria; these deviations are important and interesting, but they do not detract from the truth that *Escherichia coli*, elephants, and peas use the same genetic code for synthesizing nearly all their proteins.

Deciphering this standard code was triumphantly accomplished between 1961 and 1966 (1). Elegant genetic experiments showed that the code was read from a defined starting point in a nonoverlapping manner, with three bases (or formally a multiple thereof) specifying one amino acid, the next three bases the next amino acid, and so on (2). Confirmation of the triplet nature of the code came from cell-free **protein biosynthesis** experiments that showed which codons specified each amino acid. The template used in Nirenberg and Matthaei's pioneering experiment in 1961 was polyuridylate [poly (U)], which led to the synthesis of polyphenylalanine. Consequently, the first codon to be deciphered was UUU for phenylalanine; very shortly afterward, AAA and CCC were found in the same way to encode lysine and proline, respectively. The use of mixed-polymer templates revealed the composition, but not the sequence, of codons specifying certain other amino acids. However, Khorana and colleagues synthesized polynucleotides with defined repeating sequences, and this provided valuable assignments (3). The other key development was the discovery by Nirenberg and Leder in 1964 (4) that trinucleotides promote the specific binding of tRNA to ribosomes. Synthesis of all 64 trinucleotides led to assignments for about 50 codons by this method. Protein sequencing studies from mutants with combinations of **frameshift mutants** supported the conclusions. Furthermore, genetic studies by Brenner and Garen and their colleagues provided valuable insights into the termination codons.

By 1966, the various approaches together resulted in the complete deciphering of the code (1). It does not detract from this monumental achievement to point out that, if the code had not been established by these means, direct nucleic acid **sequencing** coupled with protein sequencing would have provided the answer shortly thereafter. Complete sequencing of the first gene was accomplished in 1972 by “classical” RNA sequencing of the coat protein gene of the single-stranded RNA **bacteriophage** MS2 (5). Rapid DNA sequencing was developed in 1978 and led to a massive increase in sequence information. Nucleic acid sequencing, in conjunction with protein sequencing, has repeatedly confirmed the assignments of the standard code, demonstrated its utilization in decoding the main genomes of virtually all organisms, and revealed the interesting deviations.

The standard code in which the 64 possible base triplets encode 20 amino acids is presented in Table 1. The code is redundant, in that most amino acids are encoded by more than one codon. This is due in part to wobble pairing between the tRNA and the codon. Redundancy leads to variations in **codon usage** in different organisms. Three of the 64 codons do not usually code for amino acids but are used as stop codons, to terminate translation. Certain codons, usually AUG, play a special role as start codons, initiating translation of the mRNA. The 21st amino acid, selenocysteine (Sec), is also directly encoded, but only in special cases (see “Recoding,” below).

2. Specialized Code Variants: the Mitochondrial Code

It was long considered that the genetic code could not be altered during evolution. It was thought that changes in codon meaning would have such a deleterious effect on protein products that the code was “frozen.” However, quite a number of cases of genetic code variation are now known in mitochondria, as well as in the nuclear systems, of some organisms (6-9). The known variants of the genetic code in mitochondria are shown in Table 2. The small number of products encoded by animal mitochondrial genomes has undoubtedly been important in permitting code alterations in these organelles. How these alterations might have occurred is considered in the section “Candida code and code reassignment theories.”

Table 2. Variations in Mitochondrial Genetic Code[a]

Organisms	UGA Stop	AUA Ile	AAA Lys	AGR Arg	CUN Leu	UAA Stop	Example
Vertebrates	Trp	Met	—	Stop	—	—	Human, frog
Tunicates	Trp	Met	—	Gly	—	—	*Halocynthia roretzi*
Echinoderms	Trp	—	Asn	Ser	—	—	Starfish, sea urchin
Arthropods	Trp	Met	—	Ser[b]	—	—	Drosophila spp., mosquito, honeybee
Molluscs	Trp	Met	—	Ser	—	—	Squid, *Mytilus edulis*
Nematodes	Trp	Met	—	Ser	—	—	*C. elegans, Ascaris suum*
Platyhelminthes	Trp	—	Asn	Ser	—	Tyr	*Fasciola hepatica, planaria*
Cnidarians	Trp	—	—	—	—	—	*Hydra, Metridium senile*
Yeasts Trp	Met	—	—	Thr	—		*Saccharomyces cerevisiae,Torulopsis glabrata*
Euascomycetes	Trp	—	—	—	—	—	*Aspergillus nidulans, Neurosporacrassa*
Protozoa	Trp	—	—	—	—	—	*Trypanosoma brucai, Parameciumspp.*

[a] From reference 7 with modifications.
[b] N = A, U, C, or G; R = A or G. *Only AGA (specifying Ser) is used in *Drosophila* and mosquitoes, while both AGA and AGG (each specifies Ser) are used in honeybee, locust, and brine shrimp.

An important feature of decoding in animal mitochondria is that, in many cases, one tRNA recognizes all four members of a codon family. This simplification has resulted in a greatly reduced number of tRNAs compared to cytoplasmic protein synthesis. Key to this relaxed specificity is an unmodified U at the first position of the anticodon of many tRNAs (10). The general point is that almost all the diversity in the genetic code can be explained by variations in the anticodons of tRNAs that bind to various codons.

Generally, animal mitochondrial mRNAs have a simpler structure than those of **prokaryotes** and other **eukaryotic mRNAs**. There is no 5′-leader sequence (11) and usually only a short poly A sequence in the 3′-trailer sequence (12). Metazoan mitochondrial mRNA usually start translation with an AUG or AUA codon and end with a UAA or UAG codon although, in mammalian mitochondria, AGA and AGG codons are used for termination (12, 13). Often, only the 5′ nucleotide of the UAA is directly encoded, and it is completed by addition of the poly A sequence at the 3′-end of the primary transcript of mRNAs (12).

The change of UGA from being a stop codon to specifying tryptophan (Trp) in all mitochondria, except those in plants, is due to change of the anticodon of $tRNA^{Trp}$ from CCA or CmCA (mC = 5–methyl C) to U*UA, where U* in most cases is cmnm ^{5}U (5-carboxymethyl-aminomethyl U), so that the tRNA ^{Trp} can decode both UGG and UGA codons by wobble pairing.

The $tRNA^{Met}$ capable of decoding both AUG and AUA codons in most mitochondria, except those of echinoderms and platyhelminthes, possesses at the first position of its anticodon 5-formyl C in vertebrates (14) and nematodes (15), $cmnm^{5}C$ in ascidia (16), and a modified C in addition to normal C in *Drosophila* (17). These modified nucleosides make it possible to decode A as well as G at the third codon position.

AAA codons are read as Asn, instead of the usual Lys, in starfish mitochondria; the first position of the corresponding tRNA anticodon is occupied by G (17), which may decode, at the first position, not only C and U but also A. The same is observed in Ser codons of *Drosophila* mitochondria, where AGU, AGC, and AGA codons (AGG is an unassigned codon) specify Ser. Ser is also specified by UCN codons (N = A, U,C or G). The single $tRNA^{Ser}$ responsible for decoding these codons possesses a GCU anticodon (17).

All AGN codons are read as Ser in most invertebrate mitochondria. In these cases, a modified G [7-methyl G in starfish and squid (17, 18)] or an unmodified U [in nematodes (15)] occupies the first anticodon position, so that these bases can recognize all four bases at the third codon position.

In ascidian mitochondria, the AGR codon (where R is A or G) is assigned to Gly. The anticodon of the corresponding $tRNA^{Gly}$ is $cmnm^{5}UCU$ (19).

3. Candida Code and Codon Reassignment Theories

In nine species of the asporogenic **yeast**, *Candida*, CUG encodes serine and not leucine as it does in the standard, nearly universal code (20-22) (Table 1). The tRNA translating this nonuniversal genetic code (tRNA ^{Ser} CAG) has been characterized (21) and shown to be charged with serine (21-26).

At present, there are two theories to explain the codon reassignment: the “codon capture” (26) and the “ambiguous intermediate” (27) theories. The former postulates that a codon changes to another codon via an unassigned codon and that the codon to be changed must disappear once from coding sequences to avoid insertion of an incorrect amino acid (neutral change of codon). The latter postulates that changes in the genetic code are relatively fast processes driven by natural selection and that reassignment of codons is facilitated by a translationally ambiguous intermediate, where the transitional codon is read simultaneously as either of two amino acids by two different tRNAs.

The genetic code change found in *Candida* species may be explained by either of these two theories. Santos et al (28) favor the ambiguous intermediate theory. They provided experimental evidence that expression in yeast cells of a tRNA ^{Ser} CAG with a mutation at position 33 (5′-adjacent to the anticodon) induces the **stress response** that allows cells to acquire thermotolerance. This may provide positive selection for the genetic code change by allowing yeast to adapt to sudden changes in environmental conditions.

On the other hand, Suzuki et al. (29) found what they term a “polysemous codon” in *Candida zeylanoides*, which used the CUG codon to encode both serine and, to a slight extent (3%), leucine. This is mediated by a single tRNA^{Ser} CAG capable of being charged with either amino acid. A genetic method demonstrated that the CUG codon is actually translated as either amino acid *in vivo*. Suzuki and coworkers emphasize that the dual assignment of the CUG codon is fulfilled by dual specificity of a single tRNA^{Ser} CAG, not by ambiguous translation using two different tRNA. Thus, they prefer the codon capture theory to the ambiguous intermediate theory. The existence of unassigned codons is also important evidence for the codon capture theory. Further experiments are necessary, however, to clarify unambiguously the evolutionary process of codon reassignment in *Candida* species (30).

4. Theories of the Origin of the Genetic Code

Two assumptions are commonly made in considering the origin of the genetic code.

1. First is the principle of continuity; namely, for any possible productive early scheme, there has to be some conceptual way that it could have evolved gradually to the modern genetic code without destroying all the fruits of prior evolution.
2. A second assumption is that the origin of the code was based on RNA. Since proteins are decoded from RNA templates and some RNA are catalytic, it is highly attractive to invoke a transitory “RNA world”. Perhaps no decoding was necessary if the genetic material (RNA) could mediate the catalytic functions directly.

Since discussion of the origin of the code which began in earnest in the late 1960s (31), one of the key imponderables has been whether there was originally a direct stereochemical relationship between primordial tRNAs and their cognate amino acids or whether the genetic code assignments were random, as in “the frozen accident theory” (32). Recent work (33) has shown selective binding of some amino acids by RNA, and the question of aminoacylation in the absence of proteins is being investigated, but the overall issue remains unresolved. Intertwined with this issue is the question of the relationship between the accepter and anticodon branches of tRNA. Noller has suggested that both parts were initially separate, with overlapping functions, and that they were later combined (34). Another suggestion, which is difficult to evaluate, is that they are directly related (35).

Another key imponderable in decoding is the origin of ribosomes. Several different approaches, including extensive but incomplete deproteinization experiments, have pointed to the largest rRNA (23S rRNA in *E. coli*) as the key component in peptidyl transferase (reviewed in (34)). Of course, even imagining the origin of 23S rRNA is a serious problem, although an attractive suggestion is that a protodomain originated as a spin-off of a ribozyme-catalyzed function (34). A different issue is the origin of translocation of the ribosome one codon at a time along the mRNA. Modern ribosomes have the ability of low-level synthesis of polypeptides on poly(U), (UC), or (A) in the absence of the elongation factors EF-Tu, EF-G, and GTP, suggesting that they contain the mechanism for catalyzing translocation (36) and putting the spotlight on the small subunit rRNA (16S rRNA in *E. coli*). An interesting speculation is that this originated as an RNA replicase (37). Regardless of origin, it is tempting to think that the translocation step size is determined in part by the tRNA anticodon delineating the codon size. The stability of a triplet interaction between codon and anticodon is insufficient on its own to mediate discriminatory decoding. If, for stability reasons, however, one envisages primordial tRNAs that read quintuplet codons in a primitive mRNA, it is difficult to imagine how those translation components could evolve to triplet decoding without destroying the benefits of prior evolution. Consideration of this difficulty has lead to an ingenious scheme for triplet decoding involving overlapping quintuplet pairing (38, 39), but whether such a scheme is a progenitor of modern triplet decoding is speculative. It has been proposed that in present-day decoding, the triplet codon interaction is stabilized by stacking ribosomal RNA (40). The particular regions of rRNA proposed have not been implicated in genetic studies to address this issue, but it is unclear whether this is because they are not involved or because they are essential (41).

Knowledge of the structure of the ribosome will be invaluable for efforts to understand present-day decoding which, in turn, will guide thoughts about plausible schemes for its evolutionary origin.

5. Recoding: Reprogrammed Decoding

5.1. Transient Reprogramming of Decoding

Excluding some specialized niches, the genetic information in the great majority of mRNA is readout according to the standard rules with the nearly universal code specifications (Table 1). However, a minority of mRNA that use the same translational components, or essentially so, are decoded in a different manner at one or more positions in their coding sequence. At these positions, readout is reprogrammed, and the phenomenon is termed *recoding*. In the first category, the meaning of a code word is redefined so that at least some of the protein product bears the consequence of the new meaning. In the second category, a proportion of ribosomes shift reading frame at a specific place in an mRNA and continue in the new frame, following the standard rules, to give a very different product from the ribosomes that did not shift frame (see Frameshifting). In the final category, a block of nucleotides is bypassed by the translocating ribosomes.

Recoding has been most frequently encountered in **viruses**, especially plant viruses and retroviruses, and in retrotransposons, such as yeast Ty elements and bacterial **insertion sequence** (IS) **elements**, but it is also known to be utilized in decoding several cellular genes. It probably occurs in all organisms.

5.2. Redefinition

The meaning of a sense codon can be redefined; for example, the codon GUG at internal positions specifies valine, but in the context in which it functions as an initiator, it specifies methionine or formylmethionine (see Start Codons). No cases are known in which the meaning of a sense codon at an internal position in a coding sequence is redefined. (Though mechanistically distinct from recoding, there are instances in which a sense codon gives the superficial appearance of acting as a stop codon. Consecutive rare codons, or some RNA structures, can cause the ribosome to pause and, on occasion, to drop off with a terminated polypeptide chain; see Stop Codons.)

On the other hand, stop codons in the standard code can be redefined to specify an amino acid. The most dramatic case involves the specification of the 21st encoded amino acid, selenocysteine. Until 1986 it was thought that only 20 amino acids were directly encoded (excluding the transient case of formyl methionine; see Start Codons). Then it was found—in **eubacteria**, **archae**, and mammals—that selenocysteine was directly encoded and that its codon is UGA, which in the standard code is a stop codon (42, 43). UGA specifies selenocysteine in only a very small number of species of mRNA in each cell. In nearly all other mRNA species, UGA specifies translation termination. In each mRNA in which UGA encodes selenocysteine, there is a particular mRNA structure that acts as a recoding signal to specify that UGA means "selenocysteine" in decoding this particular mRNA. In **Gram-negative** eubacteria, this structure is a particular stem-loop structure immediately following the UGA codon (44). In mammals, the equivalent specifying element, SECIS, is in the 3′ untranslated region (45). In archae, the available evidence indicates that the enabling structure can be in either the 3′ or 5′ untranslated region of the mRNA (46). Elegant studies in *E. coli* have shown that a special elongation factor, which does not form a complex with any tRNA other than selenocysteine tRNA, binds to the loop of the mRNA stem loop structure and effectively tethers the aminoacylated selenocysteine for delivery to the ribosome poised at the UGA (44). How the SECIS element in the 3′ untranslated region of mammalian mRNA that encode selenoproteins functions is a fascinating mystery. The problem is acute in human selenoprotein P mRNA, where 10 UGA codons occur within the coding region, and all probably specify selenocysteine.

The redefinition of stop to other sense codons is also well known, and there is considerable variation in the extent of recoding signals involved in the process. With retroviruses other than Spumaretroviruses, there is no independent ribosome entry to the pol gene that encodes **reverse transcriptase** and an **endonuclease**. Instead, ribosomes that initiate translation of the upstream *gag* gene synthesize some Gag-Pol fusion protein, in addition to the separate Gag product. In murine leukemia and related viruses, the *pol* gene is in the same frame as the *gag* gene and is separated from it only by a UAG "stop" codon. Approximately 10% of the ribosomes that read the *gag* gene insert glutamine at the UAG codon and synthesize a Gag-Pol fusion. This level of "readthrough" is dependent on a recoding signal in the mRNA and is 10^{3}-fold higher than the background error level in the absence of such signals. The recoding signal is a particular pseudoknot eight bases after the UAG (47). How this pseudoknot influences the oncoming ribosomes is unexplained. Redefinition of "stop" codons is common in plant virus decoding. In barley yellow dwarf virus, both local and distant signals are important for the redefinition (48) whereas, in tobacco mosaic virus, only the sequence of the six bases following the stop codon is relevant.

5.3. Programmed Ribosomal Frameshifting

At specific positions in the decoding of some genes, a high proportion of ribosomes shift frame and then resume triplet decoding to give an essential product (49) (see Frameshifting). This probably happens in all organisms, but notable examples are synthesis of the Gag-Pol polyprotein of many retroviruses, including **HIV**-1, human antizyme, barley yellow dwarf virus polymerase, *E. coli* release factor 2, and lambda phage G-T product. Some cases of programmed frameshifting serve an autoregulatory function (eg, *E. coli* release factor 2 and human antizyme); others produce different products from a single gene in a set ratio. The recoding signals range from distant sequences to a flanking 3′ pseudoknot, stem-loop structure, or rare codons, to 5′ sequences, or to a combination. The frameshifting is +1 in some cases (eg, human antizyme and *E. coli* release factor 2) and –1 in others (eg, HIV, barley yellow dwarf virus and mouse mammary tumor virus). Many cases of programmed –1 frameshifting involve the simultaneous slippage of the pairing of two tRNA anticodons with the mRNA. In contrast, in programmed +1 frameshifting, pairing of a single tRNA anticodon is often disrupted and the codon that enters the A site is either a stop codon with no cognate tRNA or a rare codon whose cognate tRNA is in short supply. Repairing of the tRNA anticodon 1 nucleotide along the mRNA has greatly reduced, or no, competition from an incoming tRNA specified by the zero frame codon.

5.4. Bypassing

Between codons 46 and 47 of phage T4 gene *60*, there are 50 nucleotides that are translationally bypassed with high efficiency (50). This remarkable instance of decoding poses many mechanistic questions, and it is not clear how widespread the phenomenon of bypassing is. However, low-level error bypassing has been encountered when overexpressing, for biotechnological purposes, a mammalian protein in *E. coli* (50).

6. Expanding the Code Experimentally

Redesigning the genetic code to allow the incorporation of amino acids that are not normally encoded by natural genes is a challenging task. The potential advantages of having unnatural amino acids at defined places in proteins are that they could be molecular beacons for structural studies and could open the potential for new structural and functional capabilities. Short proteins can be produced by solid-phase synthesis (see Peptide Synthesis), but longer proteins with unnatural amino acids are also desirable. The most ambitious approach is to create a 65th codon-anticodon pair from unnatural nucleoside bases having nonstandard hydrogen-bonding patterns (52). The more approachable, but still very difficult, task is to use the standard nucleotides to generate *in vivo* a tRNA that is competitive for reading a particular codon and aminoacylated with an unnatural amino acid, such as a keto-containing amino acid (53). Some success has been achieved *in vitro* (54-58) but, because of severe yield limitations, it is desirable to achieve the same goal *in vivo*.

A very promising start *in vivo* has recently been made (53). An essential requirement for a tRNA that delivers an unnatural amino acid is that it is not aminoacylated by the endogenous aminoacyl-tRNA synthetase. Instead, it needs to be recognized by a mutant synthetase and acylated with the unnatural amino acid. As a first step, Schultz and colleagues (53) isolated mutants of *E. coli* glutaminyl-tRNA synthetase that aminoacylate an engineered mutant of $tRNA^{Gln}$ that is not aminoacylated by the wild-type synthetase. This is a considerable feat, but major hurdles remain.

Genetic Disease

All of the 30,000 or more human genes can mutate, and many of the mutant alleles cause or contribute to the risk of genetic disease. In some instances, pathology occurs if only one of the two alleles at a particular locus is mutant. In other instances, both alleles must be defective. There are several sources of genetic heterogeneity in disease. Different alleles at a single locus may produce different degrees of pathology or even quite different disorders. In contrast, mutations at different loci can produce the same phenotypic changes. Mutations that arise in somatic cells can also produce disease, but they cannot be transmitted to offspring.

1. Disease, Genes, and Mutations

A discussion of genetic disease should begin with a definition of disease. Most persons use the term to indicate a departure from normal function or health. This suggests that a clear distinction exists between the healthy state and disease. Although this dichotomy may be useful to insurance companies, it is not very descriptive of biological reality. Each of us is uniquely programmed genetically to cope with greater or less success with what the environment presents to us. And ultimately we are programmed not to survive. This perception was expressed by the great British physician A.E. Garrod in his 1931 monograph *The Inborn Factors in Disease*, “It is permissible to suppose that, as in the production of those wider departures from the standard of health which receive the name of diseases, both internal and external factors are at work, so also in the causation of those lesser departures, which it is difficult to name or classify, and which may be spoken of as trifling ailments, ¼”

Diseases, then, may be thought of as deviations from normality that are sufficient to interfere with function of the organism. Many such deviations are primarily associated with specific genotypes. Others are combinations of genotypic and environmental variation. Although all are of interest, our knowledge is largely limited to those diseases that are well outside the range of normal function. In the case of inherited diseases, this means that we are largely limited to considering mutations at single loci that have a large impact on the phenotype. Results from the Human Genome Project, coupled with more sophisticated statistical techniques, are making possible the detection of smaller and more complex genetic contributions to disease risk.

As of May 2001, some 9,200 loci had been identified in the human genome. Over 7,000 loci had been assigned to specific chromosomes. Many are associated with a specific inherited variation or disease. Others are defined by the existence of their protein product or messenger RNA transcript. In some instances, a gene first observed in a nonhuman species is found to have a homolog in humans. The total number of loci is estimated to be approximately 30,000. This number is derived from the complete sequence of human DNA and is much lower than earlier estimates.

All genes have the potential to mutate. It is not known, however, what portion of the total number have the potential to mutate to a form that leads to recognizable disease. This is because many genes may cause early embryonic death if mutations occur in them. For example, any mutant form of a gene that is critical in early development may be eliminated without being observed.

2. Genotypes and Disease

The ultimate role of genes is the production of proteins of the right kind and amount in the right places and times. The vast majority of genes code for protein structures, and associated with each gene are regulatory elements—stretches of DNA that interact with other proteins to determine the amount of transcription of the gene. Most of the understanding of inherited diseases is in terms of function or malfunction of specific proteins.

Whether a mutant gene causes disease depends on several factors. Insertion or deletion of a single nucleotide in the coding region causes a shift in the reading frame during translation, leading to complete absence of the gene product. Substitution of one nucleotide for another may be equally detrimental if it causes substitution of the wrong amino acid at a functional site. Or it may have no effect at all if the amino acid substitution does not modify the function of the protein. Many such variations exist in the normal human population. Some cause small differences in function that we consider normal variation. Mutations in regulatory regions of genes may change the amount of gene product—too little or too much—but not the structure of the protein.

The phenotypic effect of these changes in gene structure depend on the role of the gene. The amounts of many enzymes normally produced are in excess of the amount needed to maintain normal metabolism. These loci are described as haplosufficient, meaning that a heterozygote that has one normal and one nonfunctional allele is phenotypically normal. Many enzyme deficiencies are inherited as recessive traits because of the need for both alleles to be *non*functional for disease to occur. Haplosufficiency also characterizes other types of proteins, such as cell cycle regulators and many receptors.

Haploinsufficiency is also observed. For example, one normal copy of a b-globin gene in hemoglobin is insufficient for manufacture of adequate amounts of b-globin, and anemia results. Again, in the case of low-density lipoprotein (LDL) receptors, one normal allele is insufficient to produce the number of functional receptors required to maintain normal levels of blood cholesterol. The transmission of these traits produces pedigrees characteristic of dominant inheritance.

One group of mutations is designated dominant negative. The name derives from the fact that the mutant allele interferes with functions of the normal allele. In a typical example, the proteins form complexes either involving one type of subunit (i.e., the product of one locus) or involving multiple subunits from different loci. The product of the mutant allele may enter into the complex but interfere with function of the complex. In the simplest case of a homodimer formed from two identical subunits, only the dimer composed of two normal subunits is functional. Both the mixed dimer and the dimer composed of two mutant subunits are nonfunctional. Because heterozygotes have reduced function, the transmission pattern is that of a dominant trait.

A variation on the previous example occurs when the mutant allele produces no protein product at all. In this case, the only subunits are produced from the normal allele, and all dimers or other multimers would be functional. This is observed in some collagen disorders, where deletion of an allele causes no phenotypic effect, the normal allele being haplosufficient. Only homozygotes for the mutant allele would generate a mutant phenotype. However, if the mutation is a minor variation in the amino acid sequence, this may interfere with production of normal collagen. The trait would appear as dominant in pedigrees.

Not all mutations or inherited syndromes involve single genes. In contiguous gene syndromes, small chromosomal deletions remove multiple closely-linked genes. The person therefore has only one copy of the genes in that segment rather than the normal two. Any genes that are haploinsufficient will affect the phenotype. The WAGR syndrome involves deletion of a small region of chromosome 11 that includes genes for *W*ilms' tumor, *A*niridia, *G*enital anomalies, and *R*etardation of growth. The WAGR syndrome is therefore the sum of the single gene defects.

3. Genetic Heterogeneity

If one considers all the possible nucleotide substitutions, insertions, and deletions in a gene that is many kilobases in size, the number of potential alleles at any one locus is enormous. In practice, one would never expect to see all possible mutant alleles in a population of finite size. However, in the case of other loci that have been extensively investigated, such as the globins, phenylalanine hydroxylase, cystic fibrosis, and Duchenne muscular dystrophy (DMD), hundreds of different mutant alleles have been identified. For the most part, these are individually very rare. In the case of the *DMD* locus, mutations are quickly eliminated by natural selection, and most mutations are found on analysis to be recent and to differ from other known mutations. In the case of other loci, a particular one or two mutations will be common, reflecting an increase in the frequency through genetic drift, founder effect, or heterozygote advantage. In the case of cystic fibrosis, some 70% of the mutant alleles in persons of European ancestry involve the identical three-nucleotide deletion, one that must have occurred many thousands of years ago to be so widely distributed.

Such allelic heterogeneity often translates into phenotypic heterogeneity. This is well illustrated in mutations of the *DMD* gene. Many of the mutations are associated with a protein product (dystrophin) that has some activity. This results in a milder form of the disease (Becker muscular dystrophy). Similar variations in severity of cystic fibrosis have been associated with different allelic combinations.

Because of the very large number of alleles at some loci, the term homozygous is often a misnomer. For rare recessive traits, it means that the two alleles are defective in their function but not that they are identical. A person with two different alleles that are functionally similar is described as a compound heterozygote. Unless the genes have been analyzed at the molecular level, one cannot be certain of true homozygosity.

Locus heterogeneity also occurs. This is the situation in which mutations at any of several loci produce the same phenotype. For example, early onset familial Alzheimer disease (FAD) is transmitted as a dominant trait and can be caused by mutations of any of three loci on three different chromosomes. The primary defect is presumably different at the molecular level, but the phenotypic results are the same.

An uncommon form of genetic heterogeneity is the production of different pathological conditions depending on where mutations occur in a gene. An example is the androgen receptor gene (*AR*), located on the X chromosome. The androgen receptor, when bound to testosterone and dihydrotestosterone, acts as a transcription factor in the nucleus. A number of mutations are known that interfere with binding and prevent the androgens from acting on target organs. The resulting disorder is known as androgen resistance. Mutations at other sites in the *AR* gene cause spinobulbar muscular atrophy.

Different populations also vary in their complements of mutant alleles. The mutations that cause cystic fibrosis occur in some 2% of persons of European origin but occur at much lower frequencies in other populations. Tay-Sachs occurs at much higher frequencies among Ashkenazi Jews. These high frequencies of detrimental genes probably arose through genetic drift and founder effect, although selective advantage may account for the high frequencies in some instances, as in sickle cell anemia in Africans. Even when the overall frequencies of mutant alleles are similar in populations, the specific alleles may differ.

4. Genetic Diseases of Somatic Cells

When inherited diseases are discussed, the traditional reference is to diseases that are transmitted from one generation to the next. Many show simple dominant or recessive inheritance according to Mendelian rules. Others are more complex, being influenced by variation at multiple loci and by environment also. The variations that can be followed in pedigrees occur in the germ lines and are therefore transmissible, even though the phenotype that we observe is based on somatic cell function.

Somatic cells, of course, have the same array of genes that are in the germ line, and they are subject to mutation as well as epigenetic alterations. The great importance of somatic cell genetics became apparent from the demonstration that mutations in somatic cells are essential parts of carcinogenesis. In the simplest case of retinoblastoma, a malignant tumor occurs when both alleles of the *RB* locus become inactive through mutation in a retinoblast. The normal restraints on cell growth no longer occur, and that cell forms a clone of cells that constitutes the tumor. The genotype of the original germline has changed in the clone of somatic cells but not in the germ cells. Retinoblastoma per se cannot be transmitted to offspring.

It has long been established that the *risk* of retinoblastoma is often transmitted as a simple dominant trait. In this case, one of the two required mutant alleles is transmitted in the germ line, and only one additional mutation is required in a retinoblast in order for the tumor to arise. This pattern has been established for a number of cancers for which high risk is found in certain families.

Somatic mutation must occur frequently at many loci. In most cases, there is no way to recognize an individual cell that has mutated. It is possible in the case of cancer because of the expansion of a clonal population from the original mutant cell. There are other instances in which somatic mutations also appear to be an essential part of the disease. For example, polycystic kidney disease is a dominantly inherited condition in which many renal cysts form. Comparison of the genotypes of the cysts with those of normal cells from the same person indicates that genetic alterations have occurred in the cysts and that each is a clone. As in cancers, clonal expansion makes it possible to detect the mutation that has occurred in a single somatic cell. Apparently two mutations are necessary, and, as in retinoblastoma, one can be transmitted through the germ line to all cells of the developing embryo. The study of somatic cell genetics is likely to be an area of great future interest as analytical techniques become ever more sensitive.

Genetic Diversity

Genetic diversity is the biological diversity that is present in the genetic material or information. Genetic diversity may be represented at the DNA level, at the level, at the **chromosomal** level, at the level, and at other higher levels, such as gene interaction.

Heterozygosity is the general measure of the genetic variation per **locus** in a given population. Suppose that a population contains *n* **alleles** at a locus, designated 1, 2, 3,¼n and with respective frequencies p_1, p_2, p_3 ,¼, p_n. Designating the frequency of the i-th allele by p_i, the heterozygosity is then defined as $H = 1 - \sum p_i^2$. When we are interested in many loci, the average heterozygosity (*H*) can be computed as an unweighted average of heterozygosities over various loci. Thus, the average heterozygosity is a simple and good measure for the genetic diversity of a population (1).

For DNA sequences, the average number of nucleotide substitutions between all possible pairs of alleles sampled in the population can be measured to evaluate the genetic diversity at the DNA level. This quantity is called the “nucleotide diversity” (1). These quantities are useful for measuring the genetic diversity within a population.

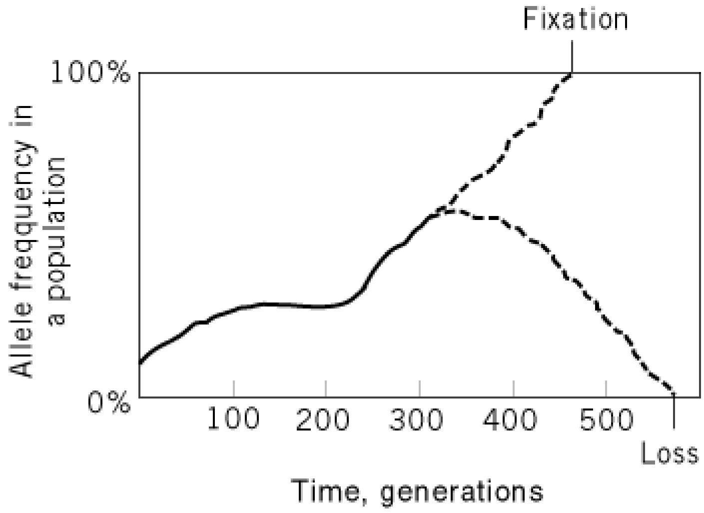
Genetic Drift

For a given gene **locus**, the frequency of a particular **allele** in a **polymorphic** population provides useful information, in that it describes the genetic composition of a given population at a particular point of time during evolution (Fig. 1). In principle, the allele frequency will never remain the same; it will always change with time because of mutation, selection, and nonrandom mating. Even when random mating occurs in a population, the allele frequency will change in a random manner over time. The random change of an allele frequency over time is called “genetic drift”. In general, the effect of genetic drift is greater the smaller the population size, and the effect of selection on allele frequencies dominates the effect of genetic drift when the population size is larger.

Figure 1. Scheme demonstrating genetic drift of an allele frequency in a population by chance over time.



Genetic drift is an important mechanism for gene evolution because it can change the genetic composition drastically over a very short period of time, particularly when the population size is extremely small. This was initially recognized by Sewall Wright (1931) and therefore known as the Wright effect (1). The Wright effect can be seen when a small number of individuals from the mother population immigrate to a new place (the founder effect) and when the population size suddenly reduces, for reasons such as climatic change or volcanic eruption (the "bottleneck effect").

For identifying genes responsible for disease at the DNA level, it is necessary to assess linkage disequilibrium or genetic association with certain marker genes. For this practice, the effect of genetic drift should be evaluated correctly in order to discriminate between the effects of selection and of genetic drift.

Genetic Marker

A genetic marker is a phenotypic variant due to a variation in the nucleotide sequence of a genome, or the phenotypic manifestation of an **allele**. The term is used frequently as a synonym of allele.

Genetic markers may affect the morphology, behavior, physiology, or chemistry of the organism, and they are defined in relation to the phenotype of the standard **wild type**. A *marker gene* is a gene whose phenotypic variants are used as genetic markers.

From a practical viewpoint we can distinguish four groups of genetic markers:

1. *Selectable* markers which enable the individuals that carry them to grow under experimental conditions that hinder similar individuals lacking the marker. Selectable markers are nearly indispensable in the genetic analysis of very large laboratory populations of **viruses**, bacteria, unicellular eukaryotes, and cultured cells. Particularly useful are the selectable markers that are also *counterselectable*; that is, certain experimental conditions allow the growth of individuals

that lack them and hinder individuals that carry them.

2. Genetic markers that are easily recognized by visual inspection of the shape, the color, and sometimes the movements of cells and organisms. They have been particularly useful in the analysis of small populations of plants and animals.
3. Genetic markers whose detection requires specific tests. Conditional lethal markers impede growth under normal conditions, but are rescued by special circumstances of the environment or the genetic background. Chemical analyses are often indispensable—for example, to detect the presence or absence of a metabolite or to distinguish the **electrophoretic** variants of a protein. Behavioral markers usually require their own specific tests. Onerous analyses can be avoided in a few cases. For example, some of the adenine auxotrophs of *Saccharomyces cerevisiae* develop a pink color under certain growth conditions; the presence of certain chemicals or certain enzymes in a cell may be revealed when they produce a colored product with certain reagents.
4. Variations in the DNA sequence that have no other phenotypic expression than the results of direct tests on the DNA (eg, restriction maps, **PCR**). Their main advantage is that they occur all over the genome, even in regions in which no other genetic markers have been located.

Genetic Suppression

Genetic suppression is the relief of a mutant phenotype by a second mutation. The second mutation gives the appearance of "suppressing" the first mutation. The suppressor mutation identifies a new site affecting the phenotype of interest, and suppression is strong evidence that the two genetic sites functionally interact. Suppressor mutations have been extremely useful for understanding genetic and biochemical phenomena. Biological systems are a tangle of interacting molecules and intersecting pathways. It should come as no surprise that mutations in one molecule are often modulated by secondary mutations in others.

Suppressor mutations can occur in the same gene as the initial mutation (intragenic suppression), or the two mutations may be in separate genes (intergenic suppression). Intragenic suppression may occur if the amino acid residues specified by the two sites must interact to give the normal function of the gene product. Intragenic suppression may also occur by the relief of a polar effect on gene expression. Intergenic suppression has been extensively used to characterize interactions between gene products. In certain cases, the suppressor mutation may establish a new pathway that supplants the pathway disrupted by the initial mutation. A special kind of suppression occurs when mutants are "rescued" by normal genes expressed from high-copy plasmids. The high concentration may facilitate an interaction between proteins that is weakened by the first mutation, or it may provide an alternative pathway to a normal phenotype. Another special kind of intergenic suppression occurs when mutations occur in transfer RNAs so that they translate stop (nonsense codons) codons as sense codons. These tRNAs (nonsense suppressors) can allow expression of genes that have suffered mutations that create stop codons within coding sequences. See "Nonsense suppression" and "tRNA suppressor" for more complete descriptions of these phenomena.

Suppressors were initially detected during studies of mutations. It was found that certain mutations express altered phenotypes only in certain genetic backgrounds. Apparently, in the non-expressing strains other genes were able to suppress these mutations. The molecular basis of these early observations has remained obscure (1), but they have been instructive for defining the principle of suppression.

In a now classic study, intragenic suppression was used to study the fundamental nature of the genetic code. Francis Crick et al. (2) showed that genes are expressed as triplets that do not overlap one another. These workers first showed that mutations that were caused by the insertion (+) or deletion (–) of nucleotides could be suppressed by a second mutation of the opposite sign, if the two mutations occurred near one another within the gene. It was concluded that genes must be read in a specific “reading frame”. Either an insertion or a deletion would shift the reading frame such that the remainder of message sequence is decoded to specify the wrong polypeptide sequence. These workers further concluded that the second mutation of the opposite sign suppresses the first mutation by restoring the initial reading frame. In between the two mutations, the gene would be translated in a wrong reading frame, but as long as the amino acid sequence of that region was not critical for protein function then the double mutant would have a wild type phenotype. Crick also used suppressor mutations to determine the size of the “codon”. It was found that although one or two insertions invariably gave a mutant phenotype, three insertions or three deletions could give a wild type phenotype. It was concluded that because the insertion or deletion of three bases did not perturb a reading frame, the genetic code is a triplet code.

Intragenic suppression can also be used to show that two amino acid within a protein molecule interact. A mutation that eliminates a critical interaction between two amino acids can sometimes be suppressed by a change in the second amino acid that restores complementarity. The first example of such an analysis is presented by Helinsky and Yanofsky (3), in which an intragenic second-site mutation restored partial function to an *Escherichia coli trpA* mutant. Such information can complement structural studies by providing confirmation of hypothetical interactions between amino acids at specific positions. Such work is greatly facilitated by site-directed mutagenesis, which allows the creation of specific mutations to test structural predictions.

Intergenic suppression is extensively used to identify and study interactions between molecules. The principle is that mutations that destroy complementary interactions between proteins may be compensated by secondary mutations that provide suitable alternative interactions. This approach has been used to identify proteins interact within biochemical, gene expression, and signal transduction pathways. This approach is also widely used to study interactions between molecules already known or suspected to interact. Examples include studies of receptor-ligand interactions and of interactions between transcription factors and promoter elements.

Another commonly used method is the identification of cloned genes that can suppress mutations when expressed at high levels. Cells are transformed with expression libraries, and suppressed isolates are selected. Suppression may occur when the overexpressed protein compensates for the defect of the initial mutation. Several molecular mechanisms are possible, and further work is usually required to elucidate the mechanism of suppression in each instance. Possible mechanisms include the restoration of a direct interaction between proteins, increasing the expression of a partially-active mutant protein, and providing a bypass of the cellular or biochemical defect of the primary mutation. A related approach, though not usually thought of as suppression, is the use of the various “two-hybrid” systems to identify interacting proteins. These are actually highly-derived examples of intergenic suppression.

Another special but widely employed kind of intergenic suppression occurs when tRNAs are mutated such that they insert a suitable amino acid at missense, nonsense and frameshift mutations. These “informational” or “translational” suppressors have been extremely useful for studying the decoding mechanisms (4). Currently, certain translational suppressors are in development as tools for protein engineering. Systems for labeling proteins with novel amino acids at specific positions would be extremely useful. Toward this end, mutant tRNAs that decode the UAG stop (classically called the “amber” codon) are being aminoacylated with nonstandard amino acids.Then these tRNAs direct the incorporation of the novel amino acid into a nascent protein if its gene has been mutated to contain an amber codon at a specific site within its coding sequence. At this time, only a few nonstandard amino acids may be incorporated in this way, but it is anticipated that it will soon be possible to label proteins with a large variety of amino acids containing affinity tags, fluors, or reactive groups (4).

Discussion of related topics can be found in “Nonsense suppression,” “Suppressor mutation,” and “Suppressor tRNA.”.

Genome

The *genome* is the totality of all of the **DNA** of an individual or a species. It is now taken to include all of the DNA, not just the **genes**. This definition is simple for the majority of genomes, but all of the minor DNA components must also be considered. For simple **viruses**, with a single **nucleic acid** molecule, the genome is obvious, although of course for RNA viruses it is **RNA** rather than DNA. For haploid **prokaryotes**, it is also straightforward, except for the **plasmids**, one copy of which is counted in the genome. Since prokaryotic strains and lineages differ by DNA sequence **polymorphism** and in the plasmids present, only genetic lineage genomes can be described with total accuracy. The genome of a species will be a compromise best representing all the known lineages, to make up a typical genome for the individuals of that species.

For **eukaryotes**, one haploid copy of the DNA of each of the diploid pairs of chromosomes (the autosomes) is included, plus one copy of the DNA of sex chromosomes. Thus the female and male genomes will differ if the sex chromosomes are different. One copy of the DNA from any **organelles** other than the nucleus, such as the mitochondria and chloroplasts, should be included; a complete list of such organelles is probably not yet available for any species, but many are normally unimportant. There is, of course, polymorphism of DNA sequences in a population of individuals, and the species’ genome is again a compromise to obtain a typical genome. The genome can be considered to include all of the information required to specify the species, but only for certain viruses has it actually been demonstrate that the lineage can be propagated from purified DNA. When the phrase “genome size” was first used to describe the total haploid DNA content, there were strong objections, based on the concept that there is additional information in the chromosomal proteins, and even in body structures, that is necessary to propagate the lineage. While that point of view is not common at present, the proof has not been made with eukaryotes that the DNA contains all of the information required for maintenance of the lineage or species.

The majority of the DNA of a genome is not in the genes themselves and their known associated regulatory sequence. While the phenomenon of **gene regulation** is beginning to be understood, little is known of the significance of the majority of the DNA, whether it has any functions other than acting as spacer between genes. In most species, a large fraction of the DNA is repeated sequences (see Repetitive DNA and Repeated DNA Sequence Interspersion) that cause genetic recombination and **unequal crossing over**, resulting in genomic rearrangements, but their overall significance is not understood.

Genomic Libraries

Early genomic libraries were viewed as a repository from which any genetic elements could be isolated for a given organism. Modern genomic libraries serve this function, but they also straddle the interface between genomic bioinformatics and functional biology. Thus, genomic sequences are increasingly understood in terms of their information content, comprising their RNA- and protein-coding sequences, as well as in terms of the overall organization of their embedded genetic program. Central to this information-based approach are new, highly sophisticated libraries of genomic DNA that maintain the structural context of genetic elements over several hundred kilobase pairs or more. Such libraries are essential for gene mapping projects, which will eventually produce an atlas of the genetic organization of many organisms. Detailed gene maps are required to interpret sequencing data that result from genome sequencing efforts. The genome sequencing projects themselves depend on high-quality genomic DNA libraries as a source of genetic material. The study of the genetic basis of disease makes use of sequence differences between individuals that can be ascertained through genomic libraries. These libraries also serve as a source of genetic probes that can be used for diagnosis and characterization of the relevant genotype of any individual.

Construction of genomic libraries requires particular attention during all stages of processing in order to minimize mechanical shearing of the cellular DNA. Nucleic acids become increasingly sensitive to shearing with increasing size, making it especially difficult to maintain the integrity of chromosome-sized species. Fortunately, specialized methods have been developed that enable the cloning of DNA fragments that are several hundred kilobase pairs or larger. The size of the genomic insert determines the type of vector into which the DNA is inserted. Inserts smaller than 10 kbp can be **cloned** into either plasmid or bacteriophage vectors. Cosmid vectors are required for fragments in the range of 10 to 40 kbp, while artificial chromosomes (ACs) are needed for even larger inserts.

Most genomic DNA library projects seek to represent a set of partially overlapping DNA fragments that collectively represent the entire genome of the subject organism. Such overlapping cloned inserts are ideal for chromosome “walking” approaches, in which the termini of one set of probes can be used to identify overlapping clones, which in turn can identify further overlapping clones downstream. In this manner, a set of clones can be derived that cover virtually any span of genetic sequences. Once prepared, such a repository facilitates the identification of genetic elements associated with any phenotype or disease. Three methods are employed for generating genomic DNA fragments of appropriate sizes for cloning. First, mechanical shearing can be used to produce relatively small inserts, although ligation into the vector with such fragments is typically inefficient. Because the shearing is random, this method produces a series of partially overlapping fragments. Second, and by far the most common method, is the use of restriction enzymes to prepare fragments. Digestion of DNA with restriction enzymes provides a great deal of control over the size of the resulting fragments. For example, endonucleases with a four-nucleotide recognition sequence cut on average every 256 nucleotides, while certain enzymes with large recognition sequences may cut approximately every 10^6 nucleotides. Unfortunately, complete digestion of genomic DNA with restriction enzymes eliminates any overlapping fragments; therefore, most genomic libraries employ partial digestion of genomic DNA. The degree of digestion thus influences the average fragment size, as well as the degree of fragment overlap. Another advantage of using restriction endonucleases is that the fragment termini are defined and readily clonable. The third method of preparing genomic DNA is to perform **PCR** using primers containing a region of random sequence. In the first PCR cycle, the random primer segments anneal to both strands throughout the genome and are extended in a 5′ to 3′ direction. In subsequent PCR cycles, any two oppositely oriented primers that are within sufficient proximity can generate a specific PCR product. The resulting PCR products can be prepared for cloning into an appropriate vector. Alternatively, the collection of genomic DNA fragments can be maintained and propagated as PCR products using fixed sequences, introduced during the PCR, as primer binding sites for subsequent rounds of amplification.

In general, genomic libraries are used for DNA-based studies, such as gene mapping and marker analysis; however, in certain cases they may also be useful as expression libraries. Many simpler organisms have few or no **introns**, so their genomic DNA can be directly expressed into messenger RNA and **translated** into protein. Furthermore, structural RNAs, such as **ribosomal** RNA and transfer RNA are not represented in most cDNA libraries and thus require genomic libraries to isolate appropriate DNA coding sequences. Finally, random genomic expression can be a productive means of generating RNA and peptide libraries for **epitope-** and **domain**-mapping exercises.

Germ Cell, Line

Germ cells are the cells in a multicellular organism that retain totipotency and are responsible for the propagation of succeeding generations of new individuals. Collectively, the germ cells comprise the germ line. Mature, fully differentiated germ cells in females are called eggs, or oocytes, and in males sperm, or spermatids. Undifferentiated germ cells present in animal embryos are called primordial germ cells, or PGCs. In dipterans such as *Drosophila*, PGCs are called pole cells. Flowering plants produce two types of germ cells, called microspores and megaspores. Microspores, or pollen grains, form within the stamen of the flower, and megaspores develop within the ovules of the carpels. A fundamental distinction between germ cells and other cells (somatic cells, or soma) is that, immediately prior to their final differentiation, germ cells undergo a specialized set of two cell divisions termed *meiosis*. Unlike *mitosis* , which is always coupled with DNA replication, the first meiotic division is not in organisms with sexual reproduction. Thus, meiosis reduces the ploidy of germ cells by one-half, most commonly from **diploid** to haploid. A new generation comes into being at fertilization, when the two different types of mature germ cells (for instance, egg and sperm) fuse to form a zygote . The egg and sperm nuclei also fuse to reconstitute the normal chromosome number. The zygote nucleus then divides mitotically, and it ultimately gives rise to all the cells of the organism.

1. Germ Line Specification

A common feature in animal development is that the germ line is segregated from the soma at a very early stage of embryogenesis. In many animals, germ cells develop in a region of the embryo whose cytoplasm contains specialized organelles, variously termed *P granules* , *polar granules* , or *germinal granules* (1). These organelles are assembled during oogenesis from maternally encoded gene products, and they localize asymmetrically within the egg either during oogenesis or immediately after fertilization. They are rich in RNA and protein, are not surrounded by membrane, and are associated with ribosomes and mitochondria.

Transplantation experiments in *Rana pipiens* (2), *Drosophila melanogaster* (3, 4) and Xenopus *laevis* (5), and genetic experiments in *Drosophila* (6), have demonstrated that the necessary information for germ cell determination is present in the germinal cytoplasm. In Caenorhaebditis *elegans*, P granules are distributed throughout the cytoplasm of the unfertilized egg. After fertilization, they become confined to the posterior end, such that they are found only in the posterior daughter of the first cleavage, called P_1 (7). In three subsequent mitoses, the P granules segregate to the more posterior daughter cell, called P_2, P_3, and P_4. The P_4 cell is the founder cell of the entire germ line. In *Drosophila*, pole cells arise from the pole plasm at the posterior end of the preblastoderm embryo and are the first cells to form. Pole plasm is distinguished by the presence of polar granules.

Many protein and RNA components of *Drosophila* polar granules have now been identified (reviewed in refs. 8-10), and their characterization broadly supports an early suggestion (11) that polar granules function by storing and regulating translation of maternal messenger RNAs required for germ cell determination. A protein component of polar granules in many organisms is the RNA helicase Vasa (12-17), and *vasa* activity is required in *Drosophila* for efficient translation of ***oskar*** and ***nanos***, two pole plasm-localized mRNAs (18, 19). Conversely, translation of these RNAs is repressed in *Drosophila* outside of the pole plasm (19-24). Polar granules in many species are frequently associated with mitochondria, and in *Drosophila*, mitochondrial ribosomal RNAs are associated with polar granules and may be essential for pole cell formation (25). Germ cells also possess other densely staining cytoplasmic organelles, usually termed nuage (26), which are structurally related to polar granules, and which in *Drosophila* share at least one molecular component with polar granules (12, 13, 27).

In the two-cell *Xenopus* embryo, the germ plasm is present in small aggregates near the vegetal pole (28). By the time of the second cleavage division, these aggregates have moved toward the cleavage furrows, so that each of the cells of the four-cell embryo receives a portion of the germ plasm. In subsequent cleavage divisions, however, the germ plasm is associated with one of the spindle poles and therefore is segregated to only one of the two daughter cells. At gastrulation, the germ plasm becomes perinuclear and is divided symmetrically at mitosis, so the number of PGCs increases from four to about 14 by the stage at which they exit the endoderm. In zebrafish, germ cells are not morphologically distinguishable until the 10- to 12-somite stage of development, when they are clustered on either side of the midline neighboring the third to fifth somite. However, analysis of the localization of zebrafish *vas* mRNA (17) suggests that, as in *Xenopus*, germ plasm is associated with the first two cleavage planes and condenses into four clumps, which do not further subdivide until after the 1000-cell stage. Microdissection studies in chick embryos suggest the germ line arises from the most central part of the blastodisc during the first 18 to 20 hours of development (the uterine stage), which includes cleavage and formation of the area pellucida (29).

Germ line specification in mammals may be quite different from that in other species, as mammalian oocytes lack a visible germ plasm (30). In mice, PGCs are first recognizable during gastrulation as a cluster of about 100 cells located within the midline extra-embryonic mesoderm posterior to the primitive streak (31). A key biological marker for totipotential embryonic cells is the transcription factor Oct-4 (32). Two tissue-specific enhancers have been mapped for the *Oct-4* gene, and reporter gene analysis indicates that the more distal one activates *Oct-4* expression in oocytes, morulae, and the inner cell mass of blastocyst-stage embryos, and then again in migratory and postmigratory germ cells. Trans-acting factors responsible for *Oct-4* activation have not yet been identified.

2. Germ Cell Migration

Once the germ cells have been specified, they follow an elaborate migration pathway within the interior of the embryo, culminating in an association with the gonadal mesoderm (genital ridge in vertebrates) to form the two embryonic gonads. At gastrulation, *Drosophila* pole cells are transferred within the embryo in the posterior midgut invagination. Subsequently, they actively migrate through the midgut epithelium, move dorsally, separate into two bilateral populations, and contact the overlying mesoderm (33, 34). They are then surrounded by the gonadal mesoderm and, together with that mesoderm, form the two embryonic gonads, each containing approximately 14 pole cells. Pole cells do not divide throughout the period of migration. Pole cells lacking maternal *nanos* activity migrate into the interior of the embryo, but fail to be incorporated into gonads (35). The Wunen protein, a probable phosphatidic acid phosphatase expressed on the surface of posterior midgut cells, repels germ cells and thereby limits the range of their migration on the gut (36). Later steps in germ cell migration are influenced by a large number of genes expressed in the soma, some of which, including *tinman* and *zfh-1* , have also been implicated in gonad formation (37-39).

In fish, PGCs migrate dorsally during epiboly and early gastrulation and form two groups of cells on either side of the notochord, where they remain throughout somitogenesis. The precise position of the PGCs along the anterior-posterior axis varies among different species of fish. Later in larval development, the PGCs resume cell division and coalesce into a gonad. In *Xenopus*, the PGCs become incorporated into the larval hindgut after gastrulation, then migrate through the hindgut mesentery to reach the genital ridges on either side of the dorsal aorta (40). In the chick embryo, PGCs move to the endoderm to a site where blood vessels form, and they are taken up in the bloodstream (32). They then leave the circulatory system near the position where the hindgut develops and associate with the hindgut mesentery. In the mouse embryo, PGCs disperse from extra-embryonic tissues at 8.0 days past coitum (dpc) and migrate into the hindgut epithelium (41). From 9.5 to 11.5 dpc they move out of the hindgut, along the dorsal mesentery, and ultimately reach the gonadal primordia.

3. When Does the Germ Cell Lineage become fully distinct from the Somatic Lineage?

In the *C. elegans* embryo, where the complete cell lineage is known, the germ-line or P lineage becomes distinct when the P_4 cell is formed at the 24- to 28-cell stage of embryogenesis (42). In *Drosophila*, the germ cell lineage is distinct from the soma from the time of pole cell formation; when transplanted into host embryos, labeled pole cells do not contribute to somatic tissues (43). Conversely, in vertebrate embryos, migrating PGCs are not irreversibly determined as germ line cells. Transplantation of fluorescently labeled migrating PGCs from *Xenopus* embryos into unlabeled hosts indicates that they retain the capacity to differentiate into a large variety of somatic tissues (44). In mice, 8.5-dpc and 12.5-dpc (but not 15.5-dpc) PGCs can be cultured and give rise to undifferentiated cells called EG cells (45, 46). When EG cells are injected into host blastocysts, they frequently contribute to germ line and somatic tissues. Mammalian germ cells change the **methylation** pattern of parentally **imprinted** genes upon differentiation; for at least one such gene, *Igf2*, the methylation pattern in EG cells is similar to that in germ cells and not somatic cells (46).

4. How do Germ Cells Retain Totipotency?

Few details are presently understood as to how germ cells retain the capacity to generate all the different tissues of the organism, while somatic cells become increasingly specialized. It has been observed that early PGCs in *C. elegans* and *Drosophila* transcribe essentially no mRNA (47, 48). This transcriptional silencing is correlated in both organisms with a lack of a specific phosphorylated form of RNA polymerase II in premigratory and migratory germ cells (49). Furthermore, *Drosophila* pole cells that lack *nanos* activity, and fail to colonize the gonad, activate transcription of numerous reporter genes prematurely (35). It has been suggested that the lack of gene expression in embryonic germ line cells is of fundamental importance to maintaining their totipotency.

Gibberellins

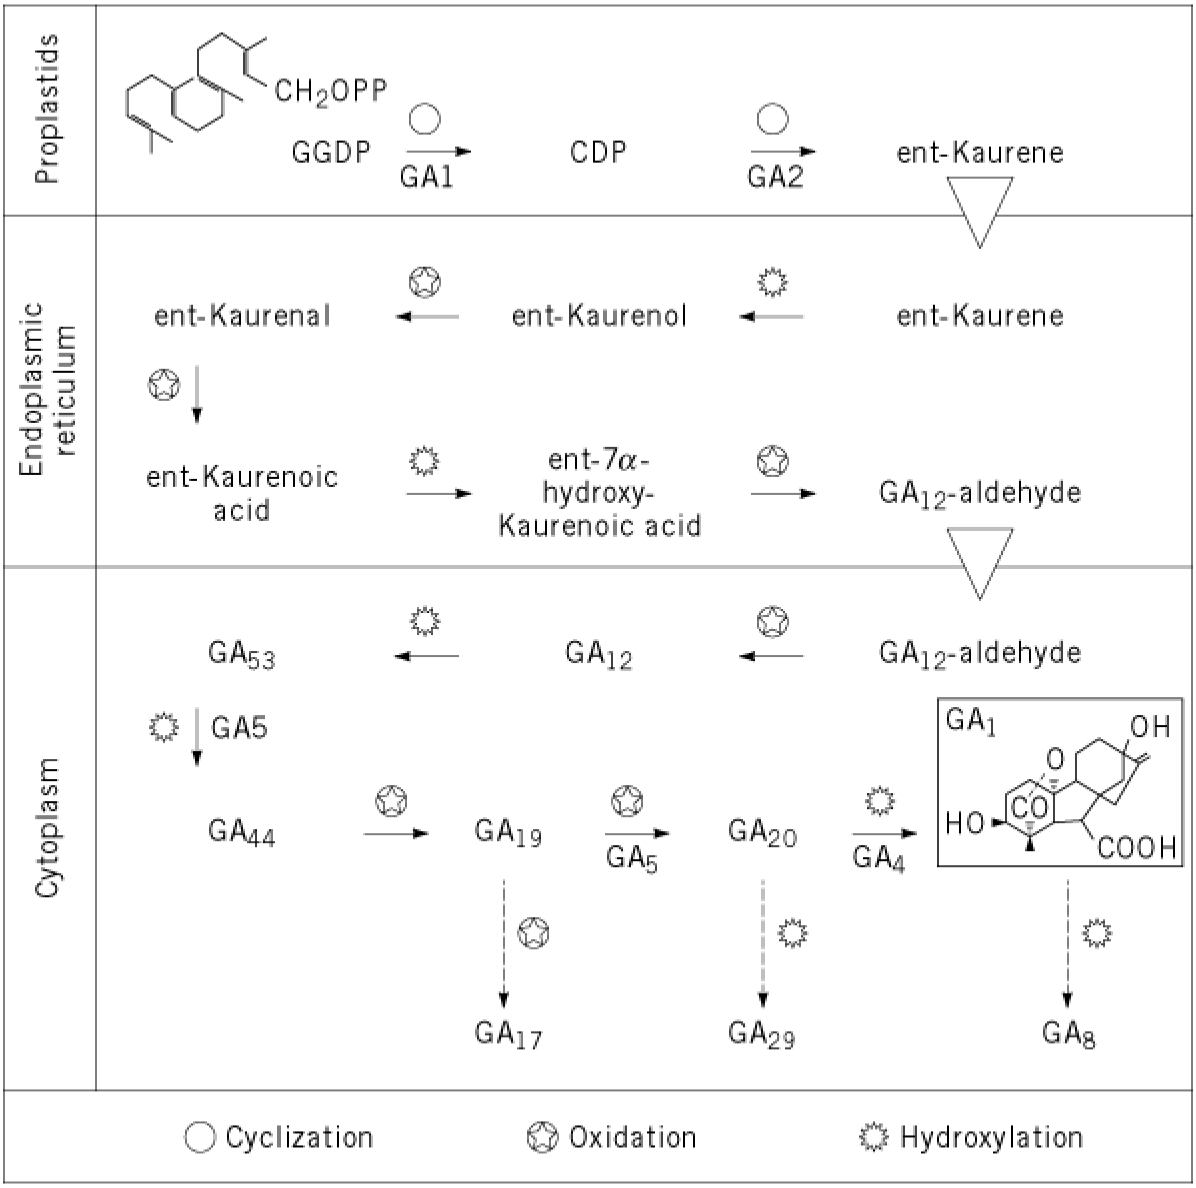
1. History

Gibberellins are plant hormones, tetracyclic diterpene carboxylic acids that were discovered in 1926 as a phytotoxin produced by the fungus *Gibberella fujikuroi*. The latter caused a pathological longitudinal growth in rice called "foolish seedling disease" (1). The active compound was isolated from the fungus in 1930 by Yabuta and Sumiki (2) and was called *gibberellin*. In 1958, a first gibberellin (GA_1) was purified from runner bean seeds (*Phaseolus coccineus*) by MacMillan and coworkers (3). Since this discovery, 112 gibberellins have been identified (4).

2. Biosynthesis and Metabolism

Gibberellins are isoprenoid compounds synthesized from C2 units by the mevalonic acid pathway. Geranyl geranyl diphosphate, a C20 molecule, serves as a donor for the entire carbon skeleton of gibberellins. Starting from geranyl geranyl diphosphate, biosynthesis of gibberellins can be divided into three stages according to the nature of the enzymes involved and their subcellular localization (Fig. 1). The pathway is well-characterized, owing to the existence of gibberellin-deficient mutants that are easily identified by their dwarfed stature (5, 6). Gibberellin-deficient mutants are blocked at a particular step in the pathway, and their **phenotype** can be reverted by external addition of active gibberellins.

Figure 1. Gibberellin biosynthetic pathway in higher plants. Steps involving GA1, GA2, GA4, and GA5 in *Arabidopsis* are indicated. (Adapted from Ref. 16)



Several **genes** encoding gibberellin-biosynthetic enzymes have been characterized, and their products seem to catalyze multiple steps. First, geranyl geranyl diphosphate is converted into *ent*-kaurene by two cyclization steps. The enzymes catalyzing these reactions are *ent*-kaurene synthase A and B, also termed *ent*-copalyl diphosphate synthase (CPS) and *ent*-kaurene synthase (KS) (7). The gene encoding the CPS has been cloned from *Arabidopsis* (*GA1*) (8), maize (*Anther ear-1, An1*) (9), pea (*LS*) (10), tomato (11), and pumpkin (12), whereas that for KS was cloned from pumpkin endosperm (13) and from *Arabidopsis* (*GA2*) (14).

The KS activity is mostly associated with stroma of proplastids in rapidly dividing plant tissues (15); however, *GA1* promoter activity is also present in fully expanded leaves (16), suggesting that gibberellins are transported to responsive tissues. In Arabidopsis ***Arabidopsis***, *GA1* gene expression appears to be highly regulated during growth and development. In addition, *GA1* promoter activity was restricted to specific cell types, such as shoot apices, root tips, developing seeds and flowers, and vascular tissue of mature leaves (17).

The second stage converts *ent*-kaurene to GA_{12}-aldehyde. *Ent*-kaurene is subjected to five sequential oxidation steps, resulting in GA_{12}-aldehyde. These reactions take place in the endoplasmic reticulum and seem to be catalyzed by a single membrane-associated cytochrome P450 monooxygenase. The gene encoding this enzyme was recently cloned from maize (*Dwarf-3, D3*) (18). Its expression was observed in seedlings, developing leaves, vegetative meristems, and roots. The predicted protein carries the Fe-binding domain that is characteristic of cytochrome P450 proteins (18).

The third stage converts GA_{12}-aldehyde to various gibberellins and takes place in the cytoplasm. The first step in this process consists of the oxidation of GA_{12}-aldehyde to GA_{12}. Subsequently, GA_{12} is subjected to various reactions, depending on the organism. In the past, genes encoding one of the major enzymes involved in these reactions, GA 20-oxidase, were characterized in different species such as pumpkin (19), *Arabidopsis* (*GA5*) (20), and spinach (21). GA 20-oxidases belong to the family of 2-oxoglutarate-dependent dioxygenases. In *Arabidopsis*, GA 20-oxidases are encoded by a small multigene family. Expression of the *GA5* gene in leaves was enhanced when plants were shifted from short-day to long-day conditions, indicating photoperiod regulation. In addition, *GA5* was down-regulated by GA_4 treatment, suggesting feedback repression of the pathway (20). Finally, a 3b-hydroxylase catalyzes the formation of biologically active gibberellins. The *GA4* locus encoding a 3b-hydroxylase was recently cloned from *Arabidopsis* (22). The gene is ubiquitously expressed, but its messenger RNA is most abundant in siliques. As with *GA5, GA4* is also subjected to a feedback regulatory mechanism (23).

Relatively few gibberellins appear to be biologically active, such as GA_1, GA_3, and GA_4. The remaining ones are the precursors or the deactivated forms of active gibberellins. The latter are generally deactivated by 2b-hydroxylation. The only deactivation mutant described thus far is the slender (*sln*) genotype of *Pisum sativum* . A mutation at this locus is responsible for a large accumulation of GA_{20}, the precursor of GA_1, and gives rise to the elongated phenotype. It was suggested that *sln* encodes a regulatory protein controlling two genes involved in the degradation pathway (24). Another process in gibberellin metabolism is their conjugation to inactive derivatives, including glucosyl ethers and glucose esters, that are found mainly in seeds (25).

3. Signal Perception and Transduction

The gibberellin biosynthesis pathway is well-characterized, but much less is known about how gibberellins are perceived by the plant and how the signal is transduced to control the expression of gibberellin-regulated genes (26, 27). Biochemical studies on barley aleurone protoplasts suggested that gibberellin binds to a receptor located at the external face of the plasma membrane (28). This receptor has not yet been isolated, however, nor has any gibberellin receptor been cloned to date.

Our current knowledge of gibberellin signaling is based mainly on the characterization of four mutants of *Arabidopsis: spy* (*spindly*), *gai* (*gibberellin-insensitive*), *rga* (*repressor of ga1-3*), and *pkl* (*pickle*). None of these mutants can be entirely reverted by exogenous application of gibberellin, supporting their role in gibberellin signaling.

The *spy* mutants were screened for their ability to germinate in the presence of the gibberellin biosynthesis inhibitor paclobutrazol, which blocks the cytochrome P450 monooxygenase involved in the oxidation of *ent*-kaurene to *ent*-kaurenoic acid (29). *Spy* mutants phenocopy wild-type plants that were repeatedly treated with GA_3, presenting a constitutive gibberellin-response phenotype that is characterized by long hypocotyls, pale green foliage, increased stem elongation, early flowering, partial male sterility, and parthenocarpic fruit development. Moreover, *spy* plants remain gibberellin-responsive. *Spy* is partially epistatic to *ga1-2*. Collectively, these data indicate that SPY is a negative regulator of at least one branch in gibberellin signaling.

The *SPY* gene was recently cloned using a T-DNA tagging approach (30). The predicted SPY protein contains a tetratricopeptide repeat of 34 amino acid residues in its *N*-terminal region. This motif is also found in some other eukaryotic and prokaryotic proteins and is proposed to form an amphipathic a-helix that mediates protein–protein interactions (31). The tetratricopeptide repeat appears to be important for the normal function of SPY, because some of the mutant phenotypes result from a deletion in this motif. The *C*-terminal region of SPY shows sequence similarity to the mammalian Ser/Thr *O*-linked *N*-acetylglucosamine (*O*-GlcNAc) transferase, which plays an important role in the regulation of the activity of various nuclear and cytosolic proteins, either directly or by inhibiting their phosphorylation (32, 33). Because certain *spy* alleles are affected in the region bearing similarity to *O*-GlcNAc transferase, this activity seems to be involved in proper functioning of the *SPY* gene product.

A second player is GAI. *Gai* mutant plants present a dwarf phenotype (reduced plant height, decrease in apical dominance, and limited seed germination), comparable to gibberellin-deficient plants. The lack of response of *gai* mutants to exogenous application of gibberellin, however, suggests that the GAI protein acts in signal transduction (34, 35). *Gai* heterozygotes show an intermediate mutant phenotype, indicating that the mutation is semidominant.

The *GAI* gene was recently isolated using *Ds* transposon tagging (36). In addition, a closely related gene named *GRS* (*GAI-related sequence*) was cloned (36). Comparison of the predicted amino acid sequences of the GRS and GAI proteins with the sequence databases showed that they are members of the VHIID family of plant transcription factors defined by Di Laurenzio et al. (37). A first member of this novel class of transcription factors was called *SCARECROW* (*SCR*) and controls cell fate in *Arabidopsis* roots. The VHIID proteins are putative transcription factors that contain three main motifs: a central –Val–His–Ile–Ile–Asp–sequence, with a Leu–X–X–Leu–Leu–sequence (where X represents any amino acid residue) in its immediate vicinity, and an –Arg–Val–Glu–Arg–sequence in the *C*-terminal region (38). The Leu–X–X–Leu–Leu–motif is a signature motif in transcriptional coactivators that mediates binding to nuclear receptors (39). The GAI protein possesses a fourth sequence in its *N*-terminal region (–Asp–Glu–Leu–Leu–Ala–) that appears important for its normal function. A nearby Ser/Thr-rich stretch is a potential target of SPY action. GAI was proposed to act directly as a transcriptional repressor of target genes that promote gibberellin-mediated processes, or indirectly as a transcriptional activator that induces the expression of such a repressor (36). This hypothesis implies that gibberellin would modulate the pathway by derepression and, therefore, by inactivation of GAI. An extragenic suppressor mutant of *gai*, called *gar2* (*gai suppressor 2*), was genetically characterized (35).

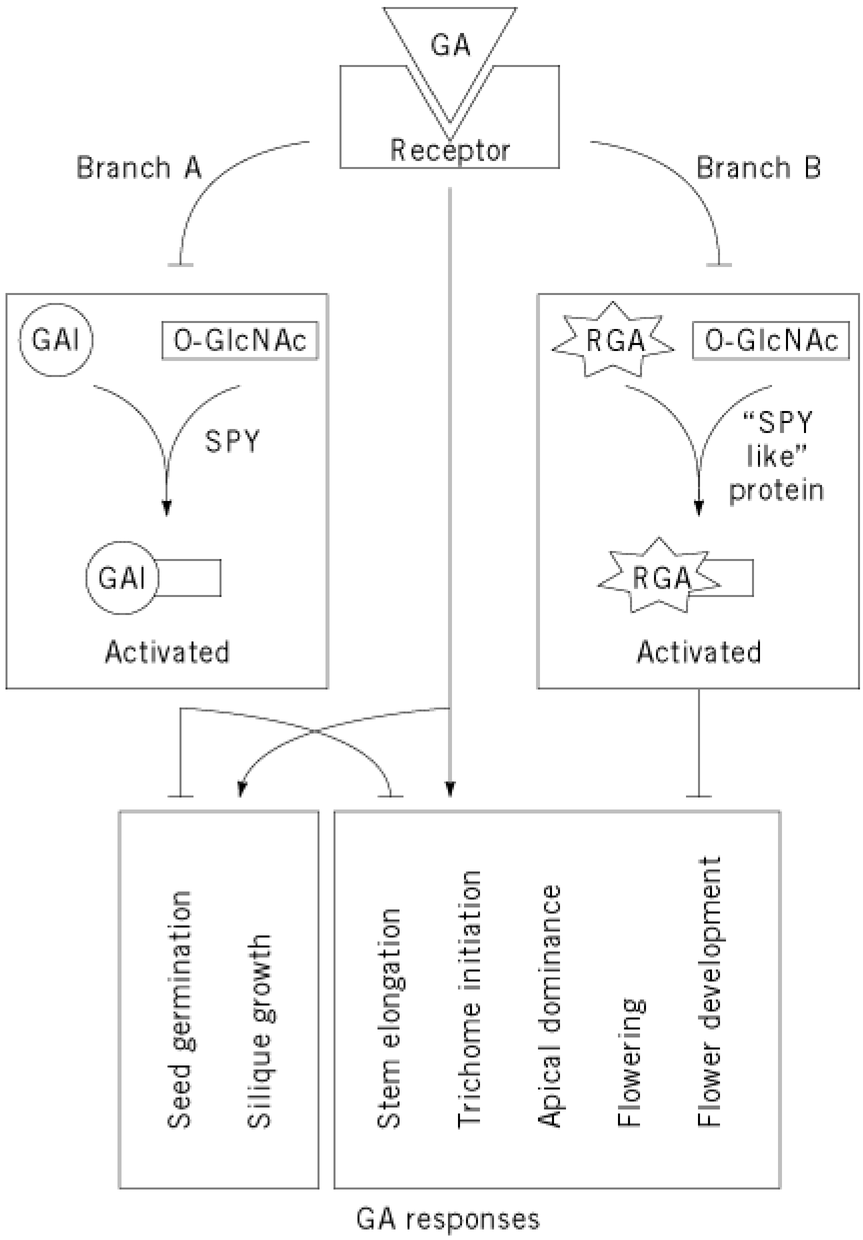
A third class of gibberellin-signaling mutants is represented by *rga* (*repressor of ga1-3*) (40). *Rga* mutants were found by screening for the ability to suppress the phenotype of the *ga1-3* mutant that is impaired in the first step of the gibberellin biosynthesis pathway (41). It is important to note, however, that the *rga* mutation does not suppress the gibberellin deficiency entirely, because it has no effect on seed germination or on silique growth. All *rga* alleles are recessive, indicating that *RGA* most probably encodes a negative regulator of gibberellin signaling.

The *RGA* gene was cloned using genomic subtraction and shown to be identical to *GRS* (38). The predicted protein is a member of the VHIID family of plant transcription factors described above. Although primarily repressing the gibberellin response, RGA may also play a role in the control of gibberellin biosynthesis (38). The RGA protein contains the –Asp–Glu–Leu–Leu–Ala–sequence and the Ser/Thr-rich region, both specific to proteins controlling the gibberellin response.

A final regulator, though difficult to place in the pathway at this point, is *pickle* (*pkl*). The *pkl* mutants present a phenotype reminiscent of gibberellin-deficient or gibberellin response mutants and exhibit abnormal root development (42). The primary root meristem of these mutants retained characteristics of embryonic tissues. This phenotype was partially suppressed by addition of gibberellin. Because the *gai pkl* double mutant exhibited a strong synergistic gibberellin-deficient phenotype, it was concluded that *pkl* is defective in the gibberellin-response pathway. The gene product PKL is proposed to be a positive regulator of gibberellin signaling (43).

Figure 2 presents a model for gibberellin signal transduction based on currently available genetic and biochemical data (38, 40, 43). Gibberellin interacts with its receptor(s), thereby activating gibberellin responses as a result of inhibition of two negative regulators (branches A and B). In branch A, SPY is acting downstream of (or modulates) GAI, because the *spy* mutant is completely epistatic to the *gai* mutation. SPY presumably activates the GAI repressor function via glycosylation. The RGA protein exerts the same function as GAI and represses the transcription of genes involved in gibberellin-regulated growth and development, or it promotes the expression of such a repressor. The repressor function of RGA is activated by SPY or a putative SPY-like protein, unknown to date. This assumption is based on the fact that the *rga* and *spy* mutations have an additive effect for the common processes controlled by gibberellins, thus indicating that SPY probably does not regulate RGA. Both *O*-glycosyltransferases would repress the common gibberellin response (stem elongation, trichome initiation, apical dominance, and flower development). In addition, the "GAI/SPY" branch blocks seed germination and silique growth.

Figure 2. Gibberellin signal transduction. The active gibberellin interacts with a membrane-associated or cytosolic receptor and activates the normal gibberellin response by blocking two repressors, named GAI (branch A) and RGA (branch B). The SPY and/or SPY-like proteins regulate the GAI and RGA proteins via glycosylation. Arrows and bars denote activation and repression, respectively.(Modified from Refs. 38, 40, and 41.)



Due to their nature, SPY/RGA/GAI would act fairly late in the pathway to induce gibberellin-regulated responses. It should be mentioned that recent evidence also suggests the involvement of heterotrimeric **G proteins** and cyclic GMP in gibberellin signaling in barley aleurone cells (44, 45). The former intermediates would play a role in the early phase of signal transfer.

4. Downstream Targets

Gibberellin control of plant growth and development is achieved by modulating the expression of specific target genes. One of the best-characterized roles of gibberellins consists in the stimulation of production of hydrolytic enzymes by the aleurone cells. These hydrolytic enzymes, such as a-amylase, a-glucosidase, and a thiol proteinase, are responsible for the breakdown of starch and proteins in the endosperm (46-48). The products of these hydrolyses are absorbed by the scutellum and used by the growing embryo. *De novo* synthesis of hydrolytic enzymes induced by gibberellin is often due to the presence of a gibberellin response element (GARE) in the promoter region of the corresponding genes (49). The identification of the GARE element has led to the isolation of a myb-like *trans*-acting factor that can bind to this region, which is closely related to c-Myb and v-Myb consensus sequences (50). Furthermore, gibberellins can stimulate stem elongation by increasing the xyloglucan endotransglycosylase activity, an enzyme that cleaves the rigid structure of the cell wall and is associated with growing tissues (51, 52). In addition, gibberellins cause microtubule reorientation favoring axial elongation (53). The tonoplast–intrinsic protein g-TIP, which maintains turgor pressure, thereby favoring wall extensibility, is also induced by gibberellin application (54). In *Petunia* flower development, gibberellin induces the expression of genes such as those of chalcone synthase, chalcone isomerase, anthocyanidin synthase, and dihydroflavonol 4-reductase, which are responsible collectively for corolla pigmentation (55-59).

5. Effects

Biologically active gibberellins are involved in key processes of plant growth and development. The best-characterized roles of gibberellins consist in the control of reserve mobilization in cereals following germination and in promotion of shoot elongation through effects on both cell division and expansion. Gibberellins are also involved in the regulation of flower and fruit development and are required for germination and seedling growth in several species (60).

Giemsa Binding

Giemsa is one of the most useful dyes for staining chromosomes in the banding patterns characteristic of different types of heterochromatin and euchromatin (see C-Banding and G Banding). It is a mixture of organic dyes including thionine, or Lauth's violet, and methylated derivatives of thionine (see Figure 1) including azure B, azure A, azure C, and methylene blue. Thionine itself stains chromosomes uniformly. The introduction of methyl groups, however, changes the properties of the molecule so that it differentially stains chromatin. The thiazine ring in the Giemsa dyes interacts with the phosphodiester backbone of **DNA** and side-stacks along the **double helix**. How this might occur in a chromatin context is not yet known. Variations in chromosomal preparations, in which the histones are removed and other chromosomal proteins digested to different extents, enhance the banding patterns obtained with Giemsa dye (see G Banding).

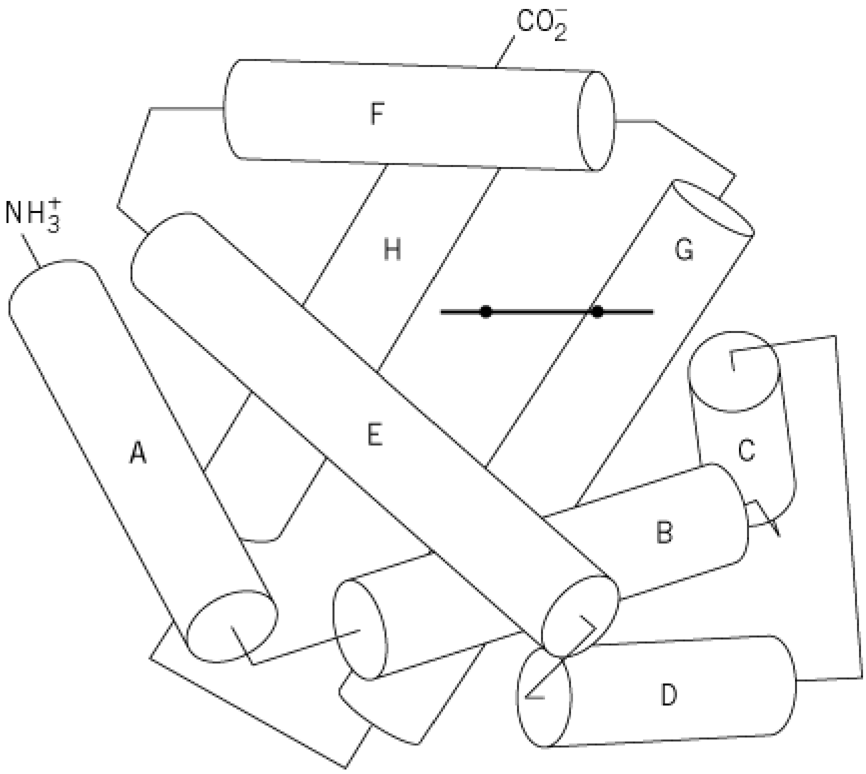
Globins

1. Definition, structure, and properties

Globins are members of a family of oxygen-binding proteins, characterized by **homologous** amino acid sequences and a characteristic protein structure known as the “globin fold.” As illustrated in Figure 1, the globin fold is comprised of eight **alpha-helical** segments, designated A through H, which are connected by loop segments AB, BC, ¼ and GH. The nonhelical segments at the amino and carboxyl termini are designated as NA and HC, respectively. The globin fold is maintained even when the sequence identity between pairs of globins is as low as 16% (2). In most vertebrates, individual globin **polypeptide chains** consist of 141 to 153 amino acid residues. Another property of the globin fold is its ability to bind a heme group, protoporphyrin IX with a ferrous iron atom at its center. The heme group is inserted in a cleft in the protein structure between the E and F helices, known as the “heme pocket.” The iron atom is linked covalently to the imidazole N_{ε}; of the “proximal” histidine residue at position F8 (the eighth residue of the F helix). There are also many van der Waals interactions between the heme group and the amino acid side chains that line the heme pocket. Under physiological conditions, the iron atom is in the ferrous state, when it is capable of binding one molecule of O_2 on the “distal” side of the heme group. The side chain of the distal His-E7 forms a hydrogen bond with one of the oxygen atoms, stabilizing the bound oxygen (see Myoglobin). In this state, the ferrous iron is hexacoordinated with one of the oxygen atoms, N_{ε}; of His-F8, and the four pyrrole nitrogen atoms of protoporphyrin IX. When oxygen is not bound, the sixth coordination site for oxygen is left vacant, and the iron atom is only pentacoordinated.

Figure 1. The globin fold. Cylinders represent the eight a-helices. The lines correspond to the interhelical regions are

not exact and signify only the connectivity of the polypeptide chain. The bold short line indicates the side view of the heme group. From Ref. 2.



2. Distribution and Classification

Globins are found in organisms as hemoglobin (Hb) or myoglobin (Mb). Their common property is the reversible binding of oxygen. Mb is present in the muscles and stores oxygen, whereas Hb is present in the blood and transports oxygen from the lungs or gills to the peripheral tissues. Mb is usually a monomer, although sometimes a dimer, comprised of a single polypeptide chain and one heme group, whereas Hb is an oligomer or polymer composed two or more globin polypeptide chains, each with a heme group. Globin oxygen-binding proteins are even found in organisms that have no muscle or blood, including insects, **plants**, and single-celled organisms such as protozoa, **yeast**, and **bacteria**. These proteins are conventionally called hemoglobins, although some call them myoglobins because of their monomeric structures. Globin **genes** are widespread in modern plants, and plant hemoglobins are believed to have evolved from an **evolutionary** ancestor common to modern plants and animals (3).

3. Modular Structure and Evolution

The globin fold is composed of four structural units, called modules M1, M2, M3, and M4 (4) (Fig. 2). In most globins, modules M1 and M4 are encoded by two corresponding exons of the **gene** (see Introns, Exons). In contrast, modules M2 and M3, which are the structural units that hold the heme group, are encoded by a single exon. In the Hb genes of leghemoglobin (from the legume root nodule) and nematode Hb, however, this single exon is divided into two exons by the insertion of one intron. It is believed that this intron was present initially in the ancestral globin gene but lost during the molecular evolution of the other globin genes (6). Consequently, the globin fold is considered to be encoded by four exons that correspond to the four structural modules. This is one of the best indications of protein evolution by exon shuffling.

Figure 2. Schematic representation of the three-dimensional structure of the human Hb-b chain and its constituent four structural modules. (**a**) The structure of the b-chain; the heme group is bound in a pocket between helices E and F. Arrows indicate the positions of the modular joints that correspond to the positions of the introns in the b-globin gene. (**b**) The first module, at the N-terminus, encoded by Exon 1. (**c**) The joined second and third modules, encoded by Exon 2; the heme group is bound by this pair of modules. (**d**) The fourth module, encoded by Exon 3. Reproduced from Ref. 5.

Globulins

Globulins are proteins that are precipitated in both distilled water and 50% saturated ammonium sulfate. This behavior contrasts with that of albumins, which show the opposite characteristics. This operational classification was very important in protein research initially, as these two characteristics were used in purification of various proteins. It is much less important today, but the name globulin is still encountered frequently.

1. Serum a_1-Globulins

In the **electrophoretic** fractionation of serum proteins, the a-globulin fraction runs closest to serum albumin. When electrophoresis is carried out in a Veronal buffer of pH 8.6, it is subfractionated into a_1 and a_2 fractions. The former contains a1-antitrypsin (antiproteinase), a_1-acid glycoprotein, a $_1$-microglobulin, a-fetoprotein, and a-lipoprotein (HDL). The a_2 fraction contains, among others, a $_2$-microglobulin (retinol binding protein), a $_2$-macroglobulin, a_2-plasmin inhibitor, haptoglobin, and ceruloplasmin.

1.1. a_1-Microglobulin

This glycoprotein (21.76% carbohydrate by weight) is present in plasma at a concentration of 1 mg/100 ml, with a molecular weight of 33,000 and unknown biological functions. It is heterogeneous in electrophoresis, but there is no proven heterogeneity in the amino acid sequence.

1.2. a_1-Antitrypsin, Inter-a-trypsin Inhibitor

These are two proteinase inhibitors in the a-globulin fraction. They inhibit many proteinases, including **trypsin** and **chymotrypsin**, but their roles in homeostasis are not clearly established (see a1-Antitrypsin).

1.3. a-Fetoprotein

a-Fetoprotein is a protein of unknown function, but structurally related to serum albumin. Its concentration in the serum is high in the fetus but very low in the adult.

1.4. Orosomucoid

This is also called a_1-acid glycoprotein and is a glycoprotein with an unusually high content of carbohydrate, 42% by weight. It may have some evolutionary relationship to immunoglobulins.

2. Serum a_2-Globulins

2.1. a_2-Microglobulin

a_2-Microglobulin is also known as retinol binding protein (RBP) and has a molecular weight of 21,000, consisting of 181 amino acid residues, a sedimentation coefficient of 2.3 S, and no carbohydrates; its structure is known (1). It binds one molecule of retinol (vitamin A) and transports it through the circulation in association with transthyretin (formerly called prealbumin, a homotetramer of 16-kDa subunits) as a 1:1 complex of 85 kDa. Its structure consists of a two-layered **up and down b-barrel** that encloses a primarily **hydrophobic** cavity designed to bind retinol. This protein is a member of a large family of ligand transport proteins of similar structures that includes beta-lactoglobulin and a bilin-binding protein.

2.2. a_2-Plasmin Inhibitor

a_2-Plasmin inhibitor is also known as a2-antiplasmin and has a molecular weight of 67,000 and carbohydrate content of 12% by weight. It inhibits serine proteinases by forming a covalent bond with the serine residue at their active sites. This protein inhibits the degradation of fibrin clots by plasmin; in individuals who lack this protein, fibrinolysis occurs at an early stage of blood clotting, leading to a premature degradation of fibrin clot and causing serious bleeding. a_2-plasmin inhibitor obstructs the action of plasmin toward fibrin by binding to specific regions of plasmin and its precursor plasminogen.

2.3. a_2-Macroglobulin

This is a homo-tetrameric glycoprotein (7% carbohydrates) of 725,000 that inhibits almost any kind of proteinase, including those belonging to the four classes of serine, **thiol**, **metallo**, and carboxyl proteinases (2). The mechanism of inhibition is entirely different from that of other proteinase inhibitors in that, instead of binding to the active sites of the target enzymes, a_2-macroglobulin entraps medium-sized proteinases of between approximately 10,000–100,000 molecular weight within its cavity. The protein has a region in its amino acid sequence that is highly vulnerable to proteolytic attack; when one or more peptide bonds are hydrolyzed in this region, a large conformational change takes place to engulf the proteinase inside the molecular cavity and to react it with a highly reactive thiol ester bond of the macroglobulin. The active sites of the entrapped proteinases are not inhibited, and they remain active toward low-molecular-weight substrates, but are inactive toward large substrates, simply as a result of steric hindrance. The altered form of a_2-macroglobulin is rapidly cleared from the blood serum, due to its internalization after binding to the receptor molecule called LRP (standing for low-density-lipoprotein receptor-related protein) on the membrane surface of peripheral cells such as fibroblasts, macrophages, hepatocytes, and so forth (see also Macroglobulins).

2.4. Haptoglobin

This is a glycoprotein (carbohydrate content of about 19% by weight) in the serum with the capacity to bind two half-molecules of free hemoglobin in the serum, as in the case of hemolytic anemia. It is composed of a_1 and a_2 chains of 9.1- and 16,000 molecular weight, plus two identical b chains of 40 kDa. Clearance of the haptoglobin-hemoglobin complex from the blood serum has a half-life of 10 to 20 min.

2.5. Ceruloplasmin

This is a blue-colored copper-containing glycoprotein, with eight copper atoms per molecule, a carbohydrate content of about 8% by weight, and a high molecular weight of 132,000. It migrates in the a_2 region, its sedimentation coefficient is 7 S, and it is made of four heterogeneous subunits.

2.6. Antithrombins

Antithrombin III is a glycoprotein (15% carbohydrate by weight) with a molecular weight of 65,000. Its concentration in plasma is 0.2 g/l. It inhibits thrombin, activated forms of blood clotting factors IX, X, and XI, plasmin, and **trypsin**. Upon association with heparin, it inhibits blood clotting.

2.7. Cobalamin-binding Proteins

(1) IF (standing for intrinsic factor) is a 114-kDa dimeric glycoprotein. It binds two molecules of vitamin B12 (cobalamin) and helps its absorption in the intestine by binding to a specific receptor.

(2) Transcobalamin I, II, and III are vitamin B_{12}-binding and transporting proteins in the bloodstream. I is a glycoprotein (carbohydrate content of 33% by weight) and has a molecular weight of 56,000. II is a simple protein of 60 kDa. (3) A protein known as R-binder (cobalophilin) also binds cobalamin.

2.8. Thyroid Hormone-binding Proteins

The thyroid hormones, thyroxin (T4) and triiodothyronine (T3), are transported by thyroxin-binding pre-albumin, thyroxin-binding globulin, and serum albumin. Thyroxin and triiodothyronine in the blood are distributed among the three proteins in the ratios 70:10:20 and 40:30:30, respectively.

1. Thyroxin-binding pre-albumin migrates on electrophoresis to the anodic side of serum albumin, has a molecular weight of 54,980, contains 0.4% sugar, and has four subunits. The serum concentration of this protein becomes low in patients with liver disorders.
2. Thyroxin-binding globulin is an acidic glycoprotein with a molecular weight of 60,000; it is present in serum at a concentration of 15 µg/ml and strongly binds thyroxin and triiodothyronine.

2.9. Steroid Hormone-binding Proteins

These include corticosteroid-binding protein (transcortin), sex hormone-binding protein, and progesterone-binding protein. Transcortin is a glycoprotein, with a carbohydrate content of 16 to 26% by weight and molecular weight of 53,000.

3. Serum b-Globulins

3.1. Transferrin

This is an iron-binding glycoprotein in the serum with a molecular weight of 77,000. When ferric ion is bound to transferrin, it will bind to the cell-membrane transferrin receptor of erythroblasts and reticulocytes and becomes internalized as a result of receptor-linked endocytosis; apotransferrin has low affinity for the receptor. The internalized transferrin releases the bound iron as the pH inside the endosome becomes lower, and then the receptor with bound apo-transferrin reassociates with the membrane, to recycle apo-transferrin into the serum. Transferrin has two iron-binding sites per molecule, but a similar protein found in hag-fish has only one iron binding site per molecule of 44 kDa. There are several genetic variants. A protein called conalbumin in egg white and lactoferrin in milk are actually apo-transferrin, with the same amino acid sequence as the transferrin in blood serum, but with different post-translational modifications . More than 60% of the iron used by blood-producing cells for the hemoglobin biosynthesis is supplied by transferrin.

3.2. b-Lipoproteins

These include low-density and very-low-density **lipoproteins** . Serum lipoproteins are noncovalent complexes of specific proteins and lipids. They constitute a lipid transport system in the bloodstream and are classified in as chylomicrons, very-low-density lipoproteins (VLDL), low-density lipoproteins (LDL), and high-density lipoproteins (HDL). They appear in the a-globulin fraction upon electrophoresis. A further subfraction, very-high-density lipoprotein (VHDL), is often identified. Each class of lipoproteins is characterized by specific apo-proteins and immunogenicities. The density classification of lipoproteins is based on lipid content; the higher the lipid content, the lower the density. The lipid content in each class of lipoproteins is not constant but varies within a certain range of values. (More details can be found under **Lipoproteins**).

3.3. b_2-Microglobulin

This is the smaller of the two polypeptide chains that constitute the histocompatibility complex antigen, but this protein does not have specific antigenicity. The amino acid sequence has a similarity to that of the constant domains of the immunoglobulin heavy chains.

3.4. Hemopexin

This is a heme-binding protein with a molecular weight of 5700 and a carbohydrate content of 20%.

4. Serum g-Globulins

Serum g-globulins constitute the secretory immune system of vertebrates and are classified asIgA, IgD, IgE, IgG, and IgM, with Ig standing for immunoglobulin. The basic structural unit of immunoglobulins may be seen in the H_2L_2 structure of IgG, where H represents the heavy chain and L the light chain. Each light chain is disulfide-bonded to one of the heavy chains, and the two heavy chains are disulfide-bonded to form a covalently associated hetero-tetrameric subunit structure. Two antigen-binding sites are formed from the two pairs of H and L chains. The structural designs of other immunoglobulins are based on this IgG structure. More details can be found under Immunoglobulins.

5. Egg-White Globulins

5.1. Ovoglobulins

This fraction of egg white contains lysozyme and ovomacroglobulin as the major proteins in the G1 and G2 fractions, respectively. Lysozyme is a small basic protein with a molecular weight of 14,300 (129 amino acid residues), sedimentation coefficient of 1.9 S, and an isoelectric point of 11. It is an enzyme that cleaves cell-wall mucopolysaccharides at b(1–4) linkages between N-acetylmuramic acid and N-acetyl galactosamine, and thus has bactericidal activity. Chicken egg-white lysozyme is now called c-type lysozyme with a distinction from g-type lysozymes, such as that with 185 residues purified from goose eggs. Hen lysozyme constitutes about 3% of egg-white proteins and is readily crystallized. See also Lysozymes.

5.2. Ovomacroglobulin

This is a large, tetrameric glycoprotein with a molecular weight of 700,000 (4 × 170,000). It has a **proteinase**-trapping activity similar to that of serum a_2-macroglobulin. The two proteins are **homologous** in amino acid sequence and to the C3, C4, and C5 components of the blood clotting proteins. Unlike a_2-macroglobulin, ovomacroglobulin lacks the internal thiol ester bond. The presence of homologous proteins has been confirmed in the chicken, goose, crocodile, and turtle egg white (3).

6. Thyroid Globulins

Thyroglobulin is a glycoprotein (10% sugar) of molecular weight 670,000, two identical subunits, sedimentation coefficient of 19 S, and pI of 4.5. It is synthesized as an iodine-free protein in the epithelium of the thyroid gland; later it is iodinated on some of its tyrosine residues by thyroid peroxidase. Two iodotyrosine residues dimerize to form the thyroid hormones 3,3′,5,5′-tetraiodothyronine (thyroxin) and 3,3′,5-triiodothyronine. Iodination also promotes the generation of covalent dimers of thyroglobulin through disulfide bond formation. Iodination of the protein is specific to the thyroid gland of vertebrates.

7. Milk Globulins

Cow's whey contains as the principal components (50 to 60%) beta-lactoglobulin, which is peculiar to ruminant milk, and alpha-lactalbumin. b-Lactoglobulin constitutes about 50% of the whey protein; it is fractionated as an albumin fraction that does not precipitate with 50% saturation ammonium sulfate, but the purified protein shows a globulinlike solubility in water. Whey protein is fractionated into three major fractions by centrifugation, and b-lactoglobulin is the major protein in the b fraction. It is a dimeric protein of 35 kDa, sedimentation coefficient of 2.8 S, and pI of 5.2. The lactoglobulin fraction includes b-lactoglobulin and immunoglobulin derived from the mother. The three-dimensional structure of this protein is similar to that of retinol-binding proteins (4).

Glucagon

Glucagon is a 29-residue, single-chain peptide hormone (MW 3485) (1). Its gene is located on human chromosome 2, and its primary structure is given in Figure 1. Glucagon has a regulatory function in glucose metabolism; in general, its effects are opposite those of insulin. It is synthesized by a-cells in the islets of Langerhans of the pancreas and in L-cells of the intestinal mucosa as a very much larger pre-pro-glucagon molecule of 180 amino acid residues. The signal peptide is removed proteolytically upon translocation of the nascent polypeptide chain into the endoplasmic reticulum, to generate proglucagon (160 residues); this contains within it other peptides. It is processed by the pro-hormone convertases 1/3 (PC-1/3) and PC-2 (see Peptide Hormones) differently in the two tissues (2). In the pancreas, proglucagon (PG) yields glucagon and glicentin-related peptide (GRPP). In the intestinal mucosa, glucagon-like peptides-1 (GLP-1) and -2 (GLP-2) and glicentin (a 69-residue peptide containing glucagon and GRPP) are produced (Fig. 2).

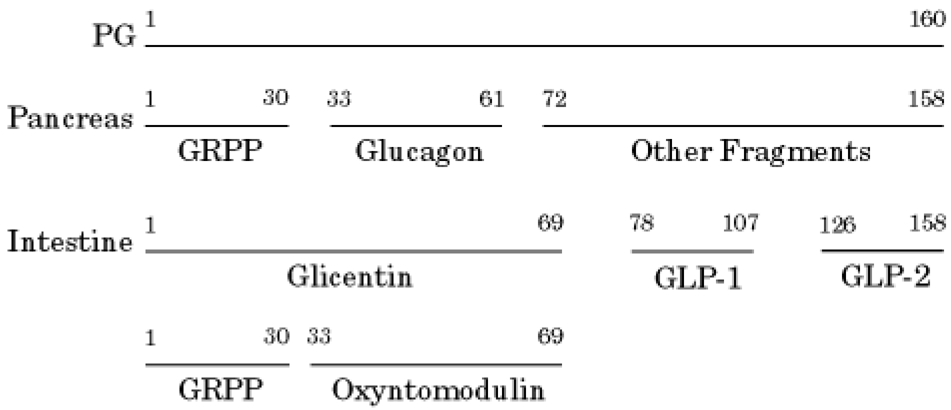
Figure 2. Proteolytic processing of proglucagon (PG) in the pancreas and in the intestine. GRPP: glicentin-related peptide. GLP: glucagon-like peptide.



The secretory granules of the a-cells contain glucagon and discharge it by exocytosis. Active GLP-1, a potent hormone that also antagonizes insulin action, is secreted from the intestine (3-6). Consequently, differential processing of pro-glucagon gives rise to two different active peptides in the regulatory pathways. Both glucagon and GLP-1 have their own specific receptor; their genes have been **cloned** and the proteins characterized in structure-function and signal transduction studies (7, 8).

In general, glucagon and GLP-1 antagonize many actions of insulin and regulate the levels of blood glucose. Like insulin, glucagon lacks a plasma carrier, and its circulation half-life is short, approximately 3 to 6 minutes. Glucagon is removed from the circulatory system primarily by the liver and kidney. The predominant effect of glucagon is on the liver, because it is the first organ perfused by blood with the pancreatic secretions. Glucagon binds to receptors on the plasma membrane and couples through heterotrimeric G-proteins to GTP-binding proteins and adenylate cyclase. The resultant increases in cyclic AMP (cAMP) and cAMP-dependent protein kinase A (PKA) levels reverse the effects of insulin on the liver. These increases elevate the circulating glucose levels by stimulating the output of glucose from the liver by glycogenesis and promoting glycogenolysis. Glucagon secretion is inhibited by glucose. In contrast to insulin, which promotes energy storage, glucagon releases energy. It also has some effect on lipid metabolism, by reducing fatty acid synthesis and increasing fatty acid oxidation and ketogenesis. Glucagon secretion does not markedly fluctuate throughout the day, but the ratio of insulin to glucagon mediates **phosphorylation** or dephosphorylation of enzymes that regulate metabolism.

In type I diabetes, the stimulating effect of hypoglycemia on glucagon secretion is reduced. In these diabetic patients, glucose fails to inhibit glucagon secretion, but insulin injections restore the effect. On the other hand, somatostatin is an inhibitor of both glucagon and insulin secretion. A potent glucagon receptor antagonist may have therapeutic use in hypoglycemia. Consequently, the roles of glucagon and GLP-1 in glucose metabolism are presently an area of diabetes research.

Glucocorticoid Response Element

The steroid hormones are a group of substances derived from cholesterol that exert a wide a range of effects on biological processes (1) by stimulating the transcription of specific **genes** (2, 3). These effects on gene expression are mediated by specific response elements within the target genes. The relationships between the different response elements that mediate the response to each of these steroid hormones are discussed in the entry Hormone response elements. This article discusses the sequence that mediates the response to one of the classes of steroid hormones, the glucocorticoids.

The glucocorticoid response element (GRE) is found in a number of different target genes that respond to glucocorticoid. It is a short element with the sequence

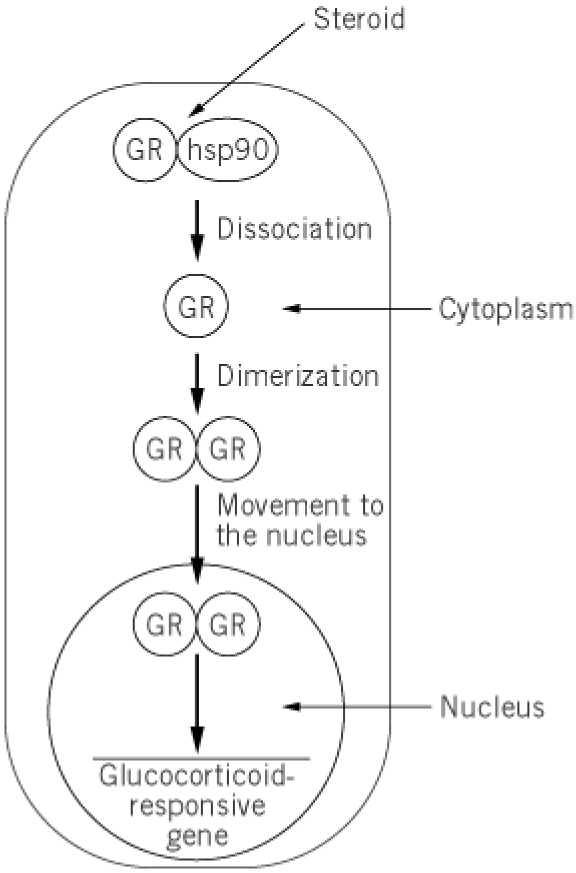
5′RGRACANNNTGTYCY3′

3′YCYTGTNNNACARGR5′

where R = purine, (ie, A or G), Y = pyrimidine (ie, C or T), and N = any base. The GRE thus consists of a 6-bp palindrome in which a 6-bp sequence (RGRACA) is repeated in the opposite orientation, with a spacing between the two halves of the palindrome of 3 bp whose sequence does not matter. This palindromic sequence is bound by two molecules of the glucocorticoid **receptor** in a dimer, which mediates the response to glucocorticoid.

In cells that have not been exposed to steroid, this receptor exists in the cytoplasm complexed to a 90-kDa heat-inducible protein, hsp90. The association with hsp90 anchors the glucocorticoid receptor in the cytoplasm and prevents it activating any genes. Upon exposure to glucocorticoid, the receptor binds to the steroid, which results in the dissociation of hsp90. This leaves the receptor free to dimerize and to move to the nucleus, where the dimer binds to the palindromic GRE (Fig. 1). This binding takes place via specific regions of the receptor known as the DNA-binding **domain** and the activation domain. The bound receptor then interacts with the basal transcriptional complex of RNA polymerase and associated factors to stimulate transcription of the steroid-responsive gene. In this manner, binding the activated glucocorticoid receptor to the GRE causes the stimulation of glucocorticoid-responsive genes following exposure of the cell to steroid (4).

Figure 1. Activation of the glucocorticoid receptor GR by steroid involves dissociation of hsp90, which permits dimerization of GR and its movement to the nucleus.



Interestingly, the glucocorticoid receptor can also inhibit the expression of specific genes, such as those encoding prolactin and pro-opiomelanocortin. This effect is achieved by the identical receptor–hormone complex that activates glucocorticoid-inducible genes. However, the DNA sequence element to which the complex binds when mediating its negative effect (nGRE) is distinct from the glucocorticoid response element (GRE) to which it binds when inducing gene expression, but the two sequences are related to one another:

GRE RGRACANNNTGTYCY

nGRE ATYACNNNNTGATCW

where N = any base, R = purine, Y = pyrimidine, and W = A or T. The similarity between the GRE and the nGRE has led to the idea that the sequence difference causes the receptor–hormone complex to bind to the nGRE in a configuration in which its activation domain cannot interact with the basal transcription complex to activate transcription in the way that occurs following binding to the positive element (5). Indeed, it has been shown that the nGRE in the pro-opiomelanocortin gene binds the glucocorticoid receptor as a trimer, rather than the dimer form that binds to the GRE and stimulates transcription (6). When bound in this manner, the GRE is likely to act simply by preventing binding of a positively acting transcription factor to this or an adjacent site, thereby preventing gene induction. In agreement with this, the nGRE in the glycoprotein hormone a subunit gene overlaps a cyclic AMP response element (CRE) and is able to inhibit gene expression only when the activating CRE is left intact (7).

Hence, the GRE and the related nGRE can bind the glucocorticoid receptor–hormone complex in distinct configurations and thereby allow glucocorticoid hormone to exert either positive or negative effects on the expression of specific target genes.

Glucocorticoids

Glucocorticoids (or glucocorticosteroids) are natural steroid hormones, or synthetic analogues, that regulate metabolic, developmental and immunological processes. The major natural glucocorticoids are cortisol (11 b,17,21, trihydroxy-4-pregnene-3,20-dione) (in humans) and corticosterone (11 b,21,d,hydroxypregn-4-ene-3,20-dione) (in rodents) (Fig. 1). Semisynthetic derivatives with greater hormonal activity than that of the natural steroids are dexamethasone, prednisone, and triamcinolone (Fig. 1). The synthesis of glucocorticoids in the zona fasciculata of the adrenal cortex and their release in the blood circulation is regulated by adrenocorticotropic hormone (ACTH), which is produced in the anterior lobe of the hypophysis, in response to stimuli coming either from the neuroendocrine cells of the paraventricular nuclei of the hypothalamus (corticotropin releasing hormone) or from the periphery (blood cortisol concentration). High blood cortisol levels reduce, by feedback inhibition, the production of both corticotropin-releasing hormone and ACTH. This regulatory circuit is called the hypothalamus–pituitary–adrenal axis (see Fig. 2). Glucocorticoid secretion is enhanced during stress conditions, such as anxiety, hunger, and trauma. Most effects of glucocorticoids (see Hormone Receptors) are mediated by the glucocorticoid receptors, which belong to the superfamily of nuclear receptors. There are two forms of glucocorticoid receptor, A and B, differing in their *C*-terminal regions. Upon binding the hormone, the receptor dimerizes, binds to glucocorticoid response elements (the **consensus sequence** is GGACAnnnTGTTCT), which are receptor-activated **enhancers**, and modulate gene transcription.

Figure 1. Structure of glucocorticoids.

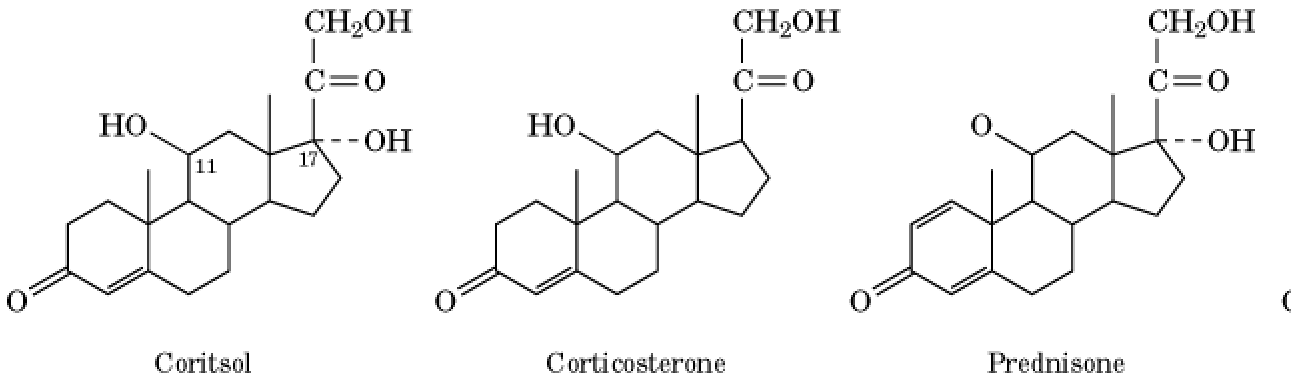

Figure 2. Regulation of cortisol production by the hypothalamus–pituitary–adrenal axis.

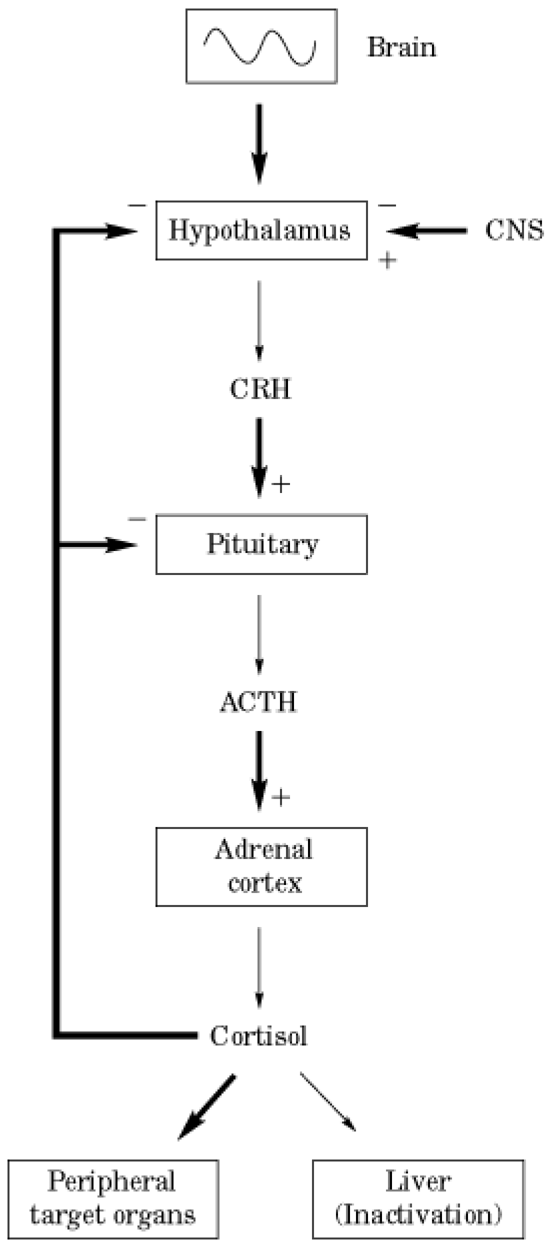

The glucocorticoids regulate the metabolism of sugars, lipids, and proteins. They stimulate glucose output from the liver, inhibit glucose utilization by tissues, and mobilize fatty acids from adipose tissue. The hormones act on muscle, bone, and lymph organs, inhibiting **protein biosynthesis** and enhancing protein degradation. Some of the amino acids released in the circulation are used for gluconeogenesis, primarily in the liver but also in kidneys. The action of glucocorticoids on gluconeogenesis represents one of the most exploited and rewarding systems for delineating the molecular mechanisms of steroid hormone action (1, 2). In gluconeogenesis, amino acids are metabolized to two-carbon precursors to be used for glucose synthesis. The biosynthesis of enzymes like tyrosine aminotransferase, alanine aminotransferase, tryptophan dioxygenase, pyruvate carboxylase, and phosphoenolpyruvate-carboxykinase, which catalyze 2C-precursor production or utilization for glucose synthesis, are induced by glucocorticoids. All steps—from binding of the glucocorticoid ligand to its receptor, to increased transcription of the genes, to translation of the messenger RNA to the respective proteins—have been studied in detail and have supported the steroid hormone gene-activation hypothesis (3). The inhibition of protein synthesis by glucocorticoids in the lymphatic system results in decreased antibody production (immunosuppression) and increased susceptibility to infection. The suppressive effects of glucocorticoids on the inflammatory response have led to new insights and a novel mechanism of action of glucocorticoids. Namely, the hormones block binding of the transcription factor NF-k B on **promoters** having NF-kB binding sites (eg, the promoter of the interleukin gene) by direct interaction between the receptor and the transcription factor, thereby inhibiting expression of the respective (eg, interleukin) gene (4).

The role of glucocorticoids in embryonic development has been investigated in transgenic mice deficient in the glucocorticoid receptor (5). These mice die within a few hours of birth because of respiratory failure due to severely atelectic lungs, probably resulting from lowered production of surfactants and from a deficiency of a glucocorticoid-inducible sodium pump. The livers of newborns have reduced capacity to activate genes for key gluconeogenic enzymes, whereas the adrenals lack a central medulla and cannot synthesize adrenaline. The hypothalamus–pituitary–adrenal axis is impaired, resulting in increased expression of corticotropin-releasing hormone and in hypertrophy of the adrenal cortex, signifying that the hypothalamus–pituitary–adrenal axis is established during fetal development, and underlining the central role of glucocorticoids in this process.

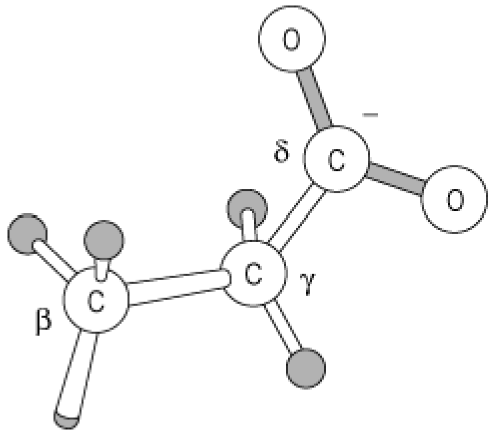
Glutamic Acid (Glu, E)

The **amino acid** glutamic acid is incorporated into the nascent polypeptide chain during **protein biosynthesis** in response to two **codons**—GAA and GAG—and represents approximately 6.2% of the residues of the proteins that have been characterized. The glutamyl residue incorporated has a mass of 129.12 Da, a **van der Waals volume** of 109 $Å^3$, and an accessible surface area of 183 $Å^2$. Glu residues are frequently changed during divergent evolution; they are interchanged in **homologous** proteins most frequently with **aspartic acid**, **glutamine**, **alanine**, and **histidine** residues.

The side chain of Glu residues is dominated by its **carboxyl group**:



This carboxyl group is normally no more reactive than are those of corresponding organic molecules, such as acetic acid. Its intrinsic pK_a value is approximately 4.3, so Glu residues are ionized and very polar under physiological conditions; consequently, very few Glu residues are buried in folded **protein structures**, and nearly all have at least the carboxyl group on the surface. The pK_a can be shifted in folded proteins, however, and either the ionized or nonionized form can be used in the protein's function. For example, **carboxyl proteinases** have one **active-site** carboxyl group function in the ionized form, another nonionized. Asp carboxyl groups have a weak intrinsic affinity for Ca^{2+} ions and are used in many calcium-binding proteins. Certain Glu residues, particularly in proteins involved in blood clotting and bone structure, are carboxylated to yield the unusual residue g-**carboxylglutamic acid**; such residues have two adjacent carboxyl groups and bind Ca^{2+} more avidly.

Glu residues differ from Asp only in having two methylene groups, rather than one, so it might be thought that they would be very similar chemically and functionally in proteins, but this is not so. The slight difference in length of the side chains causes them to have different tendencies in their chemical interactions with the peptide backbone, so they have markedly different effects on the conformation and chemical reactivity of the peptide backbone. For example, Glu residues favor the a-**helical** conformation much more than do Asp. In folded proteins, Glu residues are most frequently found in a-helices, whereas Asp residues occur most frequently in reverse turns .

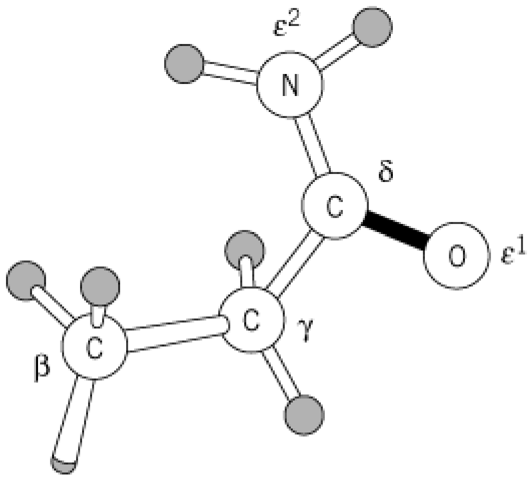
Glutamine (Gln, Q)

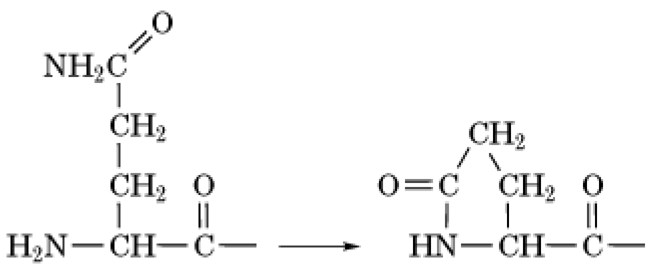
The amino acid glutamine is incorporated into the nascent polypeptide chain during **protein biosynthesis** in response to two **codons**—CAA and CAG—and represents approximately 4.0% of the residues of the proteins that have been characterized. The glutaminyl residue incorporated has a mass of 128.14 Da, a van der Waals volume of 114 Å ^{3}, and an accessible surface area of 189 Å^{2}. Gln residues have close to average conservation during divergent evolution; they are interchanged in **homologous** proteins most frequently with Glutamic Acid (Glu, E)and Histidine (His, H) residues.

The side chain of Gln residues is the same as that of glutamic acid, except that the carboxyl group has been converted to the amide:



Both amino acids occur naturally and are incorporated directly into proteins during their biosynthesis. Gln residues do not arise from amidation of Glu in proteins. The amide side chain does not ionize and is not very reactive chemically. It is polar, however, as it is both a hydrogen bond donor and acceptor. The amide group is labile at extremes of pH and at high temperatures, and Gln residues can **deamidate** to Glu, although usually less rapidly than Asn residues do.

When Gln residues are at the *N*-terminus of a peptide chain, they spontaneously cyclize:



The resulting residue of pyrrolidone carboxylic acid renders the *N*-terminus unreactive in most procedures for **sequencing proteins**, such as the Edman Degradation. This residue can be removed, however, by the enzyme pyroglutamyl amino peptidase

Glutaraldehyde

The bis-homobifunctional aldehyde glutaraldehyde

$$HCO\text{–}(CH_2)_3\text{–}CHO$$

is perhaps the most frequently used chemical crosslinking agent. Because of its effectiveness as a crosslinker, glutaraldehyde has found use as a stabilizer or fixative for samples subjected to electron microscopy, for bioprosthetic materials, and in drug delivery systems (reviewed in Ref. 1). It is also routinely used to produce bioconjugates and to immobilize proteins (see Enzyme Immobilization And Conjugation).

Crosslinking by glutaraldehyde can occur through at least two distinct mechanisms (2). The first is attack by primary amino groups of the protein on the aldehydic carbons of glutaraldehyde to form Schiff bases, which can then be rendered irreversible by suitable reductants. The second mechanism is more complex and less understood, and it results in irreversible crosslinking in the absence of reductants. This alternative mechanism involves polymerization of glutaraldehyde to form heterogeneous unsaturated polymers that differ in their length and degree of unsaturation. These polymers then undergo addition at their double bonds by other nucleophilic groups of the protein. A disadvantage of glutaraldehyde is that it often brings about extensive crosslinking and formation of insoluble complexes; however, this can be minimized through use of the two-step reaction, in which one protein is reacted with glutaraldehyde, the excess reagent removed, and the second protein then added to react with the free aldehyde groups of the first (2).

Glutaredoxin

Gluta redoxin (Grx) was discovered as a small protein that contains two thiol groups and acts as a glutathione (GSH)-dependent hydrogen donor for synthesizing deoxyribonucleotides by *Escherichia coli* ribonucleotide reductase (1). Glutaredoxin in the oxidized form has a redox-active disulfide bond (Grx-S_2) and is reduced to the dithiol form (Grx-SH_2) by two molecules of GSH in a **thiol-disulfide exchange** reaction via a GSH mixed-disulfide intermediate (2, 3). Glutaredoxin is also a general GSH-disulfide oxidoreductase that reduces either disulfide bonds by a dithiol mechanism or GSH-mixed disulfides by a monothiol mechanism (2, 3). The glutaredoxin system comprises NADPH, GSH, glutathione reductase, and glutaredoxin. It catalyzes the NADPH- and GSH-dependent reduction of disulfides and keeps the inside of the cell reduced.

Glutaredoxins exist in all prokaryotic and eukaryotic cells that contain glutathione, and they are also encoded by the genes of the larger DNA **viruses**. Glutaredoxins generally have a mass of 9 to 12 kDa, and the active site has the **consensus sequence** -Cys-Pro-Tyr-Cys- (4). Glutaredoxin in mammalian cells is identical to GSH-homocystine transhydrogenase or thioltransferase. The primary structures of glutaredoxin show only limited sequence similarity to those of **thioredoxins**, but the three-dimensional structure of glutaredoxin shows that the active site dithiol/disulfide is located at the end of a beta-strand and at the beginning of an **alpha-helix**, characteristic of the thioredoxin fold. One hallmark of glutaredoxin is a binding site for GSH that is used in both the reduction of Grx-S_2 by GSH and for substrate recognition and reduction of GSH-mixed disulfides by Grx-$(SH)_2$. Glutaredoxins have numerous functions, such as acting as hydrogen donors for reductive enzymes and transmitting changes in the oxidation/reduction potential of the GSH/GSSG (glutathione disulfide) system for protein activity during thiol redox regulation and signal transduction, or in restoring oxidatively damaged proteins after oxidative stress.

1. Glutaredoxin Functions

Glutaredoxins have been isolated from *E. coli* (1, 5), yeast (6), plants (7), and mammals (8, 9) and are encoded by **T4 bacteriophage** and vaccinia virus (10-12). *E. coli* contains three different glutaredoxins: Grx1, Grx2, and Grx3 (5). Grx1 is a highly efficient hydrogen donor for ribonucleotide reductase, either in the presence of 1 mM DTT or with the more physiological system of 4 mM GSH, NADPH, and excess glutathione reductase, when the apparent Km (Michaelis constant) for Grx1 is 0.13 µM (2, 3). The apparent turnover number of glutaredoxin as a dithiol hydrogen donor for ribonucleotide reductase is tenfold higher than that of thioredoxin. Glutaredoxin was discovered in an *E. coli* mutant that lacks thioredoxin (1), and double mutants that lack thioredoxin and glutaredoxin are viable (13). This includes *E. coli* cells that lack glutathione ($gshA^-$). In combination with a thioredoxin mutation ($gshA^-$, $trxA^-$), such cells very strongly induce (up to 55-fold) Grx1 (14). Grx3 in *E. coli* has the same active site structure as Grx1, but only 6% of the V-max with ribonucleotide reductase and a 35 mV higher redox potential (E'_O) (15, 16). The function of at least Grx1 strongly depends on the GSH-concentration and the GSH:GSSG ratio, because the E'_O of the redox-active disulfide bond in glutaredoxin determines whether it is be reduced to the active dithiol (16).

Glutaredoxin functions reducing both sulfate and methionine sulfoxide in *E. coli* and yeast (17). Synthesis of Grx1 in *E. coli* is induced via the oxyR transcription factor, and Grx1 controls its activity by reducing a disulfide bond that can be formed in the protein (18). The two glutaredoxins in yeast control the defense against superoxide and hydrogen peroxide stress, respectively, in addition to their roles in deoxyribonucleotide synthesis by ribonucleotide reductase (6).

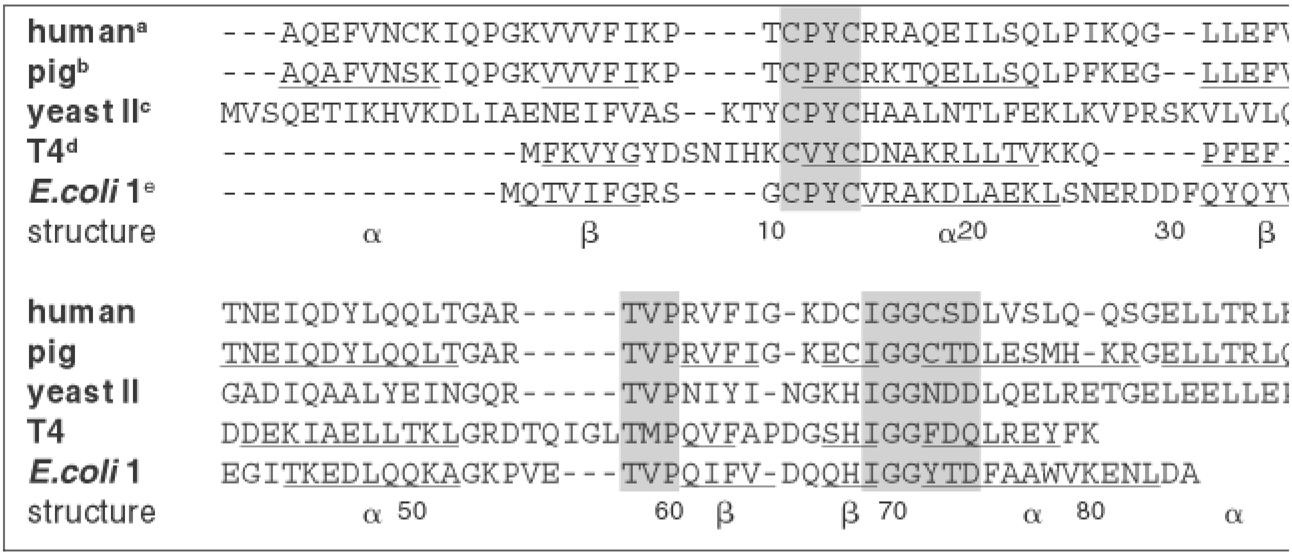
Phage T4 induces a ribonucleotide reductase upon infection of *E. coli*, and a T4 glutaredoxin (originally called thioredoxin) is also a specific hydrogen donor for the enzyme that works with GSH as a reducant (19), and a substrate for thioredoxin reductase. T4 ribonucleotide reductase uses *E. coli* Grx1 as a hydrogen donor, but not thioredoxin (19). However, T4 glutaredoxin is reduced by thioredoxin via thioredoxin reductase, favoring phage-specific DNA synthesis (20).

The transcription factor activity of nuclear factor I is regulated by glutaredoxin *in vitro*, involving formation of mixed disulfides (21). Glutaredoxin is a direct target of **oncogenic** Jun protein (22). Other roles for glutaredoxin involve reduction of dehydroascorbic acid (23) and involvement in repairing proteins that have with mixed disulfides after oxidative stress (24) or in arsenite reduction (25).

2. Amino Acid Sequences

With few exceptions [eg, see Grx2 (26)], the glutaredoxins from bacterial viruses to humans are 9- to 12-kDa proteins that have both sequence and structural homology to the members of the thioredoxin superfamily of proteins. Alignment of the amino acid sequences from diverse organisms (Fig. 1) gives a good impression of the sequence variability of these proteins. Unlike the thioredoxins, whose sequences align without gaps of more than one residue, numerous gaps of up to 5 residues are needed, in addition to the relatively long (up to 20 amino acid residues) N- and/or C-terminal extensions in some members. Several residues are strictly conserved among the glutaredoxins. The active site sequence –Cys11–Pro12–Tyr13–Cys14 (*E. coli* numbering) is the hallmark of the glutaredoxins. The tripeptide fragment that contains the proline residue with the *cis* peptide bond (Thr58–Val59–Pro60) and the residues Ile69–Gly70–Gly71–Tyr72–Thr73–Asp74 are also strictly conserved. Mammalian glutaredoxins are highly homologous to one another and, in addition to containing both N- and C-terminal extensions, contain additional non-structural cysteine residues that, analogous to the mammalian thioredoxins, might function in regulating glutaredoxin activity (9).

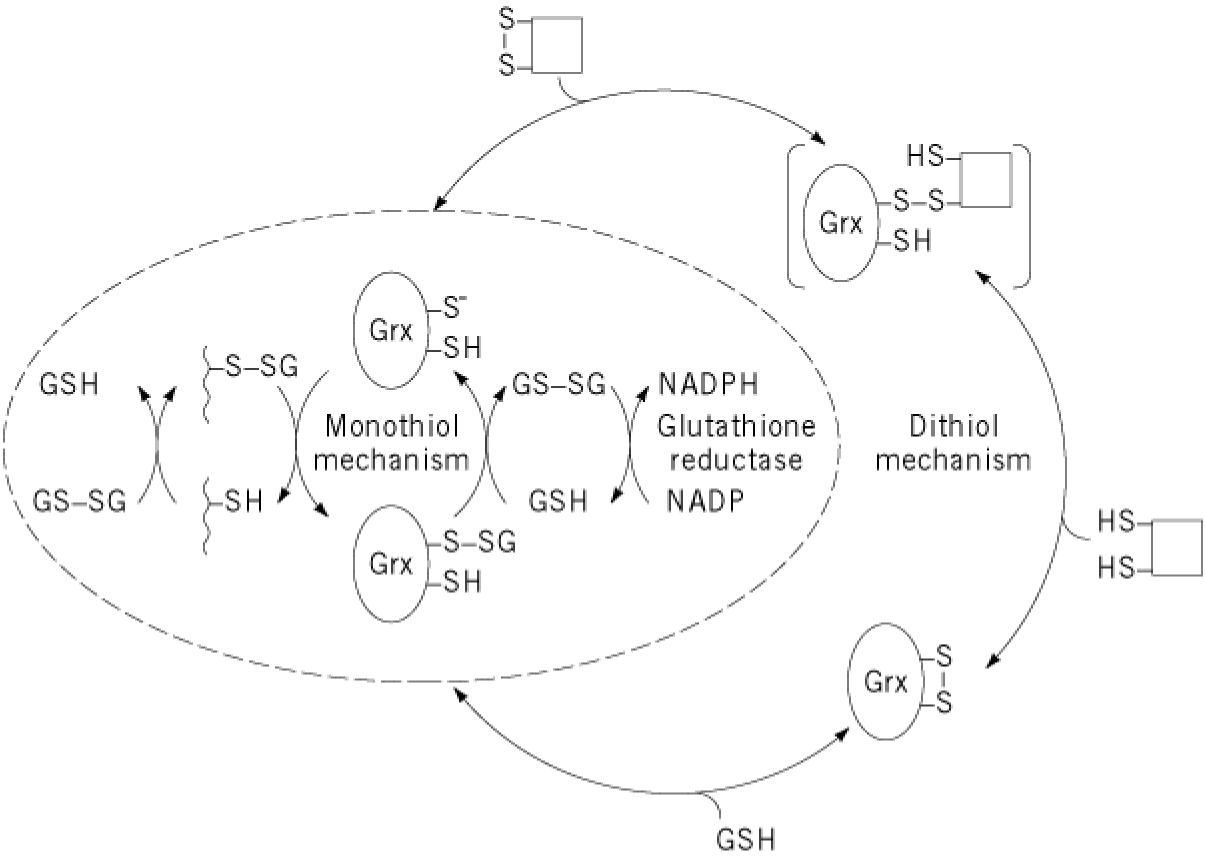
Figure 1. Amino acid sequence alignment of selected glutaredoxins. Sequences were taken from [a](9, 32); [b](33); [c](34); [d](acid sequences were aligned based on the three-dimensional structures of pig (29), T4 (28) and *E. coli* (Grx1) glutaredox



3. Mechanisms of Disulfide Reduction

As outlined in Fig. 2, glutaredoxin participates in reducing disulfide bonds in substrates by a dithiol mechanism that involves both thiol groups and a disulfide intermediate. Glutaredoxin also catalyzes monothiol reductions of GSH-mixed disulfides.

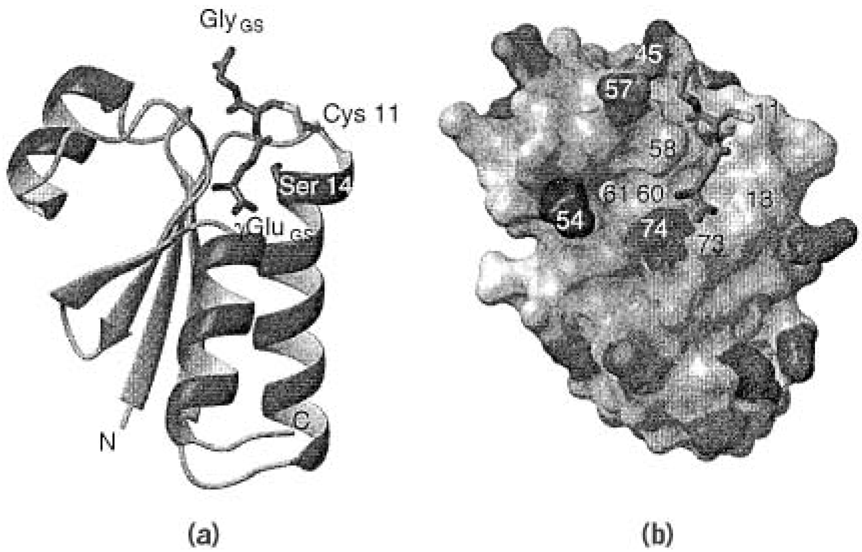
Figure 2. Mechanisms of glutaredoxin in GSH-disulfide oxidoreductions. The monothiol mechanism requires only the accessible N-terminal active-site Cys residue. The dithiol mechanism of disulfide reduction (like that in ribonucleotide reductase) requires both Cys residues (27, 35).



4. *E. coli* Grx Structure

Three-dimensional protein structures of oxidized and reduced *E. coli* Grx-1 (27), oxidized T4 Grx (28), and oxidized pig Grx (29) have been determined. In addition, the **secondary structures** and fold topology of reduced *E. coli* Grx-3 (15) and reduced human Grx (30) have also been reported. These studies confirm the presence of the thioredoxin fold that consists of a central four-stranded mixed b-sheet flanked by one a-helix on each face (Fig. 3). In addition to this core fold, the N- and C-terminal extensions observed in sequence comparisons contain two additional helical segments.

Figure 3. Representative NMR solution strucutre of *E. coli* Grx1 (C14 S mutant) in a mixed disulfide with GSH via Cys11 (27, 31). (**a**), Cartoon of the polypeptide backbone with the side chains of Cys11 and Ser14 displayed as sticks. The glutathione ligand is also displayed as a stick model whose bonds connect non-hydrogen atoms. (**b**) The molecular surface colored according to the electrostatic potential (dark gray: positive, medium gray: negative, and light gray: uncharged. Residues that interact with GSH are labeled at their approximate positions.



5. Glutaredoxin Mixed-Disulfide Complex with GSH

The intermolecular mixed-disulfide complex between *E. coli* Grx1 and GSH has been determined by NMR techniques (27). Mutation of the C-terminal active site Cys14 residue in *E. coli* Grx1 abolishes its activity as a dithiol reductant for ribonucleotide reductase (31), but retains its activity in the monothiol mechanism (Fig. 2). Overall, the polypeptide backbone in the complex is similar to that observed in the structures of the oxidized and reduced forms, also determined by NMR. The covalently attached glutathione is found in a largely extended conformation in a cleft formed by residues from three discontinuous regions of the polypeptide chain (Fig. 3). The intimate relationship between the Grx and glutathione is also confirmed by the fact that the ^{15}N T_{1r} relaxation rates of the amide nitrogen atoms of Cys and Gly of the glutathione are similar to those observed for the Grx backbone. The floor of the cleft is made up largely of contributions from Val 59, Pro 60, and Gly 71. The sides of the cleft are formed from Thr 58 on one side and Tyr 13 and Thr 73 on the other. Interestingly, many of these residues are in positions homologous to those residues that form the hydrophobic interaction surface in the thioredoxins. Two hydrogen bonds are present in a majority of NMR conformers: HN Val 59–CO Cys_{GS} and the HN Thr 73–aCO_2 gGlu_{GS}. Additional hydrogen bonds and salt bridges are observed in several structures, including $^{\varepsilon}NH_3$ Lys 45–aCO_2 Gly_{GS}, aNH_3 gGlu_{GS}–gCO_2 Glu 74, aCO_2 gGlu $_{GS}$–HN Tyr 72, aCO_2 gGlu $_{GS}$–HN Thr 73, and aCO_2 gGlu $_{GS}$–HO Thr 73. In addition, the aCO_2 gGlu_{GS} in a number of structures can be positioned directly over the N-terminus of the C-terminal a-helix, allowing for a favorable interaction with the dipole of the helix. Several of these interactions (salt bridge to C-terminus of GS, H-bond from CO Cys_{GS} to residue before the strictly conserved *cis* Pro, NH and OH of Ser to aCO $_2$ gGlu $_{GS}$) have homologous counterparts in the recognition of glutathione by **glutathione S-transferases** . These observations suggest that the details of the structural basis of noncovalent glutathione binding to Grx may be representative of a wider range of substrate interactions between members of the thioredoxin superfamily.

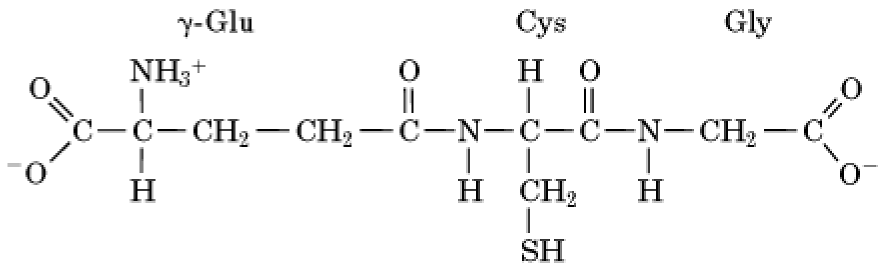
Glutathione

Glutathione was first discovered by J. de Rey-Pailhade over 100 years ago, and its structure (ie, L-g-glutamyl-L-cysteinyl-glycine, or g-Glu-Cys-Gly),



was deduced in the 1930s. It has several important functions: (i) most importantly, as a reductant; (ii) conjugation to foreign chemicals to make them more **water**-soluble, less toxic, and excretable; (iii) transport of amino acids across cell membranes; (iv) incorporation into some leukotriene structures; (v) as a **cofactor** for some enzymes; (vi) as a nontoxic storage form of cysteine; and (vii) in forming and maintaining protein disulfide bonds in the endoplasmic reticulum (ER).

Glutathione is the predominant **thiol** compound in very many cells, both prokaryotes and eukaryotes, where its total intracellular concentration is usually in the range 0.5 to 12 mM. It is present in most eukaryotes, except for those that do not have mitochondria. It is not present in many Archaebacteria, but in halobacteria it is replaced by g-Glu-Cys. Likewise, some eubacteria do not have glutathione, and it is found primarily in the bacteria of the cyanobacteria and the purple bacteria classes. It is believed that glutathione arose initially in the prokaryotic ancestors of mitochondria and chloroplasts and was acquired by eukaryotes along with these organelles.

Glutathione is synthesized from its three constituent amino acids. First, the side-chain g-**carboxyl group** of glutamic acid is joined in a peptide bond to the a-**amino group** of cysteine, by the enzyme g-glutamylcysteine synthetase. The a-carboxyl group of the resulting g-Glu-Cys is then joined in a normal peptide bond with the a-amino group of glycine, catalyzed by glutathione synthetase. Both steps are coupled to the hydrolysis of ATP. Some species of **plants** have a variant of glutathione, homoglutathione, in which the glycine residue is replaced by b-alanine, due to an **evolutionary** change in specificity of the enzyme glutathione synthetase. In **trypanosomes**, glutathione is largely replaced by the related trypanothione in which two g-Glu-Cys-Gly moieties are linked by peptide bonds through their carboxyl groups to a molecule of **spermidine**.

Glutathione is also degraded to its constituent amino acids *in vivo*, which is believed to give it an important role as a nontoxic storage form of cysteine. High levels of cysteine are toxic in some systems, in part because its amino, carboxyl, and thiol groups are well situated stereochemically to chelate metal ions, which catalyze air oxidation of its thiol group. A by-product of thiol oxidation is peroxides, which damage the cell. Glutathione is much more resistant to air oxidation and much less toxic, and it can occur safely at 10 to 100 times greater levels.

Glutathione is an essential cofactor for a number of enzymes, including formaldehyde dehydrogenase, glyoxylase, maleylacetoacetate isomerase, dehydrochlorinase, and prostaglandin endoperoxidase isomerase. The glutathione is involved transiently in the reactions they catalyze. For example, formaldehyde dehydrogenase uses NAD^+ to catalyze the oxidation of an adduct of formaldehyde and glutathione to produce *S*-formylglutathione, which is subsequently hydrolyzed by a specific lyase to yield formate and regenerate the glutathione. Glyoxylase is similar, also generating a transient intermediate adduct between its substrate, methyl glyoxal, and glutathione.

Naturally, glutathione is found in a mixture of the thiol form, GSH, and with a disulfide bond linking two glutathione moieties, GSSG. The GSH thiol group has a pK_a value of about 8.8, while the amino and carboxyl groups have normal pK_a values that are virtually the same in the disulfide form (1). There apparently are no substantial interactions between the two glutathione moieties in GSSG, and the stability of this disulfide bond is comparable to that between two other cysteine residues on unfolded peptides or proteins; the rate and equilibrium constants for thiol–disulfide exchange are close to their expected values (2).

Within the cytosol of cells, glutathione is kept primarily in the reduced GSH form, largely by reduction of GSSG by the enzyme *glutathione reductase*, at the expense of NADPH:

$$\mathrm{GSSG + NADPH + H^+ \leftrightarrow 2GSH + NADP^+} \tag{1}$$

The mechanism of this reaction is complex, as the enzyme contains a pair of cysteine residues that reversibly form a disulfide bond, plus one FAD molecule (3). As GSH and GSSG will react spontaneously with each other and with other thiol and disulfide compounds of the cell, in the thiol–disulfide exchange reaction, the ratio of GSH and GSSG reflects the general redox properties of the cell. Being present at such high concentrations, GSH is an important reductant within cells. For example, it is involved in the reduction of glutaredoxin, and it and NADPH reduce the oxidized form of vitamin C, dehydroascorbate, to the active form, ascorbate.

GSH is used for the destruction of oxidants, such as organic peroxides and H_2O_2, which would cause irreversible damage to membranes, DNA, and numerous other cellular components; this reaction is catalyzed by the enzyme *glutathione peroxidase*:

$$\mathrm{2GSH + H_2O_2 \rightarrow GSSG + 2H_2O} \tag{2}$$

This enzyme is unusual in that it has a selenocysteine residue at its active site (4).

Normally, GSH predominates over GSSG by a factor of 100 in the cytosol. This is a somewhat reducing environment that tends to keep protein cysteine residues in the thiol form (P^{SH}_{SH}) and destabilizes any disulfide bonds they may make (P^{S}_{S}),

$$\mathrm{P^{SH}_{SH} + GSSG \overset{K^{eq}}{\leftrightarrow} P^{S}_{S} + 2GSH} \tag{3}$$

although very stable disulfide bonds found in some proteins could be present under these conditions. The stability of a protein disulfide bond is determined by its intrinsic stability, K_{eq}, plus the ratio of the concentrations of GSH and GSSG:

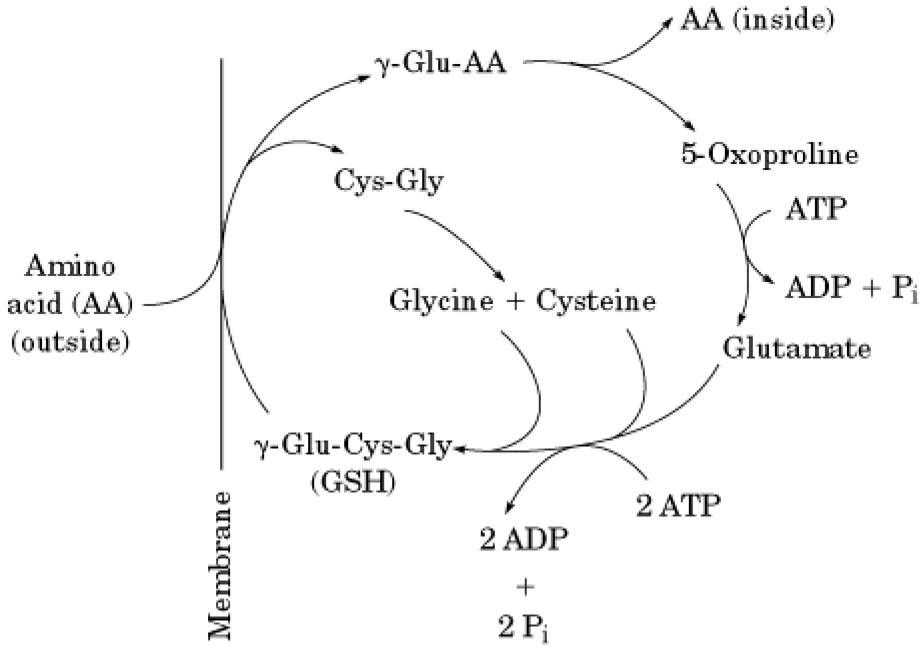
$$\frac{[\mathrm{P}_{\mathrm{S}}^{\mathrm{S}}]}{[\mathrm{P}_{\mathrm{SH}}^{\mathrm{SH}}]} = K_{\mathrm{eq}} \frac{[\mathrm{GSSG}]}{[\mathrm{GSH}]^2} \tag{4}$$

Only very stable protein disulfide bonds, with large values of K_{eq}, could be populated in the cytosol.

In the endoplasmic reticulum (ER) of eukaryotes, in contrast, GSH and GSSG are present in nearly equal concentrations (5). With 1 mM each of GSH and GSSG, the same disulfide bond would be present in the ER to an extent 100 times greater than in the cytosol. This is sufficient to permit proteins in the ER to form disulfide bonds if their conformations stabilize them (see Disulfide Bonds); if not, the protein cysteine residues will tend to remain in the thiol form. The formation of such stable disulfide bonds in proteins in the ER is catalyzed by protein disulfide isomerase (PDI). PDI can have an unstable disulfide bond at each of its two active sites, which is readily transferred to other proteins. The PDI active-site disulfide bonds are believed to be regenerated by chemical reaction of the protein with GSSG.

Glutathione is believed to be used in some cells, such as those of the mammalian liver and kidney, for the transport of amino acids (except for proline) across the plasma membrane (Fig. 1). The extracellular amino acid is reacted with intracellular glutathione that has been shuttled to the cell surface by the integral membrane protein g-glutamyltranspeptidase. This replaces the Cys-Gly dipeptide of GSH by the amino acid and produces g-Glu-amino acid. The amino acid is liberated upon degradation of the g-Glu-amino acid by the enzyme g-glutamyl cyclotransferase, which generates 5-oxoproline instead of glutamate. The driving force for uptake of amino acids by this “group translocation” type of mechanism is the destruction of the glutathione, for the Cys-Gly moiety is also degraded, by cysteinylglycine dipeptidase; regeneration of glutamate from 5-oxoproline by 5-oxoprolinase requires hydrolysis of ATP, and resynthesis of glutathione requires another two molecules of ATP. The disulfide form of cysteine, cystine, is an especially reactive amino acid substrate of this cycle. The g-Glu-CysSSCys generated by g-glutamyltranspeptidase is rapidly reduced in the cell cytosol to g-Glu-Cys and cysteine. The g-Glu-Cys can then be converted to GSH by addition of glycine, thereby bypassing the production of 5-oxoproline. On the other hand, humans lacking g-glutamyltranspeptidase have no difficulty in transporting amino acids, and there are many other types of amino acid **transporters**. The cycle is now believed to play only a minor role in transport of amino acids, except for cysteine.

Figure 1. The g-glutamyl cycle for transporting amino acids, coupled to the degradation of glutathione (GSH; g-Glu-Cys-Gly). The amino acid (AA) on the outside of the cell (left) is coupled to glutamic acid of GSH by the membrane protein g-glutamyl transpeptidase, by replacing the dipeptide cysteinyl-glycine (Cys-Gly). The amino acid is released from the g-glutamyl residue, converting it to 5-oxoproline. The concomitant degradation of GSH is the driving force for transporting the amino acid. Resynthesizing 1 mol of GSH requires the hydrolysis of 3 moles of ATP.



The g-glutamyl cycle is now believed to have a major role in higher organisms in the metabolism of leukotrienes, estrogens, prostaglandins, and many drugs and xenobiotics. All these molecules, often after their reaction with cytochrome P-450, are linked covalently to the thiol group of GSH by the large enzyme family of **glutathione S-transferases**. The resulting glutathione S-conjugate is then degraded to the Cys-Gly S-conjugate and then to the cysteine S-conjugate by g-glutamyltranspeptidase and cysteinylglycine dipeptidase, respectively. The cysteine S-conjugate is converted, by a specific *N*-acetyltransferase to the corresponding mercapturate, *N*-acetylcysteine S-conjugate, which is then excreted. On the other hand, this pathway can also sometimes lead to the generation of a toxic substance. For example, halogenated cysteine S-conjugates can generate highly reactive thiol-containing fragments through the action of cysteine S-conjugate b-lyases:

$$\underset{\text{cysteine S-conjugate}}{R-S-CH_2CH(NH_2)CO_2H} \rightarrow RSH + NH_3 + \underset{\text{pyruvate}}{CH_3C(O)CO_2H} \tag{5}$$

where RSH is the thiol form of the xenobiotic, which can be toxic.

The generally protective, antioxidative effects of GSH are reflected in the observations that decreased levels of GSH lead to clinical symptoms in humans and decreased resistance to viruses and other diseases.

Glutathione Transferase

Glutathione transferases (GSTs) are detoxication enzymes that occur abundantly in eukaryotic cells and also in prokaryotic organisms. The majority of the enzymes are found in the cytosol, but a significant proportion is also recovered in the **microsomes** and other subcellular membrane fractions. In mammalian liver tissue, GSTs represent several percent of the total protein content in both the **cytoplasm** and the endoplasmic reticulum, indicating they have important biological functions. All known soluble (mostly cytosolic) GSTs are dimeric proteins composed of two subunits of approximately 26-kDa molecular weight. In contrast, the microsomal GSTs, and probably the related membrane-bound enzymes, are trimers of 17-kDa subunits (Table 1). A plasmid-encoded GST that confers bacterial antibiotic resistance to fosfomycin is a structurally unrelated protein composed of two 16-kDa subunits. The cytosolic GSTs form both homodimers and heterodimers of closely related subunits, thereby increasing the multiplicity of GST **isoenzymes** .

Table 1. Structural and Catalytic Properties of Human Glutathione Transferases [a]

	Human Glutathione Transferase										
Property	A1-1	A2-2	A4-4	M1-1	M2-2	M3-3	M4-4	P1-1	T1-1	T2-2	MGST1 (activated)

[a] Specific activities (mol/min per mg pure protein) are given for representative substrates. Dashes represent no measurable activity; blank spaces signify missing data. Data largely compiled from the review articles by Mannervik and Widersten (1995) and Hayes and Pulford (1995).

1. Reactions Catalyzed

GSTs catalyze reactions between glutathione (GSH) and compounds with electrophilic chemical functionalities. GSH is a tripeptide, g-L-glutamyl-L-cysteinyl-glycine, that occurs in millimolar concentrations in all types of cells and in micromolar concentrations in mammalian extracellular fluids. The reactive thiol group, –SH, of the GSH cysteine residue may serve as either a nucleophile or a reductant. In both cases, the reactions are dependent on the electron-donating properties of the sulfur atom. Its reactivity is further accentuated by ionization of the thiol group to the thiolate form. One of the catalytic functions of GSTs is to decrease the pK_a value of the GSH thiol group (9.2 in aqueous solution) to make GSH ionized under physiological conditions. The pK_a value of enzyme-bound GSH may be lowered by several pH units. Judging from the known affinities of GSTs for GSH, it would appear that most enzymes are fully loaded with GSH in its thiolate form and ready to react with the incoming second substrate.

The common denominator for essentially all GST-catalyzed reactions is nucleophilic attack by the GSH thiolate group on an electrophilic site in the second substrate. The electrophilic center of the second molecule is usually a carbon atom, but it may also be electronegative atoms, such as oxygen, nitrogen, or sulfur. The GST-catalyzed reactions involving O, N, and S as electrophilic sites often lead to unstable products, which react with a second molecule of GSH:

$$\mathrm{ROOH} + \mathrm{GSH} \rightarrow \mathrm{ROH} + \mathrm{GSOH} \quad (1)$$

$$\mathrm{GSOH} + \mathrm{GSH} \rightarrow \mathrm{GSSG} + \mathrm{H_2O} \quad (2)$$

where ROOH and ROH are, respectively, a hydroperoxide and the corresponding alcohol, and GSSG is the **disulfide** form of glutathione. In effect, such reactions accomplish reduction of organic hydroperoxides, nitrate esters, and disulfides.

The carbon-centered reactions are basically of two types: additions and substitutions. Addition reactions involve molecules such as naturally occurring a,b-unsaturated carbonyl compounds and organic isothiocyanates. The substitutions reactions involve the replacement of a chemical substituent by a glutathione group. The leaving group may be a halogenide, sulfate, or other chemical substituent with sufficient electron-withdrawing potential.

Reactions involving electrophilic carbon centers usually lead to GSH conjugates that may be excreted from the cell via ATP-dependent membrane-associated transporters, such as the multidrug resistance-associated protein (MRP) (see Drug Resistance), for subsequent disposition through the gut or the urinary tract. For urinary excretion, GSH conjugates are metabolically transformed by cleavage of the two peptide bonds of the glutathione moiety, followed by acetylation into the corresponding *N*-acetyl-cysteine derivatives, mercapturic acids. These reactions are accomplished through the action of g-glutamyl transpeptidase, a dipeptidase, and an acetyltransferase (see Glutathione).

2. Discovery

GSTs were discovered in mammalian liver as enzymes catalyzing aromatic nucleophilic substitution reactions in which GSH replaces a halogen atom in an aromatic compound, such as a chloronitrobenzene derivative (1, 2). When other classes of organic compounds, with epoxide, alkene, and other electrophilic centers, were investigated, additional enzyme-catalyzed GSH conjugations were identified (3). The introduction of improved separation techniques lead to the identification of multiple forms of GST catalyzing the same chemical reaction, i.e. **isoenzymes** in the original sense of the term (4, 5). Subsequent work with purified enzymes demonstrated that although each enzyme form has its characteristic substrate specificity profile, most GSTs catalyze reactions with a wide range of electrophiles, and the majority of the active compounds are at least to some degree substrates for several GSTs.

3. Substrates

GSTs as a family of enzymes are capable of catalyzing reactions involving literally thousands of electrophilic compounds, including many of xenobiotic origin. In this respect, the GSTs display similarities to **antibodies**, which may evolve to interact with and provide protection against an almost unlimited number of molecular structures.

The majority of the known GSTs are regarded as detoxication enzymes and are catalytically active with a large number of xenobiotics, including epoxides of potent **carcinogens**, such as benzo[a]pyrene and aflatoxin. Naturally occurring substrates include a wide variety of genotoxic compounds, such as epoxides, activated alkenes, hydroperoxides, and quinones, all products of oxidative metabolism. Organic isothiocyanates are abundant in edible plants, from which they are released in high concentrations by injuries caused by insects and microbial infections.

4. Purification

Affinity chromatography methods have been developed for the purification of GSTs. Most purification procedures involve affinity matrices based on glutathione derivatives as ligands. Immobilized *S*-hexylglutathione, first used for the purification of glyoxalase I, is linked via the a-amino group of the g-glutamyl residue of glutathione to a suitable matrix (6). This adsorbent potentially combines the affinities of the H subsite of the GST active site (see below) for the **hydrophobic** hexyl substituent and of the G subsite for the GSH moiety. Another commonly used affinity matrix makes use of GSH immobilized via its thiol group (7). Elution of bound GSTs may be effected by competition using GSH derivatives with affinity for the active site of the enzyme. Alternative elution procedures involve changing the pH of the eluent to extreme values, such as pH 10 or pH 2. When applied to crude tissue fractions, affinity chromatography based on these matrices will yield mixtures of GSTs, which can be resolved by other methods. For separation of the dimeric proteins in a functional form, chromatofocusing or ion-exchange chromatography may be used. For analytical purposes, the subunits may be resolved by **reversed-phase** high-performance liquid chromatography (HPLC).

Less specific affinity methods used for the purification of GSTs include Orange A dye chromatography and **metal chelate chromatography**. The latter methods have proved useful for the isolation of the several GSTs that do not bind to affinity matrices based on glutathione derivatives.

5. Nomenclature

The International Enzyme Commission has recommended the name RX:glutathione R-transferase (E.C. 2.5.1.18) or the trivial form glutathione transferase, which has been adopted here. Another designation commonly used is glutathione *S*-transferase, but this is inconsistent with the rational name, since the group transferred is not the sulfur of glutathione. The generally accepted abbreviation GST has probably contributed to the persistence of the *S*-prefix.

In the time period when the first GSTs were discovered, the enzymes were named in accord with the reactions used for their identification: glutathione *S*-aryltransferase, glutathione *S*-alkyltransferase, and so on. With the exception of the membrane-bound transferase catalyzing the glutathione conjugation of leukotriene A_4, named leukotriene C_4 synthase, the principle of designating GSTs by their substrates or products has been abandoned, because most enzymes have very broad substrate specificities so that accurate distinctions cannot be made.

Another nomenclature system arose from the finding that the cytosolic "Y-fraction" of rodent liver could be separated by SDS-PAGE into components that corresponded to GST subunits. These subunits were distinguished by lower indices, namely Y_a, Y_b and so on, and were further subdivided into Y_{a1}, Y_{a2}. Subunits with the same mobility but different structures were identified.

A rational nomenclature for the cytosolic or soluble GSTs is based on two principles. First, the native enzymes occur as binary combinations of GST protein subunits, so that the functional properties of the dimeric protein reflect those of its constituents subunits (8). Second, the GSTs can be divided into different classes primarily based on similarities in their amino acid sequences (9). In mammals, seven classes of soluble GSTs have been identified thus far: Alpha, Mu, Pi, Theta, Sigma, Kappa, and Zeta. Sequence identities within a class are normally >50%, but they may exceed 95%. Classification of GSTs from other biological species requires further structural studies, but designations for insect enzymes (Delta) and bacteria (Beta) have been used.

In the current nomenclature (Table 1), the soluble mammalian GSTs are denoted by a capital Roman letter indicating the class (A, M, P, T, S, K, and Z) as well as two hyphenated Arabic numerals showing their subunit composition (10). Thus, GST A4-4 is a homodimer of subunit 4 within the Alpha class, and GST A1-2 is a heterodimer composed of subunits 1 and 2 from the same class. There may also be reason to distinguish allelic variants: Human GST M1a-1b is a heterodimeric member of the Mu class composed of variants of subunit 1 in the Mu class encoded by the *GST M*A* and *GST M*B* alleles. A prefix may be used to identify the biological species from which the enzyme derives, such as "h" for the major human enzyme hGST A1-1.

The mammalian membrane-bound GST first isolated from the microsome fraction is a trimeric enzyme composed of identical subunits and cannot readily be accommodated within the nomenclature system used for the soluble GSTs. It is simply referred to as microsomal GST (MGST1). The membrane-bound GST specifically catalyzing the conjugation of leukotriene A_4 is referred to as leukotriene C_4 synthase.

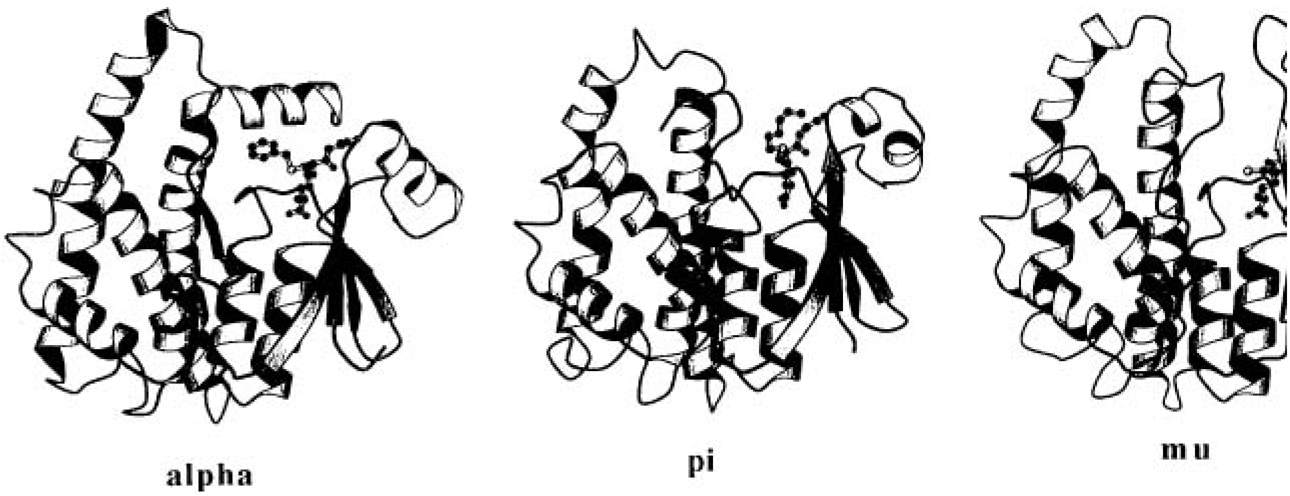
6. Structure

Three distinct categories of GST protein structures are known.

6.1. Soluble GSTs

The first category includes the soluble GSTs, which are generally dimers of equal-sized subunits, each containing an active site composed of a pocket for glutathione (the G site) and a pocket for the largely **hydrophobic** electrophilic substrate (the H site) (11). Each subunit consists of two structural **domains**; (a) an *N*-terminal domain including the first one-third of the primary structure and (b) a domain formed essentially by the remaining two-thirds of the amino acid sequence (Fig. 1). The first domain is folded into a mixed **b-sheet** flanked by **a-helices** and provides the structural basis for the G site. The second one is formed by helical segments and provides the major contributions to the H site. The fold of the *N*-terminal domain is essentially the same as the fold of thioltransferase (glutaredoxin) and selenium-dependent glutathione peroxidase. Another salient feature of the dimer is a deep cleft between the subunits that may serve as a binding site in addition to the active site cavities. The fully formed dimer appears to be a structural requirement for a catalytically active GST.

Figure 1. Schematic drawings of alpha (GST A1-1), pi (GST P1-1) and mu (GST 3-3) structures with their ligands. The been chosen to show the 2 domains and C-terminal region. From Ref. (11), with permission.



All known structures contain an *N*-capping box sequence, (Ser/Thr)–X–X–Asp, as well as a hydrophobic staple motif formed by flanking amino acid residues in the core of the folded structure. As evidenced by mutational analyses of protein folding (12), these structural signatures appear to play an important role in the nucleation and orientation of a centrally located a-helix.

6.2. Manganese-Dependent Plasmid-Encoded GST

The second category is represented by the manganese-dependent plasmid-encoded GST that is active with the antibiotic fosfomycin (13). It is a homodimer structurally related to mammalian glyoxalase I, a GSH-linked zinc protein whose structure has been determined (14). This GST is structurally unrelated to other known GSTs.

6.3. Membrane-Bound GSTs

The third category contains the microsomal MGST1 and, presumably, the additional membrane-bound GSTs. The detailed structure of MGST1 is unknown, but clearly it is not similar in structure to the soluble GSTs. The protein is a homotrimer, and the identical monomers appear to have a high content of a-helical structure.

7. Catalytic Mechanism

GSTs bind the peptide moiety of GSH in a well-defined manner so that they are specific for this thiol substrate. For all GSTs investigated, the a-carboxylate group of the g-glutamyl residue of GSH is required for the thiol group to serve as a substrate; when bound in the G subsite, the carboxylate appears to have a negative charge that is not balanced by a positively charged protein group. These observations suggest a contribution of the substrate carboxylate group to catalysis. At least for some GSTs, there is also evidence that binding of GSH induces a conformational change in the protein that promotes binding of the second substrate.

Binding of GSH to the G subsite affects the ionization of its sulfhydryl group, thereby making it more reactive. In addition, interactions with a **hydrogen-bond** donor in the active site may stabilize and orient the thiolate group for optimal interaction with the electrophilic substrate. In this manner the enzyme promotes catalysis by selecting a suitable ground-state conformation of GSH.

Binding to the H subsite also results in desolvation of the electrophilic substrate and selection of an orientation favorable for reaction with the sulfur of GSH. Some GSTs have tyrosine or other residues that afford binding specificity, as well as activation of substrates by hydrogen bonding and other electrostatic interactions.

In some, but not all, GST-catalyzed reactions, stabilization of the transition state contributes to the catalytic efficiency. Thus, the common mechanistic feature of GSTs is the activation of GSH, whereas other components of the catalytic process may differ from substrate to substrate and from enzyme to enzyme.

8. Binding Function

A ligand-binding function of GSTs of possible physiological significance was originally found in the protein fraction *Y*, of rat liver cytosol, which binds organic compounds such as certain carcinogens, dyes, and corticosteroids. The abundance of the protein (several percent of the total cytosolic protein) and its broad specificity for binding of a variety of ligands suggested a function similar to that of serum albumin in blood plasma and led to the name of "ligandin" (intracellular albumin). In the current nomenclature, ligandin corresponds to the Alpha class GST A1-1, with some contribution of the heterodimer GST A1-2. Corticosteroid binding has also been associated with GST isoenzymes of the Mu class.

The binding function of GSTs has often been ascribed to the H subsite, at which the enzyme binds the various electrophilic substrates. Some nonsubstrate compounds, especially small molecules, can bind at the H subsite with a stoichiometry of one molecule per subunit. However, X-ray crystallography studies have also shown that the deep cleft between the two GST subunits serves as an additional binding site of the dimeric structure, explaining the stoichiometry of one ligand per two subunits observed for certain ligands.

As binding proteins, GSTs have been suggested to facilitate the intracellular transport of endogenous molecules, such as heme and bilirubin, as well as other compounds of low solubility in an aqueous environment. The transport through cellular membranes of dyes, such as indocyanine green and bromosulfophthalein, which have been used in clinical liver function tests, may also be facilitated by GSTs. An auxiliary role in **active-transport** processes involving MRP and other membrane transport systems may also be suggested. However, the full significance of GSTs as binding proteins needs to be further clarified.

9. Molecular Evolution

The presence of GSH is a signature of aerobic organisms (15), as is the occurrence of GSTs. Elucidation of the details of the phylogeny of GSTs requires additional structural information. The soluble (cytosolic) GSTs are found ubiquitously, however, and all their three-dimensional structures determined, from bacteria to higher plants and mammals, have the same two-domain fold, even though sequence similarities may be undetectable. A common ancestry followed by divergent evolution is therefore indicated. The most recently discovered Kappa, Theta, and Zeta classes of

GST appear to be evolutionary precursors of the more abundant mammalian enzymes from the Alpha, Mu, and Pi classes. It has been proposed, in accordance with the symbiont theory of organelle evolution, that the Kappa class GST found in mitochondria may be a descendant from a bacterial GST. The structural similarities between the *N*-terminal domain of the soluble GSTs and other GSH-linked proteins (see text above) lends support to the hypothesis that a GSH-binding protein is a functional unit that has been combined with other functional protein units and evolved to serve diverse biological functions. The GST structure itself has evolved to fulfill alternative functions, such as that of crystallins in the eye lens of cephalopods. The various GST isoenzymes may have arisen by gene duplications, recombination of DNA segments, and random mutations .

The membrane-bound GSTs and the plasmid-encoded Mn-dependent GST seem to have undergone convergent evolution to acquire the property of catalyzing the nucleophilic attack of GSH on electrophiles. Thus, three evolutionarily unrelated superfamilies of GSTs have been recognized.

10. Differential Tissue Distribution

GSTs are found in all tissues investigated in multicellular organisms, but the expression of the multiple genes differs from tissue to tissue. Also, the enzyme distribution changes with time during the development of embryonic to adult organs. Some GSTs have a reasonably general tissue distribution, whereas others have a more restricted occurrence. Also intracellular spatiotemporal differences in GST distribution have been noted. The soluble GSTs are found mainly in the cytoplasm, but may also occur sometimes in the nucleus. The mammalian Kappa class GST is found in the mitochondrial matrix.

The differential distribution of GSTs may have toxicological consequences, since the amount and nature of a given GST will determine the capacity of a cell to resist insults from genotoxic and carcinogenic electrophiles. The presence or absence of a particular enzyme will influence the resistance **phenotype** of a tissue. In cancer cells, GSTs may contribute to drug resistance, particularly against alkylating cytostatic agents.

11. GST Genes

Mammalian cells generally appear to have more than 20 GST genes, each encoding a distinct GST subunit. In humans, as well as in rodents, the genes have been shown to be distributed on different chromosomes, and the loci for related GSTs from the same class are generally clustered on the same chromosome. In addition, pseudogenes may occur close to the active genes. This distribution supports the classification adopted for the GSTs and is in agreement with the proposal that they have diversified in evolution by gene duplication and DNA recombination.

Genetic polymorphisms are known, and the human genes for GST M1-1 and GST T1-1 are deleted in approximately 50% and 20%, respectively, of the population. The resulting enzyme deficiencies lead to increased sensitivities to gene modifications and chromosome aberrations by certain chemical agents, and they probably also lead to increased risk of contracting certain forms of cancer. On the other hand, the activity of GST T1-1 promotes the formation of mutagens from ethylene dihalogenides, and the absence of the enzyme may be advantageous under some circumstances.

12. Regulation of Gene Expression and Induction of GST Activity

The differential expression of the GSTs is governed by hormones and other factors that regulate transcription of the genes. A range of **enhancers** and other regulatory elements, shown to mediate responses in other genes, have also been shown to be functional in GST gene regulation. Particular attention has been given to the **antioxidant response element**, ARE (also called the *electrophile response element*), which has proven effective in the induction of the activity of several detoxication enzymes in mammalian systems. An extremely broad range of chemical compounds containing an electrophilic group appear to serve as inducers via ARE, suggesting that enzyme induction is a natural response to exposure to electrophiles.

13. Biological functions

GSTs serve in cellular detoxication systems and constitute the major line of defense against chemical electrophiles, many of which are genotoxic and carcinogenic. The substrates include numerous xenobiotics or their metabolically activated products—for example, epoxides of carcinogenic polyaromatic hydrocarbons. Plants produce a variety of toxic compounds as a defense against attack by insects and microorganisms, and some of them can be inactivated by GSH conjugation. For example, many edible plants produce toxic organic isothiocyanates that are substrates for human GSTs. Like their mammalian counterparts, plant GSTs are inducible enzymes that serve protective functions, one of which is to provide cellular resistance to electrophilic herbicides.

Among the biologically most important substrates are numerous oxidation products of normal cell constituents, such as lipids, nucleic acids, catechols, and other aromatic or unsaturated chemical compounds. Free-radical reactions, accompanied by chemical transformations involving reactive oxygen species, lead to a variety of electrophilic products that may cause damage to DNA and proteins. Lipid peroxidation gives rise to aldehydes and activated alkenes, and cellular oxidation of catecholamines produces ortho-quinones. These naturally occurring oxidation products, considered to be etiological factors in the development of atherosclerosis, cataract, cancer, Parkinson's, and other degenerative diseases, are all substrates of GSTs. Human GST A4-4 has particularly high activity with the lipid peroxidation product 4-hydroxynon-2-enal (Table 1), and human GST M2-2 is the most efficient enzyme with the ortho-quinone aminochrome derived from dopamine.

In addition to their catalytic functions, GSTs may serve as binding proteins (ligandin) that facilitate cellular transport of organic molecules. Some of the most abundant enzymes, such as GST A1-1, appear particularly well-suited for this purpose.

14. Biotechnology Applications

The soluble GSTs are generally stable proteins that can be produced in large quantities by heterologous expression in *Escherichia coli*. Thus, the enzymes have potential for development into useful recombinant proteins of value for biotechnical, agricultural, and medical applications. Both the catalytic and binding properties can be explored. Catalysts and binding proteins with novel specificities can be designed by a combination of mutagenesis and selection methods.

15. Glutathione Transferase as a Fusion Protein for Expression of Other Proteins

In the expression of proteins by **recombinant-DNA** methods, it is frequently found that the protein product is obtained in poor yield owing to low solubility, improper **codon usage**, **proteolytic** degradation, and so on. In many cases, these problems may be overcome by producing the desired protein product in fusion with a GST molecule. DNA encoding GST with a cleavable *C*-terminal linker to the protein to be expressed is ligated to the target DNA. GSTs are normally stable and soluble proteins that can be expressed at high levels in many cell types, and the recombinant fusion proteins usually retain these properties. The fusion protein can be purified by affinity chromatography on immobilized glutathione derivatives and, after liberation of the desired protein by proteolytic cleavage, the GST moiety can be removed by a second affinity chromatography. By this two-step purification, the desired protein may be obtained in pure form.

Glycine (Gly, G)

The amino acid glycine is incorporated into the nascent polypeptide chain during **protein biosynthesis** in response to four **codons**—GGU, GGC, GGA, and GGG—and represents approximately 7.2% of the residues of the proteins that have been characterized. The glycyl residue incorporated has a mass of 57.05 Da, a **van der Waals volume** of 48 Å^3, and an accessible surface area of 85 Å^2. Gly residues are changed during divergent evolution less frequently than average; when they are, they are interchanged in **homologous** proteins most frequently with alanine, serine, aspartic acid, and asparagine residues.

Gly is the simplest amino acid residue, with only a hydrogen atom for a side chain. Note that the a-carbon atom of Gly is not asymmetric, in contrast to the other amino acids incorporated into proteins, because it is bonded to two H atoms. Consequently, this amino acid does not occur as D or L isomers.

The absence of a larger side chain gives the polypeptide backbone at Gly residues much greater conformational flexibility than at other residues. For example, about 61% of the possible values of the torsion angles f and y of a Ramachandran Plot are permitted with a Gly residue, in contrast to the 30% with other residues; moreover, the Ramachandran plot of allowed torsion angles is symmetric. This extra flexibility tends to decrease the overall average dimensions of unfolded polypeptide chains, as the Gly residues permit the chain to reverse directions more readily. This is also used in native protein structures, where Gly residues occur most frequently in reverse turns. The extra flexibility of the Gly residue in an unfolded polypeptide chain is believed to destabilize all fixed conformations, and Gly residues decrease the tendency to adopt an **alpha-helical** conformation.

The precursors of some peptide hormones, such as melanocyte stimulating hormone, have a Gly residue at the *C*-terminus that becomes converted to an amide group enzymatically).

Glycogen Phosphorylase

Glycogen phosphorylase (E.C. 2.4.1.1) catalyzes the first step in the intracellular degradation of glycogen to form individual molecules of glucose that are used for energy needs. Glycogen is a polymeric storage form of sugar consisting of glucose joined into long chains by the elimination of water between the first carbon of one glucose and the fourth of another, forming a-1,4 links. Every four to five glucose units, a branch is introduced by an a-1,6 link, resulting in a compact, highly branched molecule, spherical in shape, and containing as many as a million glucose units. Phosphorylase carries out a phosphorolytic cleavage of the 1,4 links, as shown below:

$$(\alpha-1,4-\mathit{glucoside})_n + \mathrm{HPO}_4^{2-} \leftrightarrow (\alpha-1,4-\mathrm{glucoside})_{n-1} + \alpha-\mathcal{D}-\mathrm{glucose}-1-\mathrm{PO}_3^{2-} \qquad (1)$$

The 1,6 branchpoint links are removed by a separate enzyme, the glycogen debranching enzyme, so that phosphorylase can then degrade virtually the entire molecule. Phosphorylase exists in two forms, *a* and *b*, differing covalently only in that Ser14 is phosphorylated in form *a*. In muscle, the nervous signal for contraction, calcium release, also activates the inactive phosphorylase *b* of resting muscle through the action of phosphorylase kinase . In liver, the inactive phosphorylase of a well-fed animal is activated by the signal of the pancreatic hormone glucagon that blood sugar levels are low, again via the mediation of phosphorylase kinase. Phosphorylase was one of the first enzymes recognized to be under hormonal control by protein **phosphorylation**, as well as subject to **allosteric** controls. It can be prepared in large amounts in pure crystalline form from muscle, and this made it the subject of intense study by a number of laboratories, culminating in the determination of its three-dimensional structure at atomic resolution by X-ray crystallography. The structures of several of its forms, plus associated biochemical experiments, have resulted in a better understanding of the function of this large and complicated enzyme.

1. Discovery and Early Developments

Carl and Gerty Cori discovered phosphorylase in 1936 when they isolated a new sugar phosphate from minced muscle mixed with water and inorganic phosphate. By characterization and synthesis, they proved that the new compound was a-D-glucose-1-phosphate and showed that it was formed from glycogen by the chemical reaction depicted in equation (1). The purified enzyme required AMP for activity, and when all attempts failed to demonstrate its participation in the catalytic mechanism, as other known coenzymes did, this became recognized as perhaps the first example of an allosteric activator. In 1941, a second form of phosphorylase was isolated and crystallized that did not require AMP for activity, although the latter decreased the $\boldsymbol{K_m}$ **(Michaelis constant)** values for the substrates; this was termed the *a* form, while the first was termed the *b* form.

During the 1950s, it was discovered that phosphorylase *a* was twice the molecular weight of phosphorylase *b* and that a new enzyme, now known as a **protein phosphatase**, converted form *a* to *b*. Chemical modification of the thiol groups inactivated the enzyme, accompanied by dissociation of the *a* form into four identical subunits and dissociation of the *b* form into two identical subunits. The number of moles of AMP binding to the enzyme equaled the subunit composition of the two forms. However, under *in vivo* conditions and bound to glycogen, phosphorylase *a* is dimeric. This was the first demonstration that enzymes contain subunits (see Quaternary Structure); the only proteins known earlier to have subunits were hemoglobin and insulin. The conversion of phosphorylase *b* to *a* was shown to involve the phosphorylation of residue Ser14 of each subunit by the specific phosphorylase kinase. A second organic phosphate moiety present was discovered to be pyridoxal phosphate (PLP), a derivative of vitamin B6. The **kinetic mechanism** was proven to be rapid equilibrium random Bi–Bi, meaning that either substrate can bind first, that kinetic constants approximate binding constants, and that the rate-limiting steps are to be found in the interconversion of the ternary complexes. Graves and Wang (1) have published a comprehensive review of the literature up to 1972, a convenient date because it occurs just before the crystallographic studies provided detailed structures and insights into function and regulation.

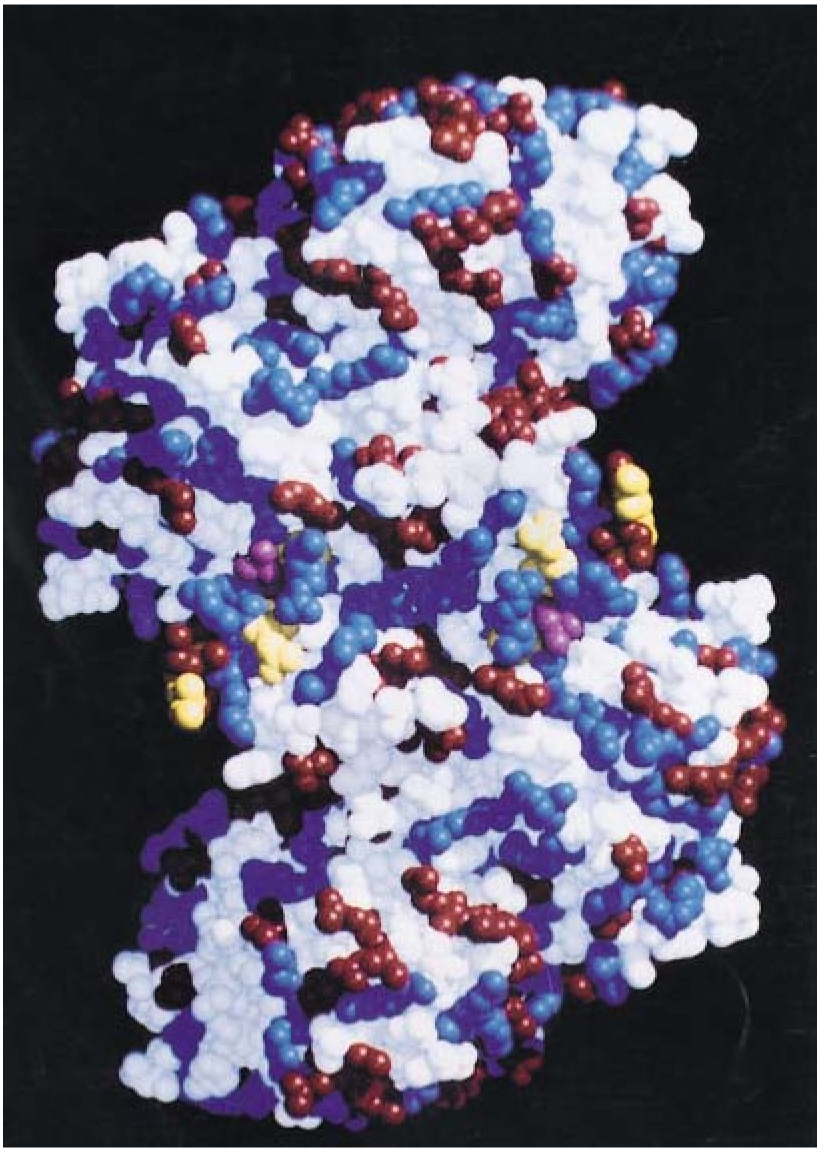
2. Structure–Function Relationships

In 1970, a new tetragonal crystal form of phosphorylase *b* was discovered in the Oxford laboratory of L. N. Johnson and her colleagues. These macrocrystals belonged to space group $P4_32_12$; and the asymmetric unit was one monomer, with the protein dimer formed by the crystallographic twofold axis, making the crystals suitable for X-ray crystallography. The crystals were grown at low salt concentrations in the presence of IMP. Isomorphous crystals of phosphorylase *a* were later grown in Edmonton, Canada, by using 50 mM glucose to force dimers. The structure of phosphorylase *b* was determined in Oxford by Johnson et al., while that of the *a* form was determined by Fletterick et al. in Edmonton, initially using phases from Oxford to locate the heavy atoms used in isomorphous replacement. The structural studies to 1979 have been summarized in a review (2).

The complete amino acid sequence of phosphorylase was determined in the Seattle laboratories of Fischer, Neurath, Titani, and Walsh by adroit use of all conventional **sequencing** technologies, just in time for use in the three-dimensional structure determination. Each subunit of phosphorylase *a* consists of a single polypeptide chain of 842 amino acids. The *N*-terminal serine is acetylated and Ser14 is phosphorylated, while pyridoxal phosphate is bound to Lys680 via a Schiff Base. Counting the three nonprotein moieties, the molecular weight of phosphorylase *a* is 97,512, while that for the *b* form subunit, often used as a molecular weight standard, is 97,434.

The tetragonal crystals of phosphorylases *a* and *b* have unit cell dimensions of $a = b = 128.4$ Å and $c = 116.4$ Å. The topology and packing are typical of a/b-type proteins, with 50% content of **a-helix** content and 30% **b-sheet** (see Protein Structure). The dimeric structures of the two forms *a* and *b* are very similar, except that in the absence of the phosphate group on Ser14, the *N*-terminal 16 residues are disordered in phosphorylase *b*. When Ser14 is phosphorylated, these residues fold into a distorted helix that is bound to the rest of the protein. Two large **domains** compose the monomer, with the *N*-terminal domain consisting of 490 residues. The latter has a core of b-sheet consisting of nine b-strands describing a 180° right-handed twist flanked by helical segments, loops, and some additional b-strands. This domain contains the AMP binding site near Tyr75 and only 10 Å from the Ser14-phosphate group. The allosteric inhibitors ATP and glucose-6-phosphate also bind here. In a helical part of the domain, some 30 Å from either the activator site that binds AMP or the catalytic site, is found the glycogen storage site, which binds oligosaccharides in a helical form slightly distorted from that of amylose. Because binding here is some 20-fold tighter than at the active site, it is suggested that phosphorylase is anchored by these sites to a glycogen particle, whether or not it is acting on other glycogen end-chains at the active site. Components of the active site and the inhibitor site for caffeine (Phe285) are found at the interface with the C-terminal domain. The latter domain contains a core of six parallel b-strands, with a twist and connectivity to surrounding a-helices that is topologically similar to the nucleotide-binding motif of the dehydrogenases, although more buried by additional helices and loops. The deep cleft between the two domains contains (a) the active site, which is buried deeply, next to the phosphate group of PLP, and (b) the entrance between Phe285 and Tyr613, which is "locked" when caffeine binds in between. The two subunits undertake many interactions when they associate to form the dimer, including shared binding sites for AMP and for the phosphate of Ser14 and long paired loops/helices (the "towers") that extend reciprocally toward the symmetry-related active sites. The dimer possesses a concave catalytic face containing the active sites and glycogen storage sites, by which it may bind to glycogen while exposing the convex control face to the action of phosphorylase kinase or phosphatase. A computer drawn space-filling model of the control face is shown in Fig. 1.

Figure 1. Space-filling model of the control face of the phosphorylase *a* dimer viewed down the twofold axis. Positively charged residues are blue, negatively charged residues are red, and the phosphate groups of the two Ser14 residues are magenta, while noncharged residues of the *N*-terminal a-helices are yellow. The *N*-terminal segments, identified by the phosphates and yellow residues, lie across the subunit interface. This T-state structure, with the phosphates fully exposed and surrounded by positive charges, represents the favored substrate for protein phosphatase. (Courtesy of Drs. R. Read and A. Muir, Department of Biochemistry, University of Alberta.) See color insert.



Studies on the catalytic mechanism of phosphorylase have been reviewed up to 1985 (3) and centered around the role of pyridoxal 5′-phosphate. The coenzyme, sandwiched between the two domains, plays an unusual structural role because its removal leads to an inactive monomer. Extensive analog studies have eliminated all parts of the coenzyme from participating in catalysis except the phosphate, which must be capable of forming a dianion. In 1977, Graves et al. found that phosphorylase *b* reconstituted with pyridoxal, and hence inactive, regained appreciable activity in the presence of inorganic phosphate (P_i), phosphite, or fluorophosphate. Furthermore, pyrophosphate showed competitive inhibition with both glucose-1-P and the activating phosphite, while binding only one mole per monomer. That same year, crystallographic studies placed only the phosphate of the coenzyme near the substrate, 7.0 Å from the latter's phosphate in these crystals, which are in the allosteric T state. These results led to the interacting phosphates hypothesis that was strengthened by a number of experiments, including the reconstitution of the enzyme with pyridoxal pyrophosphate glucose. This compound contains both substrate and coenzyme covalently linked, and the enzyme could transfer the glucose to an added oligosaccharide. This suggested that the coenzyme phosphate might act as an electrophile (Lewis acid). However, the alternative hypothesis that the coenzyme phosphate acts as a proton donor (Brønsted acid) now appears more likely, especially considering the crystallographic studies of time-resolved catalysis in the crystalline state (4). Phosphorylase catalyzes the phosphorylation of heptenitol to heptulose 2-phosphate, and the latter, a potent inhibitor, is found in the crystal structure with a hydrogen bond between its phosphate and that of the coenzyme. This suggests that in the normal phosphorolysis of glycogen, the proton of P_i attacks the glycosidic bond, cleaving it, while the substrate P_i immediately gains a proton from the PLP phosphate. The phosphate anion stabilizes the glucosyl carbonium ion, necessary to maintain the alpha anomeric configuration. The reaction is completed by a nucleophilic attack of the phosphate on the carbonium ion to form glucose 1-phosphate.

3. Regulation

The two forms of the enzyme differ markedly in their allosteric regulatory properties. The *b* form is activated by AMP or IMP and is inhibited by ATP, ADP, glucose, and glucose-6-phosphate; the *a* form is not subject to these controls, but is still inhibited by glucose. Glucose binds at the active site of phosphorylase and is a competitive inhibitor of glucose-1-P, a primitive end-product **feedback inhibition** control. The crystals of phosphorylase *a* grown with glucose are in the allosterically inhibited T state, while those of phosphorylase *b* grown with IMP are also in the T state, permitting a direct comparison of the effect of phosphorylating Ser14 on the structure (5, 6). The *b* form requires AMP for activity, but full conversion to the active R state requires substrate, while ATP and glucose-6-phosphate compete for the AMP site and represent energy and end-product allosteric controls, respectively. While the allosteric ratio of T to R for unliganded *b* is of the order of 3,000, that for the *a* form is only 10, allowing full activity of the latter with substrates alone, while only the slight activation of the *a* form by AMP is inhibited by ATP. Phosphorylase *a* may be said to have "escaped allosteric control," the latter form of regulation having been superseded by covalent modification, under extracellular hormonal and neural regulation. Because AMP binds 200 times more tightly to the *a* than the *b* form, it is obvious that a large portion of its binding energy to the *b* form is utilized in the allosteric conformational change and that the interactions of the Ser14 phosphate group must be responsible. Comparison of the two T-state tetragonal crystal structures reveal that the disordered *N*-terminal segment, residues 5–16, of the *b* form becomes an ordered helix which lies across the dimer interface in the *a* form, with eight new intersubunit hydrogen bonds between polar groups, plus additional **hydrophobic** interactions. In addition, the AMP binding site is more fully formed and capable of greater interaction with the ligand. The tighter subunit associations of the dimer in the *a* form account for it obeying the allosteric **concerted model** of Monod et al., whereas phosphorylase *b* follows the **sequential model** of Koshland et al. (with intermediate forms occurring). Thus the structural studies of phosphorylases *a* and *b* have resolved an old controversy within a single enzyme.

N-Glycosylation

Glycoproteins are characterized by the presence of carbohydrates covalently linked to amino acid residues. More than a dozen different protein–carbohydrate linkages have been identified in glycoproteins, and they are often categorized as either *O*-glycosidic (*O*-glycans or *O*-linked oligosaccharides), in which carbohydrate is covalently attached to protein via a hydroxyl group in the side chains of several amino acids, or *N*-glycosidic (*N*-glycans or *N*-linked oligosaccharides), in which sugar is covalently attached to protein through the amide nitrogen of asparagine residues. Protein glycosylation is the most diverse type of post-translational modification of proteins. The biochemical processes through which these linkages are generated are commonly called O-glycosylation and *N* -glycosylation pathways, and each pathway involves dozens of different enzymes. There are dramatic differences between these pathways in terms of their subcellular localization, the enzymes involved, the structures of the oligosaccharides synthesized, and the biological functions the glycans. *N*-Glycosylation is best characterized in animal and plant cells, but *N*-linked sugars have also been observed in bacterial glycoproteins. As we shall see, *N*-glycosylation of proteins is an exceedingly complex pathway, involving the building, trimming, and elongation of relatively large oligosaccharides as they pass through the various secretory organelles.

1. Different Types of *N*-Glycans

Examples of different types of *N*-glycan in animal cells are shown in Figure 1a. *N*-glycans contain a common pentasaccharide core composed of two *N*-acetylglucosamine (GlcNAc) residues and three mannose (Man) residues. N-Glycans are classified in three broad groups on the basis of their overall composition. *N*-Glycans that contain primarily Man residues in terminal, nonreducing positions are termed high mannose- or polymannose-type. In contrast, *N*-glycans that contain sugars other than Man in terminal nonreducing positions, such as sialic acid (NcuAc) or galactose (Gal), are classified as complex-type. A relatively simple example of a biantennary complex-type *N*-glycan (Fig. 1a) is compared to an example of a more highly branched version, known as a tetraantennary complex-type *N*-glycan. Those *N*-glycans that have features shared by both high mannose and complex-type are classified as hybrid-type. Thousands of structurally different *N*-glycans have been identified, and they may contain many additional sugars to those shown in Figure 1a. It should be noted that glycoconjugates are highly unusual in their structural motifs when compared to other classes of macromolecules . For example, most glycoconjugates, in contrast to nucleic acids and proteins, are generally branched rather than linear. The branched nature allows the generation of highly compacted and diverse structures. In contrast to nucleic acids and proteins, which are synthesized on templates, glycoconjugates are synthesized without a template, and their assembly requires the stepwise addition of monosaccharides from activated sugar precursors by individual enzymes termed glycosyltransferases. The diversity of *N*-glycan structures is generated by the inherent branching potential, the types and activity levels of the glycosyltransferases expressed in cells, the glycoprotein species, and a host of other factors (1).

2. Consensus Sequence for *N*-Glycosylation

The most common structure of *N*-glycans is the presence of GlcNAc-Asn linkages. The presence of these linkages in animal-derived glycoproteins was proven through the pioneering work of R. D. Marshall and A. Neuberger (2). Subsequent studies of many different glycoproteins and the enzymes involved in glycoprotein biosynthesis indicated that the primary **consensus sequence** for *N*-glycosylation of proteins in animals, plants, and yeast is Asn-X-Ser/Thr, where X can be any amino acid except Pro. This consensus sequence is known as the *N*-glycosylation sequon. However, Asn residues within the sequence Asn-X-Cys have also been found to be *N*-glycosylated in some animal glycoproteins (3), suggesting that this may be an alternative sequon in some special cases. For most glycoproteins, most of the Asn-X-Ser/Thr *N*-glycosylation sequons in the extracytoplasmic regions of the protein are *N*-glycosylated. In those cases where the Asn-X-Ser/Thr *N*-glycosylation sequons are not glycosylated, it has been assumed that the site is probably inaccessible to the enzyme machinery that adds the sugar residues to the Asn. In some cases, however, it is clear that amino acid residues flanking the Asn-X-Ser/Thr *N*-glycosylation sequon can modulate the efficiency of *N*-glycosylation (4, 5). The numbers and positions of *N*-glycans in proteins demonstrate tremendous diversity that is glycoprotein-specific. Some glycoproteins, such as hen ovalbumin, contain a single *N*-glycan, whereas other glycoproteins may contain dozens of *N*-glycans. The envelope glycoproteins of **HIV**-1, the AIDS virus, contains approximately two dozen *N*-glycans. The *N*-glycans in some glycoproteins at particular sites may be high mannose-type, whereas at other sites within the same glycoprotein the *N*-glycans may be multiantennary complex type. This phenomenon is referred to as “site-specific *N*-glycosylation.”

Although the *N*-glycosylation sequon is universal among eukaryotes and typically is composed of GlcNAc-Asn linkages, certain types of bacteria also synthesize glycoproteins with other carbohydrates attached to Asn residues within the *N*-glycosylation sequon. For example, Glc-Asn and GalNAc-Asn linkages are found in the halobacterial cell surface glycoproteins and flagellins (6, 7).

3. Synthesis of the Lipid-Linked Oligosaccharide

Many of the early steps in *N*-glycan biosynthesis in yeast, plants, and animals are similar, resulting in the synthesis of a high mannose-type *N*-glycan precursor (8). However, after generation of the high mannose-type *N*-glycan, there is tremendous diversity between phyla in the types of modifications they make to this precursor, as discussed below. *N*-Glycosylation in eukaryotes is initiated in the rough endoplasmic reticulum (RER), and final steps in the pathway are carried out in the Golgi apparatus. Thus, *N*-glycosylation is highly compartmentalized and is associated with the secretory organelles in eukaryotes. *N*-Glycans undergo a series of trimming and processing reactions within these organelles in a highly orchestrated pathway involving the removal and addition of carbohydrate residues. All *N*-glycans arise from a common high mannose-type *N*-glycan precursor on Asn residues. This high mannose-type *N*-glycan precursor arises from the transfer of a preformed precursor oligosaccharide linked to a lipid that has the general formula $Glc_3Man_9GlcNAc_2$-P-P-dolichol. Dolichol is a long-chain polyisoprenoid (Fig. 1b), and it serves as a membrane anchor for assembly of the lipid-linked oligosaccharide. Although glucose (Glc) residues are not commonly found on *N*-glycans in mature glycoproteins, Glc residues are essential components of the lipid-linked oligosaccharide for optimal donor activity.

This lipid-linked oligosaccharide $Glc_3Man_9GlcNAc_2$-P-P-dolichol is partly assembled on the cytoplasmic face of the RER; as the oligosaccharide grows in size by the stepwise addition of sugar residues (8), further elongation occurs in the lumen of the RER (9). The assembly is catalyzed by intrinsic membrane proteins in the RER (10). The first step in the assembly involves the acceptor dolichol monophosphate and the sugar nucleotide donor uridine diphospho-*N*-acetylglucosamine (UDPGlcNAc). The main product of the first reaction is dolichol pyrophosphoryl-GlcNAc and the side-product UMP (Fig. 1b). An important discovery in the elucidation of the *N*-glycosylation pathway was the finding that this first step is inhibited by tunicamycin, a toxic glucosamine derivative antibiotic produced by *Streptomyces lysosuperficus* (11). Because tunicamycin blocks the first step in the assembly process, cells and tissues treated with the drug are unable to synthesize glycoproteins containing *N*-glycans.

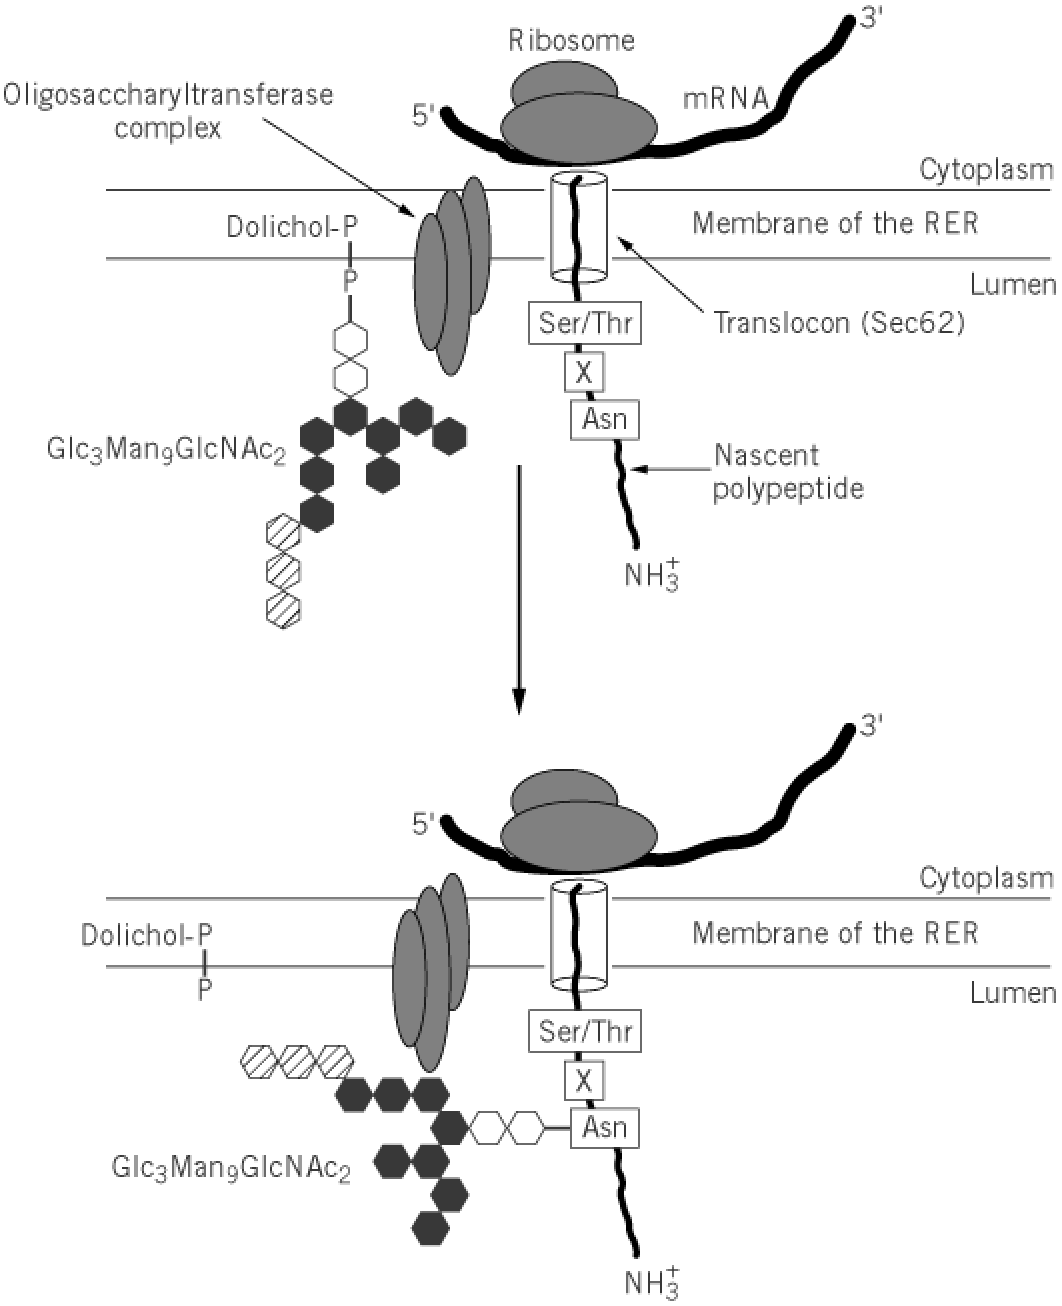
The dolichol phosphoryl-GlcNAc serves as a precursor for the assembly of the lipid-linked oligosaccharide and serves as the acceptor for a second reaction in which another GlcNAc residue is added from the donor UDPGlcNAc (Fig. 1b). The resulting main product is dolichol pyrophosphoryl-$GlcNAc_2$, and the side product is UDP. The dolichol pyrophosphoryl-$GlcNAc_2$ is the acceptor for a group of mannosyltransferases in the cytoplasmic face of the RER that add five Man residues in stepwise addition from the donor guanosine diphospho-mannose (GDPMan). The product of this reaction is a lipid-linked oligosaccharide containing 5 Man residues in a structure having the composition $Man_5GlcNAc_2$-P-P-dolichol. This intermediate is translocated into the lumen of the RER, where it is further elongated by Man addition through the donor Dol-P-Man (9). Dol-P-Man is assembled on the cytoplasmic face of the RER from dolichol phosphate and the donor GDPMan. After the addition of four Man residues from Dol-P-Man, the lipid-linked oligosaccharide has the composition $Man_9GlcNAc_2$-P-P-dolichol.

This intermediate $Man_9GlcNAc_2$-P-P-dolichol is further elongated through addition of three Glc residues to $Glc_3Man_9GlcNAc_2$-P-P-dolichol (Fig. 1b). These Glc residues are added from the donor Dol-P-Glc, which itself is assembled on the cytoplasmic face of the RER from the acceptor Dol-P and the donor uridine diphospho-glucose (UDPGlc). The final lipid-linked oligosaccharide has a total of 14 sugar residues and represents the pivotal precursor for the biosynthesis of all *N*-glycans in eukaryotes through the en bloc transfer to Asn residues in glycoproteins by the oligosaccharyltransferase complex in the membrane of the RER. It is interesting to note that 11 of the 14 residues, which are in external positions in the lipid-linked oligosaccharide, are in a-linkage, whereas the 3 core residues are in b-linkage. Since b-linked sugars are usually linear in structure and a-linkages promote turns in the structure, it is likely that the external residues of the lipid-linked oligosaccharide are tightly folded into a compact structure extending from the dolichol pyrophosphoryl core.

4. The Oligosaccharyltransferase

The oligosaccharyltransferase (OST) is a membrane-associated protein assembly that catalyzes the transfer of $Glc_3Man_9GlcNAc_2$-P-P-dolichol to Asn residues within the *N*-glycosylation sequon on nascent polypeptides in the lumen of the RER. Except for trypanosomatid protozoa, which utilize $Man_9GlcNAc_2$-P-P-dolichol, the OST in all other organisms utilizes $Glc_3Man_9GlcNAc_2$-P-P-dolichol as a primary donor. The OST requires Mn^{2+} for activity and catalyzes the formation of a C—N bond between the C-1 position of the reducing GlcNAc residue within $Glc_3Man_9GlcNAc_2$-P-P-dolichol and the amide nitrogen of asparagine with the release of P-P-dolichol (Fig. 1c and Fig. 2). It is likely that the hydroxyl groups of Ser or Thr residues within the *N*-glycosylation sequon participate in the catalysis by activating the amide nitrogen (12, 13). It has been proposed that amino acid residues within the OST force the deprotonation of hydroxyl side chains of Ser or Thr residues, which, in turn, causes them to act as a strong oxyanion for abstraction of proton from the carboxamide nitrogen of asparagine. This possible mechanism explains the conservation of Ser and Thr in the third position of the *N*-glycosylation sequon. The activated asparagine is proposed to attack the $Glc_3Man_9GlcNAc_2$-P-P-dolichol nucleophilically, resulting in displacement of P-P-dolichol from the C-1 of GlcNAc. The fact that Pro residues are not known to occur within functional *N*-glycosylation sequons suggests that close proximity between Ser and Thr residues and the Asn residue is required for optimal OST activity. Pro residues would be expected to introduce a strong bend in the polypeptide backbone, positioning Ser and Thr residues away from Asn.

Figure 2. Schematic of cotranslational *N*-glycosylation of nascent polypeptides in the RER by OST.



The OST has been purified from many sources (14) and is usually recovered as a protein complex containing from three to six polypeptides. However, other accessory proteins may also be important in efficient activity of the OST. Genetic mutations of genes encoding OST polypeptides have been identified in yeast, and the genes have been **cloned** by complementation (14-16). In yeast the genes identified to date are designated OST1, WBP1, OST3, SWP1, and OST2. Protein homologues of several of these genes have been found in higher animals. All the proteins encoded by these genes in yeast appear to be essential for optimal activity *in vivo*.

The OST is likely to be in close proximity to the translocon or Sec62 pore complex in the RER through which proteins cotranslationally enter the lumen of the RER. The catalytic domain of the OST is functionally located approximately 3–4 nm or 34×10^{-9}m from the lumenal face of the RER and acts on Asn residues within the *N*-glycosylation sequon of nascent polypeptides prior to complete translation of the proteins. Thus, *N*-glycosylation generally occurs as a cotranslational process.

5. Early-Stage Processing Pathway for *N*-Glycans in the RER

Following transfer of the $Glc_3Man_9GlcNAc_2$ to Asn residues, a series of reactions occurs in the lumen of the RER resulting in removal of the 3 Glc residues by glucosidases I and II. These trimming reactions are initiated on the nascent glycopeptide prior to complete translation. The newly synthesized glycoprotein is also subjected to an ER-localized a1,2-mannosidase, which usually removes one of the Man residues (Fig. 1d) (17). As discussed above, the presence of glucosyl residues on the $Glc_3Man_9GlcNAc_2$-P-P-dolichol is essential for optimal donor activity with the OST. But the glucosyl residues on the transferred oligosaccharide $Glc_3Man_9GlcNAc_2Asn$ also serve an important role in **protein folding** and retention in the RER.

6. Role of *N*-Glycosylation in Protein Folding

Following removal of glucosyl residues from $Glc_3Man_9GlcNAc_2Asn$ in newly synthesized glycoproteins, poorly folded glycoproteins are substrates for the enzyme UDPGlc:glycoprotein glucosyltransferase. This enzyme is capable of recognizing the high mannose-type *N*-glycan in poorly folded glycoprotein; it then catalyzes glucosylation of $Man_9GlcNAc_2Asn$ sites, using UDPGlc as a donor to generate the monoglucosylated species $Glc_1Man_9GlcNAc_2Asn$ (18). **Molecular chaperones**, such as calnexin and calreticulin, bind via carbohydrate interactions to monoglucosylated $Glc_1Man_9GlcNAc_2Asn$ (19, 20). The interactions with these chaperones facilitates other molecular interactions, leading to correct protein folding and retarding glycoprotein exit from the endoplasmic reticulum. Interaction with chaperones is an equilibrium binding, however, and the monoglucosylated $Glc_1Man_9GlcNAc_2Asn$ is available as a substrate for glucosidase II, which can remove the Glc residue to regenerate $Man_9GlcNAc_2Asn$. As indicated in Figure 1d, a cycle may develop between UDPGlc:glycoprotein glucosyltransferase and glucosidase II; this cycle continues until the glycoprotein folds in a manner that blocks its interaction with the UDPGlc:glycoprotein glucosyltransferase. The nonglucosylated glycoprotein no longer interacts with calnexin/calreticulin and exits the ER more efficiently. As discussed below, a portion of glycoprotein species with glucosylated high mannose-type *N*-glycans manage to exit the RER, and they are processed by other enzymes within the Golgi apparatus. Many glycoproteins in the RER fail to fold completely and efficiently and are degraded within the RER by proteinases. Thus, the glucosylation and deglucosylation pathway may serve a gate-keeper and quality control function.

7. Processing of *N*-glycans in the Golgi Apparatus

Following early-stage processing in the RER, glycoproteins exit the RER by vesicular transport to the Golgi apparatus. Not all glycoproteins containing glucosylated high mannose-type *N*-glycans are retained in the RER. For those that escape the action of glucosidase II in the RER, the Golgi contains an alternate pathway to facilitate their entry into the processing pathway. The Golgi enzyme, endomannosidase, acts on glucosylated oligosaccharides, such as $Glc_1Man_9GlcNAc_2Asn$ and $Glc_1Man_8GlcNAc_2Asn$ to release the disaccharide Glca1-3Man and to generate $Man_8GlcNAc_2Asn$ and $Man_7GlcNAc_2Asn$, respectively (21). The enzyme can act on a variety of glucosylated high mannose-type chains. The presence of the endomannosidase in the Golgi probably accounts for the inability of chemical inhibitors of glucosidases I and II to block completely the biosynthesis of complex-type *N*-glycans in all cells.

The resulting high mannose-type *N*-glycans, such as $Man_8GlcNAc_2Asn$ and $Man_7GlcNAc_2Asn$, are acted on by a number of a1,2-mannosidases in the cis-Golgi (17), resulting in the release of two to four Man residues and the formation of the processing intermediate $Man_5GlcNAc_2Asn$ (Fig. 1e). Although earlier observations had suggested that the Golgi contained a single a1,2-mannosidase termed mannosidase-I, recent studies have shown that there are a variety of a1,2-mannosidases. The functions of these many different a1,2-mannosidases and their specific roles in the processing pathway are not yet clear.

The resulting $Man_5GlcNAc_2Asn$ is a substrate for a key glycosyltransferase in the biosynthesis of hybrid- and complex-type *N*-glycans. *N*-Acetylglucosaminyltransferase I (GlcNAc-T-1) catalyzes the first committed step in the biosynthetic addition of sugars to the *N*-glycan by generating the GlcNAcb1-2Man linkage on a specific terminal Man residue (Fig. 1d). The action of GlcNAc-T-1 commits *N*-glycans to become either hybrid- or complex-type structures. A critical development in the discovery of a critical step in the biosynthetic process was the identification of mutated Chinese hamster ovary cell lines, termed Lec1 and Clone 15B, that are deficient in GlcNAc-T-1 (22, 23). As a consequence, the biosynthesis of *N*-glycans is halted at the level of $Man_5GlcNAc_2Asn$, and newly synthesized glycoproteins in these cell lines lack any hybrid- or complex-type *N*-glycans. Such mutational studies of Chinese hamster ovary cells have been exploited to generate many derivative cell lines containing mutations in specific aspects of the biosynthetic pathway for *N*- and *O*-glycans (24).

Following the action of GlcNAc-T-1, the product $GlcNAc_1Man_5GlcNAc_2Asn$ is the specific substrate of the medial Golgi enzyme a-mannosidase II, which removes two Man residues resulting in the formation of $GlcNAc_1Man_3GlcNAc_2Asn$ (Fig. 1e). Without the action of a-mannosidase II, *N*-glycans are committed to remain hybrid-type structures. Although early studies had suggested that there was a single a-mannosidase II, a second gene encoding a second a-mannosidase II has been identified (25). Experiments in mice in which the gene for the first a-mannosidase II was deleted have confirmed the presence of this functional alternative a-mannosidase II enzyme (26). The overall relationship between these two a-mannosidases, and whether there may be other related enzymes, is currently unclear. The product of a-mannosidase II action, $GlcNAc_1Man_3GlcNAc_2Asn$, is the substrate for a second *N*-acetylglucosaminyltransferase, GlcNAc-T-II, which adds GlcNAc in b1,2-linkage to the remaining terminal a-mannosyl residue to generate a biantennary complex-type *N*-glycan (Fig. 1e). This biantennary structure is a pivotol precursor for generation of all complex-type *N*-glycans.

8. Terminal Steps of *N*-Glycosylation

The biosynthesis of highly branched complex-type *N* -glycans from the biantennary precursor involves potential reactions with a series of other *N*-acetylglucosaminyltransferases within the medial Golgi apparatus (27). These enzymes, termed GlcNAc-T-III through GlcNAc-T-VII, add GlcNAc residues from donor UDPGlcNAc to the C–2, C–4, and C–6 positions of mannosyl residues. The resulting multiantennary products are indicated in Figure 1f. Not all *N*-glycans are subject to these reactions, since cells differ in their expression of the particular GlcNAc-Ts, and there are site-specific features of branching in glycoproteins.

Following completion of the GlcNAc-T activity within the medial-Golgi apparatus, glycoproteins exit to the trans-Golgi apparatus and trans-Golgi network (TGN), where additional modifications may occur through the actions of terminal glycosyltransferases and sulfotransferases. Some of the potential reactions are indicated in Figure 1g. Again, each cell type differs in the expression and level of these terminal glycosyltransferases, and there are site-specific features of terminal glycosylation in mature glycoproteins. In addition, many of the terminal glycosyltransferases may compete with each other for similar substrates.

In animal cells, it is typical for complex-type *N*-glycans to contain outer galactose (Gal) and sialic acid residues (28). A common sialic acid in humans is *N*-acetylneuraminic acid (NeuAc), but dozens of different sialic acids are known, and many are expressed by other animals. Interestingly, sialic acid is not generally present in plant glycoproteins. Terminal glycosylation of *N*-glycans in plant glycoproteins is different in several ways from those seen in animal glycoproteins (29). Many complex-type *N*-glycans in animal glycoproteins contain a primary terminal motif Galb1-4GlcNAc, known as the lactosamine or LN sequence (Fig. 1e). A second motif, however, known as the lacdiNAc or LDN pathway, has now been identified (30). LDN structures contain the alternative disaccharide GalNAcb1-4GlcNAc-R (Fig. 1e). The outer sugar residues may also be sulfated, as seen, for example, in pituitary hormones, which contain GalNAc-4-sulfate residues (31) (Fig. 1e), and in keratan sulfates, which contain GlcNAc-6-sulfate and Gal-6-sulfate residues. Sulfation of glycoproteins occurs in the trans-Golgi apparatus through the donor phosphoadenosine phosphosulfate (PAPS). PAPS, like the sugar nucleotide donors for glycosyltransferase reactions in the RER and Golgi apparatus, must be transported into those organelles by membrane transporters. These transporters, which are specific for each donor molecule, have been identified by molecular approaches (32).

9. Phosphorylation of *N*-Glycans in Lysosomal Enzymes

In higher eucaryotes, lysosomal hydrolases are directed to the lysosome by a mechanism that depends on specific modification of *N*-linked glycans, which allows sorting of these glycoproteins from others in the secretory pathway. The *N*-linked glycans of lysosomal hydrolases are specifically and uniquely modified in two steps to contain one or more terminal mannose 6-phosphates (M6P) (Fig. 1h). Lysosomal hydrolases bearing the M6P modification then bind to Mannose-6-P-receptors located in the trans-Golgi and are transferred to the endosome by vesicular transport. Once in the endosome, because of the lower pH, the lysosomal hydrolase disassociates from the receptor and is transferred to the lysosome. Once in the lysosome, lysosomal phosphatases remove the phosphate, rendering the process irreversible (33).

The first enzyme in the biosynthesis of the M6P modification is UDP-*N*-acetylglucosamine:lysosomal-enzyme *N*-acetylglucosamine-1-phosphotransferase (abbreviated GlcNAc-phosphotransferase). GlcNAc-phosphotransferase catalyzes the transfer of GlcNAc 1-phosphate from UDP-GlcNAc to specific a1,2-linked mannoses on high mannose oligosaccharides of lysosomal hydrolases. GlcNAc-phosphotransferase is a complex enzyme composed of three polypeptide chains with the subunit structure $a_2b_2g_2$ (34, 35). The specificity of the M6P-dependent lysosomal targeting pathway is a reflection of the substrate specificity of GlcNAc-phosphotransferase, which can only effectively utilize native lysosomal hydrolases as substrates.

The second enzyme in the pathway, *N*-acetylglucosamine-1-phosphodiester a-*N*-acetylglucosaminidase (abbreviated phosphodiester a-GlcNAcase), removes the covering GlcNAc, generating a terminal M6P. Lysosomal enzymes bearing the M6P modification then bind to one of two M6P-receptors in the trans-Golgi network and are transferred to the lysosome. Phosphodiester a-GlcNAcase is a tetramer of identical subunits (36). Unlike GlcNAc-phosphotransferase, phosphodiester a-GlcNAcase does not exhibit any specificity for lysosomal hydrolases as substrates.

Two distinct M6P-receptors have been isolated and characterized (37) (see Mannose 6-P Receptors). A high molecular weight cation-independent M6P-receptor (CI-MPR) was first described. The CI-MPR functions as a monomer, and each monomer binds two mols of M6P. In addition to binding M6P, the CI-MPR is also a high affinity receptor for insulin-like growth factor II (IGF-II) and the urokinase-type plasminogen activator receptor (uPAR). A second receptor has been described that requires divalent cations for binding of M6P (CD-MPR). The CD-MPR functions as a dimer, with each dimer binding two mols of M6P.

Several human diseases of lysosomal hydrolase trafficking result from genetic defects in the enzymes responsible for the biosynthesis of the M6P modification. Mucolipidosis II (MLII) or I-cell disease and mucolipidosis IIIA (classic pseudo-Hurler polydystrophy) result from mutations in the GlcNAc-phosphotransferase a/b-subunit gene. Mucolipidosis IIIC (MLIIIC) or variant pseudo-Hurler polydystrophy results from mutations in the GlcNAc-phosphotransferase g-subunit gene. In the absence of GlcNAc-phosphotransferase, lysosomal enzymes fail to acquire M6P; they enter the secretory pathway, and are secreted from the cell. This mistargeting of lysosomal hydrolases results in a lysosomal deficiency of many lysosomal enzymes and a severe storage phenotype. Patients with partial deficiency of phosphodiester a-GlcNAcase have been described. Like patients with GlcNAc-phosphotransferase deficiency, these patients have greatly elevated serum lysosomal enzyme levels, but do not seem to have a disease as a result of the mistargeting of lysosomal hydrolases.

The presence of the M6P or GlcNAc-1-phosphate modification blocks mannose trimming by Golgi a1,2-mannosidases. This prevents the synthesis of complex-type oligosaccharides and results in the high mannose structures typically found on lysosomal hydrolases.

10. Inhibitors of *N*-Glycosylation

Since the discovery of tunicamycin and its potent inhibition of the *N*-glycosylation pathway, a number of other antibiotics and sugar analogs have been identified that demonstrate specific inhibition of various enzymatic steps in the biosynthetic pathway (38). Most of the inhibitors commonly used today block glycosidase reactions in glycoprotein processing (Table 1). These include the inhibitors of glucosidases I and II, a1,2-mannosidases, the endomannosidase, and a-mannosidase II. Some of these inhibitors demonstrate a high degree of specificity, whereas others are more broadly active toward several enzymes. Another drug that has proven useful in studying *N*-glycosylation pathways is Brefeldin A (BFA). BFA is a fungal metabolite that interferes with protein trafficking between the Golgi apparatus and the trans-Golgi network (TGN), resulting in a blockage in glycoprotein secretion. BFA does not directly inhibit steps in the assembly or processing of *N*-glycans. In general, BFA treatment results in decreased sialylation and fucosylation of glycoproteins in those cells in which these terminal glycosylation steps occur in the TGN.

Table 1. Inhibitors of *N*-Glycosylation and Their Action Sites

Inhibitor	Action
Tunicamycin	Inhibits formation of dolichol pyrophosphoryl-GlcNAcfrom dolichol phosphate and UDPGlcNAc
Australine	
Castanospermine	
1-Deoxynojirimycin	
N-Methyldeoxynojirimycin	
DMDP (2*R*,5*R*-*bis* (Hydroxymethyl)-3*R*,4*R*-dihydroxypyrrolidine)	Inhibits glucosidase I
Bromoconduritol	
Castanospermine	
1-Deoxynojirimycin (DNJ)	
N-Methyldeoxynojirimycin	Inhibits glucosidase II
1-Deoxymannojirimycin (DMJ)	
N-Methyl-deoxynojirimycin	
DMDP	
Kifunensine	Inhibits a1,2-mannosidases
Glca1-3DMJ (GDMJ)	Inhibits endomannosidase

Swainsonine	
Mannostatin	Inhibits a-mannosidase II
Brefeldin A	Blocks translocation of proteins from ER to Golgiby blocking binding of GDP-ribosylation factor to Golgi and inhibiting GTP–GDPexchange

11. Proofreading of N-glycans

N-glycans may have other functions yet to be discovered in early steps of glycoprotein biosynthesis. The presence of specific endoglycosidases in animal cells capable of removing *N*-glycans from glycoproteins (39) suggested that some *N*-glycans may be removed after their addition to protein. These enzymes may be involved in general degradation of glycoproteins. It is also possible, however, that some sites are *N*-glycosylated and the *N*-glycan is subsequently removed in a “quality control” pathway. An enzyme has been identified in animal cells that is capable of catalyzing the de-*N*-glycosylation of proteins, known as a peptide:*N*-glycanase or PNGase; it may be involved in quality control of newly synthesized proteins by removing *N*-glycans from specific sites in a glycoprotein precursor, thereby reducing the number of *N*-glycans in the mature form of the protein. It is presently unclear whether this quality-control pathway operates on all glycoproteins in the ER or whether it specifically recognizes certain *N*-glycans in a restricted set of glycoproteins.

12. Genetic Defects in *N*-glycosylation

In recent years, a number of specific defects in the N-glycosylation pathway have been identified in humans. As mentioned above, the loss of the UDPGlcNAc:lysosomal enzyme *N*-acetylglucosamine-1-phosphotransferase in patients with I-cell disease results in a deficiency of lysosomal hydrolases and a generalized lysosomal storage disease with profound clinical consequences. In recent years, a number of individuals have been identified with decreased *N*-glycosylation of circulating glycoproteins. This deficiency, carbohydrate-deficient glycoprotein syndrome (CDGS), is due to blockage in several steps in the *N*-glycosylation pathway. CDGS is a genetic disease usually associated with major involvement of the central nervous system and mental retardation (40). However, some patients present with gastrointestinal disorder characterized by protein-losing enteropathy. Diagnosis of the disease usually involves identification of decreased glycosylation of serum transferrin, a circulating glycoprotein that normally contains two complex-type *N*-glycans. In CDGS type II patients, there is a deficiency in the Golgi processing enzyme *N*-acetylglucosaminyltransferase II (GlcNAc-T-II). Consequently, these patients synthesize glycoproteins containing the normal number of *N*-glycans, but the glycans have a hybrid-type structure. In contrast, CDGS type I is a more complex disease. Some patients with CDGS type I are unable to synthesize glucosylated dolichol-linked oligosaccharide, leading to accumulation of $_9$GlcNAc$_2$-P-P-dolichol (41). Studies in many systems have shown that the oligosaccharyltransferase is unable to utilize efficiently the Man$_9$GlcNAc$_2$-P-P-dolichol as a donor in comparison with Glc $_3$Man$_9$GlcNAc$_2$-P-P-dolichol (42, 43). Other patients with CDGS type I lack phosphomannomutase, which is required for conversion of mannose-6-phosphate to mannose-1-phosphate in the biosynthesis of GDPMan (44). Still other patients with CDGS type I are deficient in phosphomannose isomerase, the enzyme required for conversion of fructose-6-phosphate to mannose-6-phosphate, eventually leading to GDPMan (45).

Hereditary erythroblastic multinuclearity with positive acidified serum (HEMPAS) lysis test (also known as congenital dyserythropoietic anemia type II) is a disease characterized by decreased *N*-

glycosylation of glycoproteins on erythrocytes, which may be due to a deficiency a-mannosidase II (46). This decreased glycosylation is associated with crenation of the erythrocytes and subsequent hemolysis. Consistent with the possibility that human HEMPAS is associated with deficiency in a-mannosidase II is the finding that mice lacking a functional a-mannosidase II gene also develop a dyserythropoietic anemia associated with decreased *N*-glycosylation of erythrocyte glycoproteins (26).

Targeted genetic mutations in mice involving steps in the *N*-glycosylation pathway have been of great interest in recent years as scientists in the field attempt to unveil the biological functions of *N*-glycans. For example, null mutations in GlcNAc-T-I result in embryonic lethality (47, 48). It is hoped that such studies will begin to uncover many other biological functions of *N*-glycans and other potential enzymes involved in their biosynthesis.

O-Glycosylation

In **eukaryotes**, carbohydrate side-chains are added to certain amino acid residues in some protein sequences to form **glycoproteins** . In N-glycosylation, the sugars are attached in N-linkage to **asparagine residues**, and this type of glycosylation, which is initiated in the endoplasmic reticulum (ER), has been well studied. Glycans may also be added to serine and **threonine residues** in a protein, and because the hydroxyl group of these amino acids forms the link with the sugar, this type of glycosylation has been termed O-glycosylation . The enzymes that initiate glycosylation and add the individual sugars to extend or terminate the chain are glycosyltransferases, which catalyze the basic reaction:

$$\text{nucleotide} - \text{sugar donor} + \text{R-OH receptor} \rightarrow \text{nucleotide} + \text{R-O-sugar}$$

where R is a serine or threonine residue or a sugar already attached to the acceptor protein. In most cases, the nucleotide may be UDP, as for galactose and the hexosamines, or GDP, as for fucose; these donor substances are made in the **cytoplasm**. An exception is sialic acid, which is added from cytadine monophosphate-sialic acid that is made in the nucleus. There are three main types of O-glycosylation in eukaryotes, namely: (*1*) Mucin-type O-glycosylation, in which the proteins normally carry multiple O-linked oligosaccharide chains; (*2*) O-Glycosylation leading to the formation of proteoglycans; and (*3*) O-GlcNAc glycosylation of cytoplasmic and nuclear proteins.This article will focus on O-glycosylation in mammalian cells, especially relating to mucin-type O-glycosylation. Proteins are O-glycosylated, however, even in fungal cells, and these pathways will also be discussed.

1. Mucin-Type O-Glycosylation

This type of glycosylation refers to the covalent attachment of O-glycans to serines and threonines in mucin core proteins, whereby the sugars are added individually and sequentially in the Golgi apparatus. The nucleotide sugar donors are transported into the lumen of the Golgi pathway where the glycosyltransferases are positioned. The genes coding for many of the relevant glycosyltransferases have recently been isolated, **cloned**, and expressed, and it is becoming clear from their specificities that several different enzymes may catalyze the same reaction. Moreover, the existence of enzymes that can add different sugars to the same substrate means that competition can occur for the substrate, providing the locations of the different enzymes overlap in the Golgi pathway. Thus, the locations of the enzymes involved in mucin-type O-glycosylation are as important as their level of activity in determining the final composition of O-glycans added.

1.1. Initiation of Glycosylation

In mammalian cells and as far down the evolutionary scale as *Caenorhabditis elegans*, the first sugar to be added to serine or threonine in alpha linkage is N-acetylgalactosamine (GalNAc). Identifying a specific sequence that defines a glycosylation site has been difficult. Recent developments suggest that this may be largely because not one enzyme but a family of enzymes (UDP-N-acetyl-a-D-galactosamine:polypeptide-N-Acetylgalactosaminyltransferases) are involved in this reaction. These enzymes, referred to here as ppGalNAcTs, catalyze the transfer of GalNAc from UDP-GalNAc to serines and threonine residues (1). The different ppGalNAcTs have distinct but overlapping specificities for the peptide sequence, and the same enzyme can add GalNAc to both serine and threonine residues (2). Thus, the sequences flanking the serine or threonine residue influence whether or not it is glycosylated, but this cannot be inferred merely from a database analysis of in vivo substrates (3).

Knockout strains of the ppGalNAcTs are only just being prepared (4), and some redundancy is to be expected. However, the ppGalNAcTs show well-defined tissue and cell specificity of expression (5), suggesting a differential dependence of each cell type on specific enzymes. The tissue and cell specificity of the ppGalNAcTs also suggests that differences may exist in the sites of glycosylation of the same protein expressed in different cells. Identification of sites that are glycosylated in vivo has been difficult, but some data are now beginning to emerge.

The location in the ER/Golgi pathway where mucin type O-glycosylation is initiated has been controversial. There has been general agreement that GalNAc is not added in the ER, but different methods of analysis have indicated different locations (6, 7). Recent studies using immunoelectron microscopy to localize tagged enzymes in transfected cells suggest that three of the ppGalNAcTs (T1, T2, and T3) are found throughout the Golgi, with the profile of expression being different for each enzyme (8). With mucin proteins, in which hundreds of sugar side chains may be added, it may be that the addition of GalNAc does indeed occur throughout the Golgi. If some chains are initiated later in the pathway, this could contribute to the heterogeneity of composition of the O-glycans that are found in mucin preparations.

In **fungi**, serine and threonine residues are glycosylated via dolichyl phosphate-D mannose (Dol-P-Man) as an intermediate, a reaction that occurs in the ER and has not been observed thus far in higher eukaryotes. The following reactions have been established for *Saccharomyces cerevisiae*:

$$\text{GDP-mannose-Dol-P} \leftrightarrow \text{Dol-P-Man} + \text{GDP}$$

$$\text{Dol-P-Man} + \text{protein(Ser/Thr)} \leftrightarrow \text{protein(Ser/Thr)} - \text{Man} + \text{Dol-P}$$

The protein molecules that are glycosylated may be secreted or are in the cell wall. Although the classification of the yeast O-glycosylation may not fall into any of the categories defined for higher eukaryotes, multiple genes code for enzymes catalyzing the transfer of mannose from Dol-P-Man to serine or threonine residues (Dol-P-Man:protein mannosyl transferases, or PMTs). In this system, the possible redundancy of the enzymes has been investigated by producing multiple mutants, and only a triple disruption is lethal, although some of the double mutants are unable to grow without osmotic stabilization (8).

1.2. Chain Extension in Mucin-Type O-Glycan Synthesis

After the addition of GalNAc to the mucin protein, various core structures are formed by the addition of different sugars (see Fig. 1 of O-Linked Oligosaccharides). Chains are extended from these cores by the addition of N-acetylglucosamine (GlcNAc) and galactose alternately, to give polylactosamine side chains that may be straight or branched (see Figs. 2 and 3 in O-Linked Oligosaccharides). Formation of the different cores varies with the tissue, but a pathway through core 1 and core 2 is commonly used. Two genes that can add GlcNAc in b1,6 linkage to core 1 (to form core 2) have been identified (9). One of the these enzymes can also catalyze the addition of GlcNAc to form the internal branch (shown in Fig. 2 of O-linked oligosaccharides), and the other (the core 2 enzyme) can only catalyze the formation of core 2 from core 1. Where biosynthesis is through core 2, the addition of the GlcNAc is crucial for chain extension.

1.3. Chain Termination

The O-glycans carried on mucins are usually terminated by the addition of sialic acid or fucose, and this may be subject to blood group A or B dependent transferase activity (see Fig. 3A and 3B of O-Linked Oligosaccharides). The number of enzymes that catalyze the addition of sialic acid is steadily increasing and presently is at least ten (10). Not all of these enzymes act on O-glycans, but those acting at the early stages of O-glycosylation are specific for this type of glycosylation. Important enzymes in this category are those adding sialic acid in a2,6 linkage to the first sugar GalNAc, or in a2,3 linkage to galactose in core 1 (see Fig. 2 of O-Linked Oligosaccharides). The sialyltransferase that adds sialic acid in a2,6 linkage to galactose at the end of N-glycans does not add the sugar to O-glycan chains that terminate with sialic acid in a2,3 linkage. Two candidate enzymes exist (ST3 Gal III and ST3 GalIV) that could add sialic acid to galactose at the end of O-glycans, which have been reported to be selective for type I and type 2 chains, respectively. (See Tsuji et al (1996) for further discussion on nomenclature.)

1.4. Localization of Glycosyltransferases Involved in the Biosynthesis of O-Glycans in the Golgi Pathway

Organization of the Golgi apparatus can be separated into three major components: (*1*) the *cis*-Golgi network, (*2*) the Golgi stacks (*cis* medial and *trans*), and (*3*) the *trans* Golgi network, or TGN. The sizes of the various components of the pathway vary with cell type (see Golgi Apparatus). Movement of proteins through the pathway is vectorial, progressing from *cis* to *trans* via nonselective budding transport. Glycosylated proteins leave the *trans* face of the stack to be sorted to their various destinations in the TGN, where further glycosylation may also occur (11).

The glycosyltransferases are themselves type-II membrane glycoproteins, with a short amino-terminal cytoplasmic **domain**, a single transmembrane domain (typically 17 residues), a loosely folded putative stem cell region (50–100 residues), and a tightly folded globular catalytic domain of more than 325 residues, which extends into the lumen of the Golgi apparatus. Early work involving the localization of these enzymes using subcellular fractionation or detection of specific oligosaccharide structures with lectins suggested an orderly compartmentalization of enzymes corresponding to the sequential addition of sugars. More recent studies show that glycosyltransferase organization is more complex, however, and that overlap can occur even between enzymes such as the core 2 enzyme responsible for chain extension and the a2,3 sialyl- transferase ST3Gal I that effects termination (12). These enzymes both use Gal b1,3 -GalNAc-R as a substrate, and changes in their levels of activity affect the final composition of the O-glycans synthesized. Definitive mapping has only been done for a few of the many enzymes involved in O-glycan initiation and biosynthesis. However, with the production of the recombinant enzymes and, in particular, specific monoclonal antibodies directed against them, the relative positions of these enzymes should be established.

The mechanisms involved in sorting the glycosyltransferases, whether these be involved in N- or O-glycosylation, are not fully understood. Two models have been suggested to explain the distribution of these enzymes in the Golgi pathway (13, 14) (see Golgi Apparatus).

1.5. Molecules Carrying Mucin-Type O-Glycans
Although some molecules (eg, erythropoietin) may carry only one O-glycan, most of the molecules carrying carbohydrate side chains attached in this way carry multiple O-glycans and are classified as mucins; the final composition of the molecule is more than 50% carbohydrate. These molecules have a common feature in containing a tandem repeat domain, rich in serine and threonine residues, to which the O-glycans are attached. Of the eight human epithelial mucin genes that have been identified by gene cloning, all but the first (MUC1) are extracellular mucins. MUC1 is a type I transmembrane protein and resembles the membrane-associated selectin ligands (15). It is much larger, however, and the sequence in the repeats is much more conserved. The addition of sugars, even only GalNAc, results in the molecule becoming highly extended, reaching above the glycocalyx, allowing the membrane-associated mucins to influence cell-cell interactions.

The multiplicity of enzymes that can initiate mucin-type O-glycosylation and the sequential nature of the biosynthesis of the O-glycans allow for an almost infinite number of possible glycoforms to be produced from the same core protein, the final structure depending on the profile of expression of the glycosyltransferases. Studies with specific antibodies to the ppGalNAcTs are showing a marked tissue and cell specificity of expression (1, 5), and this also holds true for many of the enzymes involved in biosynthesis of the oligosaccharides, for which studies thus far have depended on looking at messenger RNA expression. Studies on the promoters governing expression of the transferases are only now beginning, but strong indications exist that tissue-specific expression may in some cases depend on the use of alternative **promoters** and alternative splicing, resulting in the production of various mRNAs with different 5′-untranslated regions (16).

1.6. Functions of Mucin-Type Glycoproteins
An obvious function of the extracellular mucins, which form an important component of the mucous layer covering some epithelial cells (eg, lining the gastrointestinal and respiratory tracts), is protection of the underlying epithelium from insult. The O-glycans play a major role in this protective function, not only in the formation of large oligomers, which makes the mucous layer viscous, but also in serving as receptors for invading microorganisms. The membrane-associated MUC1 mucin can also have a protective function but, like the selectin ligands, can also affect cell-cell adhesion.

The O-glycans on the membrane-associated mucins are generally heavily sialylated, and the resulting negative charge results in inhibition of cell-cell interactions unless a specific epitope in the oligosaccharide component can act as a ligand for a **receptor** on another cell, when cell-cell adhesion is enhanced. Study of the interaction of selectins with their glycoprotein ligands has led to detailed definition of the interacting oligosaccharide structure (see O-Linked Oligosaccharides). However, the specific oligosaccharide must be carried on a particular core protein, suggesting an involvement of the protein sequence or structure, either directly or indirectly by allowing clustering of the O-glycans.

1.7. Glycosylation Patterns, Differentiation, and Malignancy

The composition of the side chains added to a mucin core protein can vary not only in different tissues, but also with the differentiation state of a particular cell **phenotype** and with the change to malignancy (see Neoplastic Transformation). Although the changes in malignancy may or may not relate to disease progression, those observed in differentiation are likely to be functional and relate to cell adhesion.

Changes in the expression of the core 2 enzyme have been characterized both in differentiation of T cells and in cancer. Leukosialin is a major glycoprotein expressed on leukocytes, and changes in its composition of added O-glycans occur on activation of human T cells. In resting cells, the dominant O-glycan is a tetrasaccharide (disialylated core 1), whereas in activated T cells the expression of the core 2 enzyme is increased and core 2-based structures are added (17). A similar increase in the activity of the core 2 enzyme is seen in leukocytes from patients with immunodeficiency, as such that seen in Wiscott-Aldrich syndrome (9). Furthermore, the core 2 enzyme is differentially expressed in the thymus, where expression is high in the subcapsular and cortical thymocytes and low in the medullary thymocytes. In this case, the differential expression of core 2 structures correlates with the ability of the cells to interact with a lectin (galectin) synthesized by thymic epithelial cells.

Emphasizing the importance of cell phenotype in defining profiles of glycosylation, the changes in levels of enzymes in malignancy differ in various cancers. In leukemias, the core 2 enzyme can be increased, whereas it may be decreased in breast cancers (18). In breast cancer, there is also an increase in the a2,3 sialyl-transferase that adds sialic acid to core 1, resulting in an increase in the major epitope for sialoadhesin expressed on macrophages. In the colon, where the O-glycans added to the mucins are very large and complex, changes occur in carcinomas that result in increased expression of the sialylated Le^{a} and Le^{x} structures—the ligands for P and E selectins, respectively.

2. O-glycosylation leading to the formation of proteoglycans

Proteoglycans are composed of glycosaminoglycan chains (GAGs) bound to serine residues in a protein core, via a xylose-galactose-galactose bridge. Unlike mucin-type O-glycosylation, threonine residues do not seem to act as acceptors. All GAGs (chondroitin sulfate, dermatan sulfate, heparin and heparan sulfate) except hyaluronic acid are secreted as components of proteoglycans. The post-translational processing of the core protein occurs in the Golgi apparatus (19), where, after chain initiation, monosaccharides are added stepwise from the appropriate UDP-sugars. To attain their final shape, chains are then carried through a series of modifications, including sulfation (see O-Linked Oligosaccharides). There has been more progress in isolating the genes coding for and defining the core proteins of proteoglycans than in isolating the genes coding for the enzymes involved in the biosynthesis of the carbohydrate moieties added to these proteins. The GAGs are large, and where many chains are added there may be only 10% protein in the proteoglycan.

2.1. Initiation of Glycosylation

The initial, rate-limiting step in the synthesis of GAGs is the transfer of xylose from UDP-xylose to a serine residue. This step is catalyzed by UDP-D-xylose: proteoglycan core protein b-D-xylosyl transferase (xyloseT). Attempts to define a sequence in the core protein that will determine whether xylose will be added suggest that, although some limitations can be placed on the sequence flanking the serine (glycine must follow toward the carboxyl end), protein **secondary structure** may play an important role (20). The linking galactose moieties are then added, and the type of GAG to be synthesized is determined by the first hexosamine to be added, which begins the biosynthesis of the main chain.

2.2. Chain Extension

The GAGs consist of hexosamines and either hexuronic acid or L-iduronic acid or galactose units added alternately in unbranched sequence (see O-Linked Oligosaccharides). It seems likely that the enzymes that add the first hexosamine (GalN or GlcN) are different from those acting on the more peripheral regions of the chain. Which hexosamine is added determines which GAG is subsequently synthesized, and sequences in the core protein may direct the choice, as different GAGs can be added to different core proteins in the same cell.

2.3. Functions of Proteoglycans

Proteoglycans may occur intracellularly in **secretory granules**, at the cell surface, and in the extracellular matrix. The functions of proteoglycans are highly diverse, ranging from mechanical functions essential for maintaining the structural integrity of connective tissue, to effects on cell adhesion, motility, proliferation, differentiation, and morphogenesis. Many of these effects depend on binding of proteins to the GAG chains. As with the mucin molecules, these interactions can depend on the charge and are then relatively nonspecific and of low affinity, whereas others, involving a particular oligosaccharide with defined structure, are highly specific. The core protein, in addition to serving as a scaffold for the GAGs, may be involved in anchoring the molecule to the membrane.

3. O-GlcNAc glycosylation of cytoplasmic and nuclear proteins

O-linked N-acetylglucosamine linked to serine or threonine residues was discovered by Torres and Hart (21) and has since been found to be ubiquitous and abundant on nuclear and **cytoskeletal** proteins in virtually all eukaryotes, including fungi (22). This type of glycosylation occurs in the cytoplasm, not in the Golgi apparatus (the site of post-translation modification of the core proteins of mucins and proteoglycans), and it may be extremely important in modifying the activity of intracellular proteins with a wide diversity of functions. Table 1lists some of the classes of proteins that have been shown to be glycosylated in this way.

Table 1. Some Proteins Shown to be Subject to O-GlcNAc Acylation

Proteins involved in transcription (Pol II andtranscription factors)
Cytoskeletal proteins (intermediate filaments,bridging proteins)
Tumor suppressors, oncogenes (p53)
Nuclear pore proteins

3.1. O-GlcNAc and Phosphorylation

O-GlcNAc glycosylation is dynamic; the sugar turns over much more rapidly than does the protein backbone. Most of the proteins undergoing this type of glycosylation are **phosphorylated**, in some instances on the same amino acid residue, so it is suggested that the addition of O-GlcNAc is a regulatory modification analogous to phosphorylation. Many of the sites are similar to those used by some kinases, namely the glycogen synthase kinase and the MAP kinases, and in the *myc* oncogene the site has been mapped to Thr58 in the transactivation domain (23), which is also a major site of phosphorylation and a hot spot for mutagenesis in lymphomas. The glycosylation of **RNA polymerase** II at the mucin-like sequence at the C-terminal domain may indicate a role in transcriptional initiation.

3.2. O-GlcNAc and Protein Interactions

Another function of O-GlcNAc appears to be in mediating cytoskeletal assembly and organization, and a defect in the function has been implicated in Alzheimer's disease (24). Where the GlcNAc is thought to be an alternative to phosphorylation, it is accessible to modification (by a glycosyltransferase that transfers galactose to the hexosamine). When O-GlcNAc is functioning in protein-protein interactions, the sugars appear to be buried in the native molecules and are only accessible after **denaturation** or **proteolysis**.

Whereas about 50% of the sites that are glycosylated are at or near a PVS (Pro-Val-Ser) type of sequence, the other half have no apparent **consensus sequence**. It is not yet clear how many enzymes are involved in this type of glycosylation. However, a gene coding for an O-GlcNAc transferase has now been isolated and characterized. (See Hart et al (1996) for a further discussion).

3.3. Concluding Comments

Addition of sugars in O-linkage to proteins represents a post-translational modification that has far-reaching implications in affecting protein structure and function. The use of recombinant DNA technology to identify and catalog the families of enzymes involved in effecting the modifications shows that the number of genes devoted to this activity in higher eukaryotes is very large indeed. The functions affected by these modifications are also very wide ranging. The relation between structure and function of O-glycosylated proteins is therefore complex, but important tools are being developed, and the challenge is becoming less daunting. One might predict that there will be more entries dealing with the subject in any future issues of this work.

Golgi Apparatus

The Golgi apparatus receives a varied mixture of newly synthesized proteins and lipids from the endoplasmic reticulum (ER) and sends them to their correct destination in the cell. These molecules share a common pathway through the Golgi apparatus, passing, in sequence, through an ordered array of compartments, each capable of carrying out a specific set of covalent post-translational modifications. In the last compartment, they are separated from each other in preparation for final delivery.

1. Morphology

First described in 1898 by the Italian anatomist Camillo Golgi (1843–1926) using a silver impregnation technique (Fig. 1a) (1), the Golgi apparatus has the same basic structure in all **eukaryotic** cells, comprising a stack of closely apposed and flattened cisternae (Figs. 1d and 1e). Cisternae are often cup-shaped, especially toward the *trans* side (2, 3), and there are typically three to six cisternae in the stack, although up to 40 have been reported (4). Each cisterna is about 1 µm in diameter and comprises a core region, involved in stacking and containing resident enzymes, and a fenestrated rim from which transport vesicles bud and with which they fuse (5). In **plants** and **fungi**, there are multiple copies of the Golgi dispersed throughout the cytoplasm (Fig. 1d) (3). In animal cells these stacks are linked laterally, forming a bifurcating, ribbon-like structure (Figs. 1e and 1f) (6, 7), which forms a compact reticulum most often found in the pericentriolar region of the cell, adjacent to the cell nucleus (Fig. 1a and 1c) (8).

CGN
Golgi stack
TGN

Each face of the stack is apposed to a complex and extensive tubular network, best characterized in animal cells (and shown schematically in Fig. 1f). At the *cis* or entry face is the *cis*-Golgi network (CGN) (9), and at the *trans* or exit face is the *trans*-Golgi network (TGN) (10, 11). An intermediate compartment is interposed between the ER and the CGN, which is thought by many to ferry newly synthesized cargo molecules from the exit sites on the ER (the transitional element region) (12) to the CGN (13).

The Golgi apparatus is embedded in a matrix called the "zone of exclusion" because other cytoplasmic structures down to the size of ribosomes are excluded (14). Candidate components of this matrix have been identified, many of which have sequences predicting rod-like, fibrous proteins (15).

2. Biogenesis

The growth and division of the Golgi apparatus has been little studied, with the exception of the partitioning of Golgi membranes during mitosis in animal cells (16). The Golgi ribbon is converted during the early stages of **mitosis** into clusters of small **vesicles** and tubules, as well as free vesicles, a process that is thought to aid the partitioning process (17, 18). Cell-free assays (19, 20) have provided a molecular explanation of at least part of this process (21, 22).

3. Compartmentation

The Golgi apparatus comprises an ordered array of compartments through which newly synthesized proteins pass in sequence. The CGN is the entry point and is thought to be the last quality-control step on the pathway (23, 24). Properly folded cargo proteins proceed on to the stack. Misfolded proteins are returned to the ER for further rounds of folding (25) or degradation (26).

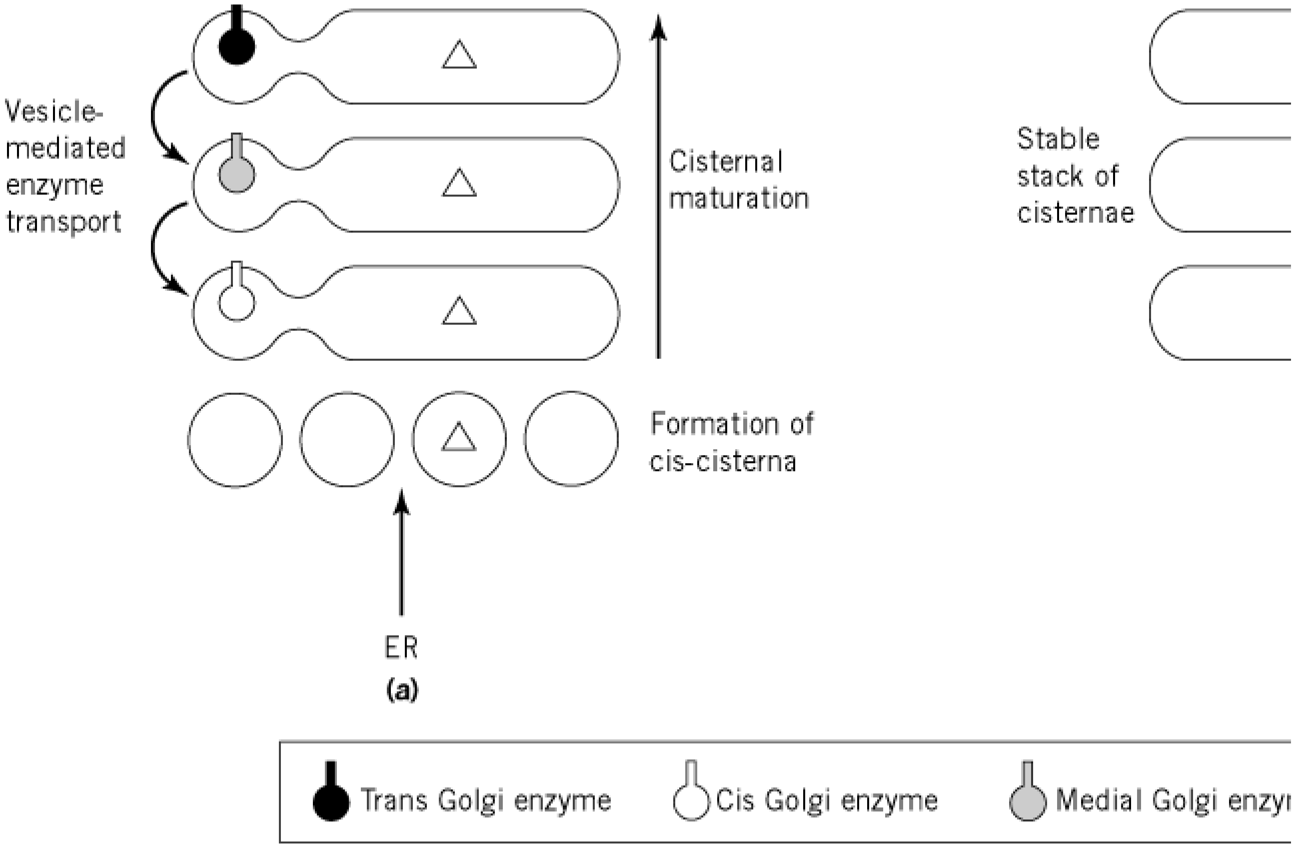
A large number of covalent modifications are carried out by the Golgi apparatus, including glycosylation, acylation, **phosphorylation**, sulfation, and **proteolytic** cleavage (27-30). ***N-Glycosylation*** is the best characterized and comprises a sequence of processing reactions that mark the passage of proteins through the Golgi stack (27, 31). The trimming of the high-mannose oligosaccharides, which are attached co-translationally in the ER, is completed in the early part of the Golgi apparatus. Construction of complex oligosaccharides is initiated in the middle part of the Golgi stack and completed in the late part. The enzymes that carry out these steps are present in two or more adjacent cisternae, generating an overlapping distribution that might help to ensure more complete glycosylation (32). Construction of complex oligosaccharides is completed in the TGN, which also functions to sort proteins and lipids. Those destined for **lysosomes** and **secretory granules** are packaged separately from those destined for the cell surface (see text below).

O-linked oligosaccharides (see O-Glycosylation) and glycolipids (33) are also assembled in a stepwise fashion as they pass, in sequence, through the stacked cisternae. The precise locations at which these steps occur must await cloning and localization of the enzymes involved.

4. Transport Through the Golgi Apparatus

Several models have been proposed to explain the ordered transport of proteins (and some lipids) through the Golgi apparatus. The two extremes are *cisternal maturation* (34) and vesicle-mediated transport (12), illustrated in Figure 2.

Figure 2. Models for transport through the Golgi stack. (**a**) Cisternal maturation envisages a dynamic stack of cisternae i
of cargo molecules, matures into the next one through the retrograde transport of Golgi enzymes. (**b**) Vesicle-mediated tı
cisternae through which a mixture of cargo molecules passes, in sequence, transported from cisterna to cisterna by vesicl



1. Cisternal maturation postulates a dynamic stack of cisternae. The *cis*-most cisterna is assembled by the fusion of transport vesicles from the ER, carrying newly synthesized cargo. Golgi processing enzymes are then delivered back from the next cisterna in the stack, which in turn receives enzymes from the next, and so on throughout the stack. In this way, each cisterna matures into the next one.

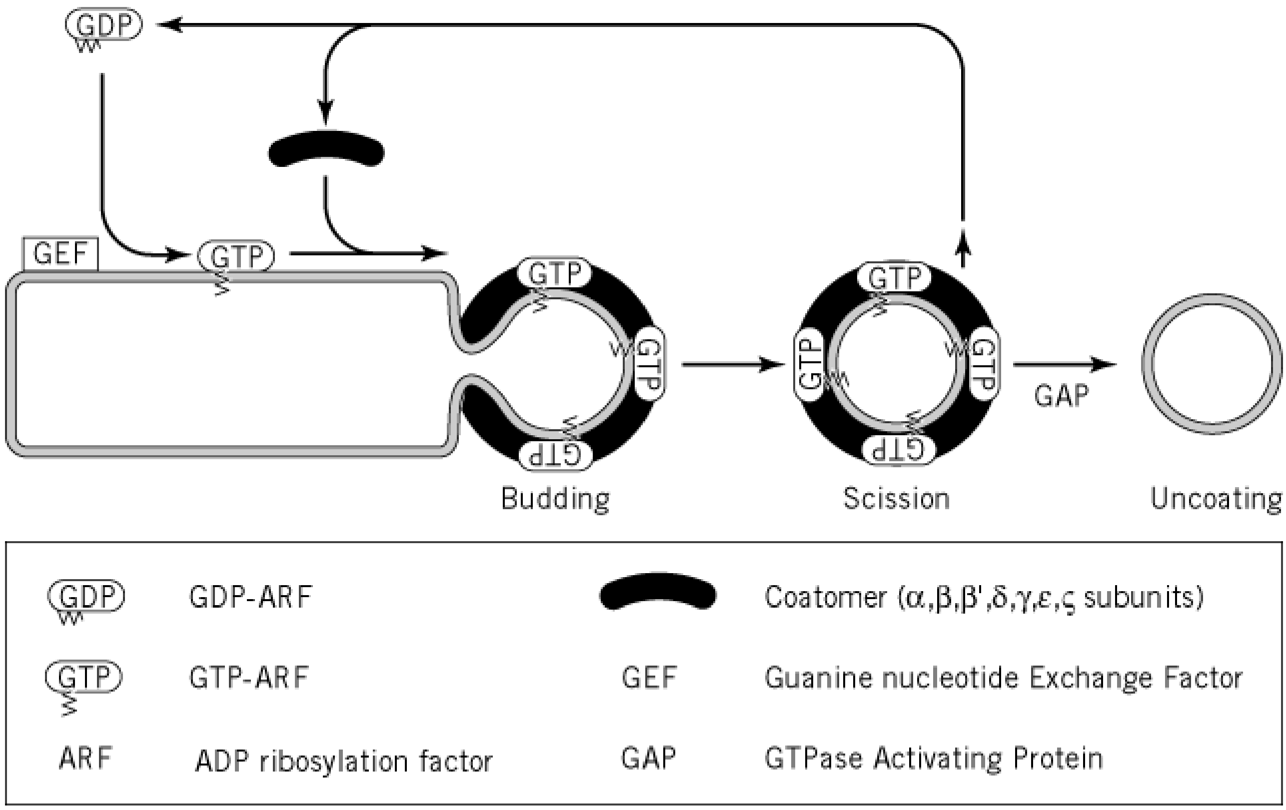
2. Vesicle-mediated transport postulates a stable stack of cisternae containing a fixed and ordered array of processing enzymes. The cargo is delivered to each cisterna in turn by **vesicles** that bud from one cisterna and fuse with the next in the stack.

There is still controversy as to whether either model, or a hybrid one, is correct. There is, however, general agreement that the vesicles mediating these pathways are COPI (Coat protomer complex I)-coated vesicles (35).

4.1. COPI-Mediated Budding

Assembly of the coat is thought to be initiated by the GTPase ARF (ADP-ribosylation factor) (36, 37) (Fig. 3). ARF exists in the cytoplasm bound to GDP, which is exchanged for GTP upon binding to Golgi membranes. This is catalyzed by a GEF (guanine nucleotide exchange factor) (38) that is sensitive to brefeldin A (39, 40). Exchange exposes a myristoyl group at the *N*-terminus of ARF, which aids Golgi binding (41). ARF then recruits coatomer , a complex of seven polypeptides (42, 43). This is either direct, through protein–protein interactions (44), or indirect, through the activation of phospholipase D by ARF, which generates phosphatidic acid to which the coatomer can bind (45). Stepwise binding of coatomer complexes is thought to cause incremental deformation of the membrane, generating a coated bud like that thought to occur for **clathrin**-coated vesicles (46). Scission generates a completed COPI vesicle and requires acyl-CoA, but it is otherwise uncharacterized (47). A GAP (GTPase activating protein) catalyzes the hydrolysis of the GTP bound to ARF (48), leading to disassembly of the coat (49) and recycling of the complexes for further rounds of budding.

Figure 3. COPI-mediated budding of transport vesicles. Stepwise assembly of coat subunits (ARF and coatomer) generate a COPI vesicle. GTP hydrolysis releases the coat subunits for further rounds of budding, leaving an uncoated vesicle that can then fuse with the target membrane. Note that proteins such as v-SNAREs, which have to be incorporated into vesicles during budding, have been omitted for clarity.



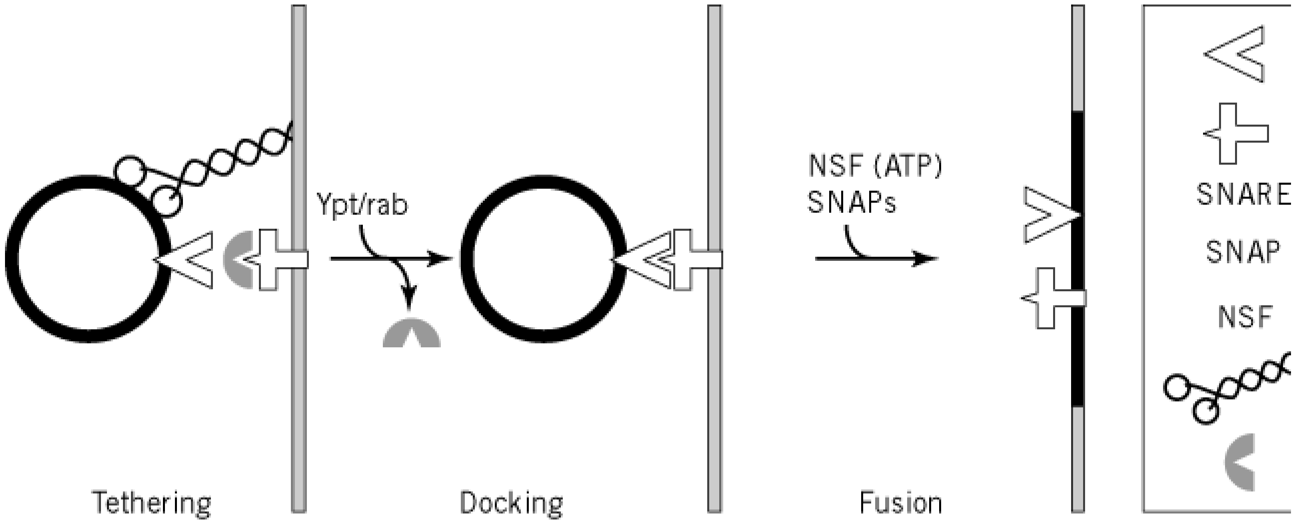
COPI vesicles are also involved in retrograde transport from the Golgi to the ER (see text below) and perhaps also from the ER to the Golgi apparatus (50). COPI coats are found on the TGN but appear not to be involved in transport from this compartment.

There are other types of coated vesicle involved in transport from the ER to the *cis*-Golgi and from the *trans*-Golgi. Two have been characterized at the molecular level. At the *cis*-side of the Golgi apparatus, COPII coats mediate the budding of cargo-carrying vesicles from the ER (50, 51). On the *trans* side, clathrin coats package lysosomal and other proteins during transport to lysosomes or upon recycling from immature granules (see text below). Although the protein constituents of both these coats differ from COPI coats, many of the underlying principles of operation appear to be the same (52). Lipids other than phosphatidic acid, and lipid exchange proteins (53), have also been implicated in budding processes. **Diacylglycerol**, in particular, appears to play a central role (54), although it is unclear whether this role is structural or regulatory.

4.2. Vesicle Docking and Fusion

After budding, Golgi transport vesicles must dock and fuse with the correct compartment. The SNARE hypothesis was put forward to explain the specificity of these transport steps (55) (Fig. 4). This hypothesis postulates a v- (or vesicle) SNARE (SNAP receptor) on each type of transport vesicle that interacts specifically with the t- (or target) SNARE in the recipient membrane compartment. SNAREs were first identified at the presynaptic membrane with which synaptic vesicles fuse during neurotransmission (56-60). Using genetic and biochemical techniques, they have now been identified at many other vesicle-mediated steps in the cell (61).

Figure 4. Targeting and fusion of transport vesicles. Transport vesicles are tethered and then docked specifically using v process. In one model (illustrated), SNAPs mediate the binding of the NSF ATPase to the v–t SNARE pair, and hydroly another model, SNAPs and NSF prime the SNAREs before they can interact with each other (139).



All but one of the SNAREs studied to date are type II membrane proteins, with most of their mass protruding into the cytoplasm (62); the exception has a Cys–Ala–Ala–X box at the *C*-terminus, so it is probably anchored by a long, hydrophobic prenyl group (63) (see Prenylation). Their sequences predict a coiled-coil structure suitable for forming paired complexes (64). Many, perhaps all, t-SNAREs are hetero-oligomers containing, in addition, a member of the SNAP25/sec9 family of proteins (65, 66). Transport vesicles can contain more than one type of v-SNARE, suggesting that multiple SNARE pairs might be used to improve the fidelity of vesicle targeting (63). Assembly of the SNARE pair is a highly regulated process. In some cases, the two membranes are initially brought together by the vesicle docking protein, p115, a process that might facilitate the efficiency with which cognate SNAREs find each other (67).

Some, perhaps all, t-SNAREs exist in an inactive form, complexed to a member of the sec1 family of proteins (68, 69), which is removed during the activation process (70). Activation of SNAREs is triggered by a member of the Ypt/rab family of small GTPases (70, 71), one or more of which is present at each vesicle-mediated transport step (72). They exist in two forms: (a) an inactive, GDP form, complexed with GDI (GDP dissociation inhibitor) in the cytoplasm and (b) an active, GTP form bound to the membrane by a prenyl group (73). Delivery of the GDP form to the correct membrane is mediated by a GDF (GDI displacement factor) (74), followed by exchange of GDP for GTP catalyzed by a GEF (75, 76). Hydrolysis of GTP by a GAP (77, 78) completes the cycle, permitting the ypt/rab to be extracted by GDI and recycled (79-81).

Formation of the cognate SNARE pair is thought to initiate the fusion process catalyzed by the ATPase NSF (*N*-ethylmaleimide-sensitive factor) (82). Binding of NSF to the SNARE pair is mediated by SNAPs (soluble NSF attachment proteins) (83) and leads to ATP hydrolysis, membrane fusion, and break-up of the SNARE pair (84, 85). The precise order of events is still disputed, especially the step at which NSF acts (86, 87). It is also unclear how these events lead to the physical merging of the two lipid bilayers.

More recently, the NSF-like ATPase p97 (88) has been implicated (together with NSF) in the rebuilding of the Golgi apparatus from fragments generated either by mitotic conditions (89) or by drug treatment (90). The fusion role played by p97 is distinct from that played by NSF, but the molecular mechanism is unknown.

5. Protein Sorting

Proteins with very different final locations within the cell are assembled in the ER and sorted in the Golgi apparatus (Fig. 5). Cargo moves to the TGN, where sorting mechanisms separate lysosomal and **secretory granule** proteins from each other and from proteins destined for the cell surface. ER and Golgi proteins have retention mechanisms that inhibit movement beyond the point in the exocytosis pathway at which they usually act. Those molecules that do escape are salvaged by retrieval mechanisms. Retrieval mechanisms also recycle membrane components of the transport machinery. All these mechanisms interpret signals on the proteins undergoing transport. These signals are most often short stretches of sequence that are either read directly by the sorting mechanism or are used to construct the sorting signal.

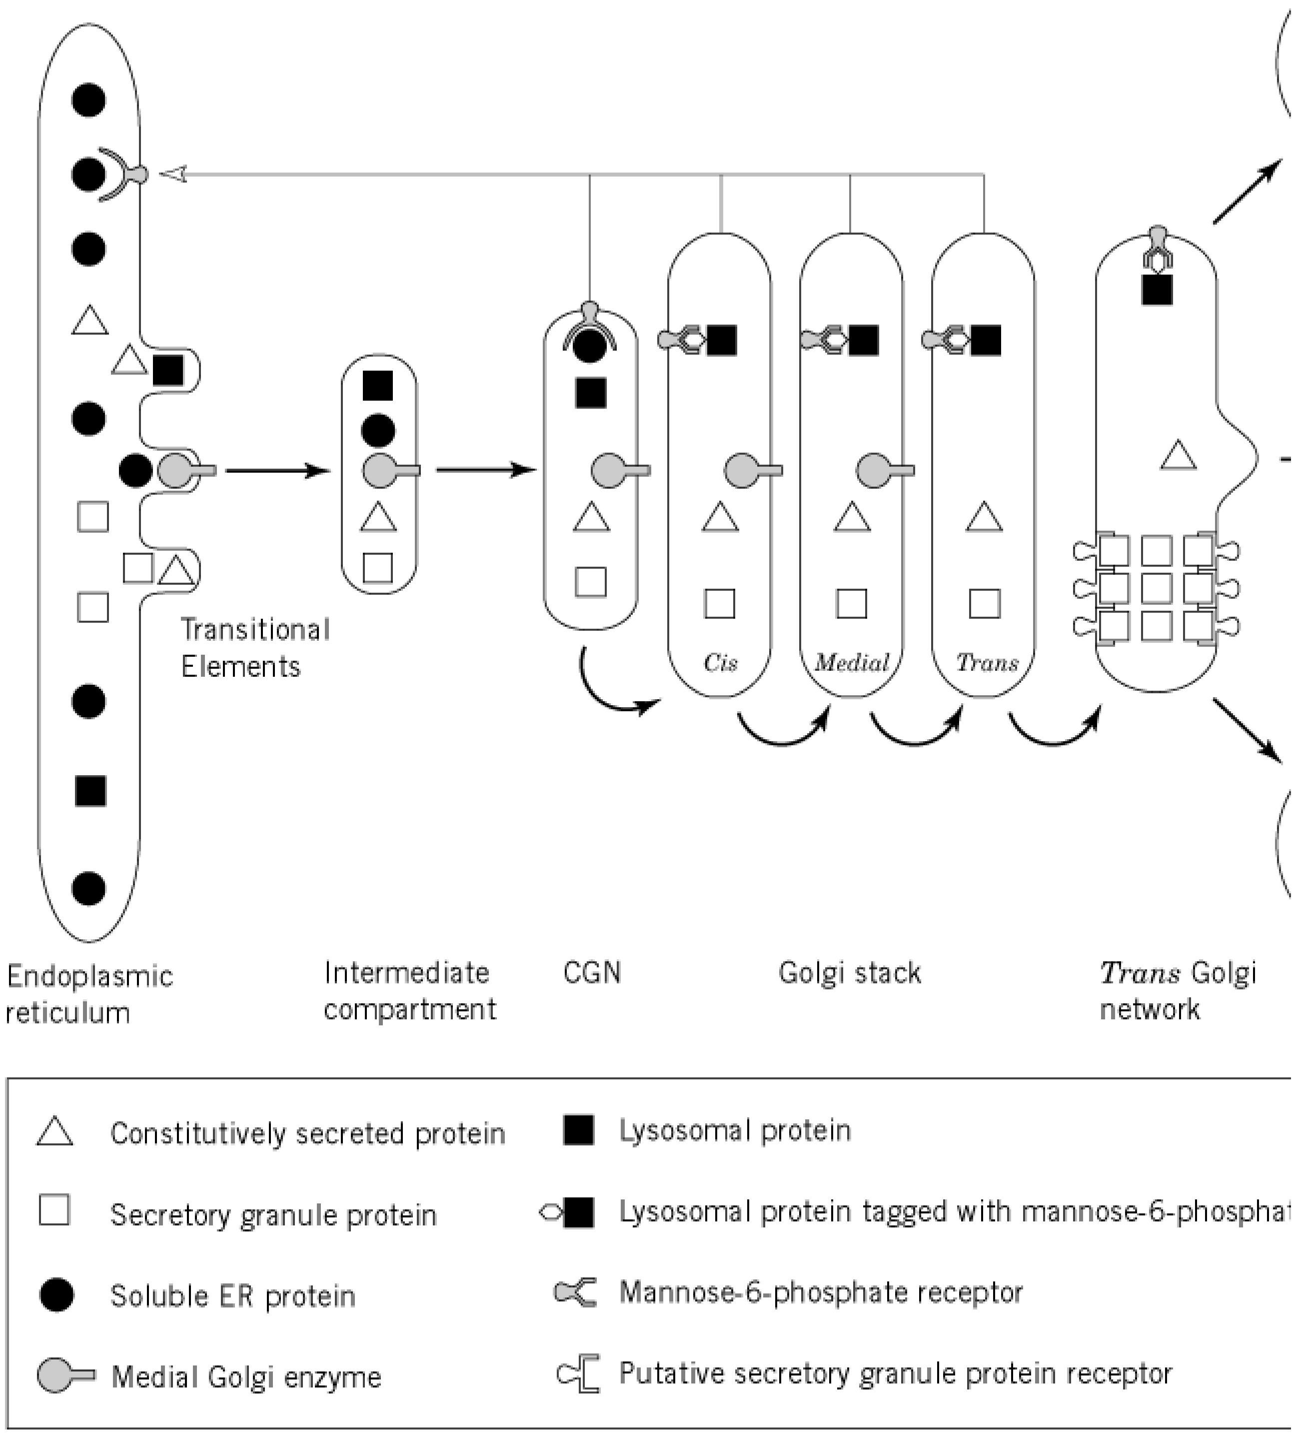
proteins are salvaged, mostly, but not exclusively, from the early part of the Golgi and are returned to the ER. Golgi enzy
Cargo proteins move to the TGN, where they are separately packaged and sent to the plasma membrane, late endosomes



5.1. The Default Pathway
The pathway from the ER to the cell surface was originally designated the default pathway because signals did not appear to be required to transport cargo through the correct sequence of Golgi compartments to the cell surface (91). This is still true for many proteins and many compartmental steps, but there is increasing evidence that some surface cargo can be selectively concentrated, especially during export from the ER (92, 93).

Two types of protein that could be involved in concentrating cargo have been described. The first are **lectin**-like proteins—for example, ERGIC53 (94) and Vip36 (95), which are thought to bind the oligosaccharides attached to many cargo proteins. In the case of ERGIC53, the lectin–cargo complex would be concentrated in transport vesicles because the cytoplasmic tail binds to coat proteins (96). The second are the p24 family of spanning proteins (97, 98), the large lumenal domains of which are thought to bind to cargo molecules by unknown means (97), aided by ancillary proteins (99). This family of proteins is selectively incorporated into transport vesicles, because their cytoplasmic tails contain a dibasic motif that binds coat subunits (100, 101).

5.2. Sorting in the TGN
All cargo molecules share the same pathway up to and including the TGN. It is here that lysosomal (102) and secretory granule proteins (103) are separated from surface cargo. Many soluble lysosomal enzymes are tagged in the early part of the Golgi apparatus with a mannose-6-phosphate signal that is constructed from some of the terminal mannose residues on the high-mannose oligosaccharide by two enzymes that recognize protein features unique to lysosomal enzymes (31, 104). The tagged enzyme moves through the Golgi stack to the TGN, where it binds the large **mannose-6-phosphate receptor** (105). The complex is specifically incorporated into clathrin-coated vesicles, because multiple signals in the cytoplasmic tail of the receptor (106) are recognized by an adaptor (107, 108). The complex is then ferried to a prelysosomal compartment (109) where, eventually, the low pH separates the enzyme from the receptor. The enzyme is delivered to lysosomes, whereas the receptor is recycled for further rounds of transport. Some lysosomal membrane proteins are also ferried in clathrin-coated vesicles. The same adaptor recognizes a signal in the cytoplasmic tail (110).

As well as a direct route to lysosomes from the TGN, there is also an indirect route via the cell surface. For soluble enzymes, this is mediated by the small mannose-6-phosphate receptor (106).

Secretory granule proteins begin to condense in the TGN, probably because of the lower pH of this part of the Golgi apparatus and the presence of calcium ions (111). Condensation is a sorting mechanism, because during this process all other proteins are largely excluded, including, in some cells, the granule proteins destined for other types of secretory granule. The outside of the condensing granule core is thought to bind to sorting **receptors**, thereby enveloping the core with a membrane that buds to form an immature **vacuole**. Maturation proceeds by a process involving vacuole fusion and retrieval of excess membrane, until a mature secretory granule is formed (112).

In polarized cells, there is more than one surface domain, and signals exist to direct surface cargo to one or other of these domains. The signals used include the bound *N*-linked oligosaccharides (113) or sequences within the cytoplasmic tail (114, 115). **GPI-anchored** proteins are thought to form “rafts” that are selectively incorporated into vesicles bound for the apical membrane domain (116).

5.3. Retention in the Golgi Apparatus
Proteins destined to remain in the Golgi apparatus are also synthesized and assembled in the ER. They are transported together with other cargo to the Golgi apparatus, but must then stop in the correct cisterna(e). The retention signal that specifies location within the Golgi apparatus is contained within the membrane-spanning domain and flanking sequences (117) and is thought to inhibit further forward transport in one of two ways. The kin recognition model (118) postulates interaction with other Golgi proteins sharing the same cisterna, generating an oligomer too large to enter the forward-moving transport vesicles. The bilayer thickness model (119) exploits the increasing thickness of Golgi membrane across the stack caused by a gradient of cholesterol. The Golgi protein moves forward until the length of the spanning domain matches that of the bilayer. Different lengths would specify different locations within the stack. There is evidence both for and against each model, but they are not mutually exclusive, and a combination of the two could serve to locate the proteins more precisely in the stack (120).

5.4. Retrieval by Retrograde Transport
Two types of retrieval operate from the Golgi apparatus to the ER. The first is a salvage process, recovering proteins that stray beyond the point in the exocytic pathway at which they operate (121). The need for salvage gave rise to the distillation hypothesis, which could help explain the need for a Golgi stack (122). The second type of retrieval is recycling, mostly of components of the vesicle

fusion machinery.

Salvage of ER proteins is mediated by short signals at the *N*- or *C*-terminus. Soluble proteins in the ER lumen use a *C*-terminal tetrapeptide (123), [KDEL in mammals, HDEL in budding yeast], whereas membrane proteins use either a double-lysine (type I proteins) (124) or a double-arginine (type II proteins) (125) motif (but see Ref. 126). Escaped lumenal proteins bind to the KDEL receptor (127), mostly located in the CGN (128), and this triggers return of the complex (129) in COPI vesicles (130) to the ER, where a change in pH is thought to effect release (131). Escaped membrane proteins with a double-lysine motif are also returned by COPI vesicles, because this motif binds directly to the coatomer component of the COPI coats (132, 133). The mechanism for returning ER proteins with a double-arginine motif is not known.

Salvage of Golgi proteins is less well understood, although there is now good evidence that it occurs (134, 135). Salvage is also an important part of secretory granule biogenesis. During maturation of immature granules, clathrin-coated vesicles recover and return proteins destined for other pathways (136).

Recycling is exemplified by the v-SNAREs. These are present in the target compartment after vesicle fusion and must be recycled to the preceding, donor compartment for further rounds of vesicle budding. The mechanism is not known, but some evidence suggests that they are not passively recycled. Instead, they direct the vesicle to the preceding compartment, in the same way that they directed the earlier vesicles to the target compartment. A t-SNARE would be needed in each of the two compartments linked by the vesicles, but only one v-SNARE. This parsimonious solution to recycling requires a mechanism to switch the specificity of the v-SNARE, depending on which of the two compartments is being targeted (137).

GPI Anchor

A large number of proteins on the surfaces of eukaryotic cells are covalently linked to a glycosylphosphatidylinositol (GPI) molecule (Table 1). GPI molecules consist of a glycan chain that, contains ethanolamine, glucosamine, and mannose residues linked to the inositol ring of phosphatidylinositol (Fig. 1). The ethanolamine in the GPI molecule is amide-linked to the carboxyl-terminal amino acid residue of the protein after it is translocated across the membrane of the endoplasmic reticulum. The GPI molecule is embedded in the lipid bilayer and is the membrane anchor responsible for retaining the protein at the cell surface. GPI-anchored proteins can be released from the membrane by highly specific phospholipases that cleave the GPI molecule. The complex structure of the GPI molecule (Fig. 1), compared to the other lipids used as membrane anchors, suggests that it has additional functions.

Figure 1. Structure of the GPI anchor. The C-terminal residue of a protein is attached via an amide linkage to the amino group of an ethanolamine phosphate in the GPI molecule (1). A conserved glycan backbone connects the ethanolamine phosphate to the phosphatidylinositol moiety. For simplicity, the sugar residues in the glycan are shown as hexagons. The exact linkages between the sugars and with the phosphatidylinositol and ethanolamine phosphate moieties (i.e., EtNP-6Mana1-2Mana1-6Mana1-4GlcNa1-6*myo*inositol), are highly conserved between protozoa and mammals. In contrast, the side chains (shown as X, Y, and Z) that are attached to the mannose residues in the glycan backbone are highly variable and can contain a variety of other sugars and additional ethanolamine phosphate groups. The hydrophobic part of the phosphatidylinositol (which will be embedded in the lipid bilayer) is shown as a 1-alkyl, 2-acyl structure, although 1,2-diacylglycerol, 1-alkylglycerol, or ceramide are also found. The hydrocarbon chain length and degree of unsaturation are also highly variable among proteins (the example shown here is for human folate-binding protein). The inositol ring can also become acylated (not shown), which makes the GPI anchor insensitive to degradation by PI-phospholipase C (PI-PLC). The sites of action of two different phospholipases that cleave GPI anchors are also shown. PI-PLC is a phospholipase C that can also cleave phosphatidylinositol and is produced by several different pathogenic bacteria [see Phospholipases C]. Although PI-PLC is not involved in physiological release processes, it is widely used in identifying and experimentally manipulating GPI-anchored proteins on cell surfaces. GPI-PLD is a GPI-specific phospholipase D and cannot hydrolyze phosphatidylinositol. GPI-PLD is abundant in mammalian plasma and may be involved in physiologically releasing GPI-anchored proteins from cell surfaces. Ins = *myo*inositol, GlcN = glucosamine, Man = mannose, EtNP = ethanolamine phosphate.

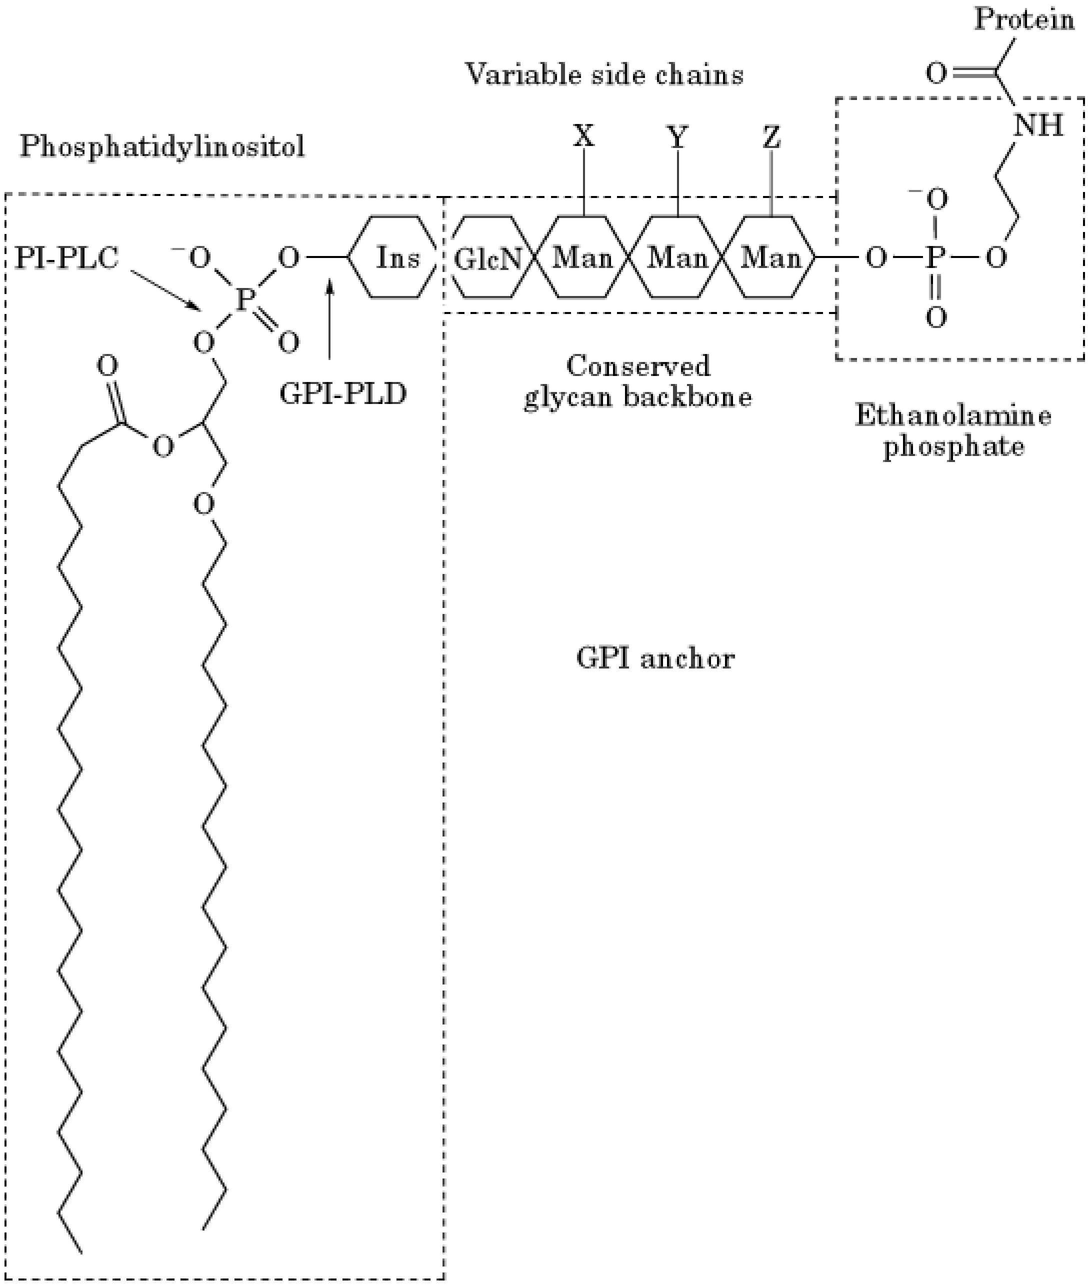

Table 1. Examples of GPI-Anchored Proteins

Alkaline phosphatase and many other ectoenzymes
Variant surface protein of *Trypanosoma brucei*
Heparan sulfate proteoglycan
Scrapie prion protein
Thy-1
TAG-1 and other neural adhesion molecules
Carcinoembryonic antigen
Decay accelerating factor

Folate binding protein
Numerous CD antigens (e.g., CD14, CD16,CD58, CD59, etc.)

Biosynthesis of GPI-anchored proteins takes place in two main stages: (1) The GPI molecule is synthesized by sequential addition of the glycan chain components to a phosphatidylinositol molecule at the cytoplasmic surface of the endoplasmic reticulum. Then, the GPI molecule is translocated across the membrane of the endoplasmic reticulum to the lumenal surface (1-3). (2) The protein is translocated, cotranslationally, into the endoplasmic reticulum. The C-terminal region of the protein contains a special type of "GPI signal peptide" that is recognized and removed by an enzyme (believed to be a transamidase) located on the lumenal surface of the endoplasmic reticulum (4). The same enzyme catalyzes coupling of the terminal ethanolamine of the GPI molecule to the newly exposed carboxyl group in an amide linkage. The attachment process is completed within a few minutes of translation/translocation, and then the GPI-anchored protein is transported through the Golgi apparatus to the cell surface by the conventional **vesicle** transport mechanisms used by other plasma membrane proteins. It should be emphasized that relatively little direct biochemical information is available about the attachment process. Efficient GPI attachment may require precise spatial and temporal coordination of the transamidase with the special GPI signal peptide of the protein and translocation of the GPI precursor. Probably for that reason, reconstitution of GPI-anchoring *in vitro* from purified components presents a formidable technical challenge.

Unlike the other types of lipid anchor, the residue to which the GPI becomes attached (designated site w; see later) is quite variable and relatively difficult to identify from just the amino acid sequence of the protein. Nevertheless, rules for predicting the existence and the location of GPI anchors in a novel protein have been devised on the basis of two sources of information from about twenty naturally occurring, GPI-anchored proteins: (1) comparison of the protein sequence predicted from its gene sequence with the identity of the C-terminal residue in the mature protein, and (2) extensive mutational analysis of the C-terminal region of a limited number of model proteins (4). This region can be divided into three parts:

1. *Hydrophobic C-terminus*. A **hydrophobic** C-terminus is essential for GPI-anchoring, although the minimum number of hydrophobic residues required for GPI-anchoring is quite variable among proteins. In most known GPI-anchored proteins, the hydrophobic region is about 15 to 20 residues long, but it can be as short as eight residues. At first sight this region looks like a hydrophobic polypeptide anchor (see Membrane Anchors), and it may in fact serve this temporary function for the short interval between completion of translation/translocation and attachment of the GPI molecule. Polypeptide anchors are generally a few residues longer, however, and usually terminate in relatively hydrophilic residues. Furthermore, mutations that make this region more like a polypeptide anchor usually result in poor GPI anchoring.
2. *Hydrophilic region*: A hydrophilic region of approximately five to seven residues is located between the hydrophobic region and the attachment site. This region exhibits no strong preference for particular amino acid residues.
3. *Cleavage-GPI attachment site*: There is no strong **consensus sequence**, but there are definite amino acid preferences in the vicinity of the cleavage site: Site w (which becomes the C-terminal residue in the mature protein): Gly, Ala, Ser, Cys, Asp, and Asn preferred. Site w + 1: no preference. Site w + 2: Gly, Ala and Ser preferred. A statistical application of the w/w + 2 preferences predict the attachment site in naturally occurring proteins with approximately 80% accuracy. Apart from its predictive value, this information can be used for engineering novel GPI-anchored proteins. Thus, constructing chimeric polypeptides that contain the extracellular domain of a polypeptide-anchored protein and a GPI signal peptide has permitted expressing many proteins in a GPI-anchored form on the cell surface.

The proteins that use a GPI anchor are quite varied. More than 100 different GPI-anchored proteins have been identified (see Table 1for examples). There is, however, no strong correlation of GPI-anchoring with particular types of protein function. For example, cell surface enzymes and adhesion molecules are found in both GPI-anchored and polypeptide anchored forms. Furthermore, although the potential for reversible membrane binding provided by a lipid anchor is useful for regulating protein distribution inside a cell, it would permit continuous loss of proteins from the cell surface (for a general discussion of factors that can affect membrane affinity of lipid-anchored proteins see Membrane Anchors). It is not known why cell surface proteins use the complex GPI molecule instead of the relatively simple lipid anchors used by cytosolic proteins. Two biophysical properties of the GPI anchor, however, may help to reduce dissociation from the cell surface: (1) The GPI anchor usually contains two relatively long (i.e., >16-carbon) unbranched acyl or alkyl chains, which in combination would have relatively high affinity for the membrane (see Fig. 1). (2) Unlike other types of lipid anchors, there is a long and relatively flexible linking molecule, the glycan backbone (see Fig. 1) between the lipid in the bilayer and the protein. This type of linkage reduces the entropy cost of membrane binding because there are minimal restrictions on translational and rotational motion of the protein (see Membrane Anchors).

Although their functional advantages are uncertain, GPI anchors confer some unusual and well-studied properties on cell-surface proteins: (1) GPI anchors are hydrolyzed by specific phospholipases that remove the hydrophobic lipid group, resulting in a protein that is no longer anchored to the membrane (see Fig. 1). GPI-phospholipase D is a secreted enzyme present in mammalian tissues and plasma and could release proteins from the cell surface. The mechanisms by which this enzyme is regulated are unknown, however (5). (2) Under some conditions, GPI-anchored proteins associate preferentially with particular types of lipid molecule in the membrane lipid bilayer. It has been suggested that GPI-anchored proteins are clustered in particular regions at the cell surface (e.g., microdomains and caveolae), but the size, composition, and functional significance of the clusters are controversial (6). (3) Cross-linking GPI-anchored proteins on the cell surface produces an activating signal in some cell types (7). Because the lipid anchor does not cross the membrane, the mechanism by which the signal is transmitted, and its possible connection to microdomains is currently an area of considerable research interest. (4) In spite of the high membrane affinity of the anchor, GPI-anchored proteins can transfer from one cell to another both *in vitro* and *in vivo* (8, 9). The precise mechanism of this process and its physiological significance are unknown. Intercellular transfer is of considerable therapeutic interest, however, because it offers a relatively efficient method for inserting novel GPI-anchored proteins (natural or engineered) into the surface of a patient's cells *ex vivo* (10).

Gram-Negative Bacteria

Two different groups of bacteria can be distinguished on the basis of the differential Gram-staining. Gram-Positive Bacteria appear bluish-purple, while Gram-negative bacteria are red. The different reactions to Gram-staining are caused by differences in the cell wall structure and composition.

1. The staining procedure and its history

The Danish physician Hans Christian Gram (1853–1938), by profession a pharmacologist and internist, worked temporarily with Friedländer in Berlin and described in 1884 (1) the staining of micrococci in lung tissues with Ehrlich's anilin-water solution of crystal methyl (gentian) violet, a cationic dye. After staining, the preparations were treated with Lugol's solution of iodine in potassium iodide and finally flushed with alcohol briefly. The bluish-purple color was retained by the Gram-positive cocci but discharged from the Gram-negative bacteria. Gram used Bismarckbraun or vesuvin for the counterstain. This method has been modified by many workers, but its essence remains unaltered, and it is still one of the widely used methods of differential staining in bacteriology. At present, the destained Gram-negative bacteria are counterstained with a red dye, e.g. safranin or fuchsin, to make a contrast between the Gram-positive and Gram-negative bacteria (2).

The crystal violet-iodine complex formed during Gram-staining is retained by the cell wall of Gram-positive bacteria, most particularly by the thick layer of peptidoglycan (murein). It is extracted from Gram-negative cells, and from Gram-positive cells of which the peptidoglycan has been removed or loosened by enzymatic (murein hydrolases or peptidases), mechanical, or antibiotic treatment. If the film of Gram-negative cells is too thick, or the bacteria are locally clumped together, the decolorization with alcohol will not be complete. Textbooks mention several exceptions to the rule, and some bacteria are described as being variable in the Gram reaction. Reliable results are dependent on standardization of the preparation of the bacterial films on slides and of performance of the staining procedure. In staining for transmission electron microscopy and energy-dispersive X-ray spectroscopy, the treatment with Gram's iodine solution has been replaced by treatment with trichloro(h^2-ethylene) platinate (3).

2. The Gram-negative cell envelope

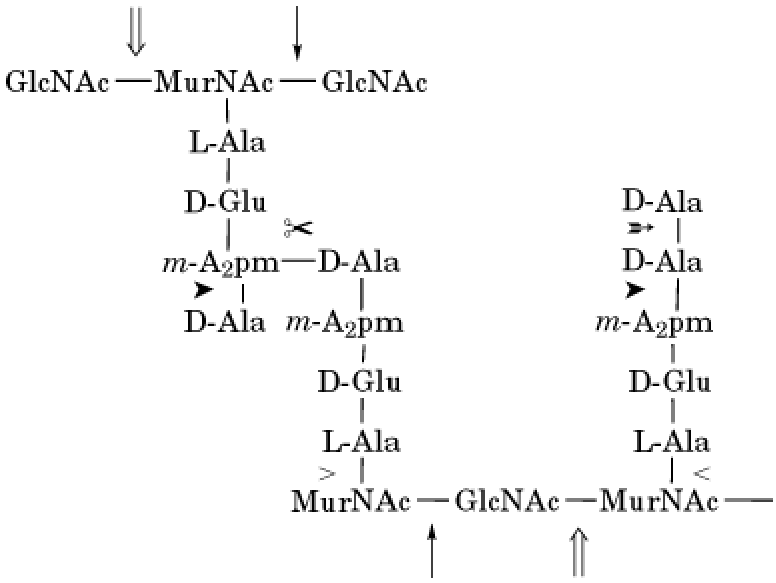
The cell envelope of Gram-negative bacteria, eg, the proteobacteria *Escherichia coli* and *Pseudomonas fluorescens*, consists of an outer membrane, which surrounds the periplasm, and the cytoplasmic or inner membrane, which delimits the protoplast. In electron microscopic pictures of thin sections, the two membranes have similar appearances. The space between the outer and the cytoplasmic membranes, the periplasm, contains soluble proteins (enzymes and components of the transport machinery) and the murein sacculus. The latter is a single-layered peptidoglycan network. Peptidoglycan is a characteristic cell-wall component of nearly all eubacteria (bacteria) but not of Archaebacteria (Archaea), and is shown schematically in Fig. 1. Its main function is to preserve the shape and integrity of the cell and to withstand the osmotic pressure of the protoplast. Peptidoglycan consists of long linear glycan chains interlinked with short peptide bridges. The chemical structure and the sequences of aminosugars and of amino acids of the peptide portion are conserved in most Gram-negative bacteria, but can vary in specific taxa, especially in Gram-positive bacteria.

Figure 1. Structure of the peptidoglycan of *Escherichia coli*. N-Acetylglucosamine (GlcNAc) and N-acetylmuramic acid (MurNAc) are interlinked in an alternating sequence by b-1,4 glycosidic bonds forming polysaccharide chains that are crosslinked by peptides consisting of L- and D-alanine, D-**glutamic acid** and *m*-diaminopimelic acid (*m*-A $_2$pm). Murein hydrolases cleave specific bonds: muraminidase; Ý b-N-acetylglucosaminidase;

D,D-carboxypeptidase;

D,D- endopeptidase;

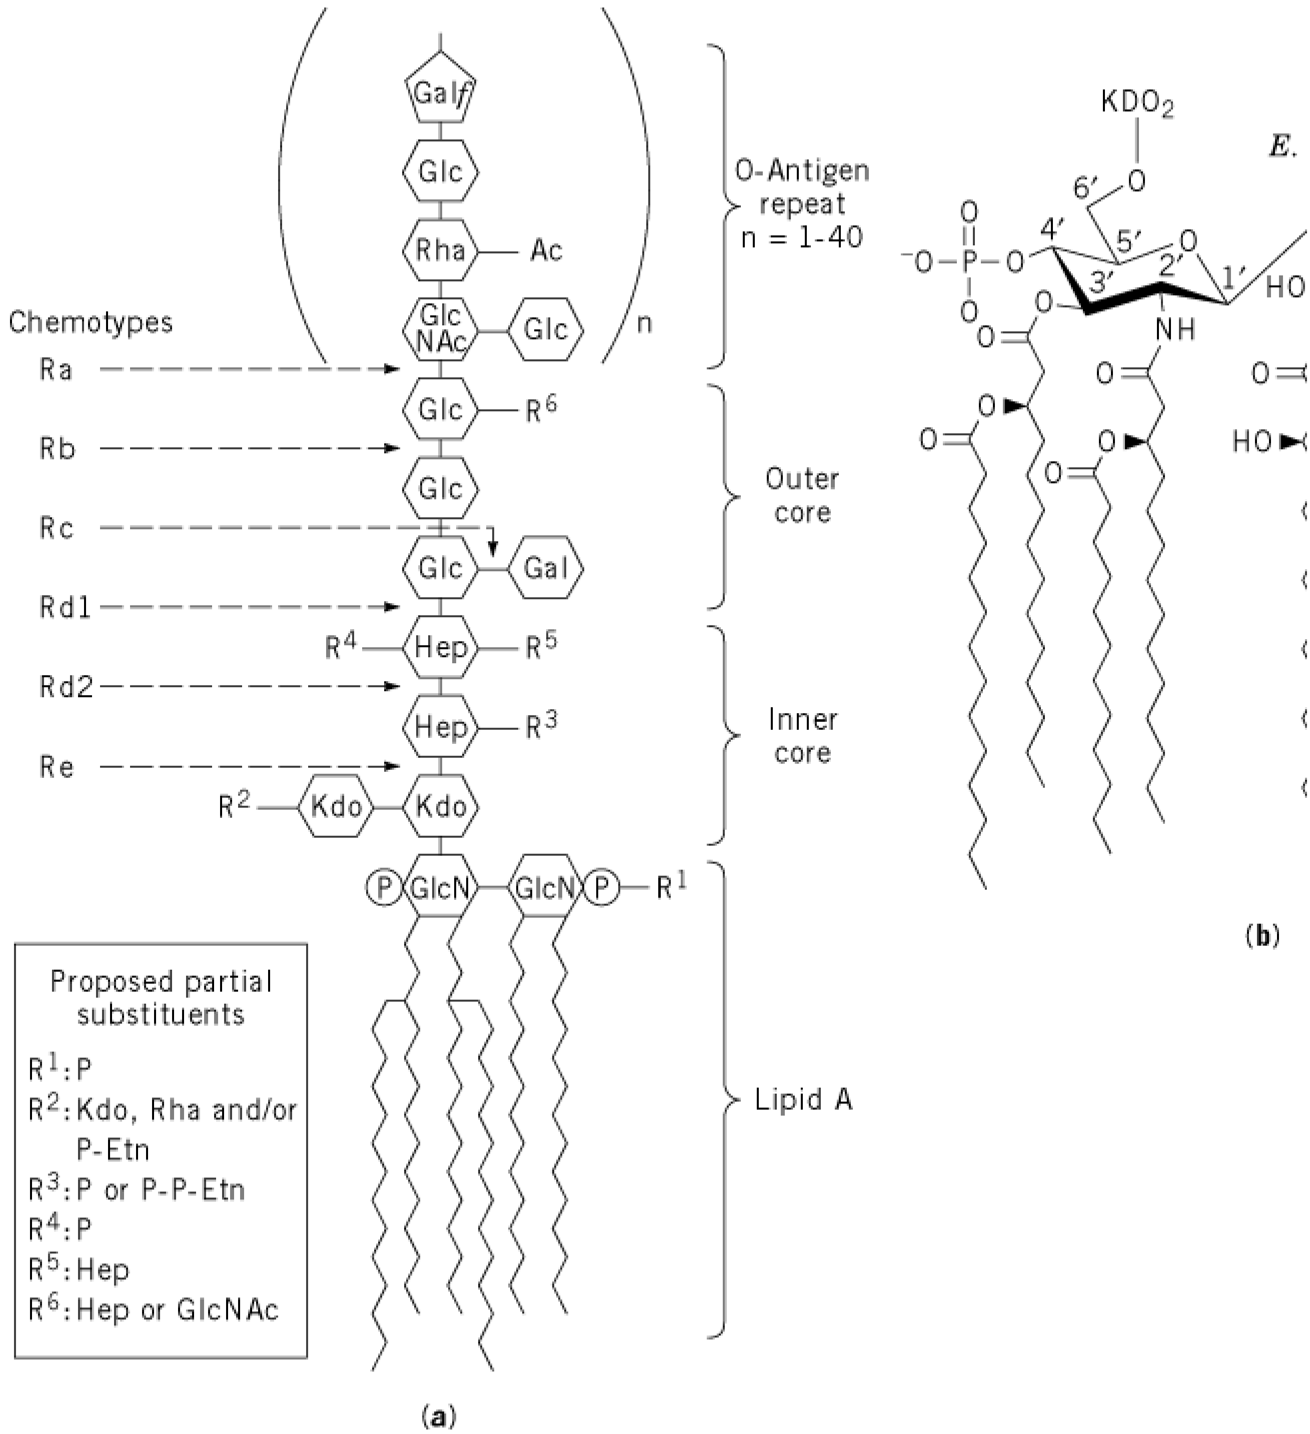
L,D-carboxypeptidase; > N-acetylmuramyl-L-alanine amidase; after J-V Höltje and EI Tuomanen (1991) J. Gen. Microbiol. 137:441–454



The disaccharide-peptide monomer is synthesized in the cytoplasm as the UDP-activated form and is translocated as N-acetylglucosamine (GlcNAc) b-1,4 N-acetylmuramic acid-(MurNAc)-pentapeptide-pyrophosphoryl-undecaprenol across the cytoplasmic membrane. In a highly controlled process, the precursor is inserted into the murein sacculus by transglycosylation in the glycan chain and subsequent crosslinking by transpeptidation between the penultimate D-alanine residue of one subunit and the *meso*-L-diaminopimelyl residue of another subunit, with release of the terminal alanine (see Fig. 1 and Penicillin-Binding Proteins). Extension of the murein sacculus is the result of a well-regulated balance between lytic and synthetic enzymatic reactions (4). Termination of the glycan strands by formation of a 1,6-anhydro-N-acetylmuramic acid residue is coupled to dephosphorylation of the undecaprenyl-P-P to undecaprenyl-P, which cycles back into the cytoplasm.

The outer membrane is organized asymmetrically. The inner leaflet consists of phospholipids, as in the cytoplasmic membrane. The major component of the outer leaflet is the lipopolysaccharide (LPS), a glycolipid that is anchored in the outer membrane by lipid A. Lipid A is the conservative part of LPS at least in Enterobacteriaceae, eg *Salmonella*, *Shigella*, *Escherichia*, *Enterobacter*, *Klebsiella* etc. and is responsible for the physiological effects of LPS in the infected host cell (endotoxin). The structure of lipid A is shown in Fig. 2(**b**). Lipid A is joined to the core of LPS, which is a spacer to the outermost and variable part of LPS, the O-specific polysaccharide. The latter is the major antigenic determinant of Gram-negative bacteria; it consists of long chains of repeating units of oligosaccharides (Fig. 2**a**). The lipophilic character of the outer membrane is presumably responsible for the exclusion of cell-damaging compounds like the bile salts of the intestine. In several bacteria, the LPS functions as a receptor for bacteriophages, eg **T_4 phage**. The core-lipid A and O-antigen subunits are synthesized as activated precursors in the cytoplasm at the cytoplasmic membrane and exported, attached to bactoprenol pyrophosphate, to the periplasm and the outer membrane (5).

Figure 2. Schematic structure of *E. coli* K-12 lipopolysaccharide (LPS). (**a**) The three parts of LPS and the sugar compositions of the core and O-specific chains. Gal, D-galactose; GlcN, D-glucosamine; Kdo, 3-deoxy-D-*manno*-octulosonic acid; Hep, L-*glycero*-D-*manno* -heptose; GlcNAc, N-acetyl-D-glucosamine; Rha, L-rhamnose; Gal*f*, D-galactofuranose; P, phosphate; P-Etn, phosphoethanolamine; Ac, acetate. (**b**) Structure of lipid A from *E. coli*. The b,1′-6-linked disaccharide of glucosamine is acylated, phosphorylated, and glycosylated with Kdo; the fatty acid residues bound to the disaccharide are laurate and myristate; after C.R.H. Raetz, Figs. 3 and 18A, in F.C. Neidhardt et al., eds., (1996) *Escherichia coli* and *Salmonella*, pp. 1035–1063. ASM Press.



Porins are transmembrane proteins formed of three identical subunits of b-barrels with short alpha-helical domains (see Alpha-helix). They are channels for the entrance and exit of small hydrophilic substances. Some porins are highly substrate-specific. Other outer membrane proteins function as phage receptors or mediate export and import. Covalently bound to peptidoglycan is the lipoprotein. Lipoproteins contain lipids covalently linked to an N-terminal cysteine residue.

The biosynthesis of all the macromolecular components of peptidoglycan and outer membrane starts in the cytoplasm. The pre-proteins and the precursors or building blocks of peptidoglycan or polysaccharides are exported across the cytoplasmic membrane by specific transport systems and are assembled in the periplasm or outer membrane. The energy for assembly cannot be provided in the periplasm by sources of the cytoplasm, so the precursors have to be in an activated state. The precursors of LPS, peptidoglycan, and capsular polysaccharides are transported using undecaprenol phosphate as a cofactor (5).

3. Taxonomy

Although all Gram-negative bacteria have basically the same cell wall structure, they do not form a homogenous taxonomical group. The systematics, and especially the phylogenetic relationships (see Phylogeny) between the bacteria, are based on different principles and features (6, 7). The Gram-reaction, ie the cell-wall type, is only one, but an important, feature of a genus or species, and there are exceptions to the rule. The cyanobacteria, which perform an oxygenic type of photosynthesis, contain a typical outer membrane with LPS. But the murein sacculus is thicker than that of proteobacteria, and in some species a polysaccharide is bound covalently to the murein. This may be one reason why several cyanobacteria stain Gram-positive.

The Gram-negative archaebacteria have cell walls of different composition; these are methanochondroitin ($[4 \rightarrow] - \beta; -\mathrm{D} - \mathrm{GluUA} - [1 \rightarrow 3] - \mathrm{D} - \mathrm{GalNAc} - [1 \rightarrow 3 \text{ or } 4] - D - \mathrm{GalNAc}-$ in *Methanosarcina*), glycoproteins, or heteropolysaccharides composed of uronic acids containing sulfate, glucose, galactose, N-acetygalactosamine, glycine, mannose, and N-acetyl-gulosaminuronic acid groups (3, 7).

Gram-Positive Bacteria

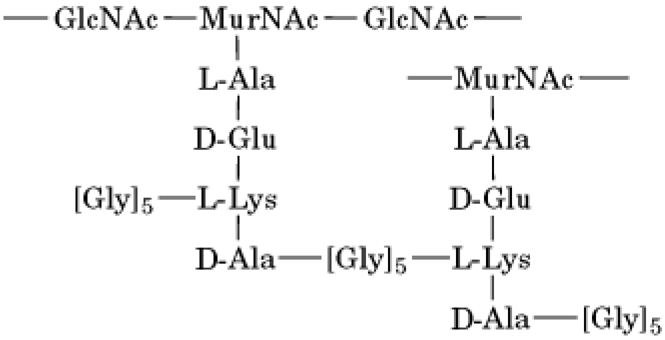
Gram-positive bacteria appear bluish-purple in the Gram stain, while Gram-Negative Bacteria are red. The crystal violet-iodine complex formed during Gram-staining is retained by the cell wall of Gram-positive bacteria.

Gram-positive eubacteria (bacteria) are found in several taxonomic groups. Typical representatives are both endospore-forming and nonsporing rods of the genera *Bacillus, Clostridium, Arthrobacter, Lactobacillus, Mycobacterium, Nocardia* and *Streptomyces*. A few archaebacteria (Archaea), such as *Methanobacterium formicicum*, also stain Gram-positive. The Gram reaction depends on both the structural formats and the chemical composition of the cell envelope (see Gram-Negative Bacteria). Gram-positive bacteria have a broader range of cell-wall types than do Gram-negative bacteria (1).

1. Type I Gram-positive cell wall

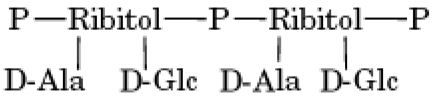
This type of cell wall consists of a thick peptidoglycan layer mixed with teichoic acids. Peptidoglycan (murein) is a polymer of glycan strands of N-acetyl-D-glucosamine and N-acetylmuramic acid linked in alternating sequence by b-1,4 linkages. The glycan strands are cross-linked by peptide chains of varying complexity, which are bound in amide links to the carboxyl group of the lactic acid residue of muramic acid (Fig. 1**a**). In Gram-positive bacteria, the amino acid composition of the peptides cross-linking the glycan strands (interpeptide bridges; Fig. 1**a**) vary considerably. In these interpeptide bridges, D-amino acids dominate, while aromatic, branched-chain, and sulfur-containing amino acids, plus histidine, arginine, and proline, are absent. In the tetrapeptide of Gram-positive bacteria, diaminopimelic acid can be replaced by lysine.

Figure 1. Schematic structure of polymers in cell walls of Gram-positive bacteria. A. Peptidoglycan with an polyglycine interpeptide bridge, $[Gly]_5$ in *Staphylococcus aureus.* B. Teichoic acid of the ribitol-phosphate type. C. Lipoprotein with fatty acids (R_1 to R_3) linked directly or via glycerol to the terminal cysteinyl residue.

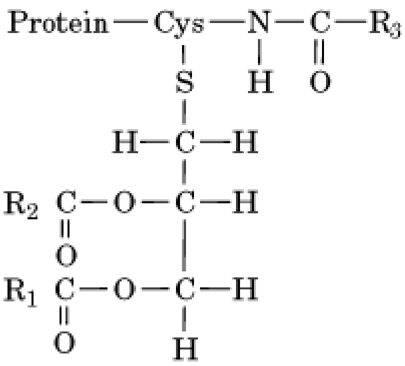


A

B



C



Teichoic acids are polymers consisting of glycerol phosphate or ribitol phosphate that are substituted with sugars and/or amino acids (Fig. 1**b**). They are covalently bound to the peptidoglycan and are exposed on the cell surface. Several Gram-positive bacteria produce, in addition to teichoic acids, *lipoteichoic acids*, which are not covalently bound to peptidoglycan but are associated with the cytoplasmic membrane through **hydrophobic** interactions. They consist of poly C1-3-glycerol phosphate linked to diglucosyl-1-3-diacylglycerol. Lipoteichoic acid penetrates the peptidoglycan and reaches the cell surface. *Teichuronic acids* of Gram-positive bacteria contain hexuronic acids (glucoronic acid or N-acetylmannosamine uronic acid) instead of polyol phosphate. Teichoic, teichuronic, and lipoteichoic acids are highly-charged polymers. Lipoproteins are present in both Gram-negative and Gram-positive cell walls. The terminal cysteine residue of the protein moiety is bound to fatty acids directly or via glycerol residues (Fig. 1**c**). Proteins are also constituents of the Gram-positive cell wall, eg **porins** and surface layer-forming proteins.

Activated precursors of the cell wall polymers are transferred across the cytoplasmic membrane (CM) bound to undecaprenol phosphate (undec-P), which was synthesized from mevalonic acid. The undec-P is recycled via undec-P-P and undec.

2. Type II Gram-positive cell wall

This type of cell wall is represented by the *Corynebacterium-Mycobacterium-Nocardia* group of bacteria. These bacteria have a thick peptidoglycan layer that is, however, penetrated by glycolipids. The muramic acid may be N-glycosylated. Long chains of *lipoarabinomannan* are anchored in the cytoplasmic membrane and penetrate the peptidoglycan layer. The external layer of the cell wall consists of lipooligosaccharides, phenolic glycolipids, glycopeptidolipids, and mycolic acids esterified to arabinogalactan, which is attached to the peptidoglycan. Mycolic acids are long-chain

(40–90 C-atoms) alcohols and fatty acids partially unsaturated and substituted with keto-, methoxy-, epoxy- and OH-groups (2).

The type II of Gram-positive cell wall stains Ziehl-Neelsen positive (acid-alcohol fastness). A mixture of the dye basic fuchsin and phenol is heated on the microscopic slides and penetrates the lipid layer. The slides are subsequently washed in distilled water and decolorized with acid-alcohol. By this procedure the fuchsin is removed from other bacteria and cells but is retained by the acid-fast bacteria. When the cells of these bacteria are treated with alkaline ethanol the lipid content of the cell wall is reduced and the cells became non-acid-alcohol-fast but remained Gram-positive. This result shows that the Gram-positive staining depends on a thick peptidoglycan layer.

3. Type III Gram-Positive Cell Wall

This type of cell wall is present in few Archaea, eg *Methanobacterium formicicum*, containing pseudomurein (1). The glycan strands of pseudomurein are composed of alternating b-N-acetyl-L-talosamine-uronic acid b-1 ← 3 N-acetyl-D-glucosamine and the tetrapeptide contains L-amino acids (Fig. 2).

Greek Key Motif

The Greek key motif describes a particular topology for arranging four **b-strands** into an antiparallel **b-sheet** in protein structures (Fig. 1). The name comes from the similarity between this b-strand topology and a decorative pattern used in ancient Greece (also called the Greek key). A common **domain** structure in proteins is the Greek key b-barrel, a type of **antiparallel b-barrel**, where two Greek key b-sheets fold together to form an eight-stranded antiparallel b-barrel.

Figure 1. Schematic representation of the topology of the Greek key motif in proteins, with individual b-strands of the b-sheet depicted as arrows. The *N*- and *C*-termini of the motif are labeled.

Green Fluorescent Protein (GFP)

GFP is a bioluminescent protein derived from the jellyfish *Aequorea victoria*. The **gene** was **cloned** in 1991, and the protein was found to have the unique property of emitting green light upon illumination with long-wave ultraviolet light without any requirement for additional cofactors or other substrates (1, 2). This has made its gene a most useful reporter gene. The 27-kDa GFP protein has a novel barrel-like protein structure comprised of 11 b-**strands** that surrounds and protects a cyclic tripeptide chromophore at its center (3). When excited by light at 470 nm, this chromophore **fluoresces** with an emission maxima of 509 nm that can be readily observed using conventional fluorescein isothiocyanate fluorescence optics.

The unique and robust properties of GFP have made it valuable for a wide range of applications. Most importantly, detection of light emission from GFP does not require any cell fixation or cell permeabilization, allowing for the first time visualization of a reporter gene in living cells. This feature has made GFP an exceptionally powerful tool in cell and transgenic biology, because expressing cells simply glow green under conventional fluorescence microscopy and confocal microscopy. Furthermore, GFP is observed in living cells, so dynamic events may be followed by making real-time or time-lapse observations. GFP has now been used as a reporter gene in cells from bacteria to human. Importantly, high levels of GFP expression have not been associated with any cellular toxicity; indeed, transgenic mice with ubiquitous expression of GFP thrive without problems. However, prolonged exposure of living cells with long-wave ultraviolet light might cause cell damage, and there may be nuclear damage caused by the generation of free radicals upon GFP excitation.

The b-barrel-like structure of GFP acts to protect its active site and has allowed numerous *N*-terminal and *C*-terminal fusion genes to be made and expressed, without loss of fluorescent activity. Consequently, GFP may be used to study the behavior of tagged proteins within living cells. Proteins have been tagged for a wide range of applications in different organisms. A few of the many examples include tagging ribonucleoprotein particles in *Drosophila* to study their trafficking into the developing egg chamber (4), tagging the histone H2B protein to study the dynamics of chromosome behavior in living human tumor cells (5), and studying **cytoskeletal** dynamics by binding GFP to F-actin in the slime mold Dictyostelium (6).

The second major use of GFP has been for cell-lineage analysis in developmental biology. GFP has not been found to be toxic in any cell type, and the fluorescence does not bleach when excited with 480-nm light. Furthermore, the protein is highly stable; for example, protein **translated** from messenger RNA microinjected into a Xenopus oocyte may still be detected at the feeding tadpole stage of development 5 days later. Thus the fate of the progeny of labeled cells can be followed over significant periods of time during development (7).

Following initial studies with the wild-type protein, several variant GFP isoforms have been generated by mutation analysis (2). Some of these mutations have improved the absorption and emission spectra of the protein, which increase the sensitivity and the versatility of the reporter gene. The mutation Ser65Thr results in an increased brightness of emission, faster fluorophore formation, and reduced photobleaching. Other novel isoforms are particularly valuable, because they emit light at new wavelengths; currently, blue-, red-, and cyan-shifted variants are available (Clontech; `www.clontech.com`), and these can be used in dual or multiple labeling studies with appropriate filters. While certain mutations affect GFP function, other 'silent' mutations have been generated that customize the gene for expression in mammalian cells or in bacteria by optimizing **codon-usage** preferences. Advances in GFP technology can be followed at the "Fluorescent protein Newsgroup" on the Internet (`http://www.bio.net/hypermail/FLUORESCENT-PROTEINS`).

The applications of GFP as a reporter gene are largely determined by its stability and sensitivity. The b-barrel-like structure that protects the chromophore is very stable, resisting temperatures up to 65°C and ionic detergents, and gives high resistance to proteinases (3). The long half-life of GFP makes it ideal for long-term cell-labeling or protein-tagging studies, but it is less suitable for monitoring dynamic changes in gene expression. To circumvent this problem, novel GFP fusion genes have been made with the PEST region of the mouse ornithine decarboxylase gene at the *C*-terminus, which destabilizes the GFP to **protein degradation**; it has a half-life of 1 to 2 hours (8).

Although GFP can be engineered to generate proteins of different half-lives and with different fluorogenic properties, less can be done to improve its sensitivity, because it lacks the ability to amplify its signal through enzymatic turnover of added substrate. In all successful applications thus far, high levels of GFP expression have had to be obtained, achieving of the order of 10^6 molecules per cell or more. The sensitivity of detection is therefore orders of magnitude less than that of other enzyme-based reporter systems, and the detected expression is not tightly coupled to changes in gene transcription.

Growth Factors

Peptide growth factors provide a critical foundation for intercellular communication in multicellular organisms and are key elements in a complex biological process. But while they promote cell growth, just as often they can have opposite, inhibitory effects on cell proliferation, or instead modulate differentiated cell function. They regulate numerous alternative cell functions that are related to, but sometimes distinct from, cell proliferation. Their activities are often distinct, one from each other, but they can also be significantly redundant; alone, they may exert one activity, but in combination have different, even opposite, effects on cells. To understand their activities, their actions must be defined individually, and then evaluated in the context of complex biological responses.

There are a number of specific characteristics that define the specific properties of a protein growth factor. First and foremost, they are proteins, usually of molecular weights ranging from 5000 to 80,000 daltons. Second, they are ligands that modulate cell function through cell-surface high affinity receptors. On binding the ligand, the receptor activates a **signal-transduction** cascade that, when evaluated on cells in culture, stimulates a proliferative response that includes (but is not limited by) thymidine incorporation into DNA and cell division.

Different peptide growth factors belong to one or another family of structurally related proteins. Hence, numerous proteins that contain sequences homologous to epidermal growth factor (EGF) belong to the EGF family, others with homology to platelet derived growth factor (PDGF) belong to the PDGF family, and still others related to **nerve growth factor** (NGF), **transforming growth factor**-b (TGF b), hepatocyte growth factor (HGF) all belong to the NGF, PDGF, TGF b, or HGF family, respectively. A representative list of these families and some of their members is shown in Table 1.

Table 1. Growth Factor Families

Growth Factor Family	Prototypic Target Cells	Acronyms
Angiopoeitins	Endothelial cells	AP1, AP2
Bone morphogenic proteins	Osteoblasts, osteoclasts, fibroblasts	BMP-1, BMP-2
Brain-derived growth factors	Motor and sensory neurons	BDNF
Ciliary neurotrophic factors	Motor and sensory neurons	CNTF
Colony stimulating factors	Macrophages, granulocytes	M-CSF, GM-CSF
Epidermal growth factors	Epidermal cells, fibroblasts	EGF, TGFA
Erythropoietin	Hematopoeitic stem cells	EPO, TPO
Fibroblast growth factors	Mesenchymal neuroectoderm cells	FGFs and KGFs
Glial-derived neurotrophic factor	Motor and sensory neurons	GDNF
Hepatocyte growth factors	Hepatocytes, endothelial cells	HGF-1, HGF-2
Insulin-like growth factors	Mesenchymal neuroectoderm cells	IGF-1, IGF-2
Interferons	Immunoregulatory cells, fibroblasts	g-IF, a-IF
Interleukins	Immunoregulatory cells, fibroblasts	IL-1, IL-2, IL-3
Neurotrophins	Motor, sensory, autonomic neurons	NGF, NT-2, NT-3
Platelet-derived growth factor	Fibroblasts, mesenchymal cells	PDGF-A. PDGF-B
Tumor necrosis factors	Fibroblasts, inflammatory cells	TNF-A, TNF-B
Vascular endothelial growth factor	Vascular, lymphatic endothelial cells	VEGF-A, B, C, D

When peptide growth factors were first being isolated and identified, they were described either by their biological activity or by the source from which they were purified. Hence, the first fibroblast growth factors (FGFs) were isolated on the basis of their ability to stimulate the proliferation of fibroblasts, NGF by its ability to stimulate nerve cells, TGFs for their ability to transform cells, HGF for its ability to stimulate hepatocytes, and PDGF because it was first purified from platelets. However, the original discovery of a peptide growth factor has seldom reflected the extent of the protein's activities or, in fact, its true physiological function. Few recall that one of the most extensively studied growth factors, EGF, was first named *urogastrone* and was originally characterized for its ability to suppress gastric acid secretion (1). A powerful peptide growth factor in its own right, EGF is a potent growth factor for epithelial cells and yet, in 1962, was isolated and purified on the basis of its ability to cause premature eruption of incisor teeth in mice and not cell proliferation per se (2). Similarly, before the advent of modern cell culture, the detection, isolation, and identification of NGF in 1953 (3), 1960 (4) and 1971 (5), respectively, were based on *in vivo* studies and tissue explants that showed increased neurite outgrowth from nerve ganglia. But is NGF a true nerve growth factor when it stimulates neurite outgrowth, but not nerve cell proliferation? Even more importantly, NGF can stimulate hematopoietic cell colony growth and differentiation (6) and has receptors on the cell surface of fibroblasts, lymphocytes, and numerous mesenchymal cell types that are unrelated to cells of neural lineage (7, 8). The detection of both ligand and receptor in reproductive tissues points to possible functions in reproduction.

In the late 1970s, and throughout the 1980s, the advent of modern methods of cell biology gave investigators the ability to grow numerous cell types in culture, and there was a flurry of activity to define the conditions in which each cell type could grow (9). The first efforts were aimed at replacing serum with tissue extracts so as to identify the active components. Hence, the growth factor literature became saturated with descriptions of "activities" known as fibroblast growth factors, endothelial cell growth factors, cartilage growth factors, milk-derived growth factors, adrenal angiogenic factor, corpus luteum growth factor, brain growth factor, pituitary growth factor, to name only a few. On applying the then developing techniques of molecular cloning, it soon became apparent that all of these seemingly disparate activities were in fact a handful of molecules: FGFs, EGFs, HGFs and PDGFs.

With the realization that, historically, peptide growth factors are a loosely defined collection of molecules that promote cell growth, there have been numerous efforts to rename the field, reorganize its nomenclature, and refine the description of peptide growth factors. While cell biologists have named these molecules "growth factors," immunologists have called them "**interleukins, lymphokines**, and cytokines". Hematologists, in turn, have coined the phrase colony stimulating factors. All descriptions are found throughout the literature and vary from field to field. In the end, the most common usage has remained the historical names given to molecules as they have been identified. When molecules are "rediscovered" because of a new heretofore unknown activity, they are classified according to their original, and ironically sometimes their least important, activity. Hence, when the adrenal angiogenic factor was sequenced and found to be identical to FGF2, it was renamed as such (10). When keratinocyte growth factor (KGF) was sequenced and found to be a member of the FGF family, it was renamed FGF7 (11). As the field has matured, and more structural and biological information has been generated, it has been possible to sort through the pleiotropic activities of growth factors and their sometimes ubiquitous distribution, to rely more heavily on their structural, rather than biological, characteristics for classification (12).

The difficulty in classifying growth factors and the attempts to distinguish them from interleukins, lymphokines, and cytokines is futile and best illustrated by an examination of their range of target cells. It has already been noted that any given growth factor can have numerous activities on any given cell type and that their activities can expand well beyond the context of their original discovery. Even more remarkable, however, is their range of target cells, which can be much greater than originally anticipated. It is here where attempts to delineate functional differences between interleukins, cytokines, and growth factors have failed. Interleukins and cytokines are generally regarded as signaling molecules with activities in the immune system. They were originally thought to be produced by the immune system, for the immune system. Yet many, if not all, interleukins are broad-spectrum proteins that, when studied in detail, regulate numerous processes outside of the immune system. Interleukin 1 (IL1), for example, acts on chondrocytes, astrocytes, fibroblasts, keratinocytes, and some neurons. Best known as a B-cell growth factor, interleukin-6 also regulates mesenchymal cell function. Perhaps even more remarkable is the observation that fibroblasts and other nonimmune cells can be sources of interleukins and not just targets, thus diminishing any differences between interleukins and protein growth factors further. As pleiotropic, ubiquitous biological effectors that control cell proliferation, the terms protein growth factor, cytokine, and interleukin describe near synonymous molecules.

Whatever classification might be conferred to growth factors, cytokines, lymphokines, or interleukins, their activities challenge the foundations of classical sciences like endocrinology, because of their peculiar, and yet necessary, mode of action. Unlike the endocrine system that relies on tissue-to-tissue communication, the growth factor system acts at the cellular level. Thus, while the endocrine pathways rely on blood-borne transportation of signaling molecules to effect change, growth factors mediate alterations in the local biological milieu. This fundamental difference in action has led investigators to rethink how cells communicate and even how they respond to endocrine stimuli. Peptide growth factors, released into the local milieu by one cell, alter the activity of an adjacent cell that is in close proximity (paracrine target) or alternatively the cell from which it derives (autocrine target). The actions of major regulatory peptides are mediated by autocrine and paracrine mechanisms that control growth factors and normal cellular homeostasis. Thus the main difference between the growth factor and cytokine pathways and the endocrine system is in the local action of growth factors. Even lymphokines produced by circulating immune cells act locally, but only after the cell producing it (eg, lymphocytes) has traveled and delivered it to its desired site of action. All growth factors are produced locally to act locally.

With this difference between endocrine and growth factor pathways in mind, it is possible to understand that when growth factors are locally released into biological fluids, they can then act to modify the actions of classic hormones arriving on site from distal sources. Hormone action has long been known to require local cellular factors to permit, mediate, and sometimes modulate responsiveness. For example, insulin-like growth factors and their binding proteins modulate hormone action (13) and TGF-b can modulate adrenal function (14). Furthermore, endocrine hormones can trigger gene expression of growth factors in target cells, which in turn modulate the local milieu and change the cell's responsiveness to further stimulation by the hormone (15).

In view of the fact that peptide growth factors act locally to modulate cell function, it comes as no surprise that there are numerous processes present in the local milieu to control their activities and ensure that their actions do not extend to unwanted targets. Of these processes, four are perhaps the most studied:

- Restricted production and release of the growth factor to limit its action
- Highly regulated receptor gene expression to limit target cell responsiveness
- Circulating inhibitors in blood to sequester and inactivate the ligand
- The binding and sequestration of growth factors at the cell surface and extracellular matrix to keep them in the local milieu

The notion that there is restricted production and release of growth factors and limited receptor expression is best illustrated by the difference between gene expression in embryonic development, fetal growth, and in adult tissues (16). At times as early as before gastrulation, the gene expression of growth factors becomes controlled in both a temporal and spatial fashion, and the role played by growth factors in development is essential in all aspects of patterning, tissue development, and differentiation. As exemplified by studies where the genes for different growth factors have been genetically knocked out, they have been shown to play a critical role during development, but are often suppressed in adult, quiescent tissues. In both cancer and wound healing, however, the genes for these same molecules are activated. In wound healing, they remain regulated until the injury has been resolved. In cancer, activation of these genes leads to uncontrolled cell growth, transformation, abnormal blood vessel growth, and ultimately tumor formation.

One particularly interesting mechanism of controlling growth factor activity appears unique to some of the paracrine factors involved in the injury and inflammatory response. Recent data suggest that molecules like FGF1, FGF2, IL1a, and Il-b can exit the cell independently of the cell's secretory endoplasmic reticulum and Golgi apparatus (17). This protein export process is mechanistically different from protein secretion and is highly specific and regulated. While its physiological significance remains unknown, the selective translocation of certain biological effectors across the plasma membrane presumably restricts their activity and allows the cell to tightly control access to the cell surface and their target cells.

The evidence for natural inhibitors of growth factors is equally compelling. For example, numerous investigators have established that genes encoding high affinity receptors for growth factors encode soluble forms of their high affinity receptors that are generated by alternative splicing of the gene's mRNA or by truncation at the cell surface (18). This form of receptor has no transmembrane domain and no signaling domain. It is secreted by cells and can bind ligand in biological fluids, thus preventing it from interacting with its cell surface (and functional) high affinity receptor. Alternatively, some cells have the ability to produce receptor antagonists that bind, but do not activate high affinity receptors. By virtue of occupying the binding site, molecules like interleukin receptor antagonist (ILRA) and angiopoietin-2 prevent a functional interaction between the ligand and its native receptor.

Perhaps the most remarkable process that appears to control the activity of growth factors stems from the observation that they often appear designed to remain in the local cellular milieu and physically sequestered outside target cells in what is presumed to be a biologically inactive form (19). This observation underlies the need for their action to remain local and predicts the existence of specific signals (eg, enzymes) to render them available to target cells.

The first type of local adhesion is characterized by a noncovalent association of growth factors with the extracellular matrix, the cell surface, or pericellular structures. This binding is often salt- and/or pH-sensitive. Representative examples of growth factors with this type-1 adhesion are shown in Table 2. In contrast, the second type of adhesion is characterized by a covalent association with the extracellular surface, through a transmembrane domain, in the growth factor's precursor. Representative examples of growth factors having this type 2 adhesion are also shown in Table 2.

Table 2. Growth Factors Associated with Cell Surface through Ionic (Type 1) or Transmembrane Domains (Type 2) in Their Precursors

Type 1 Association	Type 2 Association
Fibroblast growth factors	Epidermal growth factors
Transforming growth factor b	Tumor necrosis factors
Colony stimulating factors	G-colony stimulating factors
Insulin-like growth factors	M-colony stimulating factor
Colony stimulating factor	GM-colony stimulating factors
Interleukins 1 and 3	Stem cell growth factor
Hepatocyte growth factors	
g-Interferon	
Vascular endothelial growth factor	
Platelet-derived growth factor	
Bone morphogenic proteins	

Fibroblast growth factors (FGFs) are prototypic examples of type 1 adhesion. They have a high affinity for immobilized heparin, and immunohistochemical techniques localize FGF1 and FGF2 to the extracellular matrix, basement membrane, and cell surface of numerous tissues (20). Indeed, recent studies have identified the binding heparan sulfate proteoglycans that serve to sequester (and possibly deliver) FGFs to its high affinity receptors on target cells. TGFb has also been localized in extracellular and pericellular structures, but it is in what is thought to be a latent, biologically inert form (21). Recent studies have identified three kinds of receptors for this protein, one of which is a high molecular weight proteoglycan anchored onto the plasma membrane through phosphoinositol. Other growth factors with this type 1 adhesion include granulocyte-macrophage colony stimulating factor (GM-CSF), which binds to extracellular matrix and to heparan sulfate-related glycosaminoglycans (GAG), interleukin-3 (IL-3), hepatocyte growth factor (HGF), osteogenin (OTG), and the bone morphogenic proteins (BMP).

Type 2 adhesion is characterized by growth factors that are covalently associated with the plasma membrane because their precursor encodes a transmembrane domain that anchors it to the cell surface. In order to be active, these molecules must either be processed from the precursor to generate an active ligand or must act directly on an adjacent high affinity receptor without being further processed or released. Accordingly, these molecules may have activities that are restricted by availability. The prototypic family (and the most studied) of the growth factors with type 2 adhesion to cells is EGF. It and its structural homologues, TGFa and the heparin-binding EGF, are contained in large precursor proteins that have transmembrane domains that lock them onto the cell surface. Most of the biological studies performed with EGFs have been with the processed unbound forms, so it is less clear if their growth factor activities are maintained when they are unprocessed, at the cell surface. But recent studies using site-directed mutagenesis support the notion that the membrane-bound precursor has growth factor activity and can interact with high affinity receptors on target cells. The ability of growth factors with this type 2 adhesion to elicit a biological response is illustrated by the recent experiment showing that PDGF anchored to the plasma membrane through mutagenesis is still capable of stimulating a mitogenic response (22). Other examples of type 2 adhesion include tumor necrosis factor (TNF) and the hematopoietic factor, CSF-1 and stem cell growth factor, the ligand for the ckit protein. In all instances, each is generated from an integral membrane protein locked onto the cell surface.

It is presumed that a growth factor locked to the cell surface through a transmembrane domain can stimulate a biological response only if it is liberated from its sites of sequestration and delivered to the target cell. The molecular mechanisms that might mediate this regulation are unknown. The extracellular matrix and the various constituents that bind the growth factor are obvious targets for the combined actions of **proteolytic** and glycolytic degradation. These include **plasmins, cathepsins**, collagenases, and a wide array of glycanases, such as heparinases and heparitinases. These enzymes are normally inactive due to the presence of a macroglobulin, plasminogen activator inhibitors, proteinases like nexin, and collagenase inhibitors. In the case of the FGFs, however, it is particularly worthy to note that they are proteinase-resistant when bound to glycosaminoglycans (23). Thus the generation of an FGF-GAG complex by limited proteolysis provides a mechanism to generate a potent biologically active ligand from a pool of sequestered, biounavailable growth factor. Furthermore, glycosaminoglycan binding to some FGFs has been reported to enhance its binding to their high affinity receptor and in some instances is required for delivery (24). The mechanisms that regulate the type 2 adhesion of growth are not known, although there exist proteolytic enzymes capable of releasing the ligand from the cell (25, 26).

In the end, as the peptide growth factors that control cell growth and development have been identified and the mechanisms that regulate their activities better understood, the challenge becomes to characterize how they all act together to control normal cell function. As the use of modern molecular techniques to eliminate combinations of growth factors from the genome genetically becomes more widespread, it should be possible to provide important insight into how these factors act to control normal cell function and, ultimately, their role in whole-body homeostasis.

Growth Hormone

Growth hormone (GH), also called somatotropin or somatotropic hormone, is a protein produced in the anterior pituitary gland and is required for normal growth in vertebrate animals. Its growth promoting action is mediated by insulin-like growth factor-1 (IGF-1) whose synthesis GH stimulates in liver and other target tissues. Growth hormone also has potent metabolic actions in mammals and promotes protein synthesis and lipid degradation while restraining carbohydrate oxidation. GH is comprised of a single chain of ~200 amino acid residues with two internal disulfide bonds and a tertiary structure that includes four alpha helices bundled in an antiparallel fashion. Growth hormone is a member of a family or proteins that are produced in the pituitary glands of all vertebrates and placentae of some mammals. Family members include pituitary prolactin (PRL), placental lactogens (PL), which are also called chorionic somatomammotropins in humans, prolactin-related proteins in ruminants and rodents, proliferins in mice, and somatolactin in fish. Genes that encode most members of the GH family are comprised of five exons and four introns and appear to have arisen by duplication from a single ancestral gene before the appearance of the vertebrates. Splice junctions have been preserved throughout vertebrate evolution. Splicing and processing variants have been described for several members of the family. Growth hormone, PRL, and, presumably, their relatives signal through single-chain membrane receptors that lack intrinsic enzymatic activity, but associate with cytosolic protein tyrosine kinases. Binding of GH to a single-receptor molecule is followed rapidly by the binding of a second receptor molecule to the opposite side of GH to form a trimeric complex that brings the intracellular domains of the two receptor molecules into close apposition and activates associated protein tyrosine kinases of the JAK (Janus kinase) family, particularly JAK2. Similar events occur with PRL signalling and probably the placental lactogens as well. A large number of proteins including the GH receptor and JAK2 become phosphorylated on tyrosine residues to form docking sites for other proteins and initiate signalling cascades. Signalling to the nucleus occurs through the agency of phosphorylated Stat (signal transduction and activation of transcription) proteins and by the MAP kinase and protein kinase C pathways as well.

1. History

GH was discovered in 1921 by Evans and Long (1) as the substance present in extracts of bovine pituitary glands that increased growth in rats when given daily over a period of 3 months. A decade later, Riddle's group prepared by isoelectric precipitation a a pituitary extract that was rich in PRL, a hormone that promotes milk production (2). They subsequently found that the same partially purified extract promoted growth in pigeons and mice and questioned the existence of a separate and unique growth promoting hormone (3). The ensuing controversy foreshadowed later discoveries of the close relationship of GH and PRL in terms of their chemical structures as well as their overlapping biological activities in various assay systems. Available methods of protein purification and hormone assay were quite limited at that time, and, despite continued intense efforts by the Evans group, nearly a quarter of a century elapsed before it was established with virtual certainty that the growth promoting activity of the pituitary gland resided in a single molecular entity. In 1944 Li and Evans

(4) announced the successful isolation of a highly purified preparation of bovine GH that was apparently free of PRL and the activities of other anterior pituitary hormones. Despite its readily demonstrable efficacy in promoting growth in experimental animals, however, no therapeutic benefit to human pituitary dwarfs treated with bovine GH could be demonstrated in the subsequent decade of clinical trials. Knobil and Greep (5) found that GH of bovine or porcine origin was totally ineffective in rhesus monkeys and adopted the then unorthodox view that there might be species differences in the activities of GH. Fortuitously, their work coincided with large scale production of the newly developed Salk polio vaccine that required monkey kidney tissue for growth of the viruses and, hence, the sacrifice of large numbers of rhesus monkeys. They demonstrated that GH isolated from monkey pituitary glands promoted growth and nitrogen retention in hypophysectomized rhesus monkeys. Subsequent findings that GH prepared from monkey or human pituitaries is effective in humans provided the impetus for creation in 1960 of the National Pituitary Agency for large scale collection of human pituitaries at autopsy and centralization of the production of human GH in the United States. Human GH made available through this agency was used for basic research and for the treatment of more than 3,000 patients over the next quarter century (6).

The complete amino acid sequences of GHs derived from human (hGH), monkey (mGH), and bovine (bGH) pituitary glands were known by the early 1970s, and all efforts to modify animal GHs to forms that might be effective in humans or to synthesize human GH by chemical means were unsuccessful. Meanwhile, with the therapeutic need for the scarce hGH and the accumulating wealth of structural information on GH and its related proteins (7), GH was recognized as an attractive model protein for application of the emerging recombinant DNA technology. It was soon shown that GH could be synthesized in bacteria from mammalian DNA fused to a bacterial gene (8). Human GH was the first mammalian protein to be so produced from purely mammalian cDNA (9) and was targeted by the newly formed biotechnology company, Genentech, as the first company to develop and market recombinant protein commercially (10). Approval for clinical use of recombinant human GH was granted by the U.S. Food and Drug Administration in 1985 after several deaths from Creutzfeldt-Jakob disease attributed to pituitary hGH contaminated with the slow virus resulted in a ban on its further administration to human patients. In the decade between 1985 and 1995, ten times as many children were treated with the recombinant hormone as had been treated with the pituitary-derived hormone in the preceding quarter century, and, collectively, they are said to have grown to an additional height of about 4 miles (10). Ready availability of recombinant bovine and porcine GH has also fostered commercial application in agriculture where GH can be used to accelerate growth of domestic livestock, increase feed efficiency, decrease carcass fat, and increase milk yield. Political opposition, however, has limited its use in this regard. Overexpression of GH in transgenic cattle, sheep, and pigs has produced disappointing results, as these animals often become diabetic.

2. Biological Actions

Postnatal growth and the attainment of normal adult size is absolutely dependent upon GH in most species, but guinea pigs and some strains of chickens appear to have evolved alternative mechanisms of growth regulation that appear independent of GH and are not understood. Embryonic growth and growth in the early postnatal period in mammals is also independent of GH. Absence of GH in juvenile animals results in "dwarfism" that varies in severity from less than 25% to 65% of expected adult size. Excessive GH production during the juvenile period leads to a state of giantism in animals and humans, with some afflicted men attaining heights of over 8 feet. Transgenic mice expressing metallothionein-hGH fusion genes attained body weights that were twice more those of littermate controls (11). Cessation of growth in adult animals results from fusion and, hence, is unresponsiveness of the growth plates in the long bones rather than a lack of GH, which continues to be secreted throughout life, albeit it in decreasing amounts with increasing age. Continued overproduction of GH in human adults results in overgrowth of skin and soft tissues and deformities that result from enlargement of those bones that can continue to respond; a condition called acromegly.

The growth-promoting effect of GH is at least partially, and perhaps entirely, attributable to the actions of a growth factor, once known as somatomedin, and now called insulin-like growth factor-1 (IGF-1). GH enhances the synthesis and secretion of IGF-1 in a wide variety of tissues. IGF-1 was so named because of the similarity of both its structure and its biological effects to those of insulin (see **IGF-1**, this volume). Most of the IGF-1 in the blood originates in the liver and circulates tightly bound in a complex that contains two other GH-dependent proteins, the IGF binding protein 3 and an acid-labile protein. IGF-1 is also produced locally by cartilage progenitor cells in the growth plates of the long bones and by other cells that are targets for GH and acts locally in a paracrine or autocrine manner to stimulate cell division and differentiation. This local production and action of IGF-1 appears to be sufficient to account for the stimulation of growth by GH as selective disruption of IGF-1 expression by the liver, which severly reduces the plasma content of IGF-1, does not interfere with normal growth of mice (12). The synthesis of most of the eight different IGF binding proteins that have been described is either positively or negatively regulated by GH. These proteins appear to act as positive or negative modulators of IGF action.

GH is also an important regulator of energy metabolism in most homeothermic animals. It decreases the sensitivity of liver, muscle, and adipose tissue to the actions of insulin (see Insulin, this volume) and promotes the utilization of fat in preference to carboydrates to meet the demands of muscle for energy. Consequently, prolonged administration of GH leads to a reduction of carcass fat while promoting the accumulation of body protein through stimulation of protein synthesis. At the same time that insulin sensitivity is decreased, GH paradoxically increases the responsiveness of the insulin-producing cells of the pancreas to physiological signals for insulin secretion. Excess GH often results in temporary or permanent diabetes mellitus. In many species GH secretion is increased during fasting and, perhaps, facilitates the metabolic adaptations to decreased availability of dietary carbohydrates.

3. Secretion and Metabolism

GH is synthesized and secreted primarily by cells in the anterior pituitary gland called "somatotropes," which appear to arise from the same pool of precursor cells that also give rise to the PRL secreting cells (lactotropes). Some cells appear able to synthesize and secrete both GH and PRL and are called "somatomammotropes" or "lactosomatotropes." Immortalized cells derived from tumors of these cells (eg, GH3 cells) have been widely used as models for studying both synthesis and secretion of peptides. GH is the most abundant hormone produced and stored in the pituitary. Its expression level is about 800 times greater than that of any other pituitary hormone, and it has been estimated to comprise up to 1% of the dry weight of the human pituitary gland. In the living animal, GH is secreted intermittently in pulses spaced about 3 to 4 h apart (13). Positive input for secretion is provided by a 40 to 45 amino acid peptide, the GH releasing hormone (GHRH), which is secreted by neurons in the nearby hypothalamus and reaches the somatotropes through a unique capillary network called the hypophyseal portal system. Negative input for secretion is provided by somatostatin, a 14 amino acid peptide that is synthesized and secreted by other hypothalamic neurons. Pulsatile secretion of GH is throught to result from the periodic coordinated release of GHRH and cessation of somatostain secretion. Various environmental cues (eg, "stress") may evoke additional secretory episodes or abolish one or more secretory pulses depending upon circumstance and the species. Products of GH action, such as IGF-1, in the blood diminish pulse amplitudes by stimulating somatostatin secretion in a typical negative feedback arrangement. In addition, GH may also modulate its own secretion by exerting inhibitory actions on GHRH-secreting neurons. Recently, an additional GH secretagogue, named ghrelin, has been identified. This novel 28 amino-acid peptide is esterified with octanoate at serine 3 and appears to act on both the GHRH-secreting cells of the hypothalamus and the somatotropes.

In mammals, which have been studied more extensively than other vertebrate classes, about half of the GH found in the blood is bound to the GH-binding protein (GHBP) whose structure corresponds to the extracellular portion of the GH receptor (GHR). The GHBP is a product of the GHR gene (see below) and is thought to arise in most species by proteolytic cleavage of the GHR at the extracellular surface. The enzyme responsible appears to be the same metalloprotease that liberates the cytokine, tumor necrosis factor-a, from its transmembrane precursor (14). In rodents, the GHBP is synthesized from an alternatively spliced RNA transcript of the GHR gene. The GHBP increases the apparent biopotency of GH in the intact organism by prolonging its survival time in the blood. When added to isolated tissues or cells, the GHBP reduces bioactivity of GH by competing for hormone with cellular receptors. These effects are not contradictory, as receptor binding leads to complete degradation of the hormone/receptor complex and is likely to serve as the major route of hormone degradation. Some degradation of hormone that reaches the glomerular filtrate also occurs in the kidney. Less than 1% of the GH secreted by the pituitary is excreted intact in the urine.

4. The GH Family of Proteins

GH is a single-chain peptide comprised of 190 to 196 amino acid residues and has a molecular mass of approximately 22,000. Complete amino acid sequence data for hormones from more than 40 different species representing all classes of vertebrates have been determined either by direct analysis of the purified proteins or by deduction from the nucleotide sequences of their cDNAs. Characteristic of all the known GH molecules are the two disulfide bridges that form a long loop by coupling cysteines corresponding to Cys-53 and Cys-165 in the human sequence and a short loop involving Cys-182 and Cys-189. When these cysteine residues are used as reference points and gaps are allowed to maximize alignment of homologous regions, it becomes apparent that more than a third of the amino acid loci in all of the known GH molecules contain identical residues (Fig. 1). Homologies are almost twice as great when conservative substitutions are allowed. Amino acid sequences of GHs from animals as distantly related as humans and sharks have more than 50% identity, although there is considerably more divergence in the GHs within the bony fish. Nevertheless, more than 30 residues in addition to the four cysteines are identical throughout the species, and these appear in clusters with highest conservation in positions between residues 164 and 187 (15). The crystal structure of porcine GH was solved in 1987 (16). In three dimensions, the peptide chain of GH forms into four alpha helices encompassing residues 7 to 34 (helix I), 75 to 87 (helix II), 106 to 127 (helix III), and 152 to 183 (helix IV) (Fig. 2). The alpha helices are tightly packed and arranged in an antiparallel up-up-down-down orientation. The invariant and highly conserved amino acid residues are predominantly found within the alpha helices and presumably contribute to the integrity of the tertiary structure of the molecule. A long loop of 40 amino acids connects helices I and II, and shorter 18 and 24 residue loops connect helices II and III and III and IV, respectively. Short peptide chains are found at the amino and carboxyl termini.

Figure 1. The amino acid sequence of hGH. Shaded boxes indicate conserved amino acids in mammalian GH. The shad lines above or below the peptide chain indicate the amino acid residues present in helices **I, II, III**, and **IV**. (From: H. M Goodman, G. P. Frick, and S. Souza (1996) Species specificity of the primate growth hormone receptor. News Physiol. S 11, 157–160).

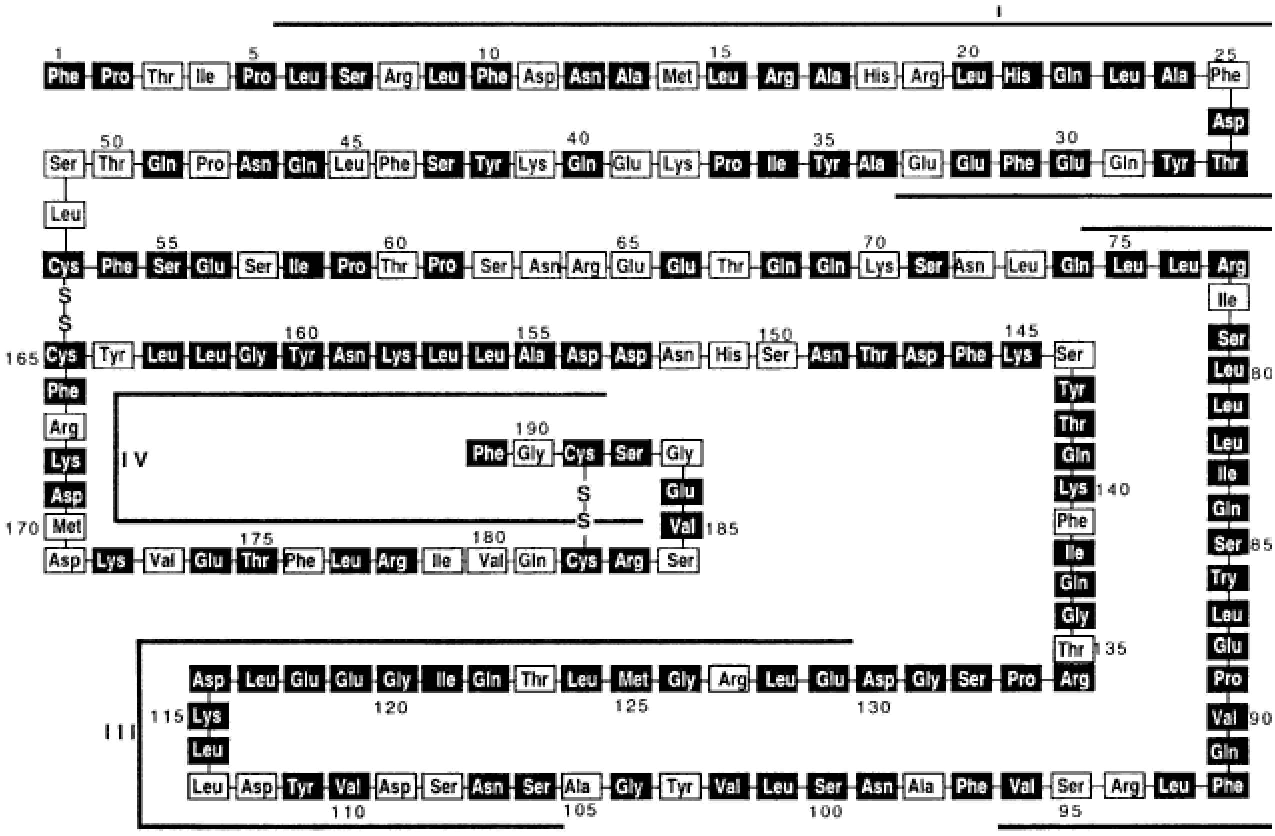

Figure 2. Tertiary structure of GH (modified from ref 14).

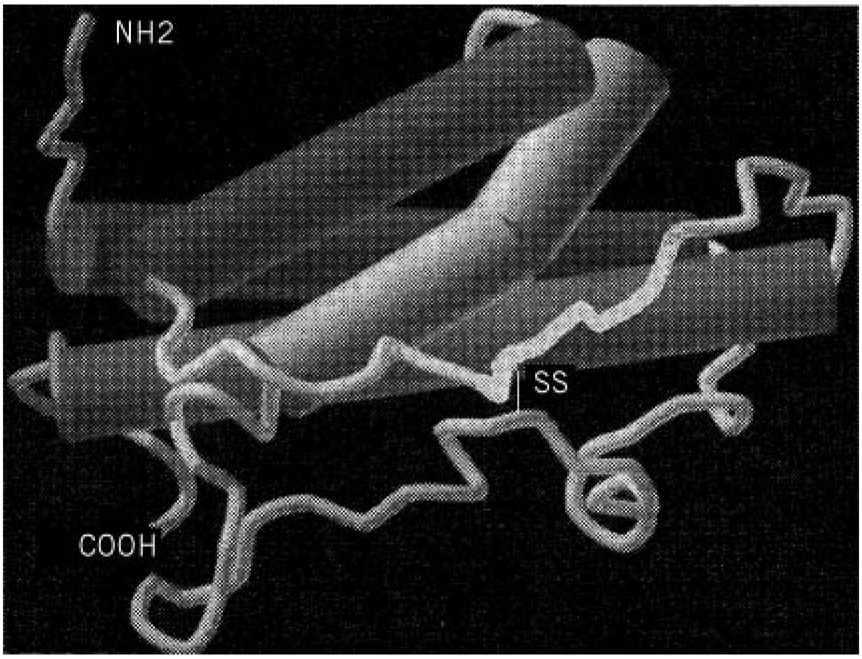

Variant forms of GH have been reported in several species. Of these, the most thoroughly studied is the so-called 20k hGH. This isoform of hGH lacks 15 amino acids (residues 32 to 46) and, consequently, has a molecular mass of 20,000, instead of the 22,000 of the predominant form discussed above (17). The 20k isoform of hGH constitutes only about 10% of the daily GH secretion and may be somewhat less potent than its 22k counterpart in some assay systems. It arises from alternative splicing of the same RNA transcript that codes for the 22k isoform (see below). Another splice variant, a 17.5 kDa form (18), has also been described, but little is known of its physiology. Processing variants include phosphorylated, glycosylated, amidated, and proteolytically cleaved forms (19). Some of these variants are found in the circulation, but their biological importance has not been established. Some modified forms of GH may be artifacts of pituitary storage or purification procedures.

As already indicated, another anterior pituitary hormone, prolactin (PRL), is closely related to GH in both its chemical and biological properties. PRL is found in all vertebrates and has a wide range of biological actions among the various species, including regulation of salt and water balance, growth, and various behaviors and functions associated with reproduction and nurturing of the young (20). PRL is named for its critical role in supporting lactation in mammals. Like GH, PRL consists of nearly 200 amino acid residues and has the same four antiparallel helix bundle tertiary structure as GH. PRL has three intrachain disulfide bridges, two of which correspond to those found in GH, and the third is located near the N terminus. PRL is about 20% identical in amino acid sequence to GH of the same species, a finding that suggested the hypothesis that the two hormones originated from a common ancestral gene (21). *A propos* of this idea, a glycoprotein with a mass of about 26 kDa that appears to be equally related to both hormones has been isolated from pituitary glands of some bony fish (22). It consists of 206 amino acids with about 24% sequence identity with both GH and PRL, and conservation of the two disulfide bridges corresponding to those in GH. Its function has not been established, but it has been named “somatolactin” because of its similarity to both GH and PRL. Somatolactin may be descended from the protein that was ancestral to both GH and PRL and, as of this writing, has not been found in tetrapod or avian pituitary glands.

Additional members of the GH family are expressed in the placenta and, hence, are confined to the mammals. The human placenta secretes a variant form of GH (GH-V), which appears to be the major form of GH present in maternal blood plasma during late pregnancy (23). GH-V differs from pituitary GH (hGH-N, for normal) in 13 of the 191 amino acids in positions that are widely distributed between residues 18 and 149 and, unlike the pituitary hormone, is glycosidated at Asn-140, which is unique to GH-V (24). It has a molecular mass of about 23 kDa. Blood plasma of pregnant women also contains a less abundant 25 kDa GH-like peptide of placental origin, which appears to arise from alternative splicing of the RNA transcript of the hGH-V gene (25) (see below). The human placenta also produces placental lactogen (hPL, more commonly called human chorionic somatomammotropin, hCS), which has both GH-like and PRL-like activities in many assay systems. It is the most abundant peptide produced by the placenta, which, in late pregnancy, may secrete as much as 1g per day. Human CS differs from the pituitary form of hGH in only 28 of the 191 amino acid residues and from hGH-V in only 40 residues, with the carboxyl terminus again showing the greatest degree of identity (24). PLs are also produced by the placentae of other species, notably ruminants and rodents, but apparently are not universally found among the mammals. Four PL and four PRL-related proteins are produced in rodent placentae, and the bovine placenta produces one PL and six PRL-related proteins. The PLs bind to GH or PRL receptors and, at least in cattle, to PL receptors, but, currently, no receptors for PRL-related proteins have been characterized. Bovine and rodent PLs and PRL-related proteins are more similar to PRL than to GH, while the placental lactogen of primates is more closely related to GH.

5. The GH Gene Family

Determination of the structures of the genes that encode the GH family of proteins reveals an even greater similarity and relationship among these proteins than the amino acid sequences. The structure of the GH gene has been determined in mammalian, avian, and piscine genomic libraries. The related PRL, PL, and somatolactin genes have also been sequenced in a variety of species. The mammalian GH genes span about 2 kb and are the smallest in the family, while the somatolactin gene is the largest and extends for about 16 kb. the mammalian PRL genes encompass about 10 kb, and the PL genes resemble those of either GH or PRL, depending upon the species. The genes that encode all of these proteins contain five exons and four introns, and, despite wide variations in the sizes of the introns, the splice junction patterns and the positions of introns with respect to the coding sequences of the protein products have been remarkably conserved. In some suborders of bony fish, eg, the salmonids, however, the fifth exon has been split by insertion of a fifth intron. With the conservation of exon/intron boundaries, the sizes of the first four exons are quite similar, ~0.1, 0.2, 0.1, and 0.2 kb respectively, but exon V ranges from ~3 kb in somatolactin to ~0.3 kb in hGH, giving rise to wide variation in the length of the untranslated 3′ end (15).

The human haploid genome contains five closely-linked GH-related genes at band segment q22–24 on the long arm of chromosome 17 (26, 27) and a single PRL gene on chromosome 6 (28). The hGH-N gene is expressed only in the pituitary and, to a much smaller extent, in some white blood cells (monocytes), while the three hCS genes and hGH-V are expressed only in the placenta. About 67 kb of the hGH gene locus, including intergenic sequences and up- and downstream flanking regions, have been completely sequenced (29). The five gene cluster itself spans about 48 kb (30) and contains the genes for hGH, designated as hGH-N (for normal); two genes for hPL, designated hCS-L (hCS-like) and hCS-A; the gene for hGH-V (for variant); and a third PL gene, hCS-B, arranged in order in the 5′ to 3′ direction. All five genes are transcriptionally oriented in the same direction and are separated by intergenic regions of 6 kb to 13 kb in length. The intergenic regions contain 48 middle repetitive Alu sequences that comprise more than 20% of the nucleotides in the hGH locus (29). A repeated P element consisting of about 1 kb is also found about 2 kb upstream from the promoters of the four placentally expressed genes. The hCS-A and hCS-B genes encode prehormones that differ by one amino acid in the leader sequence have five silent nucleotide differences, but the mature proteins are identical (31). The hCS-B gene also contains a small insertion in the 3′ untranslated region that is not found in hCS-A. The nucleotide sequence of the hCS-L gene shows 93% to 94% homology with the genes for hCS-A and hCS-B, but, because a G to A transition in the splice donor site of the second intron interferes with RNA processing at this site, a complex array of alternatively spliced mRNAs is formed, the majority of which are nonfunctional. One mRNA, however, encodes a 20 kDa protein that may be secreted (32). Expression of the hCS-A and hCS-B genes in the placenta is about 1,000 times higher than that of hGH-V or hCS-L genes (29).

Unlike the primate genome, which contains a single prolactin gene and multiple GH-related genes, the genomes of rodents and ruminants appear to contain a single GH gene and multiple PRL-related genes as judged from their nucleic acid and protein structures. PLs appear to be lacking in other mammalian groups (33). The GH locus and the PRL locus in rodents and ruminants are on separate chromosomes that appear to be homologous with their human counterparts as judged from the colocalization with other known genes. Genes for the numerous PRL-related proteins that are expressed in the placentae of cattle, sheep, rats, and mice map to the same chromosomes as PRL, and, although the entire PRL chromosomal locus has not been sequenced in any of these species, it is likely that they cluster in a fashion analogous to that seen in the human GH locus (34-37).

6. Regulation of GH Gene Expression

There are two aspects to regulation of GH gene expression; both are complex and incompletely understood. One aspect concerns the factors that determine tissue specificity and restricts GH expression to the somatotropes. The other aspect concerns the regulation of the levels of expression by the somatotropes. Expression of hGH-N, but not hGH-V, in the somatotropes is thought to be governed by remote regions of 5′ flanking DNA tens of thousands of bases upstream from the hGH-N gene. These elements, along with somatotrope-specific regulatory proteins, may reorganize the chromatin such that the transactivation factors discussed below have access to the promoter region of the downstream gene (38). Somewhat different control mechanisms may pertain to nonprimates that express only one gene at the GH locus, but, throughout the vertebrates, expression of proteins of the GH/PRL family depends upon the indispensable regulatory protein, Pit-1, which is also sometimes called GHF-1. Pit-1 is a ~290 amino acid protein that is expressed only in certain pituitary cells, the placenta and monocytes that produce GH, and, thus provides cell-specific regulation (39, 40). Pit-1 is also crucial for differentiation and growth of somatotropes during development and for the induction of the GHRH receptor and, hence, sensitivity to hypothalamic control (41). As mentioned earlier, GHRH is the hypothalamic hormone that stimulates the somatotrope to synthesize and secrete GH. In addition, Pit-1 also activates its own transcription and, thereby, maintains the differentiated function of somatotropes, lactotropes, and somatomammotropes (42).

Physiologically, GH synthesis and secretion are driven by GHRH, which acts through receptors on the somatotrope surface to increase the production of cyclic AMP, which binds to and activates protein kinase A. Protein kinase A catalyzes the phosphorylation of a variety of proteins on serine residues and, thereby, increases or decreases their activities. Among the substrates for protein kinase A in the somatotrope are nuclear regulatory factors of the cyclic nucleotide response element binding (CREB) protein family. The hypothalamic peptide somatostatin inhibits GH synthesis and secretion by blocking the actions of GHRH on cyclic AMP production and ion permeability. In addition, peripheral hormones, triiodothyronine from the thyroid gland and glucocorticoids from the adrenal cortex, enhance GH synthesis and secretion. Other paracrine (eg, activin) and circulating factors (insulin, retinoic acid, vitamin D) also act on the somatotrope to modulate GH production either positively or negatively, while yet other regulatory influences, (eg, IGF-I, free fatty acids and glucose) regulate events in the somatotrope through their actions on GHRH and somatostatin secretion.

The proximal promoter includes the TATA box sequence, which for all of the vertebrate GH genes is TATAAAA and for the PRL and somatolactin genes is TATAAAG (15). Regulation is largely conferred by critical nucleotide sequences that lie within a few hundred bases upstream of the cap site in mammalian GH genes and are the elements that bind regulatory proteins. The hGH-N gene has two binding elements for Pit-1, at 80 and 122 base pairs 5′ to the transcription initiation site. These sites are conserved at similar positions in rodent and other GH genes. The ubiquitous zinc finger protein Zn-15 binds to the so-called Z box, a highly conserved sequence located between the Pit-1 elements, and synergizes with Pit-1 (43). Other ubiquitous regulatory factors that bind to the hGH-N promoter include Sp1, AP2 (activator protein 2), NF-1 (nuclear factor-1), USF (upstream stimulatory factor), and the glucocorticoid receptor (42). There is an additional glucocorticoid binding site in the first intron of the hGH-N gene. Glucocorticoid hormones enhance GH expression by augmenting transcription and may also stabilize GH mRNA. The rat GH gene also contains a silencer element whose binding protein is specifically absent in somatotropes (44). Much less is understood concerning control of the the expression of hGH-V. Repression of hGH-V expression in the pituitary may be achieved through the agency of the P element located upstream from each of the placentally expressed genes of the GH family (29).

Despite the high degree of conservation seen in many aspects of the structure and regulation of the GH gene, some different mechanisms appear to apply for regulation of the human and rat genes. The hGH-N gene has two CREB binding sites (45), but these are lacking in the rat GH gene (46). GHRH may, therefore, directly activate the GH gene in humans, but, in rodents, its influence may be exerted indirectly via cyclic AMP response elements (CREs) in the rat Pit-1 promoter and increased synthesis of Pit-1 (47). The human Pit-1 promoter lacks recognizable CREs. The rat GH promoter, but not the hGH-N promoter contains a general hormone response element that binds to thyroid hormone receptors (48) as well as retinoic acid and vitamin D receptors (49). Accordingly, thyroid hormone enhances transcription of the rat GH gene, but not hGH-N.

7. Splice Variants

The preRNA transcripts are processed and spliced to produce mRNA that codes for a prehGH that contains a leader sequence of 26 amino acids that is cotranslationally removed. The first exon/intron boundary is of the class I type, falling between the first and second nucleotides of the glycine codon in hGH-N. The remaining exon/intron boundaries are of the class 0 type and fall between codons.

The translated portion of exon I includes 10 nucleotides: the first three codons and the first nucleotide of codon 4. Exon 2 begins with the second and third nucleotides of codon 4 and contains the codons for the remaining 22 amino acids of the leader sequence and the first 31 residues of the mature protein. Exon 3 codes for residues 32 to 71 of the 22k form of hGH. Exon 4 consists of the codons for residues 72 to 126, and exon 5 codes for the remaining 65 amino acids and the 3′ untranslated region. Codon 46 in exon 3 contains the dinucleotide AG, which can act as an alternate splice acceptor site. In about 10% of the transcripts, the 45 nucleotides at the 5′ end of exon 3 are removed along with the second intron to produce an mRNA that codes for a shorter peptide chain lacking 15 amino acids (residues 32 to 46) and with a mass of 20 kDa (17). A second, and considerably less abundant, splice variant of the hGH-N gene arises from the complete deletion of exon 3 to give rise to a 151 amino acid form with a mass of 17.5 kDa (18). Other mRNA variants lacking exons 3 and 4, and 2, 3, and 4 have been found by reverse transcription-polymerase chain reaction experiments, but it is not known if they are translated or secreted (50).

Although the hGH-V transcript is identical to the hGH-N transcript in the vicinity of the alternate splice site, no alternative splicing of hGH-V occurs at this site. This appears entirely attributable to three nucleotides present only in the hGH-N transcripts and located between the normal and the alternative splice acceptor sites at positions 17, 18, and 24 bases upstream from the alternative site (51). The transcript of hGH-V, however, is subject to alternative splicing in which the 253 nucleotides of intron 4 are retained. Because the reading frame remains open through intron 4 and into exon 5, but with a +1 frame shift, the resulting hGH-V2 transcript codes for a protein in which the 65 carboxyl terminal amino acids are replaced by a different 104 residue carboxyl tail (24). This alternatively spliced transcript represents about one-third of the hGH-V mRNA, but no hGH-V2 protein is secreted, perhaps because a hydrophobic sequence in the new carboxyl tail causes it to be retained within the synctiotrophoblast. Intron 4 may be similarly retained in alternatively spliced transcripts of hCS-A and hCS-B (52) and in bovine GH (53). Alternative splice variants of other species of GH appear not to have been studied extensively.

8. Mechanism of Action

8.1. The GH Receptor

The GH Receptor (GHR) was purified from the richest known source, the rabbit liver, by Waters and Friesen (54). It was cloned from a rabbit cDNA library using an oligonucleotide probe whose construction was based on the amino acid sequence of a fragment of the rabbit GHR (55) and identified using monoclonal antibodies raised against the purified protein in the Waters laboratory (56). Human, rodent, ruminant, porcine, and chicken GHRs were cloned soon thereafter, and the mammalian receptors were found to share 70% or greater sequence identity. The ~4 kb cDNA codes for a 620 amino acid mature protein with an 18 residue leader sequence. Hydropathy analysis indicated a single membrane-spanning region of 24 amino acid residues separating the N-terminal 246 residue extracellular domain from the 350 residue cytosolic domain. The extracellular domain contains seven cysteine residues, of which six are paired in S-S linkage, and five potential N-glycosidation sites. The intracellular domain contains no known catalytic activity but associates with a cytosolic protein tyrosine kinase, Janus kinase-2 (JAK2), which appears to bind to a proline-rich region of the receptor adjacent to the membrane-spanning domain.

The human GHR receptor is a single copy gene on chromosome 5. Its coding and nontranslated 3′ tail are encoded by nine exons, designated 2 to 10, extending over 87 kb. (57). Exon 2 codes for the signal peptide, 3 through 7 for the extracellular domain, exon 8 for the transmembrane domain, exon 9 the beginning of the cytosolic domain, and the long exon 10 (3,400 bp) codes for the bulk of the intracellular domain and the long 3′ untranslated region. At least eight variants of the 5′ untranslated region are found in the human GHR gene (58), and multiple 5′ regions are present in other GHRs indicative of multiple, perhaps tissue specific, promoters. Rodent GHR genes also contain several variants at the 5′ end as well as an additional exon (exon 8A) between exons 7 and 8 (59). Alternative splicing that replaces exons 8, 9, and 10 with exon 8A produces an mRNA that codes for the circulating GH binding protein (GHBP) in rodents (60). The GHBP has a hydrophilic carboxyl tail instead of the transmembrane and cytosolic domains of the GHR.

As with their cognate hormones, the GH and PRL receptors share many similarities in structure (61). The human GH and PRL receptor genes map to the same locus on chromosome 5 (62). The GH and PRL receptors belong to the superfamily of Cytokine/Hematopoietin receptors that includes receptors for erythropoietin, interferon, interleukins 3 and 5, the common subunit of interleukins 2, 4, 7, 9 and 15, the common subunit (gp130) of interleukins 6 and 11, oncostatin, leukemia inhibitory factor, and several others. The relationship is based on both primary and tertiary structural features of the extracellular and cytosolic domains and is also reflected in similarities in the modes of signalling of these receptors. Ligands for these receptors are four helix bundle structures as described for GH.

8.2. GH-Receptor Binding

In a brilliant series of experiments summarized in Wells and colleagues (63) at Genentech mapped the surfaces of the hGH and receptor molecules that come in contact upon binding and determined the stoichiometry of binding to be two receptors per hGH molecule (Fig. 3). High resolution X-ray crystallography of the complex of hGH bound to the extracellular domain of the GHR (64) revealed that virtually identical binding sites on the two receptor molecules bind to nonidentical sites on the surface of the four helix bundle GH molecule and came in contact with each other in their C-terminal regions in a manner that would bring the transmembrane and cytosolic domains in close apposition (Fig. 4). Their data indicated that GH sequentially binds to one receptor molecule at the so called site 1 on GH and then to a second receptor at site 2 on the hormone, the consequences of which produce a receptor dimer and the initial step in signalling. Binding is ordered due to stronger interaction between hGH and the GHR at site 1 than at site 2. Dimerization of the GH receptor upon ligand binding is prototypical of the behavior of the large superfamily of cytokine receptors and provides a basis for understanding how hormone binding can be transduced into a signal by other tyrosine kinase-dependent receptors as well.

Figure 3. Patches on the surface of hGH that bind the hGHR. Key amino acid residues whose mutation to alanine decreases binding are indicated. GH binds to its receptor first at **Site 1** and then at **Site 2**. Note that the orientation of the hGH molecule has been rotated 180° horizontally from that shown in Figure 2 (modified from ref 62).

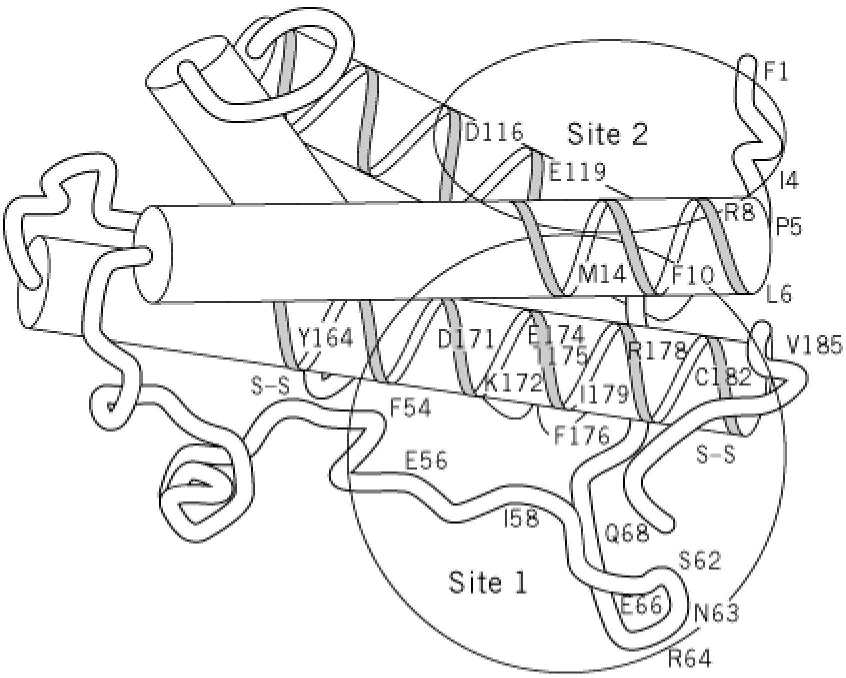

Figure 4. Three-dimensional structure of the GH:GHR complex. Two molecules of the extracellular domain of the GHR, indicated here as **BP1** and **BP2** bind to opposite faces of **hGH** and interact with other in the juxta**membrane** region. (from ref. 62).

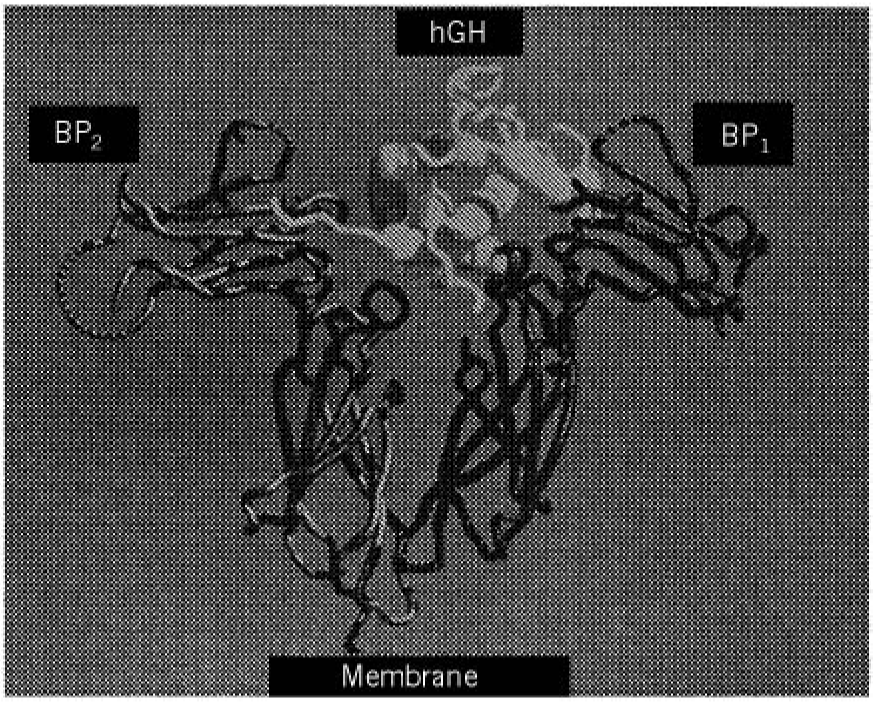

These studies defined the amino acid residues in the GH molecule that contribute to receptor binding either because they come in direct contact with the surface of the receptor or because they contribute to the tertiary structure in a way that presents the interacting amino acids in the proper orientation. "Designer" GH molecules with greater or lesser affinity for lactogenic receptors (65) have been prepared as well as GH molecules with greater affinity for the receptor or an antagonist (G120R) with a mutation in the third helix that interferes with binding at site 2 (66). The region of highest conservation in GH is near the carboxyl terminus, which encompasses amino acids that contribute heavily to site 1. One of the nonconserved amino acids in this region is located at position 171, which in all nonprimate GHs is histidine, but in all primate GHs is aspartic acid. The coordinating residue on the hGHR is arginine in position 43 in place of leucine all other receptors. The incompatibility of His171 in nonprimate hormones with Arg 43 in the human receptor decreases binding affinity 200-fold and is largely responsible for "species specificity" (67).

8.3. Signal Transduction

The primary event in GH signal transduction is the GH-induced dimerization of the GHR, which is thought to bring the cytosolic domains in close apposition resulting in activation and perhaps recruitment of the cytoplasmic tyrosine kinase, Janus kinase-2 (JAK2) and other members of the Janus kinase family (68). Activation of JAK2 results in phosphorylation of tyrosine residues in the GHR and of JAK2 itself. JAK2 appears to associate with the GHR at the N-terminal third of the cytosolic domain, within which is a critical proline-rich region adjacent to the membrane-spanning domain (box 1) that is conserved within the receptor superfamily. Because a relatively large number of cytosolic and nuclear proteins become tyrosine phosphorylated, it is likely that JAK2 has additional substrates or that other tyrosine kinases are recruited and become activated. Phosphorylated tyrosine residues serve as docking sites for other proteins that contain Src Homology 2 (SH2) domains (see **Src Homology 2**, this volume), thereby recruiting other specific proteins that may be substrates for JAK2 or adapter proteins (e.g., SHC or GRB2) that recruit or activate other proteins to the complex and initiate signaling pathways. As with other tyrosine kinase-dependent signalling, multiple pathways appear to be activated (69). One of the most prominent of these pathways involves the Stat proteins (for *s*ignal *t*ransduction and *a*ctivation of *t*ranscription) which, upon activation by tyrosine phosphorylation, form homo- or hetero-dimers with other Stat proteins, migrate to the nucleus, bind DNA, and activate transcription of particular GH-sensitive genes including the early response gene c-fos (70) and the hepatic serine protease inhibitor-1 (Spi-1) gene (71). Activation of JAK2 also directly or indirectly leads to tyrosine phosphorylation of the insulin receptor substrates, IRS-1 and 2, and to activation of phosphatidylinositol-3-kinase and can, thereby, set in motion various metabolic responses to GH (68). Another prominent signaling cascade, the MAP kinase (for *m*itogen *a*ctivated *p*rotein) pathway is also activated. MAP kinases catalyze the phosphorylation on serine residues of diverse proteins including many other protein kinases, Stat proteins, cytoskeletal proteins, and transcription factors such as Elk1, which, when phosphorylated, bind to the c-fos promoter. Stimulation of cells with GH also results in the activation of phospholipase(s), which cleaves membrane phospholipids to release diacylglycerol, which may activate various isoforms of protein kinase C. Protein kinase C catalyzes serine phosphorylation of diverse cellular proteins including DNA regulatory proteins. Finally, GH also causes a rapid increase in intracellular-free calcium (72) by a mechanism that is likely independent of JAK2 as this effect is evident in cells that only express a mutant form of the GHR that cannot bind JAK2 (73). Most of these signalling cascades participate in signal transduction by a variety of hormones, cytokines, and other extracellular signalling molecules, raising the issue of how specific and unique responses to GH are achieved in cells that are also responsive to other agonists. It is likely that the various signalling pathways activated by GH intersect, reinforce, or obtund each other in patterns that are unique to GH and to the particular target cells to produce specific responses to GH.

Gtpases

Regulatory GTPases form a large, evolutionarily related superfamily of enzymes that catalyze the hydrolysis of GTP to GDP and inorganic orthophosphate. The importance of these GTP-binding proteins lies, however, in the diverse regulatory activities that they acquire upon GTP binding and that are terminated by GTP hydrolysis. The GTPases thus act as molecular switches, active in the GTP-bound form and inactive in the GDP-bound form. GTP binding and GTP hydrolysis are both tightly regulated by other proteins (see Guanine Nucleotide Exchange Factors and RGS Proteins). These proteins thus control a GTPase catalytic cycle and determine the fraction of time that the GTPase will spend in the active states. Alternatively, the regulatory proteins can independently turn the switch on or off in response to appropriate signals.

All the GTPases share a conserved structure around the GTP-binding site, with three identifiable regions of conserved amino-acid sequence. More closely related families share further sequence similarities. The individual families of GTPases are defined by the activities that they regulate and by their conserved structures. Each family is discussed under separate entries.

1. Multiple initiation factors and elongation factors required for translation on ribosomes are regulatory GTPases. Their GTP-triggered functions include the recruitment of aminoacyl-tRNAs to the ribosome, participation in peptide bond formation and the associated movement of the nascent protein on the ribosome (see Translation). This structurally and functionally diverse group also includes proteins involved in translocation of nascent proteins across membranes, such as the signal recognition particle. Elongation factor Tu (EF-Tu) from *Escherichia coli* is the historic prototype of the GTPase superfamily. Several proteins involved with co-translational, **signal sequence**-mediated translocation of nascent proteins through membranes are GTP-binding proteins more distantly related to this group.
2. Small, monomeric GTP-binding proteins (SMGs) constitute a large family of structurally related GTPases, most in the 20- to 25-kDa size range. They mediate numerous functions in eukaryotic cells, including activation of protein kinase signaling cascades, regulation of cytoskeleton structure, **nuclear import/export**, budding and docking of membrane **vesicles** involved in subcellular organellar trafficking, and so on.
3. **Heterotrimeric GTP-binding** regulatory proteins, often referred to as G proteins, organize and convey signals from cell surface receptors to cellular effector proteins, such as **adenylyl cyclase**, cyclic GMP phosphodiesterase, **ion channels**, phospholipase C, protein kinases, and so on. Individual G proteins (about 20 in total) display distinct but nonunique selectivity among receptors and effectors. Both the GTP-binding a subunits (~40 kDa), which include a domain similar to the SMGs, and the tightly associated b and g subunits convey signals to distinct effectors.

4. **Dynamins** are GTP-binding cytoskeletal proteins involved in the budding of endocytic vesicles. They are homologous to the other GTP-binding proteins only in the immediate region of the GTP-binding pocket. Dynamins also interact with the bg subunits of the heterotrimeric G proteins.
5. **Tubulins**, the structural proteins of eukaryotic microtubules, are also GTPases but are only distantly related to the regulatory GTPases. Polymerization of microtubules is regulated in part by GTP binding to tubulin.

GTP-Binding Proteins

GTP-binding proteins are members of a superfamily of regulatory proteins whose activity is controlled by binding GTP. They act as conformational molecular switches that regulate numerous and diverse processes throughout the eukaryotes. Many GTP-binding proteins are devoted to signal transduction, mediating information transfer from receptors to intracellular effector proteins. Others regulate such diverse processes as the traffic of membrane proteins and lipids via cytoplasmic transport **vesicles**, the **cytoskeleton**-mediated control of cell morphology, **nuclear import/export**, and such membrane-reforming processes as endocytosis, protein secretion, and budding. In their GTP-bound, active forms, GTP-binding proteins can stimulate or inhibit the activity of cellular effector proteins, recruit effectors to specific intracellular sites, or sequester effectors and thus block their activity. These proteins thus lie at the convergence of multiple regulatory pathways and function as major integrators of cellular information.

GTP-binding proteins are divided into two major classes, each of which is further divided into individual families. Generally, these structurally determined groupings also indicate related functional specialization and biochemical properties. GTP-binding proteins are ubiquitous throughout the eukaryotes, however, and structurally related proteins may perform strikingly different functions in distantly related organisms.

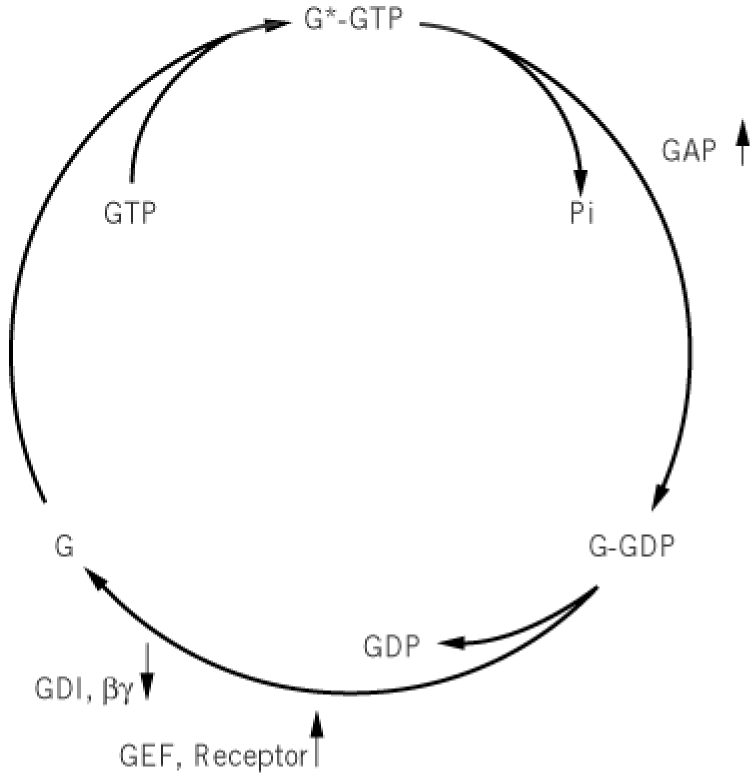
The two major groups of GTP-binding proteins are the heterotrimeric G proteins and the small, monomeric GTP-binding (SMG) proteins. SMGs are also commonly referred to as G proteins, or small G proteins, and the nomenclature is not well established. Heterotrimeric G proteins are composed of a GTP-binding a subunit (~40 to 45 kDa) and a dimer of b and g regulatory subunits (~35 kDa and 7 to 8 kDa). Heterotrimeric G proteins convey signals from receptors at the cell surface to cellular effector proteins (see Heterotrimeric G Proteins). The SMG proteins (20 to 25 kDa) are involved in more diverse functions. In addition to these two major classes, other GTP-binding proteins with related primary structures, tertiary structures, and GTPase cycles include the elongation factors of translation (with bacterial EF-Tu as prototype) and **dynamin** (see Gtpases).

Heterotrimeric G proteins are grouped according to the structures and functions of their a subunits and are named with subscripts originally linked to their functions (1, 2). Members of the G_s family were the first G proteins to be discovered as stimulators (hence “s”) of **adenylyl cyclase**. The G_i's were initially defined as cyclase inhibitors (“i”), but they also perform many other functions. The G_q's stimulate the phosphatidylinositol bisphosphate-specific **phospholipase C-b**'s. Functions of the $G_{12/13}$ family include regulation of the **rho** SMG family and of Na^+/H^+ exchangers. The bg subunits are also diverse: There are 5 Gb subunits and at least 11 Gg subunits in mammals. While not all of the 55 conceivable Gbg dimers occur, their potential diversity is huge.

The SMG proteins cluster in five major subfamilies according to their structure and function. Smaller families also exist, and assignment of some SMGs to families remains uncertain. The ras proteins constitute a family of about five proteins in mammals, although gem/kir proteins are also assigned to this group (3-6). Ras proteins were the first SMGs to be identified, because they are active and frequently observed **oncoproteins** when mutated to constitutively active forms or when overexpressed (7). Ras proteins are the prototypical and best-studied examples of the SMG group (see Oncogenes, Oncoproteins). The rac family (rac, rho, CDC42) are involved in both signal transduction and in the regulation of cytoskeletal control of cell morphology (8, 9). Rab family members (at least 20) are involved in protein secretion and endocytosis (10, 11). ARFs (at least 6) mediate the budding and fusion of intracellular membrane vesicles (12, 13). Ran mediates both inward and outward traffic of macromolecules from the nucleus (14, 15) (see **Nuclear import/export**).

Both heterotrimeric G proteins and SMG proteins act by traversing a tightly controlled cycle of GTP binding and hydrolysis. GTP binding activates G proteins (Fig. 1) (1, 16). Activation is terminated when the bound GTP is hydrolyzed by the G protein's intrinsic GTPase activity. The GDP-bound form is inactive, as is the unliganded form. Each step in this cycle—GTP binding, GTP hydrolysis, and GDP release—is relatively slow, and each can be regulated both positively and negatively. Activation—GDP dissociation and GTP binding—is promoted by guanine nucleotide exchange factors (GEFs). GEFs are also referred to as exchange catalysts. They can be either cell-surface receptors that act in response to extracellular signals or cytosolic proteins that are regulated by **allosteric** ligands or **phosphorylation**. Activation is inhibited by GDP dissociation inhibitors (GDIs), which are regulated independently. Deactivation is also accelerated by GTPase-activating proteins (GAPs), providing a third regulatory input. The net output represents the integration of all three inputs.

Figure 1. The regulatory GTPase cycle for GTP-binding proteins. GTP-binding proteins, G, are converted by GTP to the active state G*-GTP in which they can bind and activate effector proteins. Activation is terminated by hydrolysis of the bound GTP to GDP, which is usually a slow process that is accelerated by GTPase-activating proteins (GAPs). The inactive G–GDP complex is relatively stable, unless nucleotide exchange is catalyzed by a guanine nucleotide exchange factor (GEF). In the case of heterotrimeric G proteins, the GEFs are a family of cell-surface receptors that bind ligands on the extracellular face of the plasma membrane. The inactive, GDP-bound state is stabilized by GDP-dissociation inhibitors (GDI), which in the case of the heterotrimeric G proteins are the Gbg subunits.



The differing rates of each step in the GTPase cycle, along with their various modes of regulation, allow GTP-binding proteins to operate in one of three conceptually different switching modes: toggles, meters, or timers. (*1*) A GTP-binding protein that traverses the GTPase cycle only once with respect to the process that it regulates behaves as an on/off switch. It is toggled to the active state by GEF-catalyzed activation and maintains its activity until a GAP turns it off. (*2*) A G protein that traverses the GTPase cycle quickly produces a graded signal in which its fractional activation, averaged over time, is a meter of the relative inputs to activation and deactivation. (*3*) A G protein can simply allow a process to occur for a fixed period of time, the lifetime of the bound GTP prior to its hydrolysis. While these basic patterns are formally the same, the distinctive kinetic properties of each determine how a G protein will function in the cell. The ability to work in these three different ways are vital to the functional diversity of G-protein action.

Guanidination

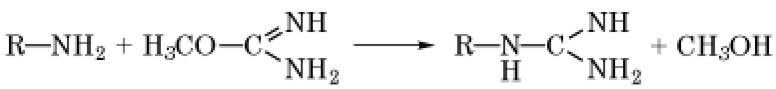
Guanidination is a method for chemical modification of amino groups in proteins. The reaction is relatively slow and proceeds primarily with the e-amino groups of lysine residues, converting them to homoarginine, much less with a-amino groups. The modified amino groups retain their positive charge with increased pK_a. Therefore, structural effects on the modified proteins are usually minimal. The function of the modified protein is usually affected only if the amino group modified intimately participates in the function.

The reaction is followed by amino acid analysis, measuring the appearance of homoarginine and the decrease in lysine. The reaction is quite specific to amino groups, but some side reactions occur with the **thiol** and imidazole groups of cysteine and histidine residues, respectively.

1. Guanidination with *O*-methylisourea

Almost all ε-amino groups of a protein are guanidinated (1) after treatment with 0.5 to 1.0 M *O*-methylisourea [I] at pH 10.1 to 11.0 and 0 to 25°C for 2 to 5 days (Scheme 1):

Scheme 1. x

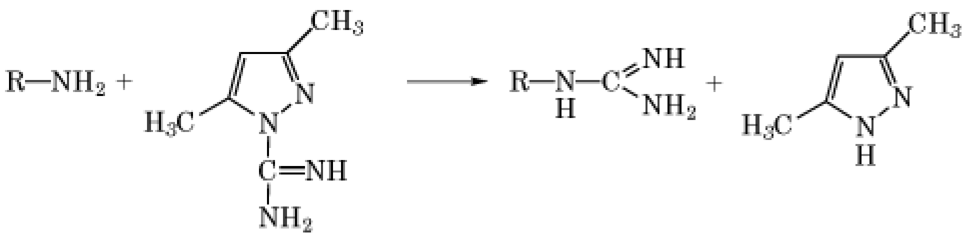


[1] *O*-Methylisourea

2. Guanidination with 1-guanyl-3,4-dimethylpyrazol

1-Guanyl-3,4-dimethylpyrazol [II] guanidinates proteins under milder conditions than *O*-methylisourea (2). Proteins need to be treated with 0.3 to 0.7 M 1-guanyl-3,4-dimethylpyrazol at pH 9.5 and 0°C for 3–7 days (Scheme 2):

Scheme 2. x



[2] 1-Guanyl-3,5-dimethylpyrazol

Guanidinium Salts

Guanidinium chloride (GdmCl) is one of the most commonly used **denaturants**. Classically, it is employed at 6*M* concentration, at which it unfolds most globular proteins into the form of a random coil. The Gdm^+ ion acts principally by competitively breaking intraprotein hydrogen bonds and forming hydrogen bonds with protein peptide bonds, although the Gdm^+ ion has also a **hydrophobic** character and can interact in this manner with protein nonpolar residues, principally aromatic groups (1).

In using guanidinium ion denaturation, one has to be careful about the selection of the entire salt, since the anion (X^-) exerts its own effect and the net result is the summation of the actions of the Gdm^+ ion and X^-. The effectiveness of Gdm^+ salts in **protein unfolding** follows strictly the Hofmeister series, with the order of denaturing ability being:

$$GdmSCN > GdmCl > GdmCH_3COO > Gdm_2SO_4$$

GdmSCN and GdmCl are strong denaturants, Gdm acetate is much weaker, and Gdm_2SO_4 is a protein stabilizer (1). It is clear that for the SCN^- salt the effect is due to the summation of two denaturing ions; the strong denaturing capacity of Gdm^+ can overcome the weak stabilization by Cl^- and CH_3COO^-. In contrast, the strongly stabilizing SO_4^{2-} ion overcomes the denaturing ability of

Gdm^+. This progression of the Gdm^+ salts along the Hofmeister series is known to reflect their preferential interactions with proteins: GdmCl exhibits preferential binding; Gdm_2SO_4 preferential hydration, ie, is excluded from the accessible surfaces of proteins (2).

Guanine Nucleotide Exchange Factors

Guanine nucleotide exchange factors (GEFs) are a structurally diverse group of proteins that are defined by a common function: catalyzing the exchange of bound GDP for GTP on GTP-binding regulatory proteins (see Gtpases and GTP-Binding Proteins). They act on target proteins as diverse as initiation factors and elongation factors of translation, the ras-like monomeric GTP-binding proteins, and the heterotrimeric G proteins. Because the GTP-binding target proteins are activated when GTP binds, the GEFs are stimulatory regulators. The GEFs are also referred to as GDP dissociation stimulators (GDSs), GDP release factors (GRFs), and GDP/GTP exchange catalysts.

The prototypical GEF is the bacterial translational elongation factor EF-Ts, which is the GEF for EF-Tu. GEFs related to EF-Ts are found in all organisms. GEFs for the heterotrimeric G proteins are cell-surface **receptors** that initiate G-protein signaling. They are based on a **hydrophobic** core of seven membrane-spanning **a-helices** that binds ligand on the extracellular face and binds G proteins on the cytoplasmic face. GEFs for the small, monomeric GTP-binding regulatory proteins in eukaryotes also fall into classes specific for their targets. While there is no globally identifiable GEF **consensus sequence** or protein structure, GEFs for a particular class of GTP-binding proteins usually share clear sequence homology, although GEFs are frequently multi-**domain** proteins that combine a GEF domain with domains that fulfill other signaling or protein–protein interaction functions. GEFs may be constitutively active, as are the GEFs for the translation factors. Alternatively, they may be regulated by ligand binding, by **phosphorylation**, by binding of yet other regulatory proteins, or by recruitment to their sites of action when they or their anchors are phosphorylated.

Despite the diversity of their structures and targets, GEFs catalyze GDP/GTP exchange by a common mechanism, shown below (where G is the target GTP-binding protein):

$$\mathrm{GEF} + \mathrm{G{\cdot}GDP} \rightleftharpoons [\mathrm{GEF{\cdot}G{\cdot}GDP}] \overset{\mathrm{GDP}}{\rightleftharpoons} \mathrm{GEF{\cdot}G}$$

$$\overset{\mathrm{GTP}}{\rightleftharpoons} [\mathrm{GEF{\cdot}G{\cdot}GTP}] \rightleftharpoons \mathrm{GEF} + \mathrm{G{\cdot}GTP}$$

Formally, binding of a GEF to its target protein decreases the affinity of the target for guanine nucleotides: It apparently converts the nucleotide binding site to a more “open” configuration. When the GEF binds, dissociation of GDP is accelerated, leaving the GEF bound to the unliganded target. Binding of guanine nucleotide to the target protein must reciprocally decrease its affinity for the GEF, and cytoplasmic GTP is in large excess over GDP, so GTP binds and displaces GEF by the same mechanism. Release of the GEF after it has promoted GDP/GTP exchange allows a single GEF molecule to act sequentially on multiple molecules of target protein. Thus GEFs are true **catalysts** of exchange: They accelerate GDP/GTP exchange but do not alter the equilibrium balance of bound GTP and GDP.

Guanine Quartet

Telomeric DNA plays an important role in stabilizing chromosomes. *Telomeres* refer to the terminal protein-DNA complexes of eukaryotic chromosomes, and the DNA sequences found in telomeres are rich in G and contain a short highly-repetitive sequence, such as $(TTGGGG)_n$. The G-rich strand at the 3′ end exists as a single-stranded overhang and is capable of forming a higher-ordered DNA structure, known as the guanine- or G-quartet, in which four strands associate. There are several ways in which the G-strand can form a very stable four-stranded structure. Indeed, the structures of a number of telomeric sequences have been determined, showing the various forms of the G-quartet structures. The d(GGGGTTTTGGGG) sequence from the protozoa *Oxytricha* forms a hairpin, and two such hairpins joins to make an antiparallel hairpin dimer, thereby resulting in a four-stranded helical structure, with the thymines forming loops at either end. The G-quartet structure was formed by the guanine residues being held together by a cyclic, head-to-tail network of hydrogen bonds and a metal ion (eg, [TEXnical Error]) located at the center. The four guanine residues were found to have a glycosyl conformation that alternates between *anti* and *syn* (see DNA Structure). Another arrangement of the tetra-stranded G-quartet is a fourfold symmetric motif in which the four G-strands are in the parallel orientation (Fig. 1) (1). The polymorphism of the quadruplex structure has been reviewed elsewhere (2). More recently, DNA molecules containing a string of isoguanines have been demonstrated to form very stable parallel tetraplex structures as well.

Figure 1. Side and end views of a parallel G-quartet DNA structure (Nucleic acid data base No. UDD023).

Guanylate Cyclases

Cyclic GMP is synthesized from GTP by the enzyme guanylate cyclase (EC 4.6.1.2) and yields pyrophosphate as a product. Cyclic GMP (cGMP) acts as a second messenger, activating cGMP-dependent protein kinases (see **Phosphorylation protein**) and/or regulating cGMP-sensitive gated **ion channels**. The role of cGMP as an intracellular messenger in vascular smooth muscle relaxation and retinal photo-transduction is well established (see -Monophosphate, cGMP)). Garbers, Goeddel and co-workers (1-3) found that the catalytic centers of guanylyl cyclases are strongly related to eukaryotic class III adenylate cyclases. Thus guanylate cyclases form a single class, in contrast to the four classes of adenylate cyclases, but they are of at least two very different types, linked to the function of the enzyme in the cell and either soluble or membrane-bound in eukaryotic cells. These two forms differ in their structure, regulation, biochemical, and physicochemical properties (4-7).

1. Membrane-bound Guanylate Cyclases

Guanylate cyclases in family I act as sensors and are often **receptors** for hormones, such as atrial natriuretic peptide (ANP), which is involved in controlling of osmotic pressure and sodium excretion in mammals. These guanylate cyclases are complex, membrane-bound enzymes comprising a receptor for specific hormones coupled to a catalytic domain similar in sequence and structure to the catalytic domain of class III adenylate cyclases (1-3). The known guanylate cyclase receptors form several subfamilies (2, 6,8). Those from sea urchins recognize speract and resact , small peptides that stimulate sperm motility and metabolism ((9),(10)). The receptors for natriuretic peptides (ANF) exist in two forms, both of which synthesize cGMP: guanylate cyclase-A (also named ANP-A), which is specific for ANP, and guanylate cyclase-B (or ANP-B) which is stimulated by brain natriuretic peptide rather than by ANP. There are at least three ANP receptors, two with guanylate cyclase activity (ANP-A and ANP-B) and one (ANP-C) that is responsible for clearing ANP from the circulation without a role in signal transduction (11). Intestinal cells contain the receptor for the *Escherichia coli* heat-stable enterotoxin (guanylate cyclase C). The endogenous ligand for this intestinal receptor is a small peptide called guanylin .

Odorant information is encoded by a series of intracellular signal transduction events thought to be mediated primarily by the second messenger cAMP. But a subset of olfactory neurons expresses a cGMP-stimulated phosphodiesterase (PDE2) and a guanylate cyclase of the receptor type (guanylate cyclase D), which demonstrate that cGMP has an important regulatory function in olfactory signaling (see -Monophosphate, cGMP)) (8). Finally, retinal guanylate cyclases (often named retGC) exist in at least two forms, retGC-E and retGC-F. They play a specific functional role in the rods and/or cones of photoreceptors and trigger a protein phosphorylation cascade (see -Monophosphate, cGMP)) (12). They consist of an apparent extracellular domain linked by a single **transmembrane region** to an intracellular domain. They are coupled to guanylate cyclase activating protein-2, which is a Ca^{2+}-binding protein that activates retGC-1 in a Ca^{2+}-sensitive manner (see Calcium Signaling). It is not known whether retGCs act as receptors, but their structures are similar to that of the other plasma membrane-bound guanylate cyclases.

The organization of all these guanylate cyclases is similar: they have an N-terminal extracellular domain that acts as the **ligand-binding** receptor region, then a transmembrane region, followed by a large cytoplasmic C-terminal region that can be subdivided into two domains, a guanylate cyclase catalytic domain and a protein kinase-like domain that is important for controlling the protein phosphorylation cascade linked to the specific signal recognized by the cognate guanylate cyclase (13, 14).

2. Soluble guanylate cyclases

The second family of guanylate cyclases is cytoplasmic and soluble and often designated sGC. They have completely different regulatory functions and always form heterodimers. The two subunits, alpha and beta, are proteins that, although different in length (from 70 to 82 kDa) and sequence, are highly related (15). Two forms of beta subunits are currently known, beta-1, which is expressed in lung and brain, and beta-2, which is more abundant in kidney and liver. The most fascinating feature of these subunits is that they bind a heme **prosthetic group**. Upon binding of nitric oxide (NO) to this heme group, the sGC catalytic activity is stimulated and generates the intracellular signaling molecule cGMP. NO, discovered in 1987, is a signal transduction molecule. Its importance has been emphasized by its role in blood circulation and cardiac muscle functioning (16, 17). Carbon monoxide (CO) also plays a role similar to that of NO (18).

Fifteen conserved cysteine residues of sGC have been mutated to serine by *in vitro* site-directed mutagenesis . All of the resulting recombinant enzymes synthesize cGMP, demonstrating that these residues are not directly involved in catalysis. On the other hand, mutation of two cysteine residues located in the N-terminal, putative heme-binding region of the beta subunit yields proteins that are insensitive to NO and lose their heme prosthetic group. In contrast, mutation of the corresponding cysteine residues of the alpha subunit does not alter their NO responsiveness, indicating that heme binding is probably a specific feature of the N-terminal domain of the beta subunit (19).

3. Similarities Between the Membrane and Soluble Guanylate Cyclases and Class III Adenylate Cyclases

In general, the genetic organizations of both enzyme types have been conserved by the localization of at least one catalytic domain in the carboxy-terminal part of the protein, coupled to a variety (in length and in sequence) of amino-terminal parts. Both forms of guanylate cyclases share a conserved domain that is fundamental for the catalytic activity of the enzyme. A similar domain is also found twice in the different forms of membrane-bound, class III adenylate cyclases from mammals, slime mold, or *Drosophila* (see Adenylate Cyclases). A polypeptide consensus pattern detects both domains of class-III adenylate kinases and guanylate cyclases: Gly-Val-[Leu/Ile/Val/Met]-$X_{0,1}$-Gly-X_5-[Phe/Tyr]-X-[Leu/Ile/Val/Met]-[Phe/Tyr/Trp]-[Gly/Ser]-[Asp/Asn/Thr/His/Lys/Trp]-[Asp/Asn/Thr]-[Ile/Val]-[Asp/Asn/Thr/Ala]-X_5-[Asp/Glu] (1, 3).

The common evolutionary origin of the adenylate cyclases and guanylate cyclases, evidenced by the apparent facility with which it is possible to build up a purine nucleoside triphosphate cyclase of broad specificity, might be relevant to the phylogeny of the catalytic center of class III adenylate cyclases (20). This similarity suggests the existence of a common ancestral purine nucleotide triphosphate cyclase. As a consequence of this interpretation of the sequence data, one might wonder whether evolution has not permitted the existence of some overlap in their specificities because a given cyclase is triggered, under appropriate regulatory conditions, to synthesize either cAMP or cGMP alternatively. This could have been used in cyclic nucleotide-mediated controls existing in eukaryotes, and it might explain the older observations that, in some cases at least, the cAMP and cGMP concentrations vary in opposite directions.

Guide RNA

Guide RNAs are cofactors for RNA **editing** in kinetoplastid protozoan parasites. They are localized in the mitochondria, where they function to direct insertion and/or deletion of uridylates (U) at specific sites of the pre-messenger RNA to generate the functional mRNA (1-5) (see RNA Editing). The guide RNAs have three domains: (i) the 5′ region sequence is complementary to the substrate pre-mRNA and acts as an "anchor." *In vitro*, this duplex formation is essential for editing to occur (6). (ii) The central domain of the guide RNA contains the information necessary to insert and/or delete uridylates in the pre-mRNA to make the mature edited sequence, which is normally around 30–40 nucleotides in length. (iii) The 3′ end of the guide RNA is characterized by an oligo (U) tail that averages 12 nucleotides in length and is added post-transcriptionally; the function of this tail is unclear. With the development of an *in vitro* system for editing, a critical role in the specificity of editing for the cognate guide RNA has been established (6).

Gurken

The *gurken* gene of *Drosophila melanogaster* encodes a protein with homology to the transforming growth factor alpha (TGF-a) class of signaling molecules. During Drosophila oogenesis, the *gurken* gene is **transcribed** in the cells of the germline. The *gurken* messenger RNA accumulates in the oocyte and is **translated** throughout oogenesis. The Gurken protein is transported to the oocyte membrane, and activates the *Drosophila* **epidermal growth factor receptor** (Egfr; also abbreviated DER), which is expressed on the adjacent follicle cells that surround the oocyte. The activation of this major transmembrane receptor regulates the expression of a number of genes in the follicle cells, and thus initiates a series of events that lead to the correct patterning of both the anteroposterior and the dorsoventral axis of the egg and embryo.

The *Drosophila* Egfr is a tyrosine kinase receptor that is used in multiple tissues and at various stages in development to regulate growth, patterning, and differentiation of various cell types. Several ligands have been found to activate the receptor during development (1). Gurken acts as a ligand that is specific to oogenesis. The Gurken protein consists of an extracellular **domain**, which harbors a single epidermal growth factor (EGF)-like domain, a **transmembrane** domain, and a short cytoplasmic domain (2). It is **homologous** to the gene *spitz* of *Drosophila*, which acts as ligand of Egfr in the embryo and in imaginal discs.

During *Drosophila* oogenesis, eggs are produced through the cooperation of the three different cell types that make up individual egg chambers; within each egg chamber, an individual oocyte is connected at its anterior to a group of fifteen nurse cells, and this cluster of 16 cells is surrounded by a follicle cell epithelium (3). Early in oogenesis, *gurken* mRNA is found in the developing oocyte, and the Gurken protein accumulates in the oocyte membrane (4). At this stage, the oocyte occupies only a small part of the volume of the egg chamber, and therefore only a limited number of follicle cells at the posterior of the egg chamber are in contact with the oocyte membrane. In this group of follicle cells, the Egfr is activated by Gurken protein, which results in the specification of these follicle cells as posterior cells. In flies that are mutant for severe loss-of-function **alleles** of *gurken*, Gurken protein is absent, and the follicle cells at the posterior end of the egg chamber are not induced to assume a posterior cell fate. They consequently develop as anterior follicle cells, which results in the production of an egg with two anterior ends. The posterior follicle cells normally send a signal back to the oocyte, which organizes the cytoskeleton of the oocyte and specifies the posterior end of the oocyte. In the mutant egg chambers, no such signal is sent from the follicle cells, and the cytoskeleton of the oocyte is misorganized. RNAs such as bicoid or ***oskar***, which should normally be localized to one end of the egg **RNA localization** are mislocalized in these mutant oocytes, and the embryos that develop inside such eggs have an abnormal antero-posterior pattern (5, 6).

In midoogenesis, the patttern of *gurken* RNA accumulation changes dramatically. At this stage, the oocyte has grown and now occupies about one-third to one-half of the egg chamber. The oocyte nucleus has moved from its initial, symmetric position to one side of the oocyte. The *gurken* RNA accumulates in the region around the oocyte nucleus, and the Gurken protein is now found in a very restricted part of the oocyte membrane, directly overlying the oocyte nucleus (2, 4). At this stage, Gurken activates the Egfr in the lateral follicle cells that contact the oocyte on the side where the nucleus is situated. Activation of the Egfr in these lateral follicle cells induces them to become dorsal follicle cells. In the absence of gurken signaling, the lateral follicle cells develop into ventral follicle cells (7). The ventral follicle cells normally regulate the production of a ventral signal that activates the **Toll** receptor protein on the ventral side of the egg and is responsible for inducing ventral cell fates in the developing embryo. In the strong *gurken* mutants, therefore, the ventralization of the follicle cell epithelium leads to an overproduction of the ventral signal, and consequently to a ventralized embryo (8).

The activation of Egfr in the follicle cells by the Gurken protein therefore has two different functions. In the early egg chamber, activation of the receptor in follicle cells situated at the termini of the egg chamber results in the induction of posterior cell fates. In midoogenesis, activation in the follicle cells on the lateral side of the egg chamber induces dorsal cell fates. The difference in response to receptor activation reflects a prepatterning of the follicle cells along the antero-posterior axis, which, in part, depends on the prior activity of the Notch signaling system (9, 10).

In the establishment of dorsal follicle cell fates, *gurken* signaling presumably leads to the formation of a broad field of dorsal cell fates, but secondary patterning mechanisms appear to operate to lead to the final, complex pattern of cell fates of the mature egg. In addition, *gurken* signaling also interacts with signaling through decapentaplegic (dpp), a molecule with homology to TGF-b. In follicle cells that receive both the *gurken* signal and the *dpp* signal, formation of dorsal appendages is repressed, and formation of operculum cell fate is induced (11, 12). The regulation of the embryonic ventral signal by activation of Egfr seems, however, to be independent of the production of dorsal anterior follicle cell fates. In situations where ectopic activation of Egfr in follicle cells is induced in parts of the follicle cell epithelium, embryos result that show only regional dorsalization, corresponding to the region of the follicle cell epithelium where Egfr was ectopically activated (13).

Haldane Relationship

This relationship of enzyme catalysis was first recognized by J. B. S. Haldane in 1930 (1) and is generally known as a Haldane. It relates the kinetic parameters for an enzyme-catalyzed reaction to the equilibrium constant K_{eq} for that reaction. As K_{eq} is a thermodynamic measurement that cannot be altered by an enzyme, the ratio of the rates in the two directions also must not change in the presence of the enzyme; consequently, a Haldane expresses the relationship between the kinetic and thermodynamic properties of an enzymic reaction. Although there are both kinetic and thermodynamic Haldanes (2), the thermodynamic Haldanes do not apply to all kinetic mechanisms and hence this discussion will be restricted to kinetic Haldanes.

For a simple Uni–Uni reaction, A $\rightleftharpoons$P, that is catalyzed by a mutase or isomerase (see **Kinetic mechanisms**), at concentrations of reactants well below the values of their Km (Michaelis constant), the rates of the forward and reverse reactions are given by the expressions $(V_1/K_a)\,A$ and $(V_2/K_p)\,P$, respectively (see Michaelis–Menten Kinetics). Here, A and P represent the concentrations of the reactants, which have K_m values of K_a and K_p, respectively. V_1 and V_2 represent maximum velocities for the forward and reverse reactions, respectively. At equilibrium, the rates of the forward and reverse reactions must be equal, and hence it follows that the relationships given in Equation 1 must hold:

$$\frac{P}{A} = K_{eq} = \frac{V_1 K_p}{V_2 K_a} \qquad (1)$$

In general terms, a Haldane is the ratio of the apparent rate constants for the reactions in the forward and reverse directions when all the substrate concentrations are relatively low. When there is more than one substrate, the apparent rate constant is given by the V/K_m value for the last substrate to add to the enzyme, multiplied by the reciprocals of the dissociation constants for the substrates that added previously. The same definition applies for the products that act as substrates for the reaction in the reverse direction. Thus, for an ordered Bi–Bi mechanism, where substrate A binds to the enzyme before B and product P dissociates before Q:

$$K_{eq} = \frac{V_1}{K_b}\frac{1}{K_{ia}} \Big/ \frac{V_2}{K_p}\frac{1}{K_{iq}} = \frac{V_1 K_p K_{iq}}{V_2 K_{ia} K_b} \qquad (2)$$

For a Bi–Bi ping-pong mechanism, in which substrate A is converted to product P, which dissociates leaving a modified enzyme, before substrate B is bound and converted to product Q, there is a Haldane for each half-reaction (see **Kinetic mechanisms** and **Isotope exchange**). When multiplied together, they give the overall equilibrium constant as shown in Equation 3 (2):

(3)

$$K_{eq} = K_{eq}1 * K_{eq}2 = \frac{V_1/K_a}{V_2/K_p} * \frac{V_1/K_b}{V_2/K_q} = \left(\frac{V_1}{V_2}\right)^2 \frac{K_pK_q}{K_aK_b}$$

Haldane relationships provide a means of checking on the correctness of a proposed kinetic mechanism. The value for K_{eq}, as calculated by using values determined for the kinetic parameters, must be in agreement with the experimentally determined value. They also have implications with respect to the catalytic efficiency of enzymes. It appears that the wide variation in the maximum velocities for enzyme-catalyzed reactions is due to the differences in the K_{eq} values for the reactions, as well as to differences in the physiological concentrations of the substrates, which are usually in the region of their K_m values (3).

Half-Life, Half-Time

The half-life of a radioisotope or of a chemical reaction can often be described by the time required for the original reactant to decrease to one-half of its original concentration. This parameter is most appropriate for first-order reactions of the type S → P in which the velocity is proportional only to the concentration of [S]:

$$\text{Velocity} = \frac{-d[\text{S}]}{dt} = k_{\text{app}}[\text{S}] \quad (1)$$

The decay of radioisotopes follows this relationship, as do all unimolecular reactions. Even when there is more than one reactant, the reaction occurs with pseudo-first-order kinetics if the other reactants are present in excess and their concentrations do not alter substantially during the course of the reaction (see Kinetics). With first-order reactions, the velocity decreases exponentially with time, as the value of [S] decreases:

$$\ln_e \frac{[\text{S}]}{[\text{S}]_0 - [\text{S}]} = 2.303 \log_{10} \frac{[\text{S}]}{[\text{S}]_0 - [\text{S}]} = k_{\text{app}}t \quad (2)$$

where t is time, k_{app} is the apparent rate constant, and $[S]_0$ is the starting concentration of S. When [S] has reached half the value of $[S]_0$ at the half-life $t_{1/2}$:

$$\ln_e 2 = k_{\text{app}}t_{1/2} \quad (3)$$

$$t_{1/2} = \frac{\ln_e 2}{k_{\text{app}}} = \frac{0.693}{k_{\text{app}}} \tag{4}$$

When known, the half-time can be used to calculate the apparent rate constant for the reaction.

The half-life can also be used to determine the final extent of a reaction. Because the velocity of a first-order reaction decreases exponentially with time (Eq. (2)), it takes a very long time to reach completion or equilibrium. For example, after one to eight half-lives, the extent of a reaction has reached respectively 50, 75, 87.5, 93.75, 96.83, 98.44, 99.23, and 99.61% of completion. After following a reaction for several half-lives, the final extent of reaction can be predicted.

Haploid

A *haploid* cell has one complete set of chromosomes characteristic of that species, except for the sex chromosomes (see X-chromosome and Y-Chromosome). It has a ploidy of one. In sexual species, only the **gamete** cells are usually haploid. The normal cell is **diploid** and has complete sets of chromosomes.

Haptens

Haptens are small molecules that can interact with specific **antibodies** but cannot induce an immune response by themselves. They can be rendered **immunogenic** by coupling to a carrier protein that will provide the necessary substrate for **antigen processing and presentation**, whereas the hapten part will contribute the epitopes. The hapten model was put forward and studied extensively by Landsteiner in the 1930s. Many haptens were variations on a cyclic organic compound, especially the phenyl ring that provided a convenient tool to play with a large variety of groups that could be replaced or transposed from one position to another. Among the most popular were 2,4-dinitrophenol and phenylarsonate. Haptens are constructed so to have an active group that can form a covalent interaction with a side chain of the protein carrier, most often a tyrosine residue (for diazotation) or lysine (formation of a covalent bond to the ε**-amino group**). The essence of the elegant work of Landsteiner was to show clearly the exquisite specificity of antibodies, because simply replacing one group by another on the phenyl ring (for instance a NH_2 group by a carbonyl) or changing the position of one group (eg, NH_2 from ortho to meta or para) was sufficient to abolish or at least severely diminish recognition by the antibody. The model also provided a nice structural basis to study cross-reactions, by systematic permutations of groups on the hapten itself or by comparing the antigenicity of the same hapten conjugated to different carriers. This approach was used much later to analyze the so-called “carrier effect” which was a first step toward elucidation of the major histocompatibility complex (MHC) restriction and understanding of the mechanisms of processing and presentation. The hapten model had, however, one major drawback on the impact of the selective theory first proposed by Ehrlich in 1901. The essence of Ehrlich's theory was that introduction of antigen selected antibodies that were supposed to preexist at the lymphocyte surface (which was demonstrated to be true some 60 years later!). As a result of the Landsteiner approach, for about 20 years, in the 1940s and 1950s, it seemed implausible that the immune system might have generated preexisting antibodies to artificial molecules that were created by chemists. This conclusion, however, simply did not take into account the enormous size of the antibody repertoire or the relative degeneracy of antibody recognition, as finally realized later and revisited by the clonal selection theory.

Immunological detection of small molecules of biological interest, such as hormones, neuromediators, or diverse ligands of small size, faces the problem of their immunogenicity and requires that these molecules be first conjugated onto a carrier protein, and there are many examples of this in the recent literature. Once the appropriate antibodies are available, detection of these molecules in a biological sample may be performed by a great variety of inhibition techniques, such as the radioimmunoassay (RIA) or the enzyme-linked immunosorbent assay (ELISA). Conversely, it may happen that small molecules behave spontaneously as immunogens, possibly inducing an undesired hypersensitization. This is the case with some reactive compounds currently used in laboratories, such as **iodoacetamide**, a commonly used alkylating agent that can induce delayed-type hypersensitivity with severe rashes. It is thought to react with cysteine thiol groups of proteins that then behave as carrier and render the small molecule immunogenic. A similar phenomenon is observed with b-lactam antibiotics, of which penicillin is the prototype, occasionally leading to the possible occurrence of anaphylactic reactions.

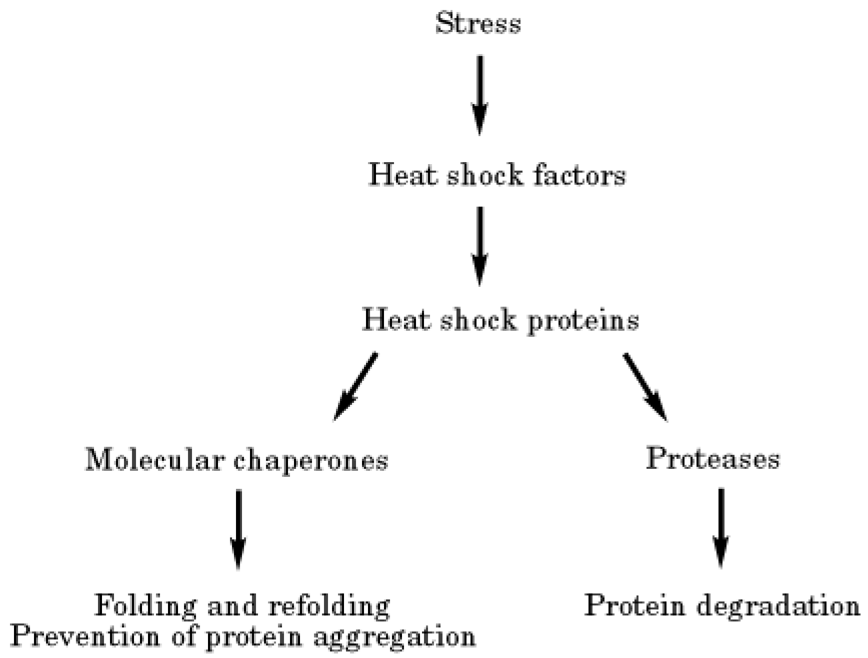
Heat-Shock Response

The heat-shock response represents the orderly cellular response to diverse forms of environmental and physiological stress, which results in the **transcriptional** activation of **genes** encoding **molecular chaperones**, proteinases, and other inducible genes for protection and recovery from stress (Fig. 1). Although the exposure of cells and organisms to heat shock may have its origins with the stress of the primordial environment, the heat-shock response has since adapted to include a diverse array of stresses, including infection with **viruses** and bacteria, exposure to transition heavy metals, amino acid analogues, pharmacologically active small molecules, and oxidants. Common to these stresses are the effects on protein biogenesis defined by events associated with **protein biosynthesis**, **protein folding**, translocation, and assembly into the final native protein or protein complex. Stress challenges protein homeostasis and results in an increased flux of non-native proteins, which, if left unprotected, are prone to misfolding and aggregation. Consequently, through the elevated synthesis of molecular chaperones and proteinases, the heat-shock response responds rapidly and precisely to the intensity and duration of specific environmental and physiological stress signals by repairing protein damage to reestablish protein homeostasis.

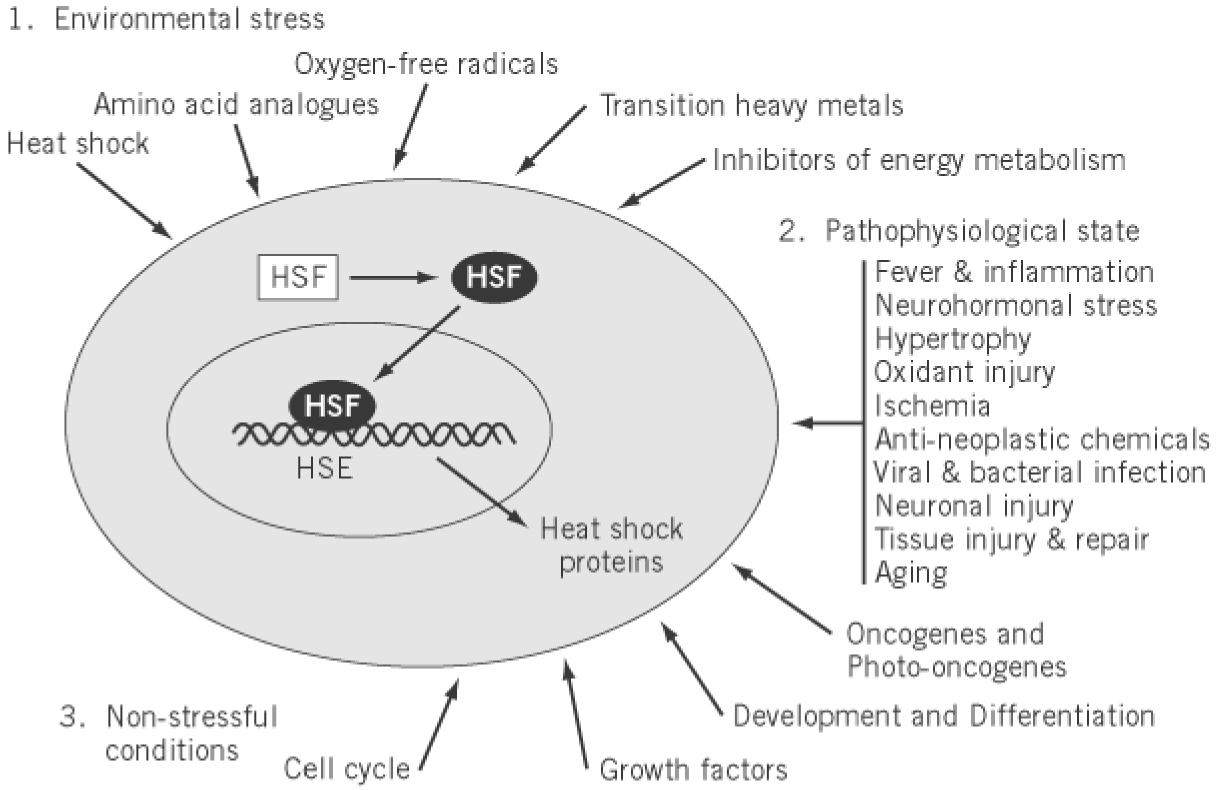
Figure 1. Stress activation of heat-shock proteins.



Studies on the heat-shock response have revealed how the cell senses stress and the role of heat-shock proteins in protecting against and repairing protein damage. While prolonged exposures to extreme stress are harmful and can result in cell and tissue death, activation of the heat-shock response by prior exposure to heat shock results in stress tolerance and cytoprotection against stress-induced molecular damage (1). Transient exposure to somewhat elevated temperatures, or reduced levels of chemical stress, cross-protects cells, tissues, and organisms against sustained, normally lethal, exposures to stress. This reveals a valuable survival strategy that “a little stress is good.”

The complexity that underlies the transcriptional regulation of the heat-shock genes is reflected by the diverse array of stress conditions, which can be distinguished into three major categories (Fig. 2): (i) *environmental stresses*, namely, heat shock, amino acid analogues, drugs, oxidative stress, toxic chemicals, heavy metals, and pharmacologically active small molecules; (ii) *nonstress conditions*, namely, the cell cycle, growth factors, serum stimulation, development, differentiation, and activation by certain **oncogenes**; and (iii) *physiologic stress*, *pathophysiologic and disease states*, namely, neuroendocrine hormones, tissue injury and repair, fever, inflammation, infection, ischemia and reperfusion, neural degenerative diseases, and cancer.

Figure 2. Conditions that induce the heat-shock response. Heat-shock gene expression is induced by environmental and physiological stress, nonstressful conditions including cell growth and development, and pathophysiological states.



This entry addresses (i) how cells utilize the stress-sensing network of the heat-shock response to regulate the transcription of genes that encode heat-shock proteins and molecular chaperones; (ii) the role of molecular chaperones in protein folding, translocation, and protection against the deleterious consequences of misfolded proteins; and (iii) the role of the heat-shock response and heat-shock proteins in cytoprotection against disease.

1. Stress-Induced Transcriptional Regulation of Heat-Shock Genes in *Escherichia coli*

The heat-shock response in *E. coli* leads to the elevated synthesis of more than 20 proteins (Table 1). Upon temperature elevation, transcriptional activation of the respective heat-shock genes is dependent upon the s factor s32, the product of the rpoH (htpR) gene, which associates with the **RNA polymerase** core enzyme (E) to form the E s32 holoenzyme that binds specifically to **promoters** of most heat-shock genes (2-4). s32 is essential for normal growth; cells lacking s32 are highly restricted in cell growth conditions and are hypersensitive to stress (5). Transcriptional activation of the principal heat-shock genes htpG, **dnaK**, dnaJ, grpE, and groEL/S requires stress-induced changes in the levels of s32. Under normal growth conditions, the concentration of s32 is very low, approximately 10 to 30 copies per cell at 30°C (6) as a result of its short half-life ($t_{1/2}$ = 1min) (7, 8). Following heat shock, s32 levels increase rapidly, due to its increased rate of synthesis of s32 (7, 9-11) and increased stability during heat shock. The consequence of elevated levels of s32 is a burst of heat-shock gene transcription (12-14).

Table 1. A Brief Summary of the Nomenclature, Location, and Function of the Major Chaperone Families

Organism	Chaperone	Compartment	Functions

hsp100	*E. coli*	ClpA,B,C	Cytosol	Roles in stress tolerance; aids in the resolubilization of heat-inactivated proteins from insoluble aggregates; regulates yeast prions
	S. cerevisiae	Hsp 104	Cytosol	
hsp90	*E. coli*	HtpG	Cytosol	Functions in signal transduction (eg, steroid hormone receptor activity); modulates protein kinase activities; refolds and maintains denatured proteins *in vitro*
	S. cerevisiae	Hsp83	Cytosol	
	Mammals	Hsp90	Cytosol	
		Grp94	ER	
hsp70	*E. coli*	DnaK	Cytosol	Functions in lamba phage replication; autoregulates the heat shock response; interacts with nascent chain polypeptides; may facilitate protein degradation by acting as a cofactor in proteolytic systems; dissociates clathrin; functions in interorganellar transport; roles in signal transduction (eg, steroid hormone receptor function); refolds and maintains denatured proteins *in vitro and in vivo* together with the Hdj-1/Hsp40 co-chaperone
	S. cerevisiae	Ssa 1-4	Cytosol	
		Ssb 1,2	Cytosol	
		Kar2	ER	
		Ssc1	Mitochondria	
	Mammals	Hsc70	Cytosol/nucleus	
		Hsp70	Cytosol/nucleus	
		Bip	ER	

		mhsp70	Mitochondria	
hsp60	*E. coli*	groEL	Cytosol	Functions in assembly of bacteriohages and Rubisco; refolds or prevents aggregation of denatured proteins *in vitro*; may facilitate protein degradation by acting as a cofactor in proteolytic systems; functions in folding of organellar proteins
	S. cerevisiae	Hsp60	Mitochondria	
	Plants	Cpn60	Chloroplasts	
	Mammals	Hsp60	Mitochondria	
hsp40	*E.coli*	dnaJ	Cytosol	Chaperone activity, essential co-chaperone activity with Hsp70 proteins to enhance ATPase rate and substrate release
	S. cereviasae	Ydj1	Cytosol/nucleus	
	Mammals	Hdj-1/Hsp40		
		Hdj-2, Hsj-1		
shsp	*E.coli*	IbpA and B	Cytosol	Suppresses aggregation and heat inactivation of proteins *in vitro*; confers thermotolerance through stabilization of microfilaments; possible roles in cell growth and differentiation
	S. cerevisiae	hsp27	Cytosol	
	Mammals	aA and aB-crystallin	Cytosol	
		hsp27	Cytosol	

A complementary stress response to misfolded proteins in the periplasm and outer membrane of *E. coli* is mediated by a second heat-shock factor, sE (s24) (15, 16). Activation of sE leads to the induction of at least 10 additional proteins, four of which have been identified: the periplasmic proteinase degP, s32, the periplasmic peptidyl prolyl cis/trans isomerase fkpA, and sE itself (17-23). Cells lacking sE are sensitive to elevated temperatures, sodium dodecyl sulfate (**SDS**)/ethylenediaminetetraacetic acid (EDTA), and crystal violet (16, 21, 22, 24). The temperature-sensitive phenotype of sE mutants can be restored by activation of a second signal transduction cascade, the Cpx pathway, revealing that *E. coli* has at least two partially overlapping stress signal cascades capable of relieving extracytoplasmic stress (25).

Studies on the regulation of the heat-shock response provide evidence for autoregulation in that the activity and/or levels of heat-shock proteins influences the expression of heat-shock genes. Mutations in the heat-shock proteins dnaK, dnaJ, or GrpE, or reduced expression of groEL/S, enhance heat-shock gene expression at normal growth temperatures and result in an extended heat-shock response after shift to high temperatures (26-28). These cells are defective in the control of s32 synthesis and exhibit increased stability of s32 (8, 27, 29). The degradation of s32 involves dnaK, dnaJ, and GrpE by targeting s32 to the ATP-dependent proteinases FtsH, Lon, **Clp**, and HslVU (30, 31). Negative regulation of s32 is mediated by interaction of a specific region of s32 with dnaK, such that deletion or mutations within this region lead to its sustained synthesis and prolonged half-life (32, 33). The interaction of s32 with dnaK, dnaJ, and GrpE is ATP-dependent, so that dnaJ, in the presence of nucleotide, increases the formation of dnaK–dnaJ–s32 complexes in the ADP state, and GrpE stimulates nucleotide exchange and dissociation of the complex (34, 35). Association of dnaK and dnaJ with s32 prevents s32 from binding to RNA polymerase, resulting in the arrest of heat-shock gene transcription (34, 36-38). In addition to sequestration of s32 from RNA polymerase, the dnaK chaperone machinery autoregulates the *E. coli* heat-shock response by the simultaneous reactivation of heat-aggregated s70 and the preferential assembly of s70 with RNA polymerase (39). The equilibrium between free active s32 and DnaK/DnaJ-bound inactive s32, therefore, constitutes an important feature of the homeostatic control of heat-shock gene regulation in *E. coli*.

2. Stress-Induced Transcriptional Regulation of Heat-Shock genes in Eukaryotes

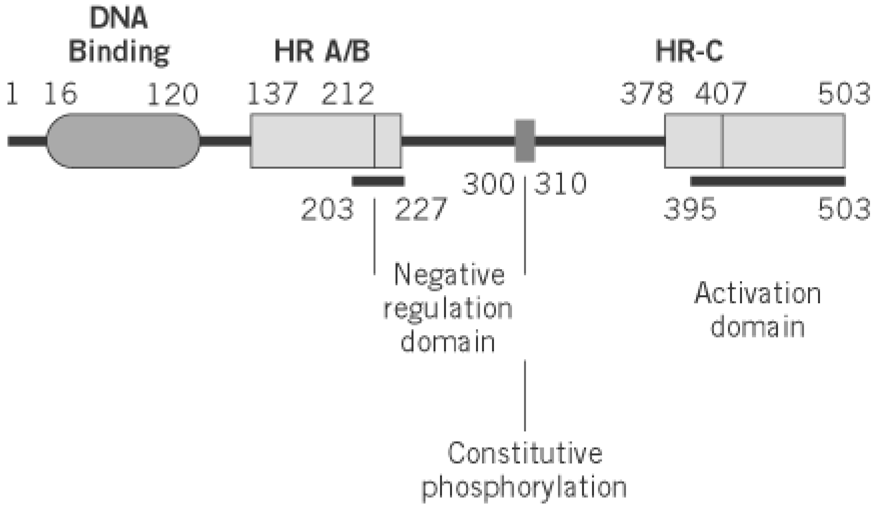
2.1. Family of Heat-Shock Factors

In higher eukaryotes, stress-induced regulation of the heat-shock response occurs principally by stress-induced activation of heat-shock factors (HSFs) from an inert to a transcription-competent **DNA-binding** state, binding to the heat-shock promoter element, and interaction with components of the basal transcription machinery, thus resulting in inducible transcription (40-43). Among eukaryotes, the complexity of HSF-dependent regulation varies among species, with yeast and *Drosophila* encoding a single HSF gene (44-46), whereas four HSF genes (HSF1 to HSF4) have been isolated and characterized in the mouse, chicken, and human **genomes**, and a distinct but functionally related family of HSFs have been characterized in plants (47-54).

Comparison of the various **cloned** HSF genes reveals an overall sequence identity of 40%, with a high degree of structural conservation (Fig. 3) in the winged helix–turn–helix motif DNA-binding domain (43, 53, 55-57), an extended 80-residue **hydrophobic** repeat (HR-A/B) involved in trimerization (46, 58, 59), and a carboxyl-terminal localized transactivation domain (51, 60-63). With the exception of the HSF in budding yeasts and human HSF4, another hydrophobic repeat (HR-C) is located adjacent to the carboxyl-terminal transactivation domain, which has been suggested to function in suppression of trimer formation by interaction with HR-A/B (50, 64-68). Also positioned between HR-A/B and HR-C are sequences that function as negative regulatory regions that repress either or both DNA binding and transcriptional activation (61, 62, 68). Other features unique to specific HSFs are the presence of an amino-terminal transactivation domain in the *Saccharomyces cerevisiae* HSF and the lack of a functional transactivation domain in human HSF4 (51). A common feature of HSFs other than from *S. cerevisiae* is the negative regulation of DNA binding or transcriptional activity.

Figure 3. General features of heat-shock factors. Schematic representation of HSF1 structural motifs [DNA binding, hydrophobic repeats (HR-A/B and HR-C), and the transcriptional activation domain] and the negative regulatory domains which influence HSF1 activity. The relative positions of these domains are indicated by the amino acid

residues indicated.

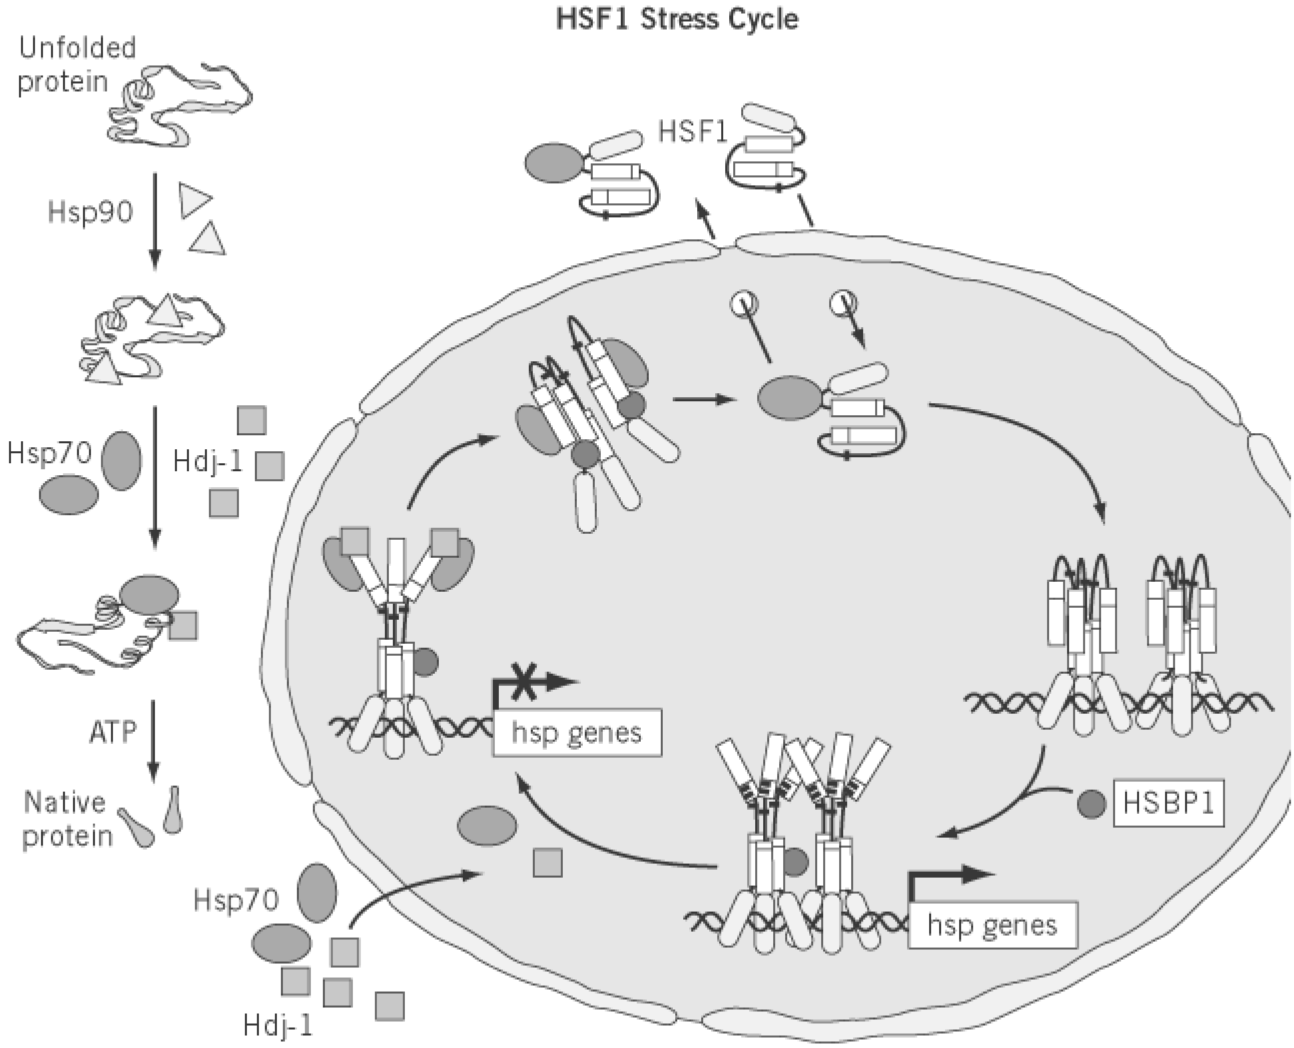


Of the HSFs coexpressed in vertebrates, HSF1 has the properties of the predominant stress-induced transcriptional activator, which acquires both DNA binding and transcriptional activity and is functionally analogous to yeast and *Drosophila* HSF (69, 70). In avian cells, HSF1 and HSF3 are coexpressed and coactivated by chemical and physiological stress, leading to the suggestion of possible redundancy, yet cells deleted for HSF3 and expressing HSF1 are severely compromised for the heat-shock transcriptional response (71-73). HSF3 also interacts with other transcription factors and can be activated, independent of stress, by the Myb oncogene via direct **protein–protein interaction** with the HSF3 DNA-binding domain (74). Myb is a growth-regulated transcription factor; consequently the interaction between Myb and HSF3 reveals a new pathway for genetic crosstalk between cell growth and the stress response. Evidence is also accumulating to indicate that HSF1 may negatively influence the transcriptional activation of other cellular genes, independent of direct binding to heat-shock elements, perhaps via protein–protein interactions with HSF1 (75). Another member of the HSF family, HSF2, in contrast to HSF1, regulates heat-shock gene expression during cell growth and differentiation. HSF2 activity was first described in human erythroleukemia (K562) cells exposed to hemin (76-78), and it was subsequently detected during murine spermatocyte differentiation (79) and embryogenesis (80, 81). The stress-sensing pathway for HSF2 activation is associated with **protein degradation**. HSF2 activity is induced, in a cell-type independent manner, in mammalian tissue culture cells by exposure to specific inhibitors of the **ubiquitin**-dependent proteasome or in cells harboring conditional mutations in components of the proteasome machinery (82). The function of the ubiquitin-dependent proteasome machinery is to degrade short-lived and misfolded proteins; therefore, activation of HSF2 by down-regulation of the protein degradative machinery reveals a requirement for heat-shock proteins, perhaps to prevent misfolding and aggregation of non-native proteins targeted for degradation.

2.2. Regulation and Autoregulation of HSF

Stress-induced activation of HSF1 is a multistep process (Fig. 4). In response to heat shock and other stresses, HSF1 translocates and relocalizes within the nucleus, oligomerizes to a DNA-binding and transcriptionally inert state, becomes inducibly **phosphorylated**, and activates the transcription of heat-shock genes. During prolonged heat shock, HSF1 activity attenuates, as characterized by transcriptional repression of heat-shock genes. Key events during attenuation include the association of HSF1 with the molecular chaperones Hsp70 and Hdj1, interaction with the negative regulator HSBP1, dissociation of HSF1 trimers from DNA, and refolding of the trimer to the monomer. Translocation of HSF1 from the cytoplasm to the nucleus has been described in *Drosophila* and mammalian cells (43, 57, 69, 70, 78, 83-86), yet others have also observed that HSF1 is localized constitutively to the nucleus (86).

Figure 4. Regulation of the heat-shock response. Activation of heat-shock factor (HSF1) is linked to the appearance of n native proteins and the requirement for molecular chaperones (Hsp90, Hsp70, and Hdj1) to prevent the appearance of misfolded proteins. HSF1 exists in the control state as an inert monomer (shown as intramolecularly and negatively regulated for DNA binding and transcriptional activity) and undergoes stepwise activation to (i) a DNA-binding compete state that is transcriptionally inert, (ii) acquisition of inducible phosphorylation, resulting in complete activation and inducible transcription of heat-shock genes, and (iii) attenuation of HSF1 activity. HSF1 activity is negatively regulated heat-shock factor binding protein 1 (HSBP1), which binds to the region of HSF1 corresponding to the heptad repeat, and Hsp70 and Hdj1, which bind to the transcriptional *trans*-activation domain thus repressing HSF1 activity.



Maintenance of HSF1 in a repressed state is delicately balanced and easily disrupted; for example, overexpression of HSF1 by transient transfection results in constitutively active HSF1; likewise, mutation of a single critical phosphoserine residue has the same derepressing effect (70, 87, 88). Acquisition of HSF1 DNA-binding activity is insufficient to activate transcription, as demonstrated by the effects of the anti-inflammatory drugs sodium salicylate, indomethacin, or ibuprofen, which induce DNA binding-competent trimers that, nevertheless, lack inducible phosphorylation and are transcriptionally active (89-91). Rather than corresponding to a nonfunctional form of HSF1, however, the salicylate-induced HSF1 can be converted *in vivo* to the fully active HSF1 by a subsequent exposure to heat shock (91).

Exposure of human cells to 42°C heat shock results in the rapid and transient inducible transcription of heat-shock genes, with maximal rates of hsp70 and hsp90 transcription occurring within 30 to 60 minutes; thereafter, the rate of heat-shock gene transcription declines rapidly, prior to the loss of HSF1 DNA-binding activity (88, 92, 93). The increased levels of heat-shock messenger RNAs following heat shock result from both transcriptional activation of heat-shock genes and the increased stability of heat-shock messenger RNAs during stress (93, 94). This results in the elevated synthesis and accumulation of heat-shock proteins.

The initial evidence that the eukaryotic heat-shock response is autoregulated was based on the effects of amino acid analogues on *Drosophila* cells. Rather than the expected transient heat-shock response, treatment with azetidine, a proline analogue, resulted in the continuous activation of heat-shock gene expression (95). An explanation for this result was that amino acid analogues induce the heat-shock response as a result of their incorporation into nascent polypeptides that misfold. Such amino acid analogue-containing nascent polypeptides would be expected to associate with Hsp70 (96); the sequestration of Hsp70 by these permanently unfolded polypeptides in turn results in activation of heat-shock gene transcription. However, unlike the heat-shock response, where attenuation is linked to the *de novo* synthesis of heat-shock proteins, Hsp70 synthesized in the presence of amino acid analogues is also misfolded, and therefore nonfunctional as a chaperone, with the consequence that the heat-shock response does not attenuate. These observations led to the proposal that heat-shock proteins are involved in autoregulation of the heat-shock response. Genetic evidence to support the autoregulation of the heat-shock response has shown that overexpression of the yeast Ssa1p (cytosolic Hsp70) dampens the heat-shock response from two different (ssa1 and ssa4) promoters for Hsp70 (97). Likewise, deletion of the ssa1 and ssa2 Hsp70 genes resulted in an unusually high level of expression of another Hsp70 gene (Ssa3p) and other heat-shock proteins in a HSF-dependent manner; these results strongly implicated HSF as a potential target for autoregulation by members of the Hsp70 family (98). The relationship between HSF and Hsp70 was further supported by a search for extragenic suppressors of the temperature-sensitive phenotype of an Hsp70 mutant (ssa1ssa2 strain), which also uncovered HSF as an interactive component of the regulatory response (99). A spontaneous mutant EXA3 that could reverse the growth defect of the Hsp70 mutant (ssa1ssa2) is very closely linked with the gene encoding HSF, and another mutation identified in the genetic screen maps to the HSF gene (100).

Biochemical evidence to support a role for molecular chaperones in the regulation of the heat-shock response have demonstrated that stress-induced HSF1 trimers were associated with Hsp70 (101-105). The Hsp70-HSF complexes are sensitive to ATP, which is typical of chaperone–substrate interactions, and can be reconstituted *in vitro* (101, 105). Through the use of HSF1 deletion mutants and direct *in vitro* binding assays, a site for Hsp70 binding was mapped on the transactivation domain of HSF1 (105). Whereas overexpression of Hsp70 inhibited completely the induction of heat-shock gene transcription, there was little or no effect on the formation of HSF1 trimers or on inducible phosphorylation of HSF1 (103, 105). This demonstrates that Hsp70 can also function as a negative regulator of HSF1 activity and that the repression of heat-shock gene transcription that occurs during attenuation is due to the repression of the HSF1 transactivation domain by direct binding to Hsp70 (101-103, 105). Although Hsp70 has a demonstrated role in the autoregulation of the heat-shock response, other molecular chaperones, such as Hdj1 or Hsp90, have also been implicated in the regulation of HSF1 activity. Hdj1 interacts with HSF1 in higher eukaryotes and negatively regulates HSF1 transcriptional activity (105). A role for members of the DnaJ family in regulation of the heat-shock response is supported by the observation in *S. cerevisiae* that the DnaJ homologue, SIS1, negatively regulates its own expression (106). However, SIS1 autoregulation requires the heat-shock element (HSE) and other sequences, suggesting that additional regulatory molecules might be involved. **HSF** may also associate with Hsp90; such interactions have been detected for yeast, rat, and rabbit Hsp90 (107, 108) but not with human Hsp90 (102, 103, 105).

Identification of the transactivation domain of HSF1 as a chaperone-binding site offers a number of intriguing possibilities for Hsp70 as a competitor for HSF1 interaction with the basal transcriptional machinery (109) or the role of Hsp70 in the conformational change of HSF1. The consequence of Hsp70 binding may render the transactivation domain inaccessible to the transcriptional machinery, thus resulting in the transcriptional repression. A related role for chaperones as regulators of transcriptional activators has also been described for the family of **steroid receptors**, although in this case multiple chaperones are recruited to maintain the activator in a repressed state by formation of a stable chaperone-substrate complex (110). It is tempting to consider that the interactions observed between p53 and Hsp70 (Hsc70) could also reflect a form of chaperone-dependent regulation of the folded state that affects the properties of the transcriptional activator (111).

3. Molecular Chaperones: Roles in Translocation, Protein Folding, and Refolding

3.1. General Features of Molecular Chaperones

Although some proteins refold spontaneously *in vitro* when diluted at low concentrations from **denaturants**, larger, multidomain proteins often have a propensity to misfold and aggregate (see **Protein folding**). Consequently, the challenge within the densely packed environment of the cell is to capture and sequester efficiently non-native proteins that may lead subsequently to either refolding or degradation. Molecular chaperones of the Hsp90, Hsp70, and Hsp60 class accomplish this by capturing non-native intermediates and, together with co-chaperones and ATP, facilitate the appearance of the folded native state (112). The Hsp70 chaperones, for example, recognize stretches in polypeptides that are rich in **hydrophobic** residues and are transiently exposed in early folding intermediates, but typically confined to the hydrophobic core in the native state (113). This contrasts to the Hsp60/GroEL chaperonin, which creates a protected environment with the properties of a "protein-folding test-tube" in which non-native proteins can undergo rounds of binding and release to acquire the native state (114, 115) . The consequence of chaperone interactions with early folding intermediates, therefore, is to shift the equilibrium of protein folding toward on-pathway events and to minimize the appearance of nonproductive intermediates that may have a propensity to aggregate as misfolded species.

The family of molecular chaperones is large; they are diverse in size and apparent structure, yet highly conserved throughout evolution and abundant under nonstress conditions (40, 112, 116). Most chaperones are abundant in growing cells and can attain concentrations of 1% to 5% of total cell protein. They are classified according to molecular size, that is, Hsp100, Hsp90, Hsp70, Hsp60, Hsp40, and small Hsps (Table 1). Biochemical studies on chaperones have shown that a common function of the chaperones Hsp104, Hsp90, Hsp70, the small Hsps, **immunophilins** (FKPB52 and CyP40), the steroid aporeceptor protein p23, and Hip (Hsp70 and Hsp90 interacting protein) is to prevent the *in vitro* aggregation of model protein substrates and to maintain the substrate in an intermediate folded state competent for subsequent refolding to the native state. A distinction among proteins with chaperone activities is that refolding to the native state requires the activity of a specific subset of chaperones, such as Hsp90, Hsp70, or Hsp60/GroEL, which are **nucleotide-binding** proteins, and the regulatory properties of chaperone-specific co-chaperones, such as p23, the immunophilins, which enhance Hsp90, dnaJ, or Hip proteins that associate with Hsp70, and Hsp10/groES, which stimulates Hsp60/groEL. The suggestion that chaperones exist as heteromeric complexes that associate with different folded intermediates allows the substrate to acquire different regulatory states.

3.2. Representative Analysis of the Hsp70 Family

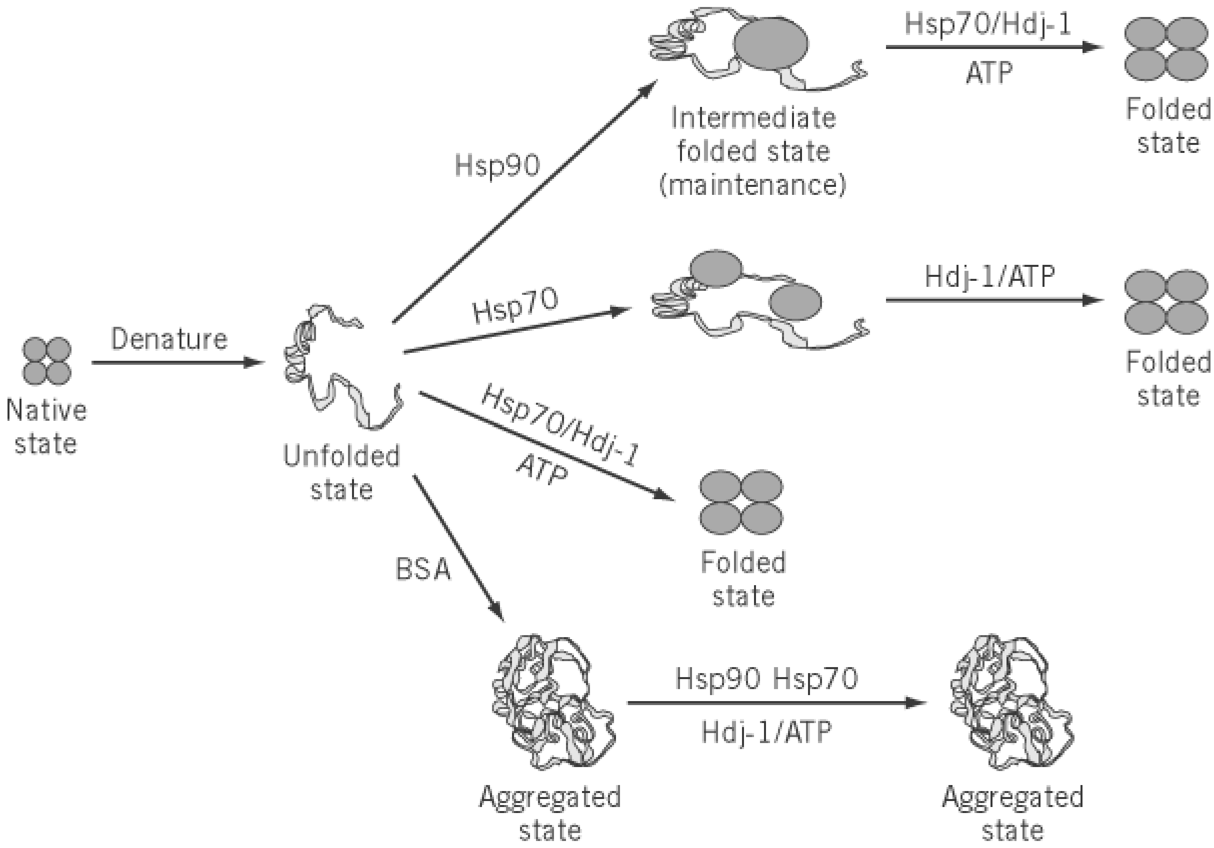
Chaperones are found in nature as functionally related protein families; for example, the eukaryotic Hsp70 proteins are found in the cytoplasm, nucleus, mitochondria, and endoplasmic reticulum, where they maintain proteins in intermediate folded states competent for translocation across the membranes of the mitochondria or endoplasmic reticulum and for subsequent refolding to the native state (116-119). In *E. coli*, the Hsp70 homologue, dnaK, originally identified in a genetic screen for host proteins required for replication of lambda phage, is also required for growth at nonpermissive temperatures (120, 121). Analysis of the structure and functional properties of Hsp70 reveals a multi-domain organization corresponding to a 45-kDa amino-terminal ATPase domain, the 18-kDa carboxyl-terminal peptide-binding domain, and a 7-kDa intra- and interdomain EEVD (Glu–Glu–Val–Asp) regulatory motif (122-124).

Hsp70 interacts with unfolded polypeptides and peptides by binding to arrays of hydrophobic residues in which acidic residues are excluded and the surrounding environment enriched in basic residues (113). Typically, such sites are often buried within the hydrophobic core of folded proteins and are only transiently exposed during protein folding. Affinity of the peptide-binding domain for denatured substrates is dependent on the nucleotide state of the ATPase. Hsp70 exhibits a high affinity for substrate when bound to ADP; upon release of ADP and re-binding of ATP, the affinity for peptides decreases and the substrate is released (125, 126). ATP is hydrolyzed to ADP, and the cycle begins again. The intrinsic ATPase of Hsp70 is exceedingly slow and stimulated by increased temperature, the presence of potassium, calcium, and magnesium ions, the presence of substrates, and the co-chaperones dnaJ and GrpE (126-129). DnaJ stimulates the dnaK ATPase and is required for both the *in vivo* and *in vitro* folding activities of dnaK. dnaJ also functions independently as a chaperone with "holding" activity and has been shown to prevent the aggregation of unfolded rhodanase and **luciferase** in an ATP-independent manner (130). The chaperone activity of DnaJ may not be essential, however, because the human homologue, Hdj-1, neither binds non-native substrates nor prevents protein aggregation. Hdj-1 is necessary for Hsp70-mediated refolding (131). The second dnaK co-chaperone is GrpE, which functions in concert with dnaJ to enhance ADP release, thus allowing the unfolded substrate to dissociate from the dnaK/dnaJ/GrpE complex, also known as the Hsp70 chaperone machine.

3.3. Biochemical Properties in Protein Folding

Among their multitude of biochemical activities, certain chaperones interact with unfolded polypeptides to "hold" non-native proteins in a refolding-competent state, whereas others can also "refold" the polypeptide to its final native state. The relationships between these events in protein folding are indicated in Figure 5. Representatives of the former class include abundant molecular chaperones, such as Hsp90 and the small Hsps. *In vitro*, these heat-shock proteins stably maintain non-native polypeptides in intermediate refoldable states that can then be subsequently refolded by the addition of nucleotide, Hsp70, and Hdj-1 (131, 132). Chaperones of the latter class include Hsp70 and groEL (Hsp60), which can both hold and refold (112, 131). The refolding activity requires accessory proteins or co-chaperones, nucleotide binding, and hydrolysis. In the absence of these co-factors, neither Hsp70 nor groEL are effective in refolding a polypeptide to the native state (124, 131, 133).

Figure 5. Biochemical properties of molecular chaperones in protein folding. The biochemical fate of an unfolded protein is presented schematically. The native protein substrate is denatured (either chemically or thermally) and acquires an unfolded state. Dilution of the denatured protein into buffer containing a nonspecific protein, bovine serum albumin, leads to the aggregated state that is not resolubilized by chaperones (Hsp90, Hsp70, Hdj1) in the presence of ATP. In contrast, dilution of the unfolded protein into the molecular chaperones Hsp70, Hdj1, and ATP results in refolding to the native, enzymatically active state. The holding or intermediate folded state is acquired by dilution into either Hsp90 or Hsp70 alone; subsequent addition of Hsp70, ATP, and the co-chaperone Hdj-1 results in folding to the native state.



While many of the biochemical properties of molecular chaperones are based on *in vitro* approaches, the situation *in vivo* is more complex due to the coexistence of multiple families of chaperones and diverse substrates within the same subcellular compartments. Most chaperones are expressed constitutively and are relatively abundant in each subcellular compartment, where they function in activities including cell signaling and regulating protein kinase activities. Chaperones including Hsp70, Hsp90, p23, and immunophilins are essential components of steroid aporeceptor complexes and necessary for steroid responsiveness (134, 135). In the unstressed cell, chaperones also modulate the folded state of polypeptides; for example, members of the Hsp70 family have a role in **protein biosynthesis** in translation elongation (117, 136), they maintain mitochondrial-targeted polypeptides as unfolded intermediates in a translocation-competent state, and they facilitate the refolding of translocation-competent proteins in concert with Hsp60 (112, 118). During periods of stress, the expression of many, but not all, chaperones is induced to cope with an increased volume of unfolded proteins. The association of unfolded proteins with chaperones may retard protein aggregation, facilitate refolding of non-native intermediates, and provide an interface with the **protein degradation** machinery.

Molecular chaperones stimulate on-pathway folding, principally by their ability to (a) function as kinetic traps to prevent off-pathway intermediates that may lead to the formation of aggregates and (b) favor folding to the native state (Fig. 5). Chaperones exhibit transient and stable interactions with non-native protein substrates; under normal conditions of cell growth, chaperones are associated with kinases and steroid aporeceptors (137). Mutations that affect protein function often lead to stable complexes with chaperones; for example, mutant forms of p53 are stably associated with Hsp70 (111, 138). In such examples, modulation of the activity or half-life of the chaperone-associated substrate may influence cellular events and pathogenesis. Both the absolute and relative abundance of chaperones influences protein biogenesis in the unstressed cell and during periods of stress, where the expression of many but not all chaperones is induced to cope with an increase in the flux of non-native proteins.

4. Role of Heat-Shock Proteins and Stress-Induced Cytoprotection in Disease

The abnormal expression of heat-shock proteins has been well documented for diseases including ischemia and reperfusion damage, cardiac hypertrophy, fever, inflammation, metabolic diseases, bacterial and viral infection, cell and tissue injury, aging, and cancer (40, 139, 140). Serum **antibodies** to the heat-shock proteins Hsp90, Hsp70, Hsp60, and small heat-shock proteins have been detected in individuals with infectious diseases and autoimmune diseases, including rheumatoid arthritis and insulin-dependent diabetes (141). These observations have led to questions whether stimulation of the immune response is the result of, or causes, cell damage, and whether the appearance of circulating antibodies to heat-shock proteins reflects the organismal response to stress and damage. Although the acute response to stress may be critical for recovery and long-term survival, the chronic expression of heat-shock proteins in diseased tissues may be deleterious to protein biogenesis and have negative effects on cell growth. Because the ability of a cell to survive stress is dependent on both the kinetics of activation and the duration of the response, changes in the environment of the cell will shift the stress-sensing capacity of the heat-shock response, with profound effects on survival, repair, and recovery.

The cytoprotective role of heat-shock proteins offers novel approaches for the treatment of diseases involving metabolic disorders, inflammation, infection, and ischemia (142, 143). Ischemia of the brain, kidney, heart, and liver results from decreased blood flow to tissues; the associated pathology that ensues reflects adaptation to decreased levels of oxygen and nutrients. Expression of heat-shock proteins are rapidly induced, during ischemia and to an even greater degree upon reperfusion associated with the appearance of oxygen-free radicals. Exposure to environmental toxins, such as xenobiotics and aromatic hydrocarbons that promote oxidative damage, could potentiate the damaging effects of ischemia and reperfusion. Cytoprotection and repair against the deleterious effects of stress and trauma can be accomplished by the overexpression of one or more heat-shock protein genes. Yeast cells engineered to overexpress Hsp70, the small heat-shock proteins, or Hsp 104 are also protected against exposure to lethal heat-shock temperatures, H_2O_2, heavy metals, arsenite, anoxia, and ethanol toxicity (1). In vertebrates, modulation of the heat-shock response or the expression of specific heat-shock proteins can limit or prevent the pathologies associated with certain chronic diseases. A class of diseases associated with the appearance of misfolded proteins are the prion diseases, which from yeast to humans are associated with changes in the folded state of the prion that correlates with conversion from a noninfective to an infective state. Among the fascinating features of prion diseases is the epigenetic transmission of an altered protein conformation, thus endowing the infectious prion with unique biological properties. Recent data on the yeast prions Ura3 and Psi, which have features in common with the scrapie prion protein, reveal that the molecular chaperone Hsp 104 has an essential role in solubility of the Psi protein and the regulation of the Psi+ phenotype (144). Whether these observations have direct implications for heat-shock proteins in neurodegenerative diseases remains an exciting dimension for future studies.

In the pathology of myocardial disease, the induction of Hsp70 is associated with both ischemia and reperfusion and therefore could reflect the appearance of damaged proteins during adaptation of the myocardium. The elevated synthesis of heat-shock proteins, therefore, could reflect the response of myocardiocytes to survive the stress by repairing protein damage. For example, the induction of Hsp70 following aortic constriction or work-overload-induced cardiac hypertrophy in animal models could reflect a response to the aberrant synthesis, accumulation, or degradation of proteins or, alternatively, a response to events that occur during the partial reentry of the myocardial cell into the growth cycle (142, 143). Does activation of the heat-shock response reflect protein damage and does this reveal a potential strategy to detect or manipulate the course of events? A correlation between the levels of Hsp70 and the degree of myocardial protection has been demonstrated; moreover, transgenic mice overexpressing Hsp70 exhibited an enhanced resistance to myocardial ischemic stress, thus providing direct evidence for a role of heat-shock proteins in cytoprotection (145-147). These studies reveal that induction of the heat-shock response by the stressed myocardium is proportional to protein damage; therefore a potential strategy would be to enhance the expression of heat-shock proteins such as Hsp70, which in turn may confer a more rapid reestablishment of normal cardiac protein synthesis and myocardial function. The activation of a heat-shock response restores normal cardiac function after injury, possibly by removal of misfolded cardiac proteins and reestablishment of normal cardiac protein synthesis (142).

As an alternative to genetic manipulation to alter heat-shock gene expression, it may be more fruitful to search for small molecules that enhance either the expression or function of heat-shock proteins. Such a pharmacological approach has been suggested, for example, based on experiments using herbimycin-A as an inducer of Hsp70 with protective effects in simulated ischemia on rat neonatal cardiomyocytes (148) and the cytoprotective activity of a hydroxylamine derivative (Bimoclomol) during ischemia and wound healing (149). Other classes of small molecules with heat-shock regulatory properties are nonsteroidal anti-inflammatory drugs (NSAIDs), cyclopentenone prostaglandins, **serine proteinase inhibitors**, and inhibitors of the ATP-dependent **ubiquitin-**dependent proteasome (89, 150, 151). Salicylates and other NSAIDs activate an intermediate form of HSF1, which potentiates the cellular response to stress (89). Pretreatment with NSAIDs such as salicylates or indomethacin (at subthreshold concentrations) both decreases the temperature threshold of the heat-shock response and confers cytoprotection (150). Exposure to aspirin or indomethacin at concentrations comparable to clinical levels results in the priming of human cells for subsequent exposure to heat shock and other stresses, the enhanced transcription of heat-shock genes, and cytoprotection from thermal injury (152). Considering that the expression of heat-shock genes occurs in response to pathological conditions, it would not be surprising if the ability of NSAIDs to activate the DNA-binding activity of HSF and Hsp70 expression contributes to their pharmacological efficacy. Another class of pharmacologically active small molecules in the pathway of arachidonate metabolism are cyclopentenone prostaglandins, which activate the heat-shock response and protect against thermal injury and viral infection (151). It is intriguing to note that this class of molecules has cardioprotective value (153). The development of pharmacologically active small molecules that influence either the regulation or function of heat-shock proteins offers a means to harness the positive cytoprotective value of the heat-shock response.

5. Summary

- Exposure of cells to stresses such as heat shock, oxidant injury, toxic chemicals, and heavy metals causes an imbalance in protein metabolism that challenges the cell to respond rapidly, yet precisely, to minimize the deleterious effects of environmental and physiological stress.
- The heat-shock response, by activation of heat-shock transcription factors, results in the elevated expression of heat-shock genes and the concomitant synthesis of heat-shock proteins and molecular chaperones.
- Molecular chaperones function in a variety of protein biosynthetic events to protect proteins from the deleterious effects of acute or chronic stress by stabilizing and refolding protein folding intermediates or facilitating protein degradation.
- Accumulation of misfolded proteins is of central importance to diseases of protein folding, including **sickle-cell** hemoglobin, cystic fibrosis, and prion diseases, in addition to complex multifactorial diseases, including bacterial and viral infections, myocardial ischemia, neurodegenerative diseases, and cancer.

6. Acknowledgments

The author was supported by a research grant from the NIH and the Fogarty International Fellowship. The assistance of K. Veraldi and S. Fox in preparation of this manuscript is appreciated.

Hedgehog Signaling

Nusslein-Volhard and Weischaus (1) first identified the *hedgehog* (*hh*) **gene** in their now famous genetic screen that generated many mutations affecting segment number and polarity in Drosophila. Since then, most of the genes discovered in that screen have been **cloned**, and the studies elucidating their functions have provided an in-depth understanding of the molecular mechanisms driving the differentiation of cells with developmentally equivalent properties. The *hh* gene encodes a secreted morphogen that induces an intracellular signaling cascade. This cascade is an integral part of the mechanisms that establish the polarity of the segments during embryogenesis and limb development. *Hh* signaling is well conserved among vertebrates as well, and genes homologous to *hh* have been cloned and studied in various groups, including human, mouse, chicken, Xenopus, and zebrafish (2).

1. Function of *hedgehog* Signaling in Drosophila Development

The *hh* gene plays important roles in both embryogenesis and disc development in *Drosophila melanogaster*. Embryogenesis of Drosophila is a dynamic process involving intricate hierarchical interactions among different gene products whose expression is defined in a temporally and spatially regulated manner. The maternal and zygotic gap gene products lay out the domains from which the insect metameric units evolve. The pair-rule genes, together with the maternal and gap gene activities, establish the repeating embryonic parasegments. The segment polarity genes then specify the anterior and posterior positional information within each evolving segment. Differential expression of the **homeotic** genes expressed within each segment establishes the unique identities of the segments. All of these interactions occurring during embryogenesis define the body plan and serve as a blueprint for pattern formation in latter development.

Hh and ***wingless*** (*wg*, a gene that encodes another signaling morphogen) are two segment polarity genes whose main function is to define the anterior/posterior polarity within each of the embryonic segments. Embryos that lack either *hh* or *wg* function are smaller than wild-type embryos, secrete cuticles that are covered with a lawn of denticles, and do not make naked cuticle (1). This phenotype characterizes many of the segment polarity genes involved in transducing either the *hh* or *wg* signals. The expression of *hh* and *wg* is initiated at the blastoderm by pair-rule gene products in the posterior and anterior compartment of the segments, respectively, and is maintained during gastrulation by interactions among the segment polarity gene products (3, 4). Thus, the loss of *wg* function does not affect initial *hh* expression but causes the gradual loss of *hh* expression at the onset of gastrulation (5-7). Similarly, the loss of *hh* function does not affect the establishment of early *wg* gene expression, but at later stages it results in the loss of *wg* expression along the posterior edge of the anterior/posterior (A/P) segmental boundary (8, 9). Although *hh* is expressed in only two rows of cells that flank the A/P boundary, *hh* mutations affect the development of the entire segment. Genetic studies have demonstrated that these long-range effects of *hh* are mediated through secondary signals such as *wg* and ***decapentaplegic*** (*dpp*) (10-13).

The *hh* signaling pathway is one of the best-studied cascades involved in embryogenesis and limb development, and it is well conserved between insects and vertebrates. In Drosophila, the components identified in this pathway include the putative *hh* receptor *patched* (*ptc*) (14, 15), the coreceptor *smoothened* (*smo*) (16, 17), the transcription factor ***cubitus interruptus*** (*ci*) (18), the **serine/threonine kinases** protein kinase A (PKA) (19) and *fused* (*fu*) (20), *suppressor of fused* (*su (fu)*) (21), *costal*-2 (*cos* -2) (20), and *slimb* (*slmb*) (22), which encodes a protein involved in the **protein degradation** of CI, the protein product of the *ci* gene.

In a developing embryo, *hh* is secreted from the posterior compartment of each segment and binds to its postulated receptor, *ptc*, which is found on the surface of the cells anterior and adjacent to the *hh*-secreting cells. The *hh* precursor protein, HH, is composed of 471 amino acid residues and consists of three functional **domains**: the signal peptide domain (residues 63–83), the N terminus, and the C terminus. The signal peptide is involved in secretion via the endoplasmic reticulum and is cleaved on secretion at the cell surface (5). The 46-kDa full-length HH precursor (F) is not detected in Drosophila embryos or in cell culture, indicating that the signal peptide is cleaved very efficiently on biosynthesis of HH. The resulting 39-kDa HH protein is called Uncleaved (U) and is detected in Drosophila embryos and discs and in cell culture. U undergoes further internal **proteolytic** cleavage, generating a 25-kDa C-terminal protein and the 19-kDa N-terminal fragment that is the active HH molecule responsible for both the short- and long-range *hh* activities. This cleavage is intramolecular and is catalyzed by sequences in the C terminus that are conserved across species and display some similarity to those of serine proteinases (12, 23). Mutation of the invariant histidine residue in this region abolishes HH autocleavage, indicating that the activity of the C terminus is crucial for HH processing (23). The autocleavage occurs between Gly257 and Cys258. In the course of the catalyzed reaction, the nucleophile that attacks the Gly257 carboxyl group is not the usual water molecule, but cholesterol, which consequently remains covalently attached to the N-terminal HH peptide after cleavage. The presence of cholesterol increases the concentration of biologically active HH at the surface of cells secreting HH (24, 25). How the cholesterol-coupled form of HH exerts its short- and long-range effects is not clear. The current hypothesis is that the short-range effect is mediated directly by HH, and that the long-range effect is mediated by the molecules whose expression is induced by HH signaling.

Both genetic and biochemical evidence suggests that the transmembrane protein PTC, the product of the *patched* gene, is the receptor for HH (14, 15, 26). However, *ptc* mutations cause the expression of *hh* target genes—including *wg, dpp*, and *ptc* itself—to be up-regulated and to become independent of an *hh* signal (11, 13, 27-29). This result suggests that *ptc* activity antagonizes the *hh* signal transduction cascade in the absence of an *hh* signal. The gene *smo* also encodes a transmembrane protein and, like *hh*, is a positive regulator of *wg* expression (16, 17). However, SMO does not appear to bind to HH (30). The simplest explanation for these findings is that *ptc* inhibits *smo* activity in the absence of an *hh* signal. When HH binds to PTC, the *ptc* inhibition of *smo* is relieved, and the intracellular cascade can induce *hh* target gene expression. That SMO and PTC **immunoprecipitate** together from cell culture in the presence or absence of HH suggests that PTC-SMO interactions are determined by a conformational change, rather than a dissociation event (31). The activation of *smo* does not require *ptc*, as SMO is constitutively active in a *ptc* mutant background (28, 30).

Genetic epistasis experiments have demonstrated that *Su(fu), fu, cos*-2, and *ci* act downstream from *ptc* and are responsible for transducing the *hh* signal into the nucleus, where *ci* activates the *hh* target genes (8, 20, 32). A perplexing phenomenon associated with *ci* as a transcription factor is that its full-length activated form has never been detected in the nucleus in vivo, not even in the nuclei of cells located at the A/P boundary, where *ci* exerts its transactivation function (18), or in mutants (eg, *ptc, cos*-2, PKA mutants) that exhibit elevated levels of CI protein (29, 33). The accepted explanation for this phenomenon is that cells require undetectable amounts of CI in the nucleus to activate the expression of target genes. CI exists in the cytoplasm as a complex consisting of COS-2, FU, and other unidentified proteins. In the absence of an *hh* signal, this complex is mainly tethered to the cytosolic microtubules (see Microtubule-Associated Proteins (MAPs)) (34-36). CI also exists as two forms: a 155-kDa transcriptionally active form and a 75-kDa N-terminal proteolytic fragment that contains the zinc-finger **DNA-binding** domain. Both forms are detected in the cytosol. In the absence of an *hh* signal, CI is degraded, and the N-terminal fragment of CI is detected in the nucleus, where it functions as a repressor, possibly because it fails to recruit its co-activator Drosophila CBP (cyclic-AMP response element binding protein) (*dCBP*) (34, 37). When the cells receive an *hh* signal, CI dissociates from the microtubule-protein complex, is not degraded, and the full-length form of CI activates *hh* target gene expression (34-36).

A large body of evidence has demonstrated that protein kinase A (PKA) antagonizes *hh* signaling.

PKA mutant clones in the anterior compartment of imaginal discs express *hh* target genes and generate the pattern duplications associated with ectopic *dpp* and *wg* expression (38, 39). As expected, increasing the PKA activity by expressing a constitutively active PKA catalytic subunit antagonizes the *hh*-induced target gene expression along the A/P boundary of the imaginal disc (29, 40). In embryos, PKA has a dual effect on *hh* signaling. Whereas loss of PKA activity leads to increased *hh* target gene expression, the constitutive activity of PKA causes up-regulation of *wg* expression in a *smo*- and *ci*-dependent manner, suggesting that PKA also has a positive function in *hh* signaling during embryogenesis (41). Because an increase in PKA activity does not interfere with *hh* function in either embryogenesis or disc development, it is unlikely that *hh* regulates PKA activity (29, 40, 41). *Ci* is at least one of the direct targets of PKA regulation in the *hh* signaling pathway. In the absence of an *hh* signal, cell culture studies show that CI is **phosphorylated** by the basal PKA activity, and this CI phosphorylation of CI leads to the proteolysis of CI to the N-terminal repressor form (42). When cells receive an *hh* signal, the proteolysis of CI is inhibited, resulting in elevated levels of activated full-length CI. This event leads to the transcriptional activation of target genes in the nucleus, presumably through the interaction with its co-activator *dCBP* (37).

The *hh* gene is also important for the patterning and growth of adult structures. The adult wings and legs are derived from pouches of larval epithelial cells called imaginal discs . Imaginal discs are composed of anterior and posterior compartments derived from groups of cells that originate from the anterior and posterior compartment of certain embryonic segments. Because homozygous *hh* mutants die before hatching, knowledge of *hh* function in patterning the adult appendages was obtained from flies that ectopically express *hh* or from the clonal analysis of *hh* mutant cells. The ectopic expression of *hh* in the anterior compartment of wing and leg discs leads to the duplication of anterior disc patterns or the development of supernumerary wings or legs, depending on the position of the HH-producing clones (10, 43, 44). Loss of endogenous *hh* function in wing and leg discs is associated with loss of patterning in both anterior and posterior compartments and loss of proximal-distal outgrowth that results in smaller appendages (10). The changes in compartment and proximal-distal patterning are mediated by *hh*-induced *dpp* and *wg* (10, 44, 45). In the wing disc, *dpp* is normally expressed along the A/P boundary. Its expression is induced in clones of anterior cells that ectopically express HH, and its expression is abolished in the absence of *hh* function (10, 13, 43). Cells located dorsally in the leg disc express high levels of *dpp*, whereas cells along the ventral A/P boundary express low levels of *dpp* and high levels of *wg*. Dorsal-anterior HH-producing clones induce ectopic *dpp* expression, whereas ventral-anterior HH-producing clones induce ectopic *wg* expression. Similarly, loss of function of *hh* in posterior cells results in a size reduction of the adult leg (10, 45). *Hh* functions similarly in other imaginal discs, such as genital and eye-antennal discs. Loss or gain of function of *hh* is associated with loss or gain of genital and eye-antennal patterns, which is most likely mediated through *dpp* (44, 46, 47).

In the eye disc, pattern formation occurs as a wave of differentiation, the Morphogenetic Furrow (MF), that moves across the disc from posterior to anterior. Undifferentiated cells lie in front of the MF, whereas a patterned array of differentiated photoreceptors and neurons remains behind. HH expression in the cells posterior to the MF drives the progression of the MF, but the mediator of the *hh* signal in the eye-antennal disc is not known. *Dpp* promotes ommatidial differentiation, and its expression is under the control of *hh* before MF formation, after which time, *dpp* autoregulates its own expression and suppresses *wg* expression to promote differentiation behind the MF (5, 23, 48-50).

2. Function of *hedgehog* in Vertebrate Development
